Whether the effect of the Tesla invention in its production of the "whirling field of magnetic force" is identical with that of a rotating physical magnet, as argued by experts and counsel, does not impress me as material to this issue. Nor does it seem material that in the one form of motor "the rotation is produced by the unaided effect of alternating out-of-phase currents," as described by counsel, and that so applied a self-starting motor is obtained. The discovery was of means and method in the polyphase rotating field motor to produce the whirling field of force, and employment thereof was patentable with or without direct-current excitation of the armature or secondary element. So the fact that its use produced a self-starting motor without the aid of such excitation cannot alone serve to limit the invention to that effect, and I find no such limitation in the terms of the patent. The quotations from the arguments of counsel and experts for the complainant in prior cases, urging the distinction of this self-starting effect in reference to the application of the generic patents to non-synchronous motors, are without force in the present controversy, and it is unnecessary to ascertain their consistency or inconsistency with the interpretation sought on this hearing. Unless limitation to self-starting motors arises out of the prior art none can be imposed upon the claims in suit.

The further propositions urged by way of defence—aside from the defence founded upon prior inventions of the synchronous type to be considered—are these (1) that the synchronous motor of the defendant is the old generator of the art, simply reversed; and (2) that the Tesla invention is not present therein, because (as asserted) "the prepondering magnetization of the" direct current displaces and obliterates the "shifting alternating-current magnetization." or Tesla "whirling field of force." However specious both propositions appear on their face and in the argument, neither of them impresses me as controlling.

I believe that no proposition in the able and extended arguments on the part of the defence have been overlooked in my consideration of this case, although it has not seemed needful to discuss all of them for the purpose of this opinion. My conclusions are that the defendant's synchronous motor structure and operation are within the generic invention as patented, and expressly covered by the claims of Nos. 381,969 and 382,281; that the invention is utilized in the defendant's motor operation, notwithstanding the introduction of direct-current excitation to make it synchronous, in lieu of the full realization of the revolving field effect for self-starting; that such supplemental aid does not escape in ngement, with or without advantage in such associations; and that, in any view the combination patents referred to are not limited to after-effect of the direct-current excitation, but apply to the defendant's combination. Decree will be entered accordingly as prayed in the bill.

Another Tesla Patent.—We have received a copy of the judgment delivered in the United States Circuit Court in the case of the Westinghouse Company against the National Electrical Company, which had reference to the patents of May 1, 1888, for the Telsa polyphase system The plaintiffs contended that these patents were infringed by the defendants' synchronous motor and alternating-current polyphase generator. The defendants contended that Tesla's invention was the rotating field mode of operation, and that this was limited to a self-starting motor so operated; that their own synchronous motor with direct-current excitation was not covered by the Tesla patents, being simply a reversed two-phase alternating-current dynamo of a prior type used as a generator; and that the claims in the Tesla patents which introduced "direct-current excitation producing synchronous operation" must be limited to such use after the motor is started by the Tesla means and method and brought up to speed. The Court held that if the invention could be so limited the defendants escaped infringement; on the other hand, if it could not, the claims of the patents were broad enough to reach the defendant's method of operation. Reviewing the Tesla discovery, the Court defined it as a method to produce in the polyphase rotating field motor, the "whirling field of force,' and employment thereof was obtainable with or without direct-current excitation of the armature or secondary element. The fact that its use produced a self-starting motor without the aid of such excitation could not alone serve to limit the invention to that effect. The theory advanced of the obliteration of the alternating-current magnetisation by that of the direct current of the secondary element of the motor was not material, as the Tesla invention was unquestionably introduced in the operation of the defendants' motor, and the structure was within the patent description. The Court, therefore, held that "the defendants' synchronous motor structure and operation are within the generic invention covered by the claims of two of the fundamental Tesla patents; that the invention is utilised in the defendants' motor operation, notwithstanding the introduction of direct-current excitation to make it synchronous in lieu of the full realisation of the revolving field effect for self-starting; that such supplemental aid does not escape infringement with or without advantage in such association; and that in any view the combination patents referred to are not limited to after-effect of direct-current excitation, but apply to the defendants' combination. Judgment was therefore entered for the plaintiffs, the decree restraining the defendants from infringing the Tesla patents.

Tesla Machine Company, of New York: capital $300,000. Directors—Nikola Tesla and Langdon Greenwood, of New York. and William Andrews, of Brooklyn.

CURRENT NEWS AND NOTES.

TESLA PATENT.—A patent was issued to Mr. Nikola Tesla April 18 on the "Art of Transmitting Electrical Energy Through the Natural Mediums." A full account of the patent will be given next week. The claims are on an improvement in the art of transmitting electrical energy to a distance which consists in the establishment of stationary electrical waves in the earth or natural conducting media and operating therefrom one or more receiving devices remote from the source of energy. Electrical oscillations are impressed on the earth or other media to produce the stationary waves, the length of which may be varied and controlled, and their neutral and nodal regions shifted.

Tesla Patent on Wireless Transmission of Electrical Signals.

A patent issued April 18 to Mr. Nikola Tesla was briefly noticed in these columns last week, the subject being "The Art of Transmitting Electrical Energy Through the Natural Mediums." Below is given a fuller account of the patent.

In the preamble it is stated that experiments and observations have tended to confirm the opinion held by the majority of scientific men, that the earth, owing to its immense extent, does not behave in the manner of a conductor of limited dimensions with respect to electrical disturbances, but much like a vast reservoir or ocean, which, while it may be locally disturbed by commotion of some kind, remains unresponsive and quiescent in a large part or as a whole. The inventor states he has discovered that notwithstanding its vast dimensions and contrary to all observations heretofore made, the terrestrial globe may in a large part or as a whole behave toward disturbances impressed upon it in the same manner as a conductor of limited size.

In the course of certain investigations he noted unsuspected behavior of sensitive instruments, which he discovered to be due to the character of electrical waves produced in the earth by lightning discharges, and which had nodal regions following at definite distances the shifting source of the disturbances. From data obtained in a large number of observations on a maxima and minima of these waves, their length was found to vary approximately from 25 to 70 meters, and these results and certain theoretical deductions led to the conclusion that waves of this kind may be propagated in all directions over the globe, and that they may be of still more widely differing lengths, the extreme limit being imposed by the physical dimensions and properties of the earth. By means of gradual improvements in the generation of electrical oscillations, electrical movements were finally reached not only approximating, but, as shown in many comparative tests and measurements, actually surpassing those of lightning discharges; and by means of this apparatus it was found possible to reproduce whenever desired phenomena in the earth the same or similar to those due to such discharges.

For example, by the use of such a generator of stationary waves and receiving apparatus properly placed and adjusted in any other locality, however remote, it is practicable to transmit intelligible signals or to control or actuate at will any one or all of such apparatus for many other important and valuable purposes, as for indicating wherever desired the correct time of an observatory, or for ascertaining the relative position of a body or distance of the same with reference to a given point, or for determining the course of a moving object, such as a vessel at sea, the distance traversed by the same or its speed, or for producing many other useful effects at a distance dependent on the intensity, wave length, direction or velocity of movement, or other feature or property of disturbances of this character.

In the accompanying figure is represented diagrammatically the generator which produces stationary waves in the earth, and an apparatus situated in a remote locality for recording the effects of these waves. The generator consists of a primary coil forming part of a transformer and consisting generally of a few turns of a stout cable of inappreciable resistance, the ends of which are connected to the terminals of a source of powerful electrical oscillations, this generally being a condenser charged to a high potential and discharged in rapid succession through the primary. *C* is a spiral-wound secondary coil within the primary, one end being connected

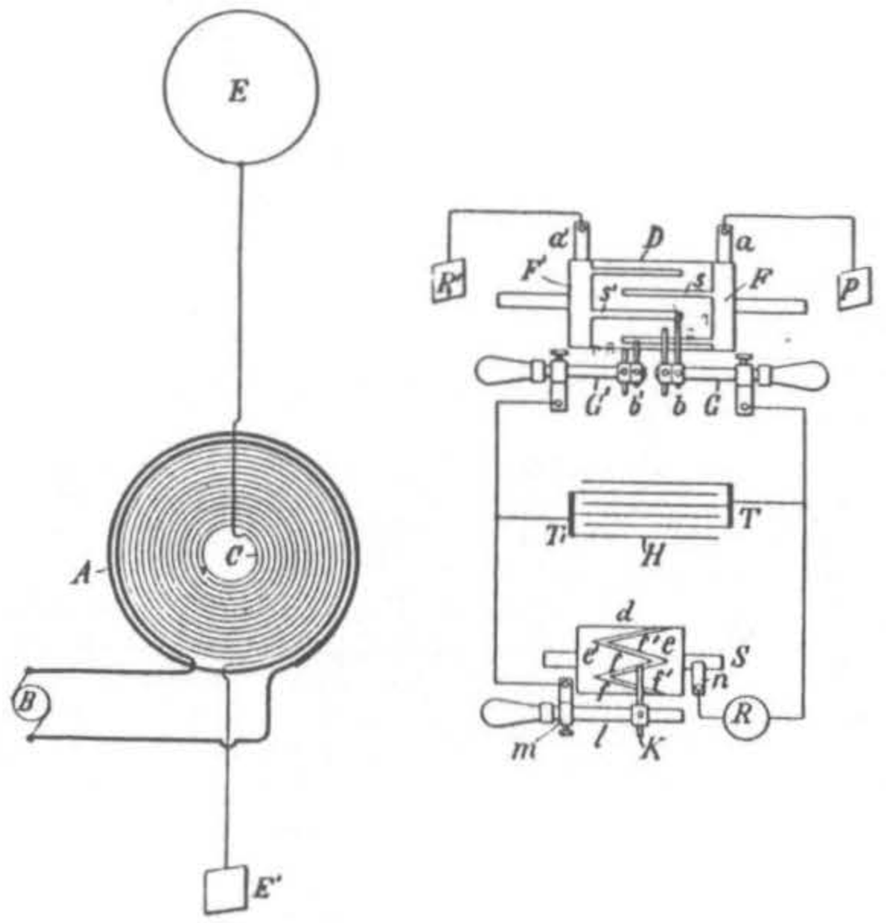

DIAGRAM OF TESLA WIRELESS SIGNAL APPARATUS.

to ground and the other to an elevated terminal, *E*. The resistance of the secondary system should be as small as practicable, its self induction as large as possible and the ground should be made with great care. The total length of the conductor from the ground plate to the elevator terminal *E*, should be equal to ¼ of the wave length of the electrical disturbance or to that length multiplied by an odd number. This relation being observed, the terminal *E* will be made to coincide with the points of maxima pressure in the secondary or excited circuit and the greatest flow of electricity will take place in the same to permit free oscillation. The inductive connection between the primary and secondary should not be very intimate as in ordinary transformers, and this is accomplished by the spiral form given to coil *C*. With this arrangement it has been possible to produce an electrical movement thousands of times greater than the initial, and activity of rates of flow have been produced measured by many tens of thousands of horse power. The powerful electrical oscillations being communicated to the ground cause corresponding vibrations to be propagated to distant parts of the globe, whence they are reflected and by interference with the outgoing vibrations produce stationary waves, the crests and hollows of which lie in parallel circles, relative to which the ground plate may be considered to be the pole. That is to say, the terrestrial conductor is tuned into resonance with the oscillations impressed upon it, just like a wire. A number of facts ascertained clearly show that the movements of electricity through the system follow certain laws with merely mathematical rigor. For the present it is sufficient to state that the planet behaves like a perfectly smooth or polished conductor of inappreciable resistance, with capacity and self-induction uniformly distributed along the axis of symmetry of wave propagation and transmitting slow electrical oscillations without sensible distortion and attenuation.

Three additional requirements seem to be essential to the establishment of the resonant condition as follows: First, the earth's diameter passing through the pole should be an odd multiple

of the quarter wave length—that is, of the ratio between the velocity of light and four times the frequency of the currents; second, the frequency should be smaller than 20,000 per second. The lowest frequency would appear to be 6 per second, in which case there will be but one load at or near the ground plate, and, paradoxical as it may seem, the effect will increase with the distance and will be greatest in a region diametrically opposite the transmitter. With oscillations still slower, the earth, strictly speaking, will not resonate, but simply acts as a capacity, and the variations of potential will be more or less uniform over its entire surface; third, the main essential requirement is that, irrespective of frequency, the wave train will continue for a certain interval of time, which is estimated at not less than 1-12 or 0.08484 of a second, and which is taken in passing to and returning from the region diametrically opposite the pole over the earth's surface with a mean velocity of about 471,240 kilo meters per second.

Fig. 2 shows a device for detecting the presence of the waves. It consists of a cylinder *D* of insulating material, which is moved at a uniform rate of speed by clock-work or other suitable motor power, and is provided with two metal rings, *F F'* upon which bear brushes *A A'* connected to terminal plates. From the rings *F F'* extend narrow metallic segments *S S'*, which by rotation of the cylinder *D* are brought alternately into contact with double brushes *b b'* carried by and in contact with conducting holders, *H H'*, supported in the metal bearings, *G G'*. The latter are connected to the terminals *T T'* of a condenser *H*, and are capable of angular displacement as ordinary brush supports. The object of two brushes in the holder is to vary at will the duration of the electrical contact with the terminal plates and the condenser. To the latter is connected a receiver *R* and a device *d* performing the duty of closing the receiving circuit at predetermined intervals of time and charging the stored energy through the receiver.

The receiver consists of a cylinder made partly of conducting and partly of insulating material which is rotated at a desired rate of speed by any suitable means. The conducting part *e* is in electrical connection with the shaft *S*, upon which slides a brush *K* capable of longitudinal adjustment in the metallic support *m*. Another brush *n* is arranged to bear upon a shaft *S*. It will be seen that whenever one of the segments *F'* comes in contact with the brush *K*, the circuit including the receiver *R* is completed and the condenser discharged through the same. By suitable adjustment the circuit may be made to open and close in rapid succession and remain open or closed during such intervals of time as may be necessary.

The terminal plates *P P'*, through which the electrical energy is conveyed to the brushes *A A'*, may be at a considerable distance from each other in the ground or one in the ground and the other in the air, preferably at some height. In the latter case the location of the apparatus must be determined with reference to the position of the stationary waves. If both plates be connected to earth, the points of connection must be selected with reference to the differences of potential which it is desired to secure. In receiving, the speed of rotation of the cylinder *D* is varied until it is in synchronism with the alternate impulses of the distant generator; the brushes being properly adjusted electrical charges of the same sign will be conveyed to each of the terminals of the condenser and with each fresh impulse it will be charged to a higher potential. In this manner the energy of any number of separate impulses may be accumulated and discharged through the receiver *R*. Thus a relatively great amount of energy may be accumulated and the receiver need not be very sensitive. It being possible to shift the nodal and ventral regions of the waves at will from the sending station, the regions of maximum and minimum effect may be made to coincide with any receiving station or stations.

By impressing upon the earth two or more oscillations of different wave length, a resonant stationary wave may be made to travel slowly over the globe. If the nodal and ventral regions are maintained in a fixed position, the speed of a vessel carrying receiving apparatus may be exactly computed from observations of the maximum and minimum regions successively traversed. In any region at the surface the wave length can be ascertained from certain rules of geometry and conversely, knowing the wave length, the distance from the source can be readily calculated. Thus the distance of one point from another, the altitude and longitude, the hour, etc., may be obtained from the observation of such stationary waves. With several generators, preferably generating different wave lengths, installed in selected localities, the entire globe could be sub-divided in different zones of electrical activity and important data could be at once obtained by similar calculations or readings from suitably graduated instruments.

New York.

New York, April 22.—The state committee charged Nikola Tesla, who is now living at the Waldorf-Astoria, is one of the directors of the newly incorporated Tesla Machine Company, which has a capital of $300,000. The company will manufacture air compressors.

EXPIRATION OF THE TESLA FUNDAMENTAL POLYPHASE PATENTS.

The expiration this week of the three Tesla patents covering fundamentally the rotary-field type of electric motor marks the close of the first stage of one of the several epochal developments of the modern electrical era. It would be interesting to review the great rôle that the invention covered by these patents has played in electrical engineering and in industrial electrical progress, but what is probably at present uppermost in the minds of all interested directly in this branch, is the effect of the expiration of the 1888 Tesla patents toward opening up to the world at large a department of the industry which, for seventeen years, has been a monopoly under the Federal constitutional provision that so wisely grants this privilege as a reward for the labors of the inventor, and to encourage others through invention to add to the wealth and to the well-being of the country. As in the case of the termination of other close patent monopolies, there is unfortunately no clear understanding at the present moment as to the actual situation developed by the expiration of the 1888 Tesla patents. The litigation of the past has had relation only to two sets of polyphase patents—those just expired and the 1893 Tesla split-phase group—and little or no specific information is obtainable in regard to the situation now presented, even from those who have taken an active part in this litigation. To complicate the matter still further, it is announced by the owners of the patents just expired that more than a score of other patents relating to polyphase motors and polyphase operation are yet active, the inference being that it is by no means conceded that the polyphase

art is opened wide by the expiration this week of the three 1888 Tesla patents.

Of the three patents which have just expired, the first has been defined by the courts as covering the apparatus by which the polyphase system is put in practice; the second as covering the electrical transmission of power by the method of operation described in the first patent, which patent also covers a different construction of motor; and the third as covering a specific construction of motor embodying the invention of the other two patents. In considering these three patents, the courts in various decisions have held them, broadly, to cover the system of producing power from an electric motor by means of a rotary field. It is, therefore, reasonable to assume that the expiration of these three patents releases to the world the principle of the rotary field. As to the split-phase patents, the consideration of their validity was so bound up with the rotary-field principle that their affirmation by the courts is now subject to challenge, which doubtless will be offered. While the rotary-field principle was invariably sustained in all litigation, the invention by Tesla of the split-field principle was denied by two courts of first instance, one of which was sustained on appeal and the other reversed.

Naturally, during the seventeen years' life of the patents just terminated, many subsidiary patents have been issued, which latter, owing to the coutrolling issue of the rotary field, have not figured in litigation or, at least have not been subject to interpretation by courts. To what extent this line of patents may narrow the effect of the termination of the life of the fundamental patents is a matter for judgment by those intimately interested, or for determination ultimately by the courts. If litigation with respect to these subsidiary and detail patents should ensue, it is to be hoped that during its course some principle may be established making a clear distinction between invention proper and improvement merely incident to the normal development of a basic invention. The criterion which the courts have in the past so freely applied—that lack of prior conception is a presumption in favor of real invention—is certainly of doubtful value when applied to an art closed to the world during its period of development.

Tesla and the Polyphase Patents.

By B. A. Behrend.

In May, 1888, were granted to Nikola Tesla, from Smiljan Lika, border country of Austria-Hungary, a series of patents, which are commonly known as the fundamental Tesla patents. These patents expired on the 4th of May, 1905.

The genius of Tesla has been instrumental in stimulating, if not in creating, a wonderful industry—wonderful in magnitude, and wonderful in the ingenuity of the apparatus used in the accomplishing of the transmission of power over long distances.

Great ideas are rarely the exclusive property of individual men. The history of the evolution of thought shows distinctly that novel ideas arise in certain generations simultaneously in the minds of some of the most talented men whose personalities, as it were, thus represent the ideas and lend them their names; and so it has undoubtedly been with the ideas and inventions that form the basis of the polyphase system. The official sanction of the Patent Office, depending as it does as much upon the technicalities observed in wording the claims as upon the character and ingenuity of the invention itself, can hardly be taken as a criterion of the originality of the inventor. The function of the Patent Office is rather to be compared with the function assumed by the courts in recording deeds of property than as a scientific court passing upon the inventor's work. The paramount importance of the Patent Office lies in the fact that, as no property can be rightfully owned without a deed therefor, no man can use his ideas and inventions without obtaining a deed, which deed we call a letters patent. You may use your ideas without such letters patent only to find that some one else, by applying for and securing such patent after you have put out your invention, has secured the deed from the Patent Office.

But we are not concerned here with the philosophy of patent law and the existing conditions—we want to pay a tribute to Nikola Tesla, the ingenious inventor who, by a "sort of glorified common sense and unfailing intuition, picked his way through puzzling mazes of complicated phenomena, and protected himself from the pitfalls and the alluring by paths ensnaring smaller intellects." With Nikola Tesla, in this country and in Europe, worked a host of capable and ingenious engineers, and their work, vivified by the ingenuity of Tesla's inventions, has become one of the greatest monuments of engineering achievement crowning the work of the nineteenth century. Let us turn our attention for a moment to Tesla's remarkable paper, entitled "A New System of Alternate-Current Motors and Transformers," read at the meeting of the American Institute of Electrical Engineers, in New York, on May 16, 1888. This paper, even when considered in the light of subsequent discoveries and knowledge, is one of the most brilliant pieces of engineering thought, teeming with suggestions and ideas, animated with an intuition of the highest order, and giving an exposition of the working of the induction motor in a manner which resembles the methods pursued in the "Experimental Researches on Electricity," of the great master, Michael Faraday.

For seventeen years, the Tesla patents have formed the nucleus of the electrical industry. Through plenty of litigation and decisions they have survived, as all things survive the struggles of this world, only to expire, and it must be said that the expiration of these patents is looked upon in general as a very happy event. We do not wish to say that the monopoly which these patents created has been abused; we do not wish to say that the progress in this field has not been as vigorous as it would have been had the patents not been quite so sweeping; the field is so wide and the desire for vigorous competition so strong, that the expiration of these patents will give the electrical industry a new stimulus, and it must be borne in mind that, after all, these patents do not represent the only valuable ideas on the subject of polyphase alternating-current systems. Many are the inventions and ideas which have been originated by others, and which have made the polyphase system practicable. We all know how great is the difference between mere ideas, which are as plentiful as blackberries, and the working out of these ideas into practical form, which often requires the expenditure of as much genius as was required for the evolution of the idea itself. Ideas appear to me to be somewhat like what Darwin called "variations," from which, by a process of selection, *those* ideas are singled out which can hold their own, and are developed into practical form, while the greater number of ideas are cast aside, unfit, condemned to be destroyed in the struggle for existence.

Nikola Tesla and his patents have had their day; the art of electrical engineering, the capital invested therein, the users of polyphase electrical machinery, all are grateful to Nikola Tesla and to those who have developed his ideas.

The Expiration of the Tesla Patents.

By William Stanley.

In 1885 Prof. Galileo Ferraris, of Turin, discovered the electromagnetic rotating field, and applied his invention to the operation of a rotating field motor. On May 1, 1888, Mr. Nikola Tesla received United States patents covering the broad application of the Ferraris discovery of alternating-current motors. In 1888 Mr. George Westinghouse purchased the Tesla patents and contracted with Prof. Ferraris to exploit his inventions in this country, paying to the great Italian savant the munificent sum of 5,000 lire—$1.000—for such right. The Ferraris applications for United States patents were then entrusted to the Westinghouse (Tesla) attorneys, and having promptly died in the patent office, were followed by new applications drawn in the name of Mr. Tesla. These later applications exactly described the original (1885) discovery of Ferraris, the United States rights to which had been purchased by Mr. Westinghouse, as stated above. As a result of these various moves we have the original (1885) Ferraris split-phase motor patented by Tesla in 1890, and still in force, and the subsequent 1888 patents by Tesla, now expired.

The advent of the rotary field motor patents in 1888 was of great importance to the art, for while these patents did not disclose means for constructing commercial alternating-current motors, yet they threw a strong light on the art, illuminating its future. The expiring Tesla patents were usefully drawn and were sufficiently comprehensive to protect the subject they disclosed, yet it is doubtful if they would have been maintained and their validity established in the courts had they not fallen into the hands of the "Patent Pool Trust." The owners of the Tesla patents, realizing the great weight of public opinion and its effect upon the courts before which the patents would surely be brought for adjudication, early began a systematic campaign of personal publicity, in which the wonderful achievements of Mr. Tesla were set forth with the coloring of a gold mine prospectus; and their efforts to fasten attention upon the inventor and his work were ably supplemented by numerous startling statements, promises and disclosures that he himself constantly poured forth. Surely, at this time his oracular activity was remarkable.

When, therefore, the Tesla patents were brought into court and the picturesque wizardship of the patentee was frequently contrasted with the simple and modest researches of prior investigators, the courts quite innocently swallowed the bait prepared for them and rendered verdicts for the "Patent Pool Trust." To-day the Tesla (1888) patents have ceased to exist, the "Patent Pool" campaign is over, the object for which the patents were created has been accomplished and all pecuniary interest in the maintaining of patents have vanished. There is now, it seems to me, no valid reason why all engineers in this country may not unite in the future "to render unto Cæsar the things that are Cæsar's," and may further find expression for the sentiment by prefixing the name of Ferraris to devices containing the principles he first discovered.

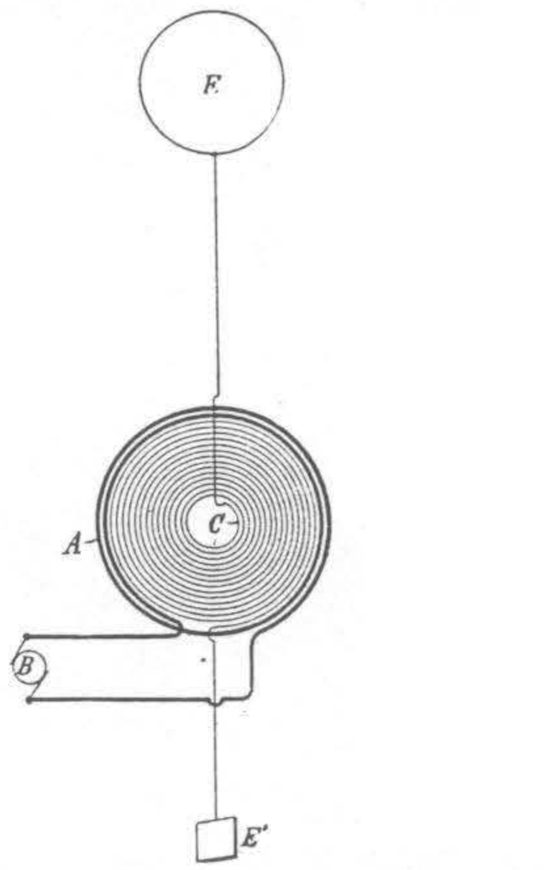
Polyphase Patents.

The Westinghouse Electric & Manufacturing Company has announced in connection with the expiration this week of the three fundamental Tesla patents, that it holds numerous other patents relating to polyphase synchronous motors and subsidiary apparatus. Seven of these patents were granted to Nikola Tesla on dates between September 3, 1889, and January 2, 1894, the subjects being as follows: Induction motors; the use of the induction motor as a starting device for the synchronous motor; relation between the number of poles on generator and motor, and four patents on the split-phase method of operating motors. Three of the list of patents were granted to Hutin and Leblanc, the subjects being damping devices for alternating-current motors, variable-speed induction motors, and alternating-current transformation. Nine patents were granted to Mr. B. G. Lamme, the subjects being induction motors, starting arrangements for induction motors, and alternating-current motor. Of the

remaining patents, two were granted to Mr. William Stanley for an alternating-current motor with compensated field and a self-regulating transformer (1892), another to Nolan for armature core construction and two others to Dusinberre for induction motors.

Tesla's Method of Transmitting Electrical Energy Through Space.

Nikola Tesla of New York city, who, as is well known, has done much work of an original nature in the direction of the transmission of electrical energy through space, has recently been granted a patent (No. 787,412, April 18, 1905) upon such a method for the propagation of energy. The title of the patent is "Art of Transmitting Electrical Energy Through the Natural Mediums." Application for it was made May 16, 1900, and renewed June 17, 1902.



A fact now of common knowledge is that when electrical waves or oscillations are impressed upon such a conducting path as a metallic wire, reflection takes place, under certain conditions, from the ends of the wire, and in consequence of the interference of the impressed and reflected oscillations the phenomenon of "stationary waves" with maxima and minima in definite fixed positions is produced. The existence of these waves indicates that some of the outgoing waves have reached the boundaries of the conducting path and have been reflected therefrom. Mr. Tesla has been led to believe from his observations that notwithstanding its vast dimensions the terrestrial globe may in a large part or as a whole behave toward disturbances impressed upon it in the same manner as a conductor of limited size.

In the course of certain investigations which he carried on for the purpose of studying the effects of lightning discharges upon the electrical condition of the earth it was observed that sensitive receiving instruments arranged so as to be capable of responding to electrical disturbances created by the discharges at times failed to respond when they should have done so, and upon inquiring into the causes of this unexpected behavior it was discovered to be due to the character of the electrical waves which were produced in the earth by the lightning discharges and which had nodal regions following at definite distances the shifting source of the disturbances. From data obtained in a large number of observations of the maxima and minima of these waves their length has been found to vary approximately from 25 to 75 kilometers, and these results and certain theoretical deductions led Mr. Tesla to the conclusion that waves of this kind may be propagated in all directions over the globe and that they may be of still more widely differing lengths, the extreme limits being imposed by the physical dimensions and properties of the earth.

Recognizing in the existence of these waves an unmistakable evidence that the disturbances created had been conducted from their origin to the most remote portions of the globe and had been thence reflected, the idea was conceived of producing such waves in the earth by artificial means with the object of utilizing them for many useful purposes for which they are or might be found applicable. This problem was rendered extremely difficult, owing to the immense dimensions of the planet, and consequently enormous movement of electricity or rate at which electrical energy had to be delivered in order to approximate, even in a remote degree, movements or rates which are manifestly attained in the displays of electrical forces in nature and which seemed at first unrealizable by any human agencies. But by gradual and continuous improvements of a generator of electrical oscillations, for which Mr. Tesla had previously obtained a patent, he finally succeeded in reaching electrical movements or rates of delivery of electrical energy which he believed not only approximated, but, as shown in many comparative tests and measurements, actually surpassed those of lightning discharges, and by means of this apparatus he found it possible to reproduce, whenever desired, phenomena in the earth the same as or similar to those due to such discharges.

In the figure, (A) designates a primary coil forming part of a transformer and consisting generally of a few turns of a stout cable of inappreciable resistance, the ends of which are connected to the terminals of a source of powerful electrical oscillations, diagrammatically represented by (B). This source is usually a condenser charged to a high potential and discharged in rapid succession through the primary. But when it is desired to produce stationary waves of great lengths an alternating dynamo of suitable construction may be used to energize the primary. A spirally wound secondary coil (C) within the primary has the end nearer to the latter connected to the ground (E') and the other end to an elevated terminal (E). The physical constants of coil (C), determining its period of vibration, are so chosen and adjusted that the secondary system (E' C E) is in the closest possible resonance with the oscillations impressed upon it by the primary. It is, moreover, of the greatest importance in order to still further enhance the rise of pressure and to increase the electrical movement in the secondary system that its resistance be as small as practicable and its self-induction as large as possible under the conditions imposed. The ground should be made with great care, with the object of reducing its resistance. Instead of being directly grounded, as indicated, the coil (C) may be joined in series or otherwise to the primary (A), in which case the latter will be connected to the plate (E'). The total length of the conductor from the ground-plate (E') to the elevated terminal (E) should be equal to one-quarter of the wave length of the electrical disturbance in the system (E' C E), or else equal to that length multiplied by an odd number. This relation being observed, the terminal (E) will be made to coincide with the points of maximum pressure in the secondary or excited circuit, and the greatest flow of electricity will take place.

In order to magnify the electrical movement in the secondary as much as possible, it is essential that its inductive connection with the primary (A) should not be very intimate, as in ordinary transformers, but loose, so as to permit free oscillation—that is to say, their mutual induction should be small. The spiral form of coil (C) secures this advantage, while the turns near the primary (A) are subjected to a strong inductive action and develop a high initial electromotive force. These adjustments and relations being carefully completed and other constructive features indicated rigorously observed, the electrical movement produced in the secondary system by the inductive action of the primary (A), will be enormously magnified, the increase being directly proportionate to the inductance and frequency and inversely to the resistance of the secondary system. It is practicable to produce in this manner an electrical movement thousands of times greater than the initial—that is, the one impressed upon the secondary by the primary (A), and the inventor claims to have thus reached activities or rates of flow of electrical energy in the system (E' C E) measured by many tens of thousands of horsepower. Such immense movements of electricity give rise to a variety of novel and striking phenomena, among which are those already described. The powerful electrical oscillations in the system (E' C E) being communicated to the ground cause corresponding vibrations to be propagated to distant parts of the globe, whence they are rflected, and by interference with the outgoing vibrations produce stationary waves, the crests and hollows of which lie in parallel circles relatively to which the ground-plate (E') may be considered to be the pole. Stated otherwise, the terrestrial conductor is thrown into resonance with the oscillations impressed upon it just like a wire. More than this, the movement of electricity through it follows certain laws with nearly mathematical precision. It will be, however, sufficient to state that the planet behaves like a perfectly smooth or polished conductor of inappreciable resistance with capacity and self-induction uniformly distributed along the axis of symmetry of wave propagation and transmitting slow electrical oscillations without sensible distortion and attenuation.

TESLA'S METHOD OF TRANSMITTING ELECTRICAL ENERGY THROUGH SPACE.

Besides the above, three requirements seem to be essential to the establishment of the resonating condition.

First—The earth's diameter passing through the pole should be an odd multiple of the quarter-wave length—that is, of the ratio between the velocity of light and four times the frequency of the currents.

Second—It is necessary to employ oscillations in which the rate of radiation of energy into space in the form of hertzian or electromagnetic waves is very small. To give an idea it may be said that the frequency should be smaller than 20,000 per second, though shorter waves might be practicable. The lowest frequency would appear to be six per second, in which case there will be but one node, at or near the ground-plate, and, paradoxical as it may seem, the effect will increase with the distance and will be greatest in a region diametrically opposite the transmitter. With oscillations still slower the earth, strictly speaking, will not resonate, but simply act as a capacity, and the variation of potential will be more or less uniform over its entire surface.

Third—The most essential requirement is, however, that irrespective of frequency the wave or wave train should continue for a certain interval of time, which estimated to be not less than one-twelth or probably 0.08484 of a second and which is taken in passing to and returning from the region diametrically opposite the pole over the earth's surface with a mean velocity of about 471,240 kilometers per second.

The presence of the stationary waves may be detected in many ways. For instance, a circuit may be connected directly or inductively to the ground and to an elevated terminal and tuned to respond more effectively to the oscillations. Another way is to connect a tuned circuit to the ground at two points lying more or less in a meridian passing through the pole (E'), or, generally stated, to any two points of a different potential.

The Brooklyn Eagle May 9, 1905

VERDICT AGAINST TESLA.

Wireless Telegraph Inventor, Defeated in Civil Suit Tried at Riverhead, Will Appeal.

(Special to the Eagle.)

Riverhead, L. I., May 9—At the opening of the county court here yesterday afternoon, Judge Jaycox presiding, the action against Nikola Tesla, the well known electrician and wireless telegrapher expert, to recovr on a land deal, was the first case tried and Judge Jaycox directed verdict for the plaintiff, Dr. James S. Warden, for $610.97. The defendant put in no testimony, but at the conclusion of plaintiff's case the defendant moved to dismiss the complaint. Judge Jaycox refused, however, and upon plaintiff's motion judgment was directed for him.

From the testimony it was revealed that Mr. Tesla agreed to purchase a tract of land for $25 an acre containing "410 acres more or less." It was shown that Tesla agreed to take an option for two years by paying 4 per cent. on the total purchase price. After he had failed to pay for six months suit was commenced.

The case was tried once before, and at that time, also, a judgment was directed for plaintiff without going to the jury. An appeal was taken to the Appellate Division and the case sent back for a retrial. Upon the first hearing and also upon the one yesterday, defendant contended that the tract by measurement did not contain 410 acres, and even though it did, it was not so stated in his agreement, and he, therefore, could not pay money on a piece of property not knowing definitely how much property there was and consequently, how much money was due on a "more or less" tract.

The piece of property that Tesla wanted to buy is located near his big experimental tower and buildings ot Wardenclyffe, L. I.

The case will be again appealed.

TESLA PATENT ON WIRELESS TRANSMISSION OF ELECTRICAL SIGNALS.

An U.S.A. patent was issued on April 18 to Mr. Nikola Tesla for "The Art of Transmitting Electrical Energy through the Natural Mediums." We are indebted to the *Electrical World* for the abstract of this patent given below:

In the preamble it is stated that experiments and observations have tended to confirm the opinion held by the majority of scientific men, that the earth, owing to its immense extent, does not behave in the manner of a conductor of limited dimensions with respect to electrical disturbances, but much like a vast reservoir or ocean, which, while it may be locally disturbed by commotion of some kind, remains unresponsive and quiescent in a large part or as a whole. The inventor states he has discovered that notwithstanding its vast dimensions and contrary to all observations heretofore made, the terrestrial globe may in a large part or as a whole behave toward disturbances impressed upon it in the same manner as a conductor of limited size.

In the course of certain investigations he noted unsuspected behaviour of sensitive instruments, which he discovered to be due to the character of electrical waves produced in the earth by lightning discharges, and which had nodal regions following at definite distances the shifting source of the disturbances. From data obtained in a large number of observations on a maxima and minima of these waves, their length was found to vary approximately from 25m. to 70m., and these results and certain theoretical deductions led to the conclusion that waves of this kind may be propagated in all directions over the globe, and that they may be of still more widely differing lengths, the extreme limit being imposed by the physical dimensions and properties of the earth. By means of gradual improvements in the generation of electrical oscillations, electrical movements were finally reached not only approximating, but, as shown in many comparative tests and measurements, actually surpassing those of lightning discharges; and by means of this apparatus it was found possible to reproduce whenever desired phenomena in the earth the same or similar to those due to such discharges.

For example, by the use of such a generator of stationary waves and receiving apparatus properly placed and adjusted in any other locality, however remote, it is practicable to transmit intelligible signals or to control or actuate at will any one or all of such apparatus for many other important and valuable purposes, as for indicating wherever desired the correct time of an observatory, or for ascertaining the relative position of a body or distance of the same with reference to a given point, or for determining the course of a moving object, such as a vessel at sea, the distance traversed by the same or its speed, or for producing many other useful effects at a distance dependent on the intensity, wave-length, direction or velocity of movement, or other feature or property of disturbances of this character.

In the accompanying figure is represented diagrammatically the generator which produces stationary waves in the earth, and an apparatus situated in a remote locality for recording the effects of these waves. The generator consists of a primary coil forming part of a transformer and consisting generally of a few turns of a stout cable of inappreciable resistance, the ends of which are connected to the terminals of a source of powerful electrical oscillations, this generally being a condenser charged to a high potential and discharged in rapid succession through the primary. *C* is a spiral-wound secondary coil within the primary, one end being connected to ground and the other

to an elevated terminal, E. The resistance of the secondary system should be as small as practicable, its self-induction as large as possible, and the ground should be made with great care. The total length of the conductor from the ground-plate to the elevator terminal, E, should be equal to one-fourth of the wave-length of the electrical disturbance or to that length multiplied by an odd number. The relation being observed, the terminal, E, will be made to coincide with the points of maxima pressure in the secondary or excited circuit, and the greatest flow of electricity will take place in the same to permit free oscillation. The inductive connection between the primary and scondary should not be very intimate as in ordinary transformers, and this is accomplished by the spiral form given to coil C. With this arrangement it has been possible to produce an electrical movement thousands of times greater than the initial, and activity of rates of flow have been produced measured by many tens of thousands of horse-power. The powerful electrical oscillations being communicated to the ground cause corresponding vibrations to be propagated to distant parts of the globe, whence they are reflected, and by interference with the outgoing vibrations produce stationary waves, the crests and hollows of which lie in parallel circles, relative to which the ground-plate may be considered to be the pole—that is to say, the terrestrial conductor is tuned into resonance with the oscillations impressed upon it, just like a wire. A number of facts ascertained clearly show that the movements of electricity through the system follow certain laws

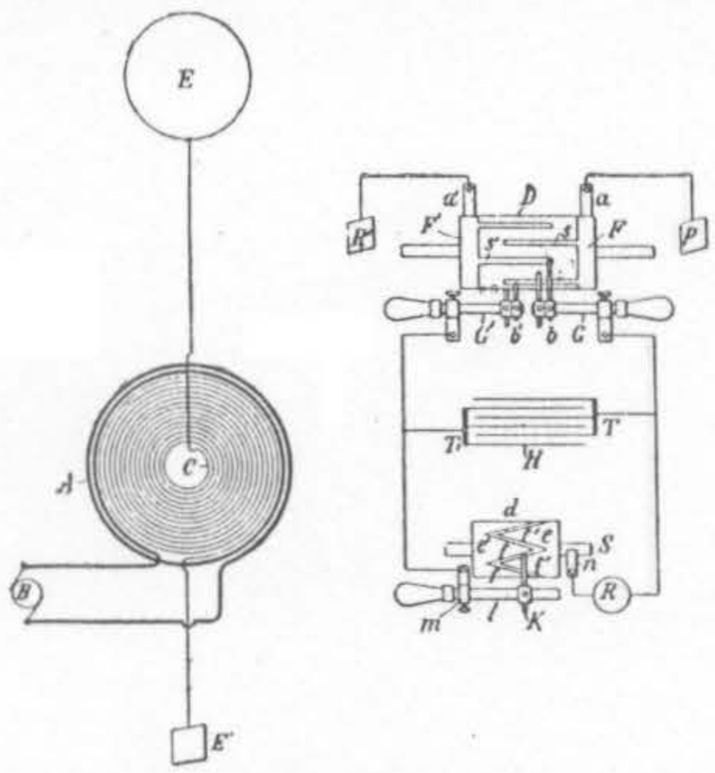


Diagram of Tesla Wireless Signal Apparatus.

with merely mathematical rigour. For the present it is sufficient to state that the planet behaves like a perfectly smooth or polished conductor of inappreciable resistance, with capacity and self-induction uniformly distributed along the axis of symmetry of wave propagation, and transmitting slow electrical oscillations without sensible distortion and attenuation.

Three additional requirements seem to be essential to the establishment of the resonant condition, as follows: First, the earth's diameter passing through the pole should be an odd multiple of the quarter wave-length—that is, of the ratio between the velocity of light and four times the frequency of the currents. Second, the frequency should be smaller than 20,000 per second. The lowest frequency would appear to be six per second, in which case there will be but one load at or near the ground-plate, and paradoxical as it may seem, the effect will increase with the distance, and will be greatest in a region diametrically opposite the transmitter. With oscillations still slower, the earth, strictly speaking, will not resonate, but simply acts as a capacity, and the variations of potential will be more or less uniform over its entire surface. Third, the main essential requirement is that, irrespective of frequency, the wave train will continue for a certain interval of time, which is estimated at not less than one-twelfth, or 0 08484 of a second, and which is taken in passing to and returning from the region diametrically opposite the pole over the earth's surface with a mean velocity of about 471,240 km. per second.

Fig. 2 shows a device for detecting the presence of the waves. It consists of a cylinder, D, of insulating material, which is moved at a uniform rate of speed by clockwork and other suitable motor power, and is provided with two metal rings, $F\,F'$, upon which bear brushes, $A\,A'$, connected to terminal plates. From the rings, $F\,F'$, extend narrow metallic segments, SS', which by rotation of the cylinder, D, are brought alternately into contact with double brushes, $b\,b'$, carried by and in contact with conducting holders, HH', supported in the metal bearings, $G\,G'$. The latter are connected to the terminals, $T\,T'$, of a condenser, H, and are capable of angular displacement as ordinary brush supports. The object of two brushes in the holder is to vary at will the duration of the electrical contact with the terminal plates and the condenser. To the latter is connected a receiver, R, and a device, d, performing the duty of closing the receiving circuit at predetermined intervals of time, and charging the restored energy through the receiver.

The receiver consists of a cylinder made partly of conducting and partly of insulating material, which is rotated at a desired rate of speed by any suitable means. The conducting part, e, is in electrical connection with the shaft, S, upon which slides a brush, K, capable of longitudinal adjustment in the metallic support, m. Another brush, n, is arranged to bear upon a shaft, S. It will be seen that whenever one of the segments, F, comes in contact with the brush, K, the circuit, including the receiver, R, is completed, and the condenser discharged through the same. By suitable adjustment the circuit may be made to open and close in rapid succession and remain open or closed during such intervals of time as may be necessary.

The terminal plates, $P\,P'$, through which the electrical energy is conveyed to the brushes, $A\,A'$, may be at a considerable distance from each other in the ground or one in the ground and the other in the air, preferably at some height. In the latter case the location of the apparatus must be determined with reference to the position of the stationary waves. If both plates be connected to earth, the points of connection must be selected with reference to the differences of potential which it is desired to secure. In receiving the speed of rotation of the cylinder, D, is varied until it is in synchronism with the alternate impulses of the distant generator; the brushes being properly adjusted, electrical charges of the same sign will be conveyed to each of the terminals of the condenser, and with each fresh impulse it will be charged to a higher potential. In this manner the energy of any number of separate impulses may be accumulated and discharged through the receiver, R. Thus a relatively great amount of energy may be accumulated and the receiver need not be very sensitive. It being possible to shift the nodal and ventral regions of the waves at will from the sending station, the regions of maximum and minimum effect may be made to coincide with any receiving station or stations.

By impressing upon the earth two or more oscillations of different wave-length, a resonant stationary wave may be made to travel slowly over the globe. If the nodal and ventral regions are maintained in a fixed position, the speed of a vessel carrying receiving apparatus may be exactly computed from observations of the maximum and minimum regions successively traversed. In any region at the surface the wave-length can be ascertained from certain rules of geometry, and, conversely, knowing the wave-length, the distance from the source can be readily calculated. Thus the distance of one point from another, the altitude and longitude, the hour, etc., may be obtained from the observation of such stationary waves. With several generators, preferably generating different wave-lengths, installed in selected localities, the entire globe could be sub-divided in different zones of electrical activity, and important data could be at once obtained by similar calculations or readings from suitably graduated instruments.

The Polyphase Patent Situation.

Last week we referred to a list of patents issued by the owners of the recently expired Tesla fundamental rotary field patents. A notice accompanying the list stated that certain manufacturers are offering to supply polyphase induction and synchronous motors and apparatus for use therewith because certain of the Tesla patents have expired, and intending purchasers of polyphase apparatus are notified that numerous other patents relating to these subjects are still in force. Below is given an analysis of the various patents named in the list, together with a brief account of the litigation in which some of the patents have figured. In addition to the patents in the list above referred to are several others which in a minor way have also figured in this same litigation.

TESLA PATENTS.

Of the Tesla patents the most important are the two fundamental patents on the split-phase system. These are Nos. 511,559 and 511,560, issued December 26, 1893, on applications filed December 8, 1888. Both of these patents have been in litigation for some years.

Judge Thompson, of the Southern District of Ohio, filed an opinion February 6, 1901, sustaining the patents in a suit brought against the Dayton Fan & Motor Company. The courts held that the first-mentioned patent covered the case of an alternating current passing through one energizing circuit and inducing a second current in the other energizing circuit; and also the case of two motor energizing circuits connected in derivation or multiple arc with the main circuit from the source. The second patent was held to cover apparatus for carrying out the method by derivation. It was also held that the retardation of phase by artificial means and its conversion from an element of disadvantage to one of usefulness in the transmission of electric power, must be regarded as evidence of invention. The court also pronounced against the defense that the inventions of the two patents in suit are covered by a prior patent issued to the same inventor, No. 416,193, issued December 3, 1889, on an application filed May 30, 1889. The claims of this patent are for an alternating-current motor having two or more energizing circuits, the coils of one circuit being composed of conductors of large size or low resistance and those of the other of fewer turns of wire of smaller size or higher resistance; also the combination with long and short field cores of energizing coils, including in independent circuits, the coils on the longer cores containing an excess of copper or conductor over that in the others; also, a field magnet composed of magnetic plates having an open center, and pole pieces or cores of different length, coils surrounding the cores and included in independent circuits, the coils on the longer cores containing an excess of copper, the longer cores being set in recesses in the iron core formed by the plates. It was held that in this latter patent there is claimed only a specific form of construction and not the method or process by which all motors of its class are operated. This decision was sustained on appeal in an opinion filed November 5, 1902. Judge Severen, who wrote the opinion, defined patent No. 511,559 as relating to a method or methods of transmitting alternating currents proceeding from one original source to both of the energizing circuits of a motor, and at the same time retarding the phases of the current in one circuit to a greater or less extent than in the other. The second patent was defined as relating to means employed in the transmission of electrical power to a motor through divided currents derived from a single current proceeding from the generator; the said divided currents being so regulated with reference to each other as to arrive at their destination in the motor-alternator.

In an opinion filed August 22, 1901, in a case in which the Catskill Illuminating & Power Company was defendant, and in which the Sheeffer meter figured as the alleged infringing device, Judge Lacombe held that two claims of the first patent were infringed and the first claim of the second patent. The second claim of the latter patent was stated to be restricted to apparatus in which the energizing currents are connected in derivation of multiple arc with the supply circuit, and this claim was declared not to be infringed. The Catskill suit was appealed and in an opinion written by Judge Townsend and filed February 25, 1903, the court below was reversed. It was held that the two patents were invalid on the ground that the system covered by the patents in suit was fully described in an article by Prof. Ferraris printed in an Italian journal April 22, 1888, which date was prior to the invention by Tesla.

The same two patents figured in litigation in the Massachusetts Circuit Court. On March 11, 1903, Judge Colt dismissed a bill alleging infringement of the patents by the Stanley Instrument Company on the ground that it had been shown by Judge Townsend that the Tesla patents were anticipated by the Ferraris publication. Upon appeal, in an opinion written by Judge Putnam, filed September 9, 1904, Judge Colt's decision was reversed, it being held that the testimony of a witness, Mr. Page, had established that Tesla had conceived the invention prior to the date of the Ferraris publication. Owing to the conflict in the two decisions on appeal, the case came before the United States Supreme Court on petition for a writ of certiorari. This was denied on the grounds that the two courts had before them substantially different records and therefore there was no conflict. The two patents were sustained in the United States Circuit Court for the Eastern District of Pennsylvania in a suit involving the Guttmann wattmeter. The opinion was rendered by Judge Archbald, who dismissed the defenses based upon patents issued to Dumesnil and Cabanellas and on the Ferraris publication, declaring the two patents to be valid. In another case before the United States Circuit Court for the Western District of New York, decided February 9, 1904, involving also the Guttmann meter, Judge Hazel held the two above patents to be valid, the defense being the Ferraris publication.

In still another case involving the Sheefer meter, Judge Kohlsaat, in an opinion filed March 26, 1904, sustained the patents, basing his decision upon previous decisions in their favor. Judge Buffington, in the United States Circuit Court for the Western District of Pennsylvania, on March 28, also sustained the patents in a case involving the Sheefer meter, basing his decision upon prior decisions sustaining the patents.

No. 416,194.—*Electric motor, December* 3, 1889. *Application filed May* 20, 1889. An induction motor with field and armature of equal strength when energized by a given current; the combination with field and armature coils of equal mass, of energizing coils containing equal amounts of copper. The specification states that such a motor will give the maximum output for the material used.

No. 445,207.—*Electromagnetic motor, January* 27, 1891. *Application filed May* 20, 1889. The motor is of the split-phase induction type, and is a self-starting, single-phase machine. There are on the motor two energizing circuits, one of which is connected directly to the source of supply of current, while the second circuit is placed in inductive relation to the first, the two circuits being constructed with different time constants. In the operation of this motor the current impulses in the first, or primary, coils produce currents in the secondary coils, and by the conjoint action of the two an unsymmetrical revolving field is obtained. There are three claims. In the Scott and Janney case it was held that this patent did not conflict with the patents there in suit, as it carried a distinct invention.

No. 459,772.—*Electromagnetic motor, September* 22, 1891. *Application filed April* 6, 1889. The seven claims relate to the combina-

tion of an induction motor used as a starting device for a synchronous motor. The induction motor is mounted on the same shaft with the synchronous motor, the number of poles of each being so chosen as to give to the former motor a speed greater than that of the latter. The use of a self-starting, split-phase induction motor is disclosed in the drawings, but not referred to specifically in the claims.

No. 487,796.—*System of electrical transmission of power, December* 13, 1892. *Application filed May* 15, 1888. The four claims cover a multipolar generator with independent armature circuits used in combination with a motor having independent energizing circuits, the type of neither the generator nor the motor being specified. The drawings show two-phase generators and motors, all of which are of the synchronous type. The claims dwell upon the use of a number of motor poles greater or less than the number of generator armature circuits.

No. 511,915.—*Electrical transmission of power, January* 2, 1894. *Application filed May* 15, 1888. *No.* 555,190.—*Alternating motor, February* 25, 1896. *Application filed May* 15, 1888. These two patents figured as a single issue in a suit against the Scott & Janney Co., decided September 27, 1899, in the United States Circuit Court of the Eastern District of Pennsylvania. Judge McPherson, in his opinion, held that the invention of the patents was for a specific method of obtaining difference of phase, namely, by induction instead of self-induction, and therefore they did not conflict with the fundamental rotary field and the fundamental split-phase patents. The motor has two independent energizing circuits through only one of which current from the source is passed. In the second circuit the current is produced by the inductive effect of the current in the first circuit.

STANLEY PATENTS.

No. 469,809.—*System of Electrical Distribution, March* 1, 1892. This is known as the Stanley transformer patent, issued on an application by William Stanley, Jr., filed August 15, 1888, and has been subject to litigation. On April 26, 1901, Judge Coxe handed down a decision in two suits of the Westinghouse Co. against the Saranac Lake Electric Light Company, alleging infringement of two patents on transformers, one issued to Rankin Kennedy, the other being the present patent. An abstract of the decision in this case was given in our columns in the issue of May 4, 1901. Judge Coxe held the Kennedy patent to be void, and upheld the Stanley patent on the ground that in this patent Stanley first described how to make a regulating transformer. He discovered that he could remedy existing faults by regulating the length of the wire on the primary coil of the transformer and laid down the following rule: "He determines the correct length of the primary coil by winding on wire after the transformer, in circuit, is connected with the dynamo until the loss of voltage represented by the formula C^2R equals the predetermined loss of energy to be suffered in the system." The patent came up on appeal from this decision, and Judge Lacombe, on January 14, 1902, wrote an opinion sustaining the lower court. Judge Lacombe stated the Stanley rule as follows: "It says you may determine the proper length of the primary coil by connecting the transformer in circuit with the dynamo with which it is to be used, and then wind on the wire until the loss indicated by the formula C^2R within the secondary can equal a certain loss of degree." He also held that this rule is part of the invention disclosed and claimed in the patent. The same patent is now in course of litigation, the defendants being the Montgomery Electric Light & Power Company. On June 18, 1904, Judge Coxe handed down an opinion in this suit again sustaining the patent, holding, first, that Stanley made a valuable invention; second, that the invention is described in the patent with sufficient clearness to enable skilled electricians to practice it without difficulty; and third, that the defendant had appropriated the invention, though its transformers were not designed in the manner pointed out by Stanley. An abstract of this opinion appeared in our issue of July 23, 1904. An injunction was granted but, as noted in our columns last week, the order for the injunction has been reversed on appeal on the grounds that in view of the large importance of the controversy the rights of the party should be reserved for decision until the final hearing of the case, which will come up in due course. In this case the alleged infringing device was a Wagner transformer.

No. 508,188.—*Alternate-current electric motor, Nov.* 7, 1893. *Application filed Oct.* 23, 1888. The motor is of the single-phase commutator type, and is similar to a repulsion motor in that the stator field winding constitutes the primary circuit. The secondary (rotor) circuit, however, is not closed upon itself directly, but is connected to a supplemental coil, which surrounds the armature, and through which there flows current, produced by induction from the primary

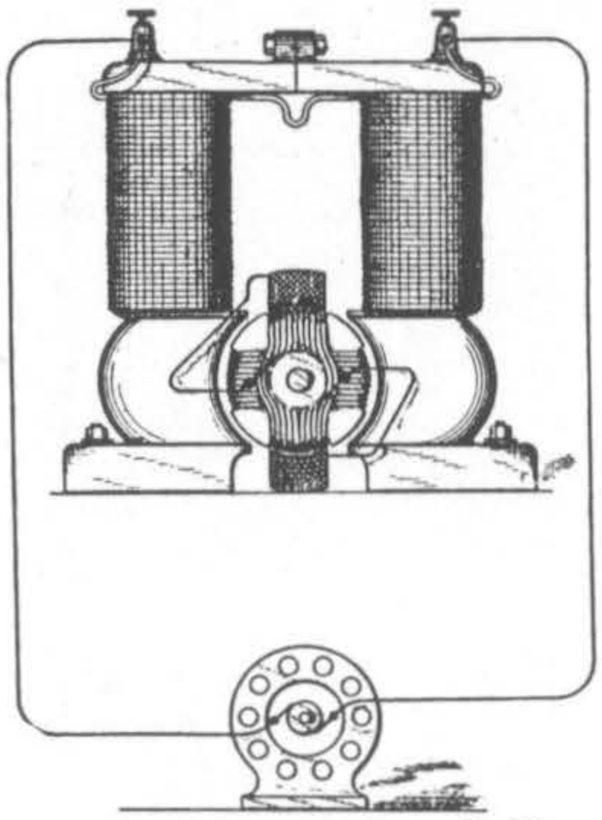

FIG. 1.—STANLEY, NO. 508,188.

circuit, in a direction to assist the polarizing effect of the current in the armature coils. There are four claims covering the combination shown in the accompanying illustration.

LAMME PATENTS.

No. 519,862.—*Method of and means for starting synchronous motors, May* 15, 1904. *Application filed April* 5, 1893. The invention contemplates the applying to the armature of the motor a starting current of low potential and large volume, thereby causing the armature to excite the field magnets by induction, and then gradually increasing the potential of the starting current to that of the supply circuit. The 9 claims, in addition to the general method of operation, cover the means for obtaining the variable potential. This patent is now in litigation, with the Indianapolis, Shelbyville & Southeastern Traction Company as defendant.

No. 582,132.—*Alternating-current motor, May* 4, 1897. *Application filed October* 30, 1895. The motor is of the induction type, having a revolving primary and stationary secondary. The invention relates to the construction of the stationary member. A starting resistance of proper value is included in the secondary circuit, and means provided in order to short-circuit the resistance when the motor reaches normal speed. The 15 claims cover the construction of the stator of the Westinghouse Type B motor.

No. 599,940.—*Non-synchronous electric motor, March* 1, 1898. *Application filed April* 30, 1894. The invention deals with the shape and size of the primary coils of an induction motor. Each coil of the distributed primary winding embraces an arc which is either greater or less than that resulting from dividing the entire circumference by the product of the number of poles and the number of phases. The object is to produce a sinusoidal distribution of field magnetism. There are four claims.

No. 609,990.—*Means for controlling non-synchronous alternating-current motors, August* 30, 1898. *Application filed March* 11, 1896. This patent relates to the use of a variable primary impressed e.m.f. for varying the speed of the motor. The four claims are for the combination with a primary member of a secondary member pro-

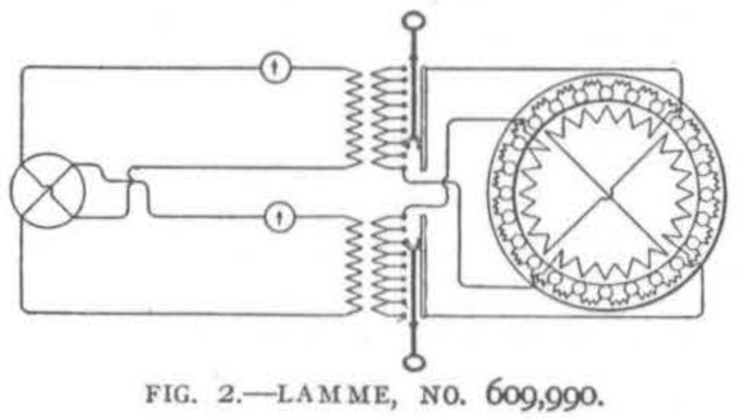

FIG. 2.—LAMME, NO. 609,990.

vided with a comparatively high-resistance winding directly short-circuited on itself, and means for varying the e.m.f. applied to the primary whereby the speed of the motor is varied; a small degree

of magnetic leakage between the primary and secondary; means for varying the speed of the motor consisting of a transformer for supplying current to the primary and means for varying the relation between the primary and secondary, thereby varying the e.m.f. supplied by the secondary; and means for varying the active lengths of the transformer secondary, whereby the e.m.f. applied to the primary of the motor is varied.

No. 609,991.—*Method of and means for securing constant torque in polyphase motors, August* 30, 1898. *Application filed February* 10, 1898. The motor is of the induction type, and has a comparatively high resistance in the secondary winding and a low degree of magnetic leakage, so that normally its torque increases continually with decrease of speed, and becomes maximum at standstill. In each of the supply circuits is placed a reactive coil, the core of which becomes saturated by a predetermined amount of current, the result being that the torque remains practically constant (at a reduced value) from standstill to that speed at which the current

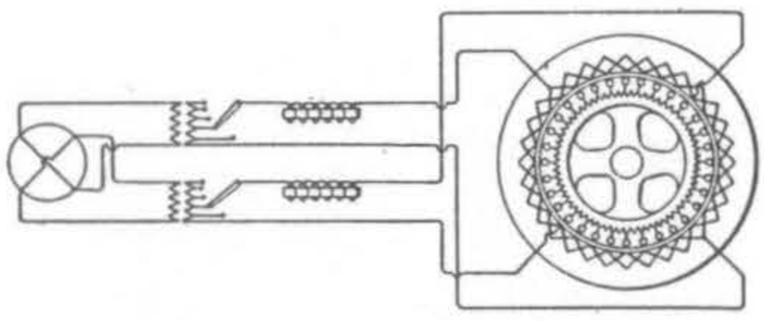

FIG. 3.—LAMME, NO. 609,991.

flows, causing the saturation of the cores of the choke coils. There are four claims, the first of which reads as follows: The combination with an induction alternating-current motor having a comparatively high resistance, secondary winding and a low degree of magnetic leakage, of a reactive coil in each of the supply circuits the core of which becomes saturated by a predetermined amount of current whereby a substantially constant torque is secured.

No. 610,067.—*Induction motor, August* 30, 1898. *Application filed July* 22, 1897. This patent relates to the construction of squirrel-cage secondary windings for the rotor of an induction motor, and the four claims refer to the use of ventilating blades on the resistance rings.

No. 633,856.—*Distributed winding for electrical machines, September* 26, 1899. *Application filed February* 6, 1899. The patent relates to mechanical details of the end connectors for the windings, which are covered by 8 claims. J. P. Mallet is a co-patentee. As usually constructed the portions of the armature conductors located in the slots of the core are in the form of bars, the ends of these bars being properly connected outside the core by means of end-connectors of suitable form, which are riveted and soldered or bolted to the ends of the bars.

No. 644,865.—*System of electrical distribution, March* 6, 1900. *Application filed June* 14, 1899. The invention refers to the method of obtaining e.m.f's lower than the normal voltages of a two-phase

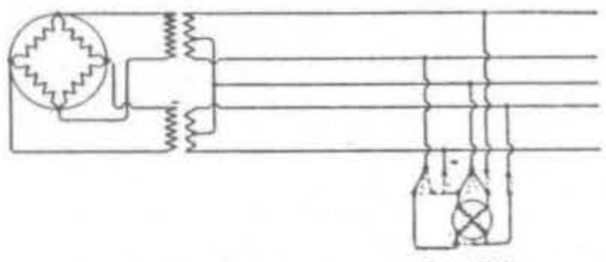

FIG. 4.—LAMME, NO. 644,865.

system by connecting the coils of the receiver between adjacent leads, or between adjacent single leads and a joint intermediate lead of the supply system. There are eight claims covering the various combinations of e.m.f's in quadrature obtainable from symmetrically and unsymmetrically disposed two-phase circuits. The cut shows the method by which can be obtained a voltage seven-tenths of normal value, at which e.m.f. the exciting volt-amperes for an induction motor, when lightly loaded, will be approximately one-half of the normal.

No. 759,183.—*Method of utilizing single-phase, alternating-current energy, May* 3, 1904. *Application filed December* 26, 1901. The invention refers to the use of the commutator type of single-phase motor, which was described fully in our issue of February 13 of last year. There are 8 claims relating to the proper proportioning of the field and armature windings.

HUTIN AND LEBLANC PATENTS.

No. 592,272.—*Alternating-current electrodynamic machine, November* 13, 1904. *Application filed August* 20, 1892. The invention relates to damping devices for preventing oscillations in the speed of synchronous motors and generators. There are six claims which cover the use of paths of low electrical resistance located within the path of the magnetic flux of the machine, at the margin of the interpolar space. This patent is now in litigation, the Bullock Electric Manufacturing Company being defendant.

No. 553,469.—*Alternating-current motor, January* 21, 1896. *Application filed November* 17, 1892. According to the patent, the secondary resistance of an induction motor is to be decreased in direct ratio with the frequency of the secondary circuit, so as to maintain the rotor torque at a constant maximum whatever may be the speed of rotation. Although the resistance is to be varied mechanically and the five claims cover means for producing the variation, the specification discloses no means other than the manual operation of a rheostat.

No. 12,223 (*reissue*).—*Alternating-current transformation, May* 24, 1904. *Original, No.* 754,371, *March* 8, 1904. There are two separate transformers in which the individual magnetic fluxes are in time quadrature. Two-phase e.m.f's may be obtained (or supplied) by winding similar coils on the cores of the two transformers, while three-phase e.m.f's may be supplied (or obtained) by passing around one of the magnetic cores for one of the three phases a number of turns proportionate to the sine of a certain arbitrarily chosen angle, and around the other core a number of turns proportionate to the cosine of the same angle; and for the other two phases using numbers proportionate to the sine and cosine of the same angle plus $2\pi/3$, or minus $2\pi/3$, respectively. The six claims cover the method in general without reference to specific apparatus.

DUSINBERRE PATENTS.

No. 763,379.—*Alternating-current induction motor, June* 28, 1904. *Application filed February* 27, 1904. The starting resistance of the revolving secondary is mounted in the form of a helix concentric with the shaft of the rotor, and variation in the effective length is accomplished by means of a contact device movable longitudinally upon the shaft. There are 12 claims covering the constructive details.

No. 763,547.—*Alternating-current induction motor, June* 28, 1904. *Application filed February* 27, 1904. The invention relates to means for automatically decreasing the resistance of the secondary circuit as the speed increases. The auxiliary resistance is assembled in spiral form and mounted so as to rotate with the motor shaft, which shaft also carries a contact device operated by centrifugal force whereby the amount of resistance included in the secondary circuit is decreased with increase of speed. The four claims cover the constructive features.

NOLAN PATENT.

No. 582,481.—*Fastening means for core plates of electrical machines, May* 11, 1897. *Application filed January* 20, 1897. In a circumferential groove in the core spider there is placed a spring metal ring which extends outside the groove and against a shoulder

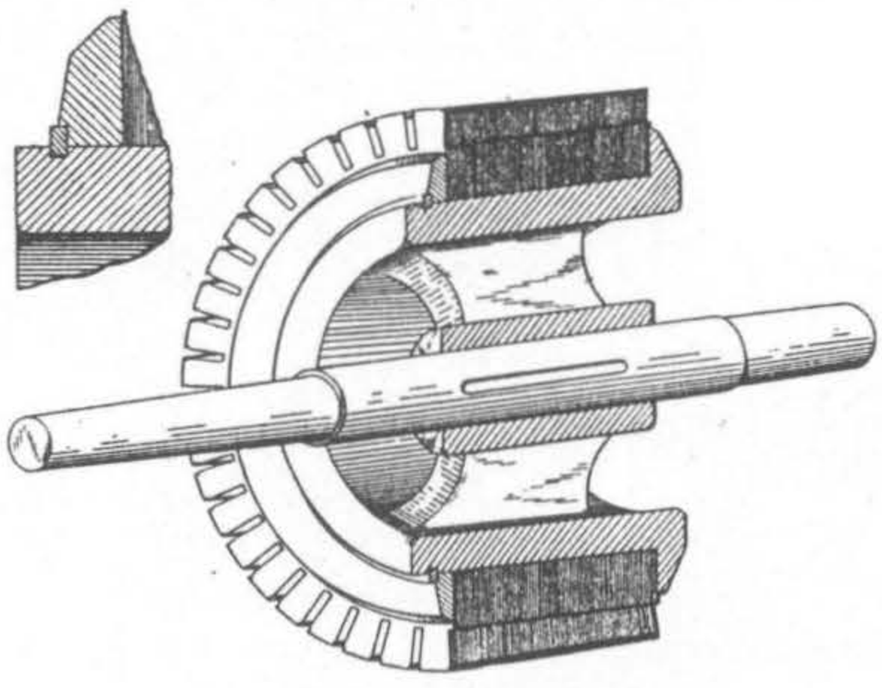

FIG. 5.—NOLAN, NO. 582,481.

on an annular plate between which and a flange on the core the laminæ are clamped. The construction is illustrated in Fig. 5 and is covered by four claims. This patent is now in litigation, the Bullock Electric Manufacturing Company being defendant.

TESLA'S VALUABLE PATENTS EXPIRE.

"Wizard" Inventor Has Drawn Princely Income on Electrical Monopoly.

A great stir has been created among electricians everywhere by the announcement that the famous patents of Nicola Thesla covering the alternating current dynamo, have just expired. They have been widely known for years as the "three fundamental patents." Their expiration is an event in the world of electricity, not second in importance to the dying out of the Bell telephone patents. The alternating motor has been a monopoly.

Tesla has been drawing princely royalties on these patents, much of which the picturesque inventor is said to have applied to his experiments in wireless telegraphy. His mysterious tower at Wardencliffe, Long Island, is said to have been built in part by money subscribed by J. Pierpont Morgan, and in part out of the royalties from the motor patents.

In 1885 Prof. Galileo Ferraris, of Turin, Italy, discovered the electromagnetic rotating field, and applied his invention ,according to William Stanley, to a rotating field motor. In 1888 Tesla received United States patents covering the broad application of the Ferraris discovery. George Westinghouse bought the Tesla patents and also the rights of Ferraris.

The fundamental Tesla patents have been for years in the possession of what is called the "Patent Pool Trust." They have been attacked many times in the courts, but without success. It is now generally believed by electricians that the expiration of the patents releases to the world at large the immensely important principle of the rotary field. There will be a grand scramble everywhere to make the Tesla motor now invariably used without paying any more royalty to Tesla. The Westinghouses announce they have a number of subsidiary patents, and will fight.

The Tesla Patents.—The series of American patents generally known as the fundamental Tesla patents, which have played such a conspicuous part in the electrical industry during the two last decades, expired on the 4th of this month. Mr. B. A. Behrend takes the opportunity of paying a tribute to Tesla's work in an article contributed to the *Electrical World* of New York. The genius of Tesla has been instrumental in stimulating, if not in creating, a wonderful industry—wonderful in magnitude, and wonderful in the ingenuity of the apparatus used in the accomplishing of the transmission of power over long distances. After discussing the evolution of scientific principles and the patent system, the author deals with the personal achievements of Tesla, the ingenious inventor who, by a "sort of glorified common sense and unfailing intuition, picked his way through puzzling mazes of complicated phenomena, and protected himself from the pitfalls and the alluring by-paths ensnaring smaller intellects." With Tesla, in America and in Europe, worked a host of capable and ingenious engineers, and their work, vivified by the ingenuity of Tesla's inventions, has become one of the greatest monuments of engineering achievement crowning the work of the nineteenth century. Turning to Tesla's remarkable paper, entitled "A New System of Alternate-Current Motors and Transformers," read at the meeting of the American Institute of Electrical Engineers in New York on May 16, 1888, the author remarks that this paper, even when considered in the light of previous discoveries and knowledge, is one of the most brilliant pieces of engineering thought, teeming with suggestions and ideas, animated with an intuition of the highest order, and giving an exposition of the working of the induction motor in a manner which resembles the methods pursued in the "Experimental Researches on Electricity" of the great master, Michael Faraday. While stating, however, that for 17 years the Tesla patents have formed the nucleus of the electrical industry, Mr. Behrend points out that these patents do not represent the only valuable ideas on the subject of polyphase alternating-current systems. He predicts that the expiry of the patents, aided by vigorous competition, will give the electrical industry a new stimulus.

Expiry of Tesla Patents.—The American patents in connection with rotating magnetic fields as applied to electric motors, granted to Mr. Nikola Tesla in 1888, expired on May 5th.

News of Tesla. — From the *Globe* of May 19th we cull the following, for which we take no responsibility:—"At last, Mr. Nikola Tesla, after a long isolation in his experimental tower of Wardenclyffe, Long Island, has broken silence in a United States patent recently granted to him. It appears from the specifications that he has been sending electrical oscillations through the ground by means of a powerful transformer having one end of the secondary coil to earth and the other to an elevated metal disk, probably the colossal griddle on the summit of his tower. He was led to do so by observing that lightning discharges produce electric waves or oscillations in the ground, varying in length from about 25 to 70 metres. His apparatus produces waves of similar kind, which travel to great distances, and they not only transmit messages, but control or actuate apparatus for other purposes—such as indicating the time of an observatory, determining the position and distance of bodies, and the course or speed of a ship at sea.

"According to his patent, the electric waves from the earthplate travel to distant parts of the earth, and are there reflected back on themselves, producing by interference with the outgoing waves a series of stationary waves having crests and hollows lying in parallel circles round the earthplate as a pole. By impressing on the earth two or more oscillations of different wave length, a resonant stationary wave can be made to travel slowly over the globe. A delicate receiving apparatus has been invented for detecting these resonant waves. It consists essentially of a condenser charged from the ground and discharged through an indicating or a recording instrument. In any part of the globe, the wave-length of a resonant stationary wave can be found by mathematics, and the distance of the place from the source of waves calculated. A ship can thus find its latitude or longitude, time, &c. With several generators in chosen localities, the entire globe could be sub-divided into different zones of electrical activity, and important data obtained from observation of the waves."

The New York Sun June 15, 1905

SUBWAY DANGERS.

Mr. Tesla's Views of Possibilities and Proper Equipment.

To the Editor of The Sun—Sir: The flooding of the subway is a calamity apt to repeat itself. As your readers will remember, it did not occur for the first time last Sunday. Water, like fire, will break loose occasionally in spite of precautions. It will never be possible to guard against a casual bursting of a main; for while the conduits can be safely relied upon under normal working conditions, any accidental obstruction to the flow may cause a pressure which no pipe or joint can withstand.

In fact, if we are to place faith in the gloomy forecasts of Commissioner Oakley, who ought to know, such floods may be expected to happen frequently in the future. In view of this it seems timely to call to public attention a danger inherent to the electrical equipment which has been thrust upon the Interborough company by incompetent advisers.

The subway is bound to be successful, and would be so if the cars were drawn by mules, for it is the ideal means of transportation in crowded cities. But the full measure of success of which it is capable will be attained only when the financiers shall say to the electric companies: "Give us the best, regardless of expense."

It is to be regretted that this important pioneering enterprise, in other respects ably managed and engineered, should have been treated with such gross neglect in its most vital feature. No opportunity was given to myself, the inventor and patentee of the system adopted in the subway and the elevated roads, for offering some useful suggestion, nor was a single electrician or engineer of the General Electric and Westinghouse companies consulted, the very men who should have been thought of first of all.

Once large sums of money are invested in a defective scheme it is difficult to make a change, however desirable it may be. The movement of new capital is largely determined by previous investment. Even the new roads now planned are likely to be equipped with the same claptrap devices, and so the evil will grow. "Das eben ist der Fluch der boesen That, dass sie fortzeugend Boeses muss gebaeren."

The danger to which I refer lies in the possibility of generating an explosive mixture by electrolytic decomposition and thermic dissociation of the water through the direct currents used in the operation of the cars. Such a process might go on for hours and days without being noticed; and with currents of this kind it is scarcely practicable to avoid it altogether.

It will be recalled that an expert found the percentage of free oxygen in the subway appreciably above that which might reasonably have been expected in such a more or less stagnated channel. I have never doubted the correctness of that analysis and have assumed that oxygen is being continuously set free by stray currents passing through the moist ground. The total amperage of the normal working current in the tunnel is very great, and in case of flooding would be sufficient to generate not far from 100 cubic feet of hydrogen per minute. Inasmuch, however, as in railway operation the fuses must be not hard, in order to avoid frequent interruption of the service by their blowing out, in such an emergency the current would be of much greater volume and hydrogen would be more abundantly liberated.

It is a peculiar property of this gas that it is capable of exploding when mixed with a comparatively large volume of air, and any engineer can convince himself by a simple calculation that, say, 100,000 cubic feet of explosive might be formed before the danger is discovered, reported and preventive measures taken. What the effect of such an explosion might be on life and property is not pleasant to contemplate. True, such a disaster is not probable, but the present electrical equipment makes it possible, and this possibility should be, by all means, removed.

The oppressiveness of the tunnel atmosphere is in a large measure due to the heat supplied by the currents, and to the production of nitrous acid in the arcs, which is enhanced by rarefaction of the air through rapid motion. Some provision for ventilation is imperative. But ventilation will not do away with the danger I have pointed out. It can be completely avoided only by discarding the direct current.

I should say that the city authorities, for this if for no other reason, should forbid its use by a proper act of legislation. Meanwhile, the owners of adjacent property should object to its employment, and the insurance companies should refuse the grant of policies on such property except on terms which it may please them to make. N. Tesla.

New York, June 15.

Tesla Split-Phase Patent Litigation.

An opinion has been rendered by the United States Circuit Court of Appeals for the Third Circuit (Western Pennsylvania) in a suit involving the Tesla split-phase patents, in which he Jefferson Light, Heat & Power Company was alleged to have infringed these patents in having used a meter involving the split-phase principle. The case had previously come before the court on an appeal from an order granting a preliminary injunction. This order of the lower court was reversed pending a plea that the case was *res adjudicata* in view of a decision rendered in the United States Circuit Court of Appeals sitting in New York in the case of the Catskill Illuminating & Power Company, the decision of this court being that the Tesla split-phase patents were invalid through anticipation. Subsequently the present cause proceeded to a hearing, resulting in a decree overruling the bill of *res adjudicata,* declaring infringement and granting an injunction. From that decree the defendant appealed on the ground that inasmuch as the Catskill case was defended by the Diamond Meter Company, and the present case is defended by the same company, the Catskill case was *res adjudicata* of everything involved in the present case. The opinion was written by Judge Acheson, and the court held that the Diamond Meter Company did not avowedly or openly conduct the defense in the Catskill case, and having concealed its connection with the case while it was pending, it is now too late for it to set up the decree in that case as an estoppal against the complainant in the present case. The plea was overruled and the granting of a preliminary injunction by the court below affirmed.

The United States Circuit Court of Appeals for the First District in a suit involving also the Tesla split-phase patents, in which the Stanley Instrument Company was the defendant, has denied a petition of the latter to file a supplementary bill in the nature of a bill of review, or to amend the judgment on appeal. In this case the lower court decided against the split-phase patents and was reversed on appeal. Application was then made to the Supreme Court for a writ of certiorari on the grounds of conflict with the action of the Catskill case, which was denied. The petition of the present cause was based on the grounds that certain English Tesla patents on identically the same subject matter as the patents in suit expired in 1903, and that this expiration was a complete defense as against the patents in suit. The court held that since the foreign patents expired only a few days after the decree was entered in the lower court and before the appeal was heard, the question of laches on the part of the petitioner could not be wholly overlooked. The court held, however, that the merits of the case with respect to the identity of the foriegn and American patents are so clearly against the petitioner that it was not necessary to pronounce on the question of laches. In order that the term of a foreign patent may be limited by a domestic patent, it is essential that the inventions covered by the two patents should be identical. This is not true with respect to the patent cited in this suit. While it is true that one claim of the British patent neces-

sarily includes all the elements of the American patents, it also includes other elements establishing a new combination which is an essential, novel and patentable improvement on what was claimed in the patents before the court on appeal. This claim covers not only the mere improvement on either split-phase invention or polyphase invention separately, but it covers an invention by which a convertable motor is produced. This necessarily takes the case out of the field of identity with either the earlier polyphase or the later split-phase patents. The petition was denied.

Tesla on Subway Dangers.

The New York *Sun* of June 16 printed the following letter from Mr. Nikola Tesla:

The flooding of the subway is a calamity apt to repeat itself. As your readers will remember, it did not occur for the first time last Sunday. Water, like fire, will break loose occasionally in spite of precautions. It will never be possible to guard against a casual bursting of a main; for while the conduits can be safely relied upon under normal working conditions, any accidental obstruction to the flow may cause a pressure which no pipe or joint can withstand.

In fact, if we are to place faith in the gloomy forecasts of Commissioner Oakley, who ought to know, such floods may be expected to happen frequently in the future. In view of this it seems timely to call to public attention a danger inherent to the electrical equipment which has been thrust upon the Interborough Company by incompetent advisers.

The subway is bound to be successful, and would be so if the cars were drawn by mules, for it is the ideal means of transportation in crowded cities. But the full measure of success of which it is capable will be attained only when the financiers shall say to the electric companies: "Give us the best, regardless of expense."

It is to be regretted that this important pioneering enterprise, in other respects ably managed and engineered, should have been treated with such gross neglect in its most vital feature. No opportunity was given to myself, the inventor and patentee of the system adopted in the subway and the elevated roads, for offering some useful suggestion, nor was a single electrician or engineer of the General Electric and Westinghouse companies consulted, the very men who should have been thought of first of all.

Once large sums of money are invested in a defective scheme it is difficult to make a change, however desirable it may be. The movement of new capital is largely determined by previous investment. Even the new roads now planned are likely to be equipped with the same claptrap devices, and so the evil will grow. "Das eben ist der Fluch der boesen Thut, das sie fortzeugend Boeses muss gebaeren."

The danger to which I refer lies in the possibility of generating an explosive mixture by electrolytic decomposition and thermic dissociation of the water through the direct currents used in the operation of the cars. Such a process might go on for hours and days without being noticed; and with currents of this kind it is scarcely practicable to avoid it altogether.

It will be recalled that an expert found the percentage of free oxygen in the subway appreciably above that which might reasonably have been expected in such a more or less stagnated channel. I have never doubted the correctness of that analysis and have assumed that oxygen is being continuously set free by stray currents passing through the moist ground. The total amperage of the normal working current in the tunnel is very great, and in case of flooding would be sufficient to generate not far from 100 cubic feet of hydrogen per minute. Inasmuch, however, as in railway operation the fuses must be set hard, in order to avoid frequent interruption of the service by their blowing out, in such an emergency the current would be of much greater volume and hydrogen would be more abundantly liberated.

It is a peculiar property of this gas that it is capable of exploding when mixed with a comparatively large volume of air, and any engineer can convince himself by a simple calculation that, say, 100,000 cubic feet of explosive might be formed before the danger is discovered, reported and preventive measures taken. What the effect of such an explosion might be on life and property is not pleasant to contemplate. True, such a disaster is not probable, but the present electrical equipment makes it possible, and this possibility should be, by all means, removed.

The oppressiveness of the tunnel atmosphere is in a large measure due to the heat supplied by the currents, and to the production of nitrous acid in the arcs, which is enhanced by rarefaction of the air through rapid motion. Some provision for ventilation is imperative. But ventilation will not do away with the danger I have pointed out. It can be completely avoided only by discarding the direct current.

I should say that the city authorities, for this if for no other reason, should forbid its use by a proper act of legislation. Meanwhile, the owners of adjacent property should object to its employment, and the insurance companies should refuse the grant of policies on such property except on terms which it may please them to make.

The New York World June 25, 1905

Thomas A. Edison Talks of His Search for Radium and of the Future of Electricity.

Says Marconi Is Right and Tesla Wrong as to the Means of Talking from One Side of the World to the Other.

Thomas A. Edison has been devoting his days for some time past to a keen search for radium, the newly discovered metal which promises such wonderful results in healing the sick, making the blind to see and curing malignant cancers.

In an interview with a representative of The World at Menlo Park a few days ago Mr. Edison said:

"I have hunted for this new substance in a thousand places and chemically examined no end of specimens of ore from different mines and mountains, but thus far have not succeeded in finding it in any quantity. I have, however, reached some decided conclusions on the subject.

"Radium is similar to X-rays in its power to pass through substances, and its effects are apparently as injurious to investigators. This is especially true of the X-rays. My wife is unwilling to have me experiment with [illegible] any more. One of my eyes was drawn out of focus, and my stomach was more or less affected, so that I was seriously inconvenienced in my laboratory work. Besides this, my assistant died about a year ago from the effects of their baneful influence; and now his brother, another assistant, is suffering from a red discoloration of the flesh on his breast and arms, although he has not been making any X-ray experiments for a year. Strange that the injury from their influence should only manifest itself twelve months after laboratory investigations ceased!"

"What have you under way now?" inquired the World representative. "Do you believe with Tesla that we shall be able to talk around the world one of these days?"

"No," answered the Wizard, "I do not look for developments in that line. The wonderful thing that will be more and more developed is wireless telegraphy. Marconi is all right and is bound sooner or later to perfect his system. He has just been married, and is not working as hard at present as he did at first. But he will come out all right, and we shall have the oceans bridged by wireless telegraphy. That was a remarkable performance the other day when the steamship Campania was never out of communication with one side or the other of the Atlantic ocean. It shows what we are coming to.

"Cables will not be superseded. Business will only be increased for both wireless and cable companies, just as the telegraph and telephone supplement each other.

"The Japs are making splendid use of wireless telegraphy in the present war with Russia. They are a wonderful little people and are up to date in everything. They will revolutionize things in the Orient when the war is over, and will spur on China to be more like the Western nations.

"I admire the Japs because they are up to date. I don't believe in war and am a man of peace. The only kind of war that interests me is one between the great 'captains of industry,' in which the one with the biggest brain wins every time. The Japs when once peace is declared will enter upon an industrial campaign and buy all the improved labor-saving machinery they can. Then they will make things lively for us.

"The machine nations will lead the world and decide the issues between the other countries."

"What do you mean by machine nations?"

"Why," replied the Wizard, "those that use labor-saving machinery. In the last analysis the three or four great nations of the world will be those that are up-to-date in making and manufacturing goods cheaper and better than any one else and [illegible] more intelligent and wide-awake. Commerce will be the great thing after all, which nations will strive after.

"Coming back to wireless telegraphy again, cannot the messages be intercepted by outsiders?"

"There is not the least danger from that," said the Wizard in reply. "Any important message by cable or overland even now is sent by code, and that is what will be done when wireless messages are sent. When you forward a cable message from New York to London it goes through the hands of four or five operators. And the way you protect your secret is by using code words. The same thing can be done with wireless messages. The Japs certainly understand this game to perfection, for they seemed to be posted on every move of the enemy on land or sea.

"Electricity is still in its infancy, and you will find that the Japs will employ it to still greater uses. I am not in the least alarmed at the yellow peril. I wish I had a lot of Japs in my laboratory.

"Speaking of telegraphy," continued the Wizard, "the General Superintendent of the Lackawanna Railroad was here yesterday and told me a very interesting thing. At the recent Railroad Congress in Washington, out of the seventy-five officials at one of the banquets given forty-three of them (or over half) were old operators. And they were very proud of the fact that they had risen from the ranks. Not a few of the most prominent men in the United States have been 'knights of the key.' All of which goes to show that an operator may have a big future ahead of him."

I know Mr. Edison is very busy with some interesting experiments and has 14,000 cells at work in trucks and delivery wagons throughout the country. The results obtained from actual work he will finally embody in the contracted battery.

NIKOLA TESLA SAYS WE WILL SOON BE TALKING CLEAR AROUND THE WORLD.

Replies to Wizard Edison in Vigorous Fashion—Beating the Lightning Flashes—His Compliments to His Rivals.

The article to which Mr. Tesla refers in the following letter was an interview with Thomas A. Edison, in which, in reply to The World reporter's question, "Do you believe with Tesla that we shall be able to talk around the world one of these days?" Mr. Edison said: "No, I do not look for developments in that line. The wonderful thing that will be more and more developed is wireless telegraphy. Marconi is all right, and is bound sooner or later to perfect his system." Mr. Tesla's letter is as follows:

New York, June 30, 1905.

To the Editor of The World:

Sir—My attention has been called to an article in The World of last Sunday, announcing in an interview that I am wrong in my wireless propositions. Such statements, authorized or not, are apt to produce erroneous impressions regarding my work as well as the state of the art. For my protection and your readers' enlightenment, I only need to quote the following passage from one of my specifications which was filed five years ago in the United States Patent Office and in descriptive of some results attained by me about that time:

"In the course of certain investigations which I carried on for the purpose of studying the effects of lightning discharges upon the electrical condition of the earth I observed that sensitive receiving instruments arranged so as to be capable of responding to electrical disturbances created by the discharges at times failed to respond when they should have done so, and upon inquiring into the causes of this unexpected behavior I discovered it to be due to the character of the electrical waves which were produced in the earth by the lightning discharges, and which had nodal regions following at definite distances the shifting source of the disturbances. From data obtained in a large number of observations of the maxima and minima of these waves I found their length to vary approximately from twenty-five to seventy kilometres, and these results and theoretical deductions led me to the conclusion that **waves of this kind may be propagated in all directions over the globe**, and that they gated in all directions over the globe, and that they may be of still more widely differing lengths, the extreme limits being imposed by the physical dimensions and properties of the earth. Recognizing in the existence of these waves an unmistakable evidence that the disturbances created had been conducted from their origin to the most remote portions of the globe and had been thence reflected,

Beat Lightning Flashes.

I conceived the idea of producing such waves in the earth by artificial means, with the object of utilizing them for many useful purposes for which they are or might be found applicable. This problem was rendered extremely difficult owing to the immense dimensions of the planet, and consequently enormous movement of electricity or rate at which electrical energy had to be delivered in order to approximate, even in a remote degree, movements or rates which are manifestly attained in the displays of electrical forces in nature, and which seemed at first unrealizable by any human agencies; but by gradual and continuous improvements of a generator of electrical oscillations, which I have described in my Patents 454, 622 and 645,576, I finally succeeded in reaching electrical movements or rates of delivery of electrical energy not only approximately, but, as shown in comparative tests and measurements, **actually surpassing those of lightning discharges**, and by means of this apparatus I have found it possible to reproduce whenever desired phenomena in the earth the same as or similar to those due to such discharges. With the knowledge of the phenomena discovered by me and the means at command for accomplishing there results I am enabled not only to carry out many operations by the use of known instruments, but also to offer a solution for many important problems involving the operation or control of remote devices which for want of this knowledge and the absence of these means have heretofore been entirely impossible. For example, by the use of such a generator of stationary waves and receiving apparatus properly placed and adjusted in any other locality, however remote, it is practicable to transmit intelligible signals or to control or actuate at will any one or all of such apparatus for many other important and valuable purposes, as for indicating wherever desired the correct time of an observatory, or for ascertaining the relative position of a body or distance of the same with reference to a given point, or for determining the course of a moving object, such as a vessel at sea, the distance traversed by the same or its speed; or for producing many other useful effects at a distance dependent on the intensity, wave length, direction or velocity of movement, or other feature or property of disturbances of this character."

A Bit of Sarcasm.

Permit me to say on this occasion, that if there exist, to-day, no facilities for wireless telegraphic and telephonic communication between the most distant countries, it is merely because a chain of misfortunes and obstacles have delayed the consummation of my labors, which might have been completed three years ago. In this connection I shall well remember the efforts of some, unwise enough to believe that they can gain an advantage by throwing sand in the eyes of people and retarding the progress of invention. Should the first messages across the seas prove calamitous to them, it will be a punishment regrettable but fully deserved.

In my article in the Century of June, 1900, and subsequent publications in a technical journal (Electrical World and Engineer), I have carefully and conscientiously prepared them for the impending revolution.

I may add that any expert, not a blacksmith or woodchopper in electrical experiments whose cheeks are covered with horn-back alligator skin, and who is thus enabled to make use of my patented devices without my permission and public acknowledgment, can easily enough girdle the world with electric messages, and in Smardis's fashion achieve fame and distinction, cheap and unprofitable. With these marvellous appliances an engineer possessed of knowledge and skill not greater than my own could throw this planet out of its orbit.

NIKOLA TESLA.

THE ELECTRICAL EQUIPMENT OF THE SUBWAY.

The fact that there are a great many people who take Mr. TESLA seriously, notwithstanding the fact that for some years past he has been more distinguished for magnificent promises than for brilliant performances, gives greater significance than it would otherwise have to his persistent effort to discredit the electrical equipment of the Rapid Transit Subway. The method of this attack is not exactly that which one would expect from a gentleman of Mr. TESLA's professional reputation. It is by the publication of letters full of vague generalities, so worded as to impress the public without inviting the specific and authoritative contradiction which would follow them if they consisted of definite statements. So far as they admit of paraphrasing into clear-cut declarations of opinion, Mr. TESLA's views respecting the electrical equipment of the Subway are that the system chosen and installed was preferred because it was cheap and not because it was good; that it is far behind the present state of the are in plan and in detail; that a serious mistake was made in not adopting the alternating system of distribution, "popularly known as the two, three, multi, or polyphase"; that the system selected was one invented by him and discarded years ago for later, riper, and more perfect devices; that in planning it no engineer of the General Electric or Westinghouse Company was consulted or permitted to give advice; that the mechanical appliances installed are cheap and inferior; that the Interborough management imposed upon its technical advisers the obligation of wasteful economy in first cost; and that in consequence of the absence of safeguards against the leakage of currents into the ground, insulating materials and ground water are decomposed and converted into highly explosive gases which at any moment may blow the whole Subway into another county and do incalculable damage to life and property.

With the strictly technical points of an impeachment of this kind the daily newspaper press does not need to concern itself. With the practical side if there be one, it may properly concern itself very intimately. As certain specific statements are likely to be of more interest to the reader than abstractions or generalities, we will confine our comments to them.

The electrical equipment of the Rapid Transit Subway is probably not perfect, but it is unquestionably the best ever installed in this or any other city. The instructions of the Interborough management to its electrical engineer were to provide the best of everything, and there was absolutely no restriction in the matter of cost imposed at any stage of the work. The alternating current and the polyphase induction motor, which Mr. TESLA believes in, were carefully studied and rejected This was not because they would have cost more than the system approved, for they would have been materially cheaper; but because they were not the best for use in the circumstances. To have adopted them would have saved perhaps a third or a quarter of the cost of installation. It is doubtful if a single induction motor of the kind referred to by Mr. TESLA was then used in the United States for traction purposes. On the other hand, the system adopted is identical in principle with that which has been tested in practice in London and Paris, in Brooklyn for the operation of the elevated lines, and by the engineers of the Pennsylvania, the New York Central, and the Long Island Railroad. In details the development has been advanced in the Subway equipment beyond any previous experience. Since trains began running it has been critically watched, and in every respect has vindicated the judgment of the experts responsible for its adoption and installation. As we said, it is not perfect, but it comes nearer to that standard than any system elsewhere in use.

That Mr. TESLA was not called in consultation as to plan or details is probably true. The work was done under the immediate direction of one of the most accomplished and discreetly conservative electrical engineers of the United States, Mr. L. B. STILLWELL, who was from the outset and still is the Electrical Director of the Interborough Company. He stands well at the head of his profession. On a comparison of experiences it would probably be found that Mr. STILLWELL has been intrusted with the expenditure of a thousand dollars in constructive work for every dollar thus intrusted to the judgment of Mr. TESLA. When the latter began his campaign of criticism, Mr. STILLWELL declined a newspaper controversy, on the reasonable ground that the points involved were such as could best be decided by a jury of experts, and offered, if Mr. TESLA would present before the American Institute of Electrical Engineers a paper containing specific and definite criticisms of the Subway equipment, to meet him in a full and frank discussion which would be equally open to every electrical engineer in the United States. The fact that Mr. TESLA declined this invitation would seem to close the incident so far as he is concerned.

THOMAS A. EDISON ON RADIUM AND THE FUTURE OF ELECTRICITY.

Says Marconi is Right and Tesla Wrong as to the Means of Talking from One Side of the World to the Other.

THOMAS A. EDISON has been devoting his days for some time past to a keen search for radium, the newly discovered metal which promises such wonderful results in healing the sick, making the blind to see, and curing malignant cancers.

In an interview with a representative of the *World* at Menlo Park a few day ago Mr. Edison said:

"I have hunted for this new substance in a thousand places, and chemically examined no end of specimens of ore from different mines and mountains, but thus far have not succeeded in finding it in any quantity. I have, however, reached some decided conclusions on the subject.

"Radium is similar to X rays in its power to pass through substances, and its effects are apparently as injurious to investigators. This is especially true of the X rays. My wife is unwilling to have me experiment with them any more. One of my eyes was drawn out of focus, and my stomach was more or less affected, so that I was seriously inconvenienced in my laboratory work. Besides this, my assistant died about a year ago from the effects of their baneful influence, and now his brother, another assistant, is suffering from a red discolouration of the flesh on his breast and arms, although he has not been making any X-ray experiments for a year. Strange that the injury from their influence should only manifest itself twelve months after laboratory investigations ceased!"

"What have you under way now?" inquired the *World* representative. "Do you believe with Tesla that we shall be able to talk around the world one of these days?"

"No," answered the Wizard, "I do not look for developments in that line. The wonderful thing that will be more and more developed is wireless telegraphy. Marconi is all right, and is bound sooner or later to perfect his system.

"Cables will not be superseded. Business will only be increased for both wireless and cable companies, just as the telegraph and telephones supplement each other.

"The Japs are making splendid use of wireless telegraphy in the present war with Russia. They are a wonderful little people and are up to date in everything. They will revolutionise things in the Orient when the war is over, and will spur on China to be more like the Western nations.

"I admire the Japs because they are up to date. I don't believe in war, and am a man of peace. The only kind of war that interests me is one between the great 'captains of industry,' in which the one with the biggest brain wins every time. The Japs when once peace is declared will enter upon an industrial campaign and buy all the improved labour-saving machinery they can. Then they will make things lively for us.

"The machine nations will lead the world and decide the issues between the other countries."

"What do you mean by machine nations?"

"Why," replied the Wizard," "those that use labour-saving machinery. In the last analysis the three or four great nations of the world will be those that are up-to-date in making and manufacturing goods cheaper and better than anyone else, and that are more intelligent and wide-awake. Commerce will be the great thing, after all, which nations will strive after."

TESLA'S REPLY TO EDISON.

Says "We shall soon be Talking Round the World."

AS we said last week, Mr. Edison was reported to have said to an interviewer of the *New York World* that he did not believe with Tesla in being able to talk round the world, but that he thought Marconi would, sooner or later, perfect his system.

Nikola Tesla has replied. He says:—

In the course of certain investigations which I carried on for the purpose of studying the effects of lightning discharges upon the electrical condition of the earth I observed that sensitive receiving instruments arranged so as to be capable of responding to electrical disturbances created by the discharges at times failed to respond when they should have done so, and upon inquiring into the causes of this unexpected behaviour I discovered it to be due to the character of the electrical waves which were produced in the earth by the lightning discharges, and which had nodal regions following at definite distances the shifting source of the disturbances. From data obtained in a large number of observations of the maxima and minima of these waves I found their length to vary approximately from twenty-five to seventy kilomètres, and these results and theoretical deductions led me to the conclusion that waves of this kind may be propagated in all directions over the globe, and that they may be of still more widely differing lengths, the extreme limits being imposed by the physical dimensions and properties of the earth. Recognising in the existencs of these waves an unmistakable evidence that the disturbances created had been conducted from their origin to the most remote portions of the globe, and had been thence reflected, I conceived the idea of producing such waves in the earth by artificial means, with the object of utilising them for many useful purposes for which they are or might be found applicable.

Beat Lightning Flashes.

This problem was rendered extremely difficult owing to the immense dimensions of the planet, and consequently enormous movement of electricity or rate at which electrical energy had to be delivered in order to approximate, even in a remote degree, movements or rates which are manifestly attained in the displays of electrical forces in nature, and which seemed at first unrealisable by any human agencies; but by gradual and continuous improvements of a generator of electrical oscillations, which I have described in my Patents Nos. 645576 and 649621, I finally succeeded in reaching electrical movements or rates of delivery of electrical energy not only approximately, but, as shown in comparative rests and measurements, actually surpassing those of lightning discharges and by means of this apparatus I have found it possible to reproduce, whenever desired, phenomena in the earth the same as or similar to those due to such discharges. With the knowledge of the phenomena discovered by me, and the means at command for accomplishing these results, I am enabled, not only to carry out many operations by the use of known instruments, but also to offer a solution for many important problems involving the operation or control of remote devices which, for want of this knowledge and the absence of these means, have heretofore been entirely impossible. For example, by the use of such a generator of stationary waves and receiving apparatus properly placed and adjusted in any other locality, however remote, it is practicable to transmit intelligible signals, or to control or actuate at will any one or all of such apparatus for many other important and valuable purposes, as for indicating wherever desired the correct time of an observatory, or for ascertaining the relative position of a body or distance of the same with reference to a given point, or for determining the course of a moving object, such as a vessel at sea, the distance traversed by the same or its speed; or for producing many other useful effects at a distance dependent on the intensity, wavelength, direction or velocity of movements, or other feature or property of disturbances of this character.

A Bit of Sarcasm.

Permit me to say on this occasion that if there exist to-day no facilities for wireless telegraphic and telephonic communication between the most distant countries, it is merely because a series of misfortunes and obstacles have delayed the consummation of my labours, which might have been completed three years ago. In this connection I shall well remember the efforts of some, unwise enough to believe that they can gain an advantage by throwing sand in the eyes of people and retarding the progress of invention. Should the first messages across the seas prove calamitous to them, it will be a punishment regrettable but fully deserved.

THE TRANSFORMATIONS OF MATTER.*

SOME twenty years ago the suggestion that matter can be destroyed could be discussed on metaphysical grounds only. The indestructibility of matter, complemented by its sister doctrine of the conservation of energy, formed one of the pillars upon which the whole system of physics appeared to rest, and Herbert Spencer—whose acquaintance with physics was by no means his strong point—declared in his "First Principles" that if we could suppose matter to be destructible, both science and philosophy would be impossible. Recent discoveries have, however, changed all that, and both the indestructibility of matter and the conservation of energy find themselves exposed to a frontal attack which it seems impossible that they can long resist.

Now it is plain that these discoveries, while overthrowing our best-settled conceptions of matter and energy, yet raise a great many more puzzles than they solve. While atoms are shown to be no longer atoms, and energy is produced apparently from nowhere without the previous expenditure of work, electricity, at one time thought to be merely a form of energy, now appears as a component, and perhaps the sole component, of matter. Yet till now no one could say what electricity was, and every new discovery seemed to make its behaviour more and more mysterious. It seemed to have mass, and one of the most popular theories of English electricians was that all mass was electromagnetic in its origin. It behaved in most cases like a liquid, yet a liquid some of whose particles attracted, while others repelled, each other seemed inconceivable; and it was proved to be entirely exempt from the laws of gravitation which govern the behaviour of all other liquids. Nor did any of the new discoveries quite square with the hitherto observed laws of electrical phenomena. It has always been said that a gas cannot act as a conductor of electricity, yet the fact that the atmosphere becomes a conductor under the influence of the electrons emitted by radium proves the best test of its presence. Again, Sir William Ramsay's emanation, which eventually becomes positive and negative electricity, will remain for years on the surface of metals such as bismuth, and will then resist the efforts of liquids like concentrated sulphuric acid to remove it. Moreover, many of these effects can be imitated by reactions in which the so-called radio-active metals have nothing to do. An electric discharge of high tension and frequency, such as M. Tesla showed us how to produce, will discharge an electroscope as readily as radium. So will the rays emitted by a sheet of clean metal on which the ultra-violet rays of the sun or of an electric light fall. So will the gases emitted by the flame of a burning candle or a piece of red-hot metal; and so will the formation of acetylene by the decomposition of carbide of calcium or the dissolution of sodium amalgam in water. And above all is the crowning mystery of the evolution of helium from the radium emanation and its transformation into electricity. How can a gas consisting, like other gases, of atoms of known weight come into existence from a metallic salt into whose composition this gas does not enter? And how can a gas disappear leaving nothing behind it but a substance which presents hardly any of the properties of matter? Plainly a synthesis which can afford a reasonable explanation of these incoherent and apparently contradictory facts is required if physical science is to be saved from chaos.

Such a synthesis has now been furnished by M. Gustave Le Bon, whose just-published book on "L'Evolution de la Matière" (Paris: Flammarion) is a republication and amplification of the separate studies and articles which have appeared over his signature during the last eight years. His theory is that matter, instead of being, as it appears to us, the most stable and reposeful of all natural things, is, in fact, never at rest, but is always changing from one form to another. Once, he says, the world was a nebula, consisting apparently entirely of ether. From causes which we cannot even guess at, this ether became condensed into the atoms as known to modern chemistry, the energy thus stored up being that which is liberated when the atom is dissociated or split up as in the now familiar case of radium. But this process of dissociation, instead of being rare and occasional, is always going on with all substances, and always with the same result, which is the production of an emanation like that already made evident by Sir William Ramsay, Prof. Rutherford, and others in the case of radium and thorium. This emanation, though not itself electrified, transforms itself into what he calls the ionic fluid, which in turn gives rise first to positive and negative ions, or almost infinitely small masses of matter combined with charges of positive and negative electricity, and then to detached electrons or corpuscles of negative electricity only, having no material support. These negative electrons, in which alone, according to him, the inertia varies with the speed at which they travel, are the cause of

* From the *Athenæum*.

those Hertzian waves which are emitted whenever a discharge takes place from an electrified point, and only differ from waves of light in their far greater wave-length. Finally, the same negative electrons give rise when stopped to the Röntgen rays, which are one of the last stages by which matter sinks back into the ether from which it originally came. For this is the end towards which all material things are tending. Whether they are reborn we cannot tell, until we know something of the cause which first gave them birth; but that matter is every day taking one step the more on the road to death M. Le Bon has no doubt whatever. From matter to emanation, from emanation to electricity, from electricity to ether, are the stages of transformation which he has as yet succeeded, in his opinion, in identifying. Yet he warns us that these are probably only a few of those through which matter finally has to pass. Already he thinks he can detect a difference between the rays emitted by metals when exposed to different parts of the solar spectrum. Nor are all the negative electrons exactly alike. Their unequal deviation in a powerful magnetic field shows, according to him, that they are composed of divers elements, which, he suggests, may be arranged on the sun-and-planet system which other observers have ascribed to the atom. And at the other end of the scale there are probably many intermediate stages, of which we as yet have no knowledge. All the chemical elements are probably formed, as Prout thought, from one element, and crystals may be the intermediary form between "brute" and living matter. The theory that electrons are, in fact, centres of vortical strain in the ether he looks on with favour; but as we do not know how these vortices came first to be formed, it does not advance us much.

Further discussion of M. Le Bon's theory the *Athenæum* leaves for another article; but it may be said that full details of the experiments by which he seeks to prove it are given in his book, while the care and pains which he has bestowed upon his researches during many years make it impossible that it should be lightly regarded. And if the views now put forward by him emerge triumphant from the controversies that they will doubtless arouse, we fancy that his researches will be considered as important for the twentieth century as those of Darwin were for the nineteenth.

Tesla on the Peary North Pole Expedition.

The New York *Sun* of July 16 prints the following letter from Mr. Nikola Tesla:

Everybody must have been pleased to learn that Commodore Peary has finally obtained the financial assistance which will enable him to start without further delay on his important journey. Let us wish the bold navigator the most complete success in his perilous undertaking, in the interest of humanity as well as for his own and his companions' sake and the gratification of the generous donors who have aided him. But, while voicing these sentiments, let us hope that Peary's will be the last attempt to reach the pole in this slow, penible and hazardous way.

We have already sufficiently advanced in the knowledge of electricity and its applications to avail ourselves of better means of transportation, enabling us to reach and to explore without difficulty and in a more perfect manner not only the North, but also the South Pole, and any other still unknown regions of the earth's surface. I refer to the facilities afforded in this respect by the transmission of electrical energy without wires and aerial navigation, which has found in this novel art its ideal solution.

Many of your readers will, no doubt, be under the impression that I am speaking merely of possibilities. As a matter of fact, from the principles involved and the experiments which I have actually performed, not only is the practical success of such distribution of power reduced to a degree of mathematical certitude, but the transmission can be effected with an economy much greater than possible by the present method involving the use of wires.

It would not take long to build a plant for purposes of aerial navigation and geographical research, nor would it cost as much as might be supposed. Its location would be perfectly immaterial. It might be at the Niagara, or at the Victorian Falls in Africa, without any appreciable difference in the power collected in a flying machine or other apparatus.

A popular error, which I have often opportunity to correct, is to believe that the energy of such a plant would dissipate itself in all directions. This is not so, as I have pointed out in my technical publications. Electricity is displaced by the transmitter in all directions, equally through the earth and the air; that is true, but energy is expended only at the place where it is collected and used to perform some work. To illustrate, a plant of 10,000 hp, such as I have been planning, might be running full blast at Niagara, and there might be but one flying machine, of, say, 50 hp operating in some distant place, the location being of absolutely no consequence. In this case 50 hp would be all the power furnished by the plant to the rest of the universe. Although the electrical oscillations would manifest themselves all over the earth, at the surface as well as high in the air, virtually no power would be consumed. My experiments have shown that the entire electrical movement which keeps the whole globe a-tremble can be maintained with but a few horsepower. Apart from the transmitting and receiving apparatus, the only loss incurred is the energy radiated in the form of Hertzian or electro-magnetic waves, which can be reduced to an entirely insignificant quantity.

I appreciate the difficulty which your non-technical readers must experience in comprehending the working of this system. To gain a rough idea, let them imagine the transmitter and the earth to be two elastic bags, one very small and the other immense, both being connected by a tube and filled with some incompressible fluid. A pump is provided for forcing the fluid from one into the other, alternately and in rapid succession. Now, to produce a great movement of the fluid in a bag of such enormous size as the earth would require a pump so large that it would be a greater task to construct it than to build a thousand Egyptian pyramids. But there is a way of accomplishing this with a pump of very small dimensions. The bag connected to the earth is elastic, and when suddenly struck vibrates at a certain rate. The first artifice consists in so designing and adjusting the parts that the natural vibrations of the bag are in synchronism with the strokes of the pump. Under such conditions the bag is set into violent vibrations, and the fluid is made to rush in and out with terrific force. But the immense bag—the earth, is still comparatively undisturbed. Its size, however, does not exempt it from the laws of nature, and just as the small bag, so too the earth, responds to certain impulses. This fact I discovered in 1899.

The second artifice is to so adjust the transmitter that it will furnish these particular impulses. When all is properly done the large bag is thrown into spasms of vibration, and the effects are bewildering. But no power is yet transmitted, and all this colossal movement requires little energy to maintain. It is like an engine running without load.

Next let your readers imagine that at any place where it may be desired to deliver energy a small elastic bag, not unlike the first, is connected to the large one through a tube. The third artifice consists in so proportioning the parts that the attachment will be responsive to the impulses transmitted, this resulting in a great intensification of the vibration of the bag. Still the pump will not furnish power until these vibrations are made to do work of some kind.

To conduce to an understanding of the fourth artifice, that of "individualization," let your readers follow me a step further, and conceive that the flow of energy to any point can be controlled from the place where the pump is located at will, and with equal facility and precision, regardless of distance, and, furthermore, through a device such as the combination lock of a safe, they will then have a crude idea of the processes involved. But only when they realize that all these and many other processes not mentioned, and related to one another like the links of a chain, are completed in a fraction of a second, will your readers be able to appreciate the magical potencies of electrical vibrations and form a conception of the miracles which a skilled electrician can perform by the use of these appliances.

I earnestly hope that in the near future the conditions will be favorable for the construction of a plant such as I have proposed. As soon as this is done it will be possible to adapt electrical motors to flying machines of the type popularized by Santos Dumont. There will be no necessity of carrying a generator or store of motive energy and consequently the machine will be much lighter and smaller. Owing to this and also to the greater power available for propulsion, the speed will be considerably increased. But a few of such machines, properly equipped with photographic and other appliances, will be sufficient to give us in a short time an exact knowledge of the entire earth's surface. It should be borne in mind, however, that for the ordinary uses of a single person a very small machine of not more than one-quarter horse-power, corresponding to the work of two men, would be amply sufficient so that when the first plant of 10,000 hp is installed, the commodity of aerial flight can be offered to a great many individuals all the world over. I can conceive of no improvement which would be more efficient in the furtherance of civilization than this.

[1227.]—**Tesla Coil.**—If you will kindly refer to my book, "Electrical Instrument Making for Amateurs," at p. 109, *et seq.*, you will find description and cut of the manner of building a Tesla. Of course, unless your supply is an alternating one, you will be obliged to rig up some form of contact-breaker, either electro-magnetic, mechanical, or mercurial, and please note that unless you have had some experience in coil making, so as to be able to appreciate the nicety required in insulating the primary from the secondary, &c., you will very likely not succeed the first time. S. BOTTONE.

The Colorado Springs Gazette September 6, 1905

NIKOLA TESLA SAYS HE IS NOT INDEBTED TO DUFFNER

Nikola Tesla, the wizard of the world electric, has answered C. J. Duffner in the county court at this place.

Duffner brought suit recently for $899.22, which he claimed to be the balance due him for acting as caretaker for Nikola Tesla's house of experimentation on Nob hill.

Tesla came into the court yesterday morning accompanied by his attorney, M. L. Brown, and declares that he never employed Duffner at the time alleged for the purpose alleged or at any other time for any other purpose and that he is not indebted to the plaintiff.

In the original complaint Duffner alleges that he was employed by Tesla as caretaker of the Nob hill house January 1, 1903, at $18 a week, and that he continued in that capacity until July 2, 1904. Tesla, Duffner says, remitted $558.41 of the $1,332 due him for services and also owed him $25 for coal and building paper.

That Nikola Tesla should quarrel about money is odd, for while here he acquired the reputation of being absolutely without an idea of the value of money. For instance, one day he wanted to construct a large barrel. Being short of barrel hoops he came to the city, went to a bicycle repairing shop and ordered a wagon load of bicycle rims, which he used for hoops. He had a habit of setting his house afire by pressing electric buttons to see how general a conflagration he could start in how few seconds and he employed a private fire department to extinguish the flames after he had ignited it.

The New York Herald September 7, 1905

Nikola Tesla Sued.

[SPECIAL DESPATCH TO THE HERALD.]

COLORADO SPRINGS, Col., Wednesday.—Nikola Tesla, electrical inventor, of New York, has been made defendant in a suit here to recover $900 in wages.

THE ARTS AND
THE DRAMA

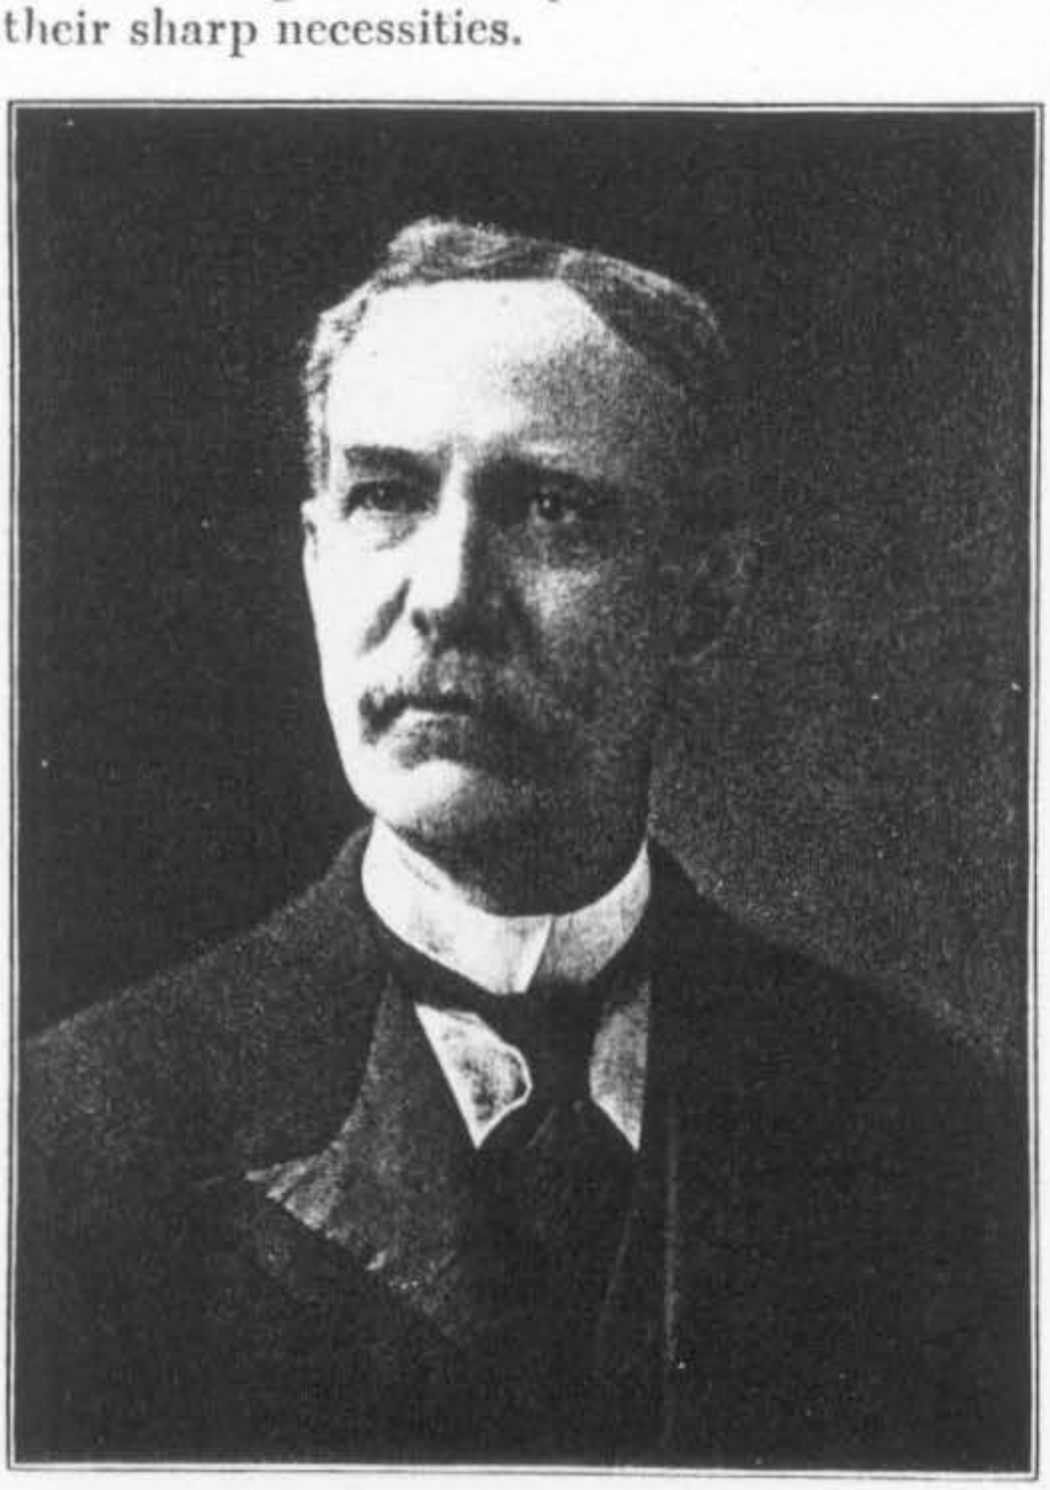
AFTER being a wanderer for twenty-five years, William Lawson went into the Harrison Street station in Chicago the other day and asked to be restrained from following the open road. He wished, he said, to settle down, but his legs had the roaming habit. He wanted to be held—rendered stationary—rooted to some spot on mother earth. He thought of going home and "becoming a man." The newspaper that printed this interesting paragraph only opened this vista into the life of William Watson—no, no, William Lawson—and then closed it again. It is left for the speculative reader to imagine why he of the good, sound-sense name acquired the vagrant habit. One would suppose that William Lawson would keep the general store at Squirrelville, and would know all the folks, and have no passion stronger than his obstinate intention to avoid the road tax. But Lawson, it appears, has escaped all taxes. The commonplaceness of life has never been his. He had never wearied to the innermost soul of him at the aspect of his neighbor's woodshed; he knew nothing of those arranged, pestering, persistent entities—such as the coal bill, the ice bill, and the grocer's order boy with his matutinal demand upon the domestic ingenuity,—which kill the fancy and murder the joy in the most buoyant of us. For William Lawson there had been a quarter of a century of whimsical exploration. He had watched the dawn, grown familiar with the stars, sipped of the brooks—if nothing better offered—and made himself intimate with all the little brothers of the wild. He, like Jaques, had journeyed far and had seen how other men live, and to glimpse other men's lives is the most fascinating thing in all the world except to have a sense of expectancy in regard to your own. Why, then, should William Lawson, who triumphed over dull destiny and refused to play the rôle of grocer in a banal world, have deliberately foregone his enviable madness and returned to sanity and the dull paths of penitence? It is not as if Lawson's heart was dead within. That, apparently, is as young as ever it has been. The innumerable roads and byways of the world still beckon him; there are still habitations which he has not seen, forests which he has not penetrated, fields in which he has not slept. There is still, as Percy B. Shelley would have remarked, had he known William Lawson, "a spirit in his feet." In these circumstances, it seems nothing less than a waste to want to "go back home!" At home, no doubt, the rain barrel is in the same old place, the barn

WILLIAM ALLEN WHITE

Whose article, "The Kansas Conscience," appears in this issue of THE READER

door is off its hinges, the fence lies prone among the protesting hollyhocks. There are two or three women who, for a quarter of a century, have enjoyed the marvel of the mysterious disappearance, to be deprived now of their sad entertainment, and to suggest odd jobs for William Lawson to do. It seems, all things considered, a mistake for William Lawson to return. He says he has seen almost all the world, but no doubt if he were to go over it again with more care he would observe some entertaining trifles which have thus far escaped him. The wanderers have always appealed to the fancy of poets. No idea is more enchanting than that of him who in the night and the storm comes knocking at the door, sits for a moment by the hearth, gives one wild kiss to the home-keeping maiden, and flies on, driven by the Lords of Destiny, upon his endless quest. William Lawson, had his heart been as valiant as it is youthful, might have shared with this immortal figure the fame which is his right. But he has faltered. His imagination has failed him. Or perhaps he has acquired rheumatism from lying too long under the stars. At any rate, by this time he is no doubt back home, stifling in the lean-to bedroom and washing in an ugly china bowl. The days of his dreams are over. He has voluntarily come back into civilization, which shuts us all up in box stalls—some have bare stalls and some a gorge of grain—but all of us are sure of harness and of weary feet. And yet, to have been wise for a quarter of a century must mitigate the folly of a life! There will always be something about William Lawson that will cause his neighbors to regard him with curious eyes. Little children will wistfully make his acquaintance. He can, if he will, contribute to the Sunday syndicates. And to the last, he will have his memories.

SOMEHOW the famous "bread line" of New York City, which has for so many years stretched itself along Broadway to the side door of a large bakery, has become closely identified in fiction with Albert Bigelow Paine's novel of the same name. And the story contains a deal of biographical information, for it was the outcome of Mr. Paine's venture in 1897, with Irving Bachellor, Orson Lowell and Frank VerBeck, to establish a juvenile magazine, which they called *Youth and Home,* and which was short-lived. Not that Mr. Paine actually had to seek his nightly loaf, as so many poor mortals have to do, but it was a very handy and sarcastic outlet for him to point a moral and adorn a tale. Mr. Paine is a typical example of the modern writer; he began, as so many others have, with a volume of verse, "Rhymes by Two Friends," the co-author being William Allen White—a production which these two young Kansas men thought



ALBERT BIGELOW PAINE

the world was waiting for. After this, in 1895, Mr. Paine came to New York, where he gained experience in syndicate writing, and invented, with Ruth McEnery Stuart, those delightful Gobolinks, which, made with pools of ink upon white paper, are the joy of children and the fear of parents. As a juvenile writer, Mr. Paine rapidly proved himself possessed of imagination and a quick comprehension of the child taste. That is why, as editor of the league department of the *St. Nicholas Magazine,* he has so successfully

called forth the efforts of young writers and artists. But the "Bread Line," published in 1900, is virtually Mr. Paine's first distinctive book. Thomas Nast, the cartoonist, read it and selected Mr. Paine as his biographer on the strength of it. He, too, had started a magazine, with the same direful results. Soon after the death of Nast, Mr. Paine gathered together his material and traced a most varied career in a work that is noteworthy and interesting. At present Mr. Paine is engaged upon a life of Capt. B. S. Osbon, Farragut's signal officer. And in the midst of his editorial duties he finds time to write extensively for the magazines.

THE family of Bret Harte has been afflicted with many misfortunes recently. The eldest son has been stricken with blindness; Miss Bret Harte, a concert singer, has been prostrated with ill health, and many minor misfortunes have been added to fill their cup of ill luck to the full. A number of the old friends of Bret Harte have been raising a subscription to minister to their sharp necessities.

ELROY MC KENDREE AVERY

Author of a new twelve-volume "History of the United States and Its People"

ARIZONA appears to be not so eager for statehood as she is for independence. The efforts of a certain faction to induce a union between her and New Mexico, and thus present to congress the aggregate of citizenship which will entitle the two territories to be admitted to the union as one state, has been repudiated with courtesy but decision by both democrats and republicans in Arizona.

"While we entertain for the people of our sister territory," says the protest forwarded to Congress by the voters of Arizona, "the most kindly feelings and sympathize with them in their efforts for admission as a state into the Union, yet we profoundly believe that the union of the two territories as one state would be inimical to the best and highest interests of both, and particularly harmful to the people of Arizona. To be compelled against our will and desire to lose our identity and be merged into the proposed state, in which we have so little voice, wounds our pride and violates our sense of justness and fairness. Therefore, as a patriotic and law-abiding people, we confidently appeal to the Congress of the United States to avert the disaster that threatens us; and, rather than force upon us this proposed union, to allow us to remain a territory indefinitely."

This is to be laid before both houses of Congress; the Governor of Arizona will make a protest on behalf of his people through the Secretary of the Interior; and the President will be asked to embody in his annual message a recommendation against joint statehood. Should these efforts fail and Arizona be forced into partnership with what may be termed our Spanish-American territory, New Mexico, the matter will be carried to the supreme court. The question would, in that event, be an interesting one. Can Congress impose statehood on a community? Can an act of union be forced upon a self-governing state that desires to remain in that condition of comparative autonomy which a state of the United States enjoys?

Senator Beveridge and other senators advocate the union of the two territories, and have gone the length of making a hasty tour of Arizona to acquaint themselves with her condition, resources, etcetera, etcetera. It is not too much to say that if they are sensitive to swift impressions they must have

been bewildered by the paradoxes, physical and sociological, that Arizona presents. At once the most ancient and the most modern, the most foreign and the most native, the most fertile and the most barren, the most stupendous and the most squalid, the most beautiful and the most disheartening of sections, in her geographical and in her social features, she amazes and fascinates. To have seen her deserts, her cañons, her remains of ancient cities, is to remember her forever as the monument to a savage and fascinating past; to witness the methods by which she overcomes her disadvantages of semi-aridity, the enterprise she shows in certain of her towns, the engineering ability and industrial activity she has achieved, is to think of her as the very modern of the moderns. The remnant of the old life still lives there side by side with the alert, energetic, ambitious young American element, which pioneers with contemporary science in electricity, hydraulics, chemistry and engineering at its command.

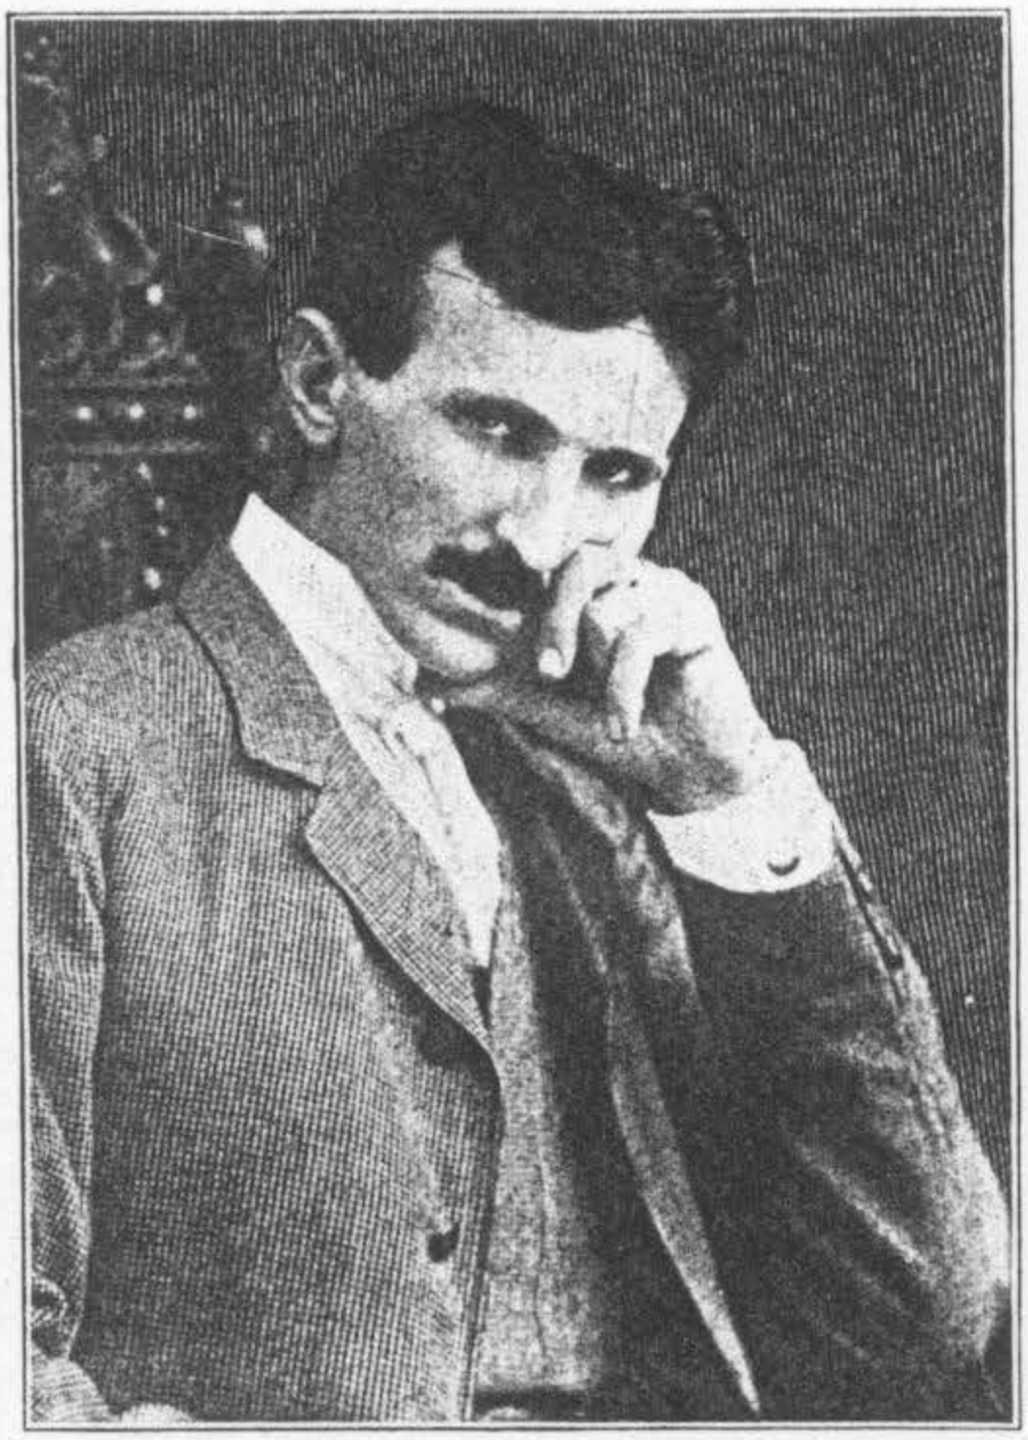
Arizona is one of the most strongly individualized of any territory that ever laid the foundations of an independent-minded state; and she should not be compelled to merge her individuality in that of an adjoining state uncongenial, in some ways, to her, and moved by ideas and ideals at variance with her own.

A VERY large proportion of the American literary brotherhood has essayed newspaper work before venturing upon the less ephemeral forms of pen product. Richard Harding Davis once made a list of the successful authors who had begun their careers under the tuition of a city editor, and the list was long and honorable. Burges Johnson, author of "Rhymes of Little Boys," is an instance in point. Mr. Johnson is an Amherst man, and after leaving college worked on newspapers, venturing finally into the publishing business. Essays and verse, both serious and light, have been his achievements thus far.

MR. John McCutcheon, the cartoonist, has taken a dash to Russia to enable him to work with more definiteness and understanding in cartoons relating to the various phases of the Russian question.

ARTHUR TRAIN

Assistant to District Attorney Jerome, of New York, and author of "McAllister and His Double"

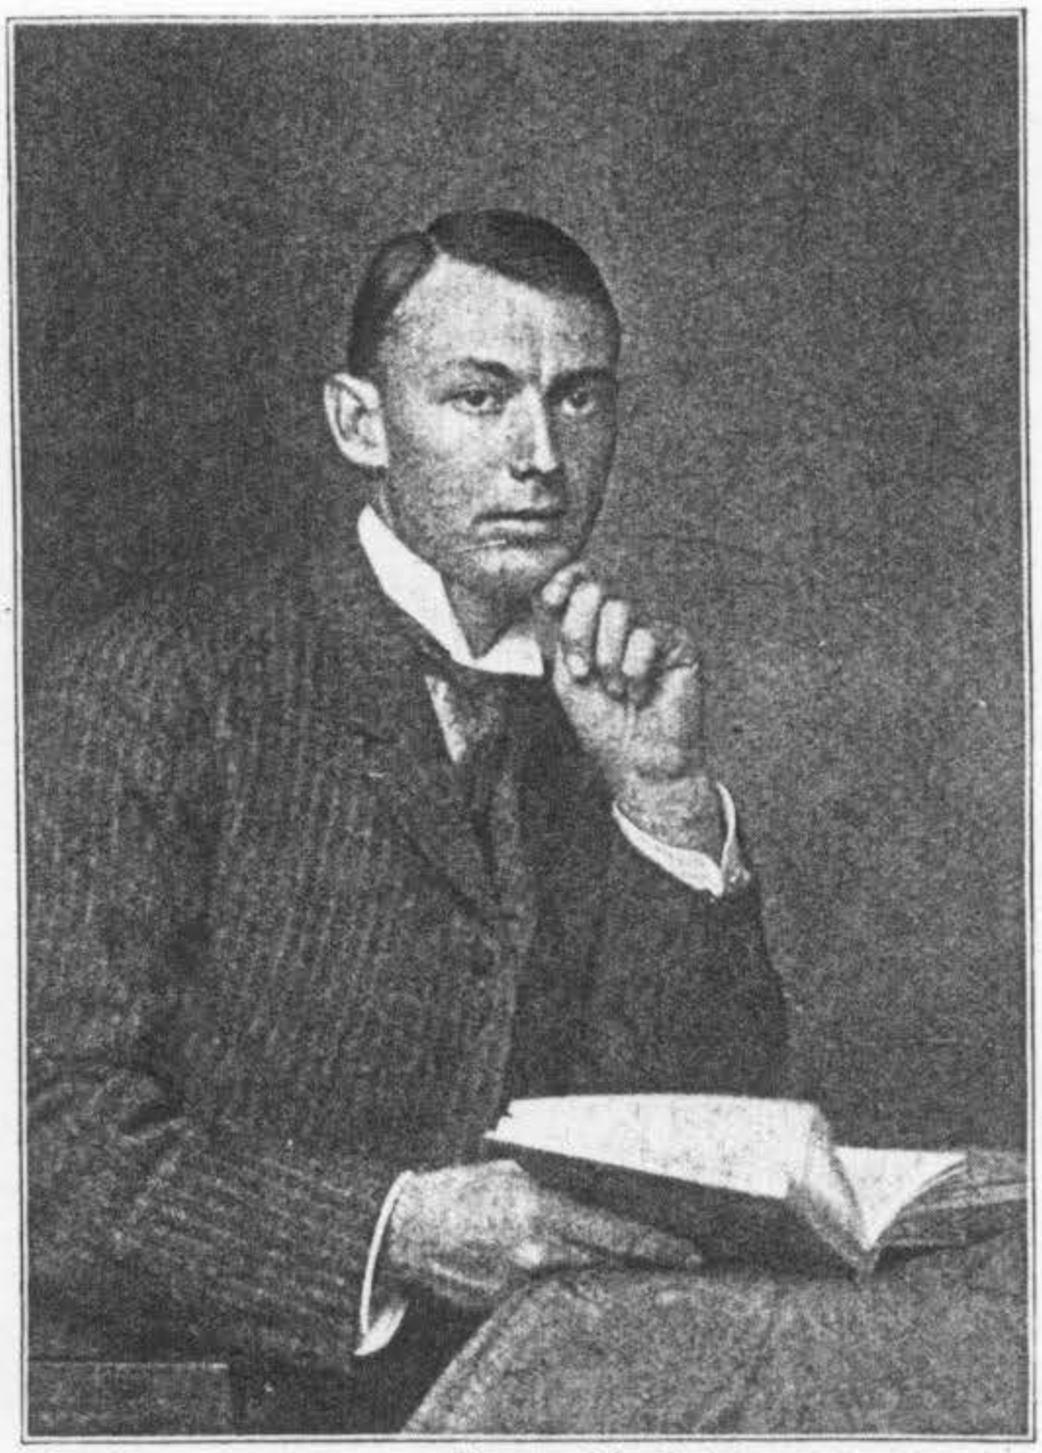


IN a recent magazine article Thomas Dixon, Jr., again solves his favorite problem, the negro and what to do with him. This time Booker T. Washington and "some dangerous aspects of his work at Tuskegee" are made the centers of attack. As usual, there is no mistaking Mr. Dixon's meaning. He knows what he wants to say and says what he thinks he knows. He writes with clearness and with vigor; his style is always energetic and often picturesque. In this latest tilt at the black windmill Mr. Dixon is more conservative, and therefore more convincing, than usual. Admit a few early premises, and Mr. Dixon can write the negroes out of the country and set them up in Liberia, a peace-keeping, God-fearing people, masters of their own destinies and the happy bosses of a free republic.

"If allowed to remain here the negro race in the United States will number sixty million at the end of the century by their present rate of increase." Mr. Dixon doubtless has the figures to prove this statement, but

figures are all things to all men. To Mr. Dixon they are simple, straightforward and free from guile. At the close of the war, forty years ago, there were four million negroes enfranchised. By the last census there were eleven million scattered over the country. Mr. Dixon doesn't say so, but no doubt with these amiable figures and a Dixon lead pencil he can turn out sixty million at the end of the century. But how does he know the present rate of increase will be maintained? He doesn't know, of course. He assumes, and the conclusion based on the assumption is made the foundation for his "irreconcilable conflict". To believe that this rate will remain unchanged is to believe that physical and social conditions will remain unchanged. It is ninety-five years to the end of the century. A long time for even the Meads and the Persians. What Mr. Dixon really knows is that the colored man's conditions are changing rapidly and that all the changes tend to a lowering of the present rate. The negro no longer draws strength from the soil. He has swapped the fresh air of the plantation for the foul air of the alley. The cabin and the corn-patch know him no more. He has become a sophisticated but unsanitary man about town. With the city comes cocaine. The corner drug store, unaided, will make Mr. Dixon's "present rate of increase" look like an overheated thermometer in a cold-storage house. Late hours, dissipation, idleness, these and other alluring dangers call to him beyond his power to resist. It is an unequal struggle, in which he withers and falls, a victim of progress, a martyr to civilization. Mr. Dixon is a modern abolitionist, deeply serious, intensely earnest. But in his enthusiasm for the "cause" he forgets some things he knows better than any one else.

THE accusation—if such it may be termed—of plagiarism brought against Mrs. Katherine C. Thurston by Mr. Lewis in an article which draws close parallels between the plot, circumstances and scenes of "The Masquerader" and Mr. Zangwill's "The Premier and the Painter," has brought forth a letter of frank and honest disavowal from Mrs. Thurston. She says that her first feeling upon reading the heading of Mr. Lewis' article was one of resentment, "but," she adds, "as I read the article itself, I confess that my anger gave place to amazement, for certainly the facts brought forward by Mr. Lewis are to me very amazing, forming, as they do, the most extraordinary case of dual suggestion that has come within my knowledge. For let me state, finally and most emphatically, that I have never seen a copy of Mr. Zangwill's 'The Premier and the Painter'; the book has never been discussed—or even mentioned—in my presence; the story, even in the most shadowy outline, has never been related to me."



This has the utter accent of truth, and none will be so ungenerous as to doubt Mrs. Thurston's statement. Nor is the thing so marvelous after all, for fact itself has fairly taken the suggestion from Mrs. Thurston's book, as the newspaper annals of the past month bear witness. The occurrence of this case, so singularly resembling the "impossible" story of "The Masquerader," occurred in Rome. Count Adriano Beniculli, an eccentric nobleman, charged his valet with having indirectly caused the death of the Countess Beniculli. The evidence offered in court brought to light the fact that, taking advantage of an extraordinary resemblance between himself and his valet, the count employed the latter to impersonate him at various social functions at Rome and elsewhere, while he devoted himself to his hobby of collecting and repairing ancient locks. Paolo, the valet, provided with money and appropriate raiment, was received everywhere in the best society, and acquitted himself, apparently, more creditably than the count had done. Meeting the Countess Beniculli at a ball, the valet paid her assiduous attention. He was, in truth, infatuated with the charm of this great lady, who accepted his attentions with a certain gratitude. For many years she and her husband had not lived together, and she had come to think of him as a semi-madman. She found him instead, a sane, handsome and magnetic gentleman, from whom it was a compliment to receive attentions. She became reconciled, as she believed, to her husband, and a period of happiness followed to be broken in a tragic manner one day when the countess and the valet drove to Rimini, and walking toward some of the caves, were interrupted by a peasant woman, who rushed upon

Whose new book, "The Mountain of Fears," is to appear in October

Paolo, accusing him of having deserted her. The truth came out, and the countess, who seems to have had a character in strong contrast to these men, knelt at the feet of Paolo's wife begging her pardon. She returned alone to her palace, thinking heaven knows what thoughts concerning the tricks of fate, and was that same night found dead in her room. She had poisoned herself and got safe beyond all chance of further disappointment and mockery. She left a letter explaining the facts to her husband and saying that she was unwilling to sully the records of her ancestry. A pathetic figure, worthy the art of a nobler d'Annuncio! Count Beniculli may have been moved to a belated remorse, and a realization of the dignity of his countess. At any rate he brought suit against the valet.

Whether the poor countess would, in the event of her pseudo-husband having been a man superior in character to her actual lord, have proved as complaisant and unconventional as the heroine of Mrs. Thurston's romance, may not be known. The Countess Benieulli would, perhaps, in any case, have been more solicitous about her honor than about her happiness. Mrs. Thurston's heroine could not satisfy herself with "honor" which may, in the circumstances, have seemed a fetich. She took happiness with eager hands, scandalized the subscribers to *Harper's Bazar,* and won the approval of a number of argumentative persons who thought she showed singularly good sense—for a heroine—in taking a good man in exchange for a bad one, "without benefit of clergy" or unnecessary explanation to a captious public.

THE Ben Greet Woodland Players have met with gratifying success in the West. On the college campuses and at parks they have presented "Midsummer's Night Dream," "As You Like It," "Much Ado About Nothing," "Twelfth Night," "Comedy of Errors" and "The Tempest." In the last play only they failed to attain that high

standard they have set for themselves. But the company acted both a *Ferdinand* and a *Miranda* of the adequate spiritual measure. Not the least interesting feature of these performances has been the Shakespearean songs sung to tunes of the sixteenth and seventeenth century. A number of these have been arranged by Arnold Dolmetsch, apostle of old-time tunes and instruments.

HENRY ARTHUR JONES

The dramatist, author of "The Manœuvers of Jane," "The Case of Rebellious Susan," etc.

NOTWITHSTANDING the ever increasing number of deaths and injuries caused by reckless automobilists, the criminally careless chauffeurs have almost invariably escaped punishment. As ruthless and insolent as any patrician of Rome in the days of its self-debasement, these drivers of our modern chariots leave their dead lying in the road and escape by the combined means of their speed and of their falsified numbers; for it transpires that the wanton automobilist does not lay himself liable to responsibility by carrying a recorded number, but changes the number to suit the occasion. In spite of efforts more or less earnest, the police find it impossible or impolitic to track these up-to-date murderers to their homes, if such men can be said to have homes, and the injured pay their own hospital bills, and the dead go unavenged in consequence. It is noticeable, since the occurrence of the summer accidents, that many of the finest machines are run with conspicuous care, the occupants being unwilling to be classed with that band of conscienceless marauders who are bringing automobiling into disgrace.

France is trying to meet the exigencies of the situation by building speedways on which nothing but automobiles are to be allowed. Such a speedway ninety miles in length is being constructed by Biarritz, at a cost of $1,600,000, along the coast at Arcachon. Here the speed madness may have its way, with none to hinder nor make afraid, while on other thoroughfares moderation of pace can be rigidly enforced.

SCIENTISTS will feel a keen interest in the new theory of the creation of the universe offered by Professor F. R. Moulton and Professor Thomas C. Chamberlain, of the University of Chicago. These men, three years ago, proved to their own satisfaction, that Laplace was mistaken in his ring theory of the nebular hypothesis. Professor Moulton said in class room the other day:

"To prove the nebular 'ring' theory the combined momentum of all the parts of the solar system at present ought to equal the momentum of the sun at the time when it extended to the orbit of Neptune, or in the beginning. I have worked with the problem a long time, and I am convinced that the solar system now has only one two-hundred-and-fiftieth of the momentum it had when the sun extended out to Neptune."

These two radical scientists, having satisfied themselves three years ago that calculations would not substantiate the ingenious theory of Laplace, have been at work, aided by a grant from the Carnegie Institute at Washington, formulating what they have called the spiral theory.

"Professor Chamberlain and myself be-

lieve," says Professor Moulton, "a second sun—a disturbing sun—moved down near our sun and caused on our sun enormous tides, thousands of miles high. The tides were similar to the tides of the sea. Our tide was at the point nearest the disturbing sun and the other tide was on the opposite side. The matter shot toward the disturbing sun. Ordinarily it would have been straight up, but the disturbing sun moved around in an elliptical sort of orbit. Consequently all the masses thrown off were in a spiral direction, one after another, which accounts for the orbits of the planets. The swollen masses were attracted to the large nuclei which made them into planets."

Hence the good round earth!

The results worked out are to be published presently, Professor Moulton treating the astronomical, and Professor Chamberlain the geological phase of the question. It remains to be seen what comment is made by the critical scientists of Germany, Italy and France.

MRS. H. A. M. Keays, author of that intensely interesting novel, "He that Eateth Bread with Me," is engaged upon another problem novel, the title of which is to be "The Work of Our Hands." Divorce was the matter dealt with in the first book; wealth is to be the subject of its successor. Mrs. Keays adjusts her life, so far as residence goes, to the convenience of her sons. For the past two years she has lived at Ann Arbor, where her sons were attending the University of Michigan, and has now moved to Cambridge that the young men may finish their collegiate course at Harvard.

THERE are many uses to which humor may be put, and one of these might well be to restrain the humorist from being amusing at the wrong time and in the wrong place. It is a commonplace for lovers of poetry to sigh: "Oh, that Wordsworth had possessed a sense of humor and had spared us much that was maudlin and more that was dull!" A more subtle accusation may be brought, however, against such a poet as Sidney Lanier, who lacked humor sufficient to restrain his humor. No lover of Lanier at his best can bring himself to endure the presence in his volume of the poems which the author was pleased to consider humorous, and which it seems rather too confiding of his publishers to offer to a public that is under the necessity of judging Lanier by severe standards as the result of the high position now accredited to him. A well-developed sense of humor would have shown the writer of "The Marshes of Glynn" that it was not his *metier* to be amusing, and that, indeed, he could not well be amusing without being ridiculous.

JAMES HUNEKER

Dramatic editor of the New York *Sun*, author of "The Iconoclasts," etc.

WILLIAM Vaughn Moody is industriously at work upon a volume of short poems—poems which, it is safe to say, will be greeted by the public with intense interest. Mr. Moody has expressed himself with a poetic truth and loveliness rare enough in these utilitarian days, and he has now to confirm the pleasant suspicion that he is a poet of sustained power. It is said that he has not yet entered upon the composition of the third book of his trilogy.

NELSON LLOYD

Author of "Mrs. Radigan"

AT the present time, in view of the great revival of interest in Victor Hugo, it may be of interest to recall a story concerning his relations with the late Louise Michel, the famous anarchist, who, despite the fact that she enjoyed world-wide notoriety as an anarchist, was universally respected for her boundless sympathy with all who suffered and for her heroic self-sacrifice. The incident was told by Hugo's private secretary, M. Lesclide, and published in the Parisian press at the time of his death, in 1885.

During the siege of Paris Hugo gave most liberally to the poor and necessitous. He was assisted in the distribution of his alms by his friend, Madame Paul Leurice, who was herself a most bountiful giver. One day Madame Leurice came to Victor Hugo, telling a pitiful story of a poor woman whom she had found in the most terrible state of destitution and *misère*. Hugo at once gave her a hundred francs for her needy *protégée*. Now, despite the high prices which ruled in consequence of the siege, a hundred francs could be made to go a long way in providing against starvation, so the poet was very much surprised to receive word from Madame Leurice next day that the poor woman was "as badly off as ever".

"Well, what of the hundred francs of yesterday, then?"

"Ah, the hundred francs. She has given them away to poor mothers, to little children, starving of hunger and perishing with cold."

"Good! Here is another hundred francs, but upon the express condition that she keeps them for herself."

"Is it only on that condition he gives them?" asked the poor woman when Madame Leurice gave her the poet's message.

"Exactly."

"'Then take them back! Thank Victor Hugo for his good intentions, for which I am grateful."

Madame Leurice was embarrassed. She dared not take the money back to Victor Hugo, so, after scolding the woman and calling her "Obstinate Louise," she handed her the money unconditionally.

The "Obstinate Louise" was Louise Michel, the "Red Virgin." And the money was spent as before, to relieve other hungry women and their children.

"WHY, he's the translator of Maeterlinck," is the usual exclamation when one is asked something concerning Alfred Sutro, the dramatist. The book stores will assert that he never wrote plays, and you might believe them if you did not know that several of his dramas had been presented in London last year, and that two or three were to be given here; one, "The Walls of Jericho," with James K. Hackett in the leading rôle, and another, "The Maker of Men," a curtain piece for Margaret Illington. But if English critics can be relied on, his plays are of conventional design; yet of Alfred Sutro, the translator, naught can be said but that he is excellent. The beauty of Maeterlinck in English reveals a keen sense of the Belgian's style. There seems to be a poetic sympathy existing between these two men; the most fluent English takes the stead of the most fluent French. This is a rare instance of a man winning reputation as a translator. Marcel Schwab's French

version of "Hamlet" is another example, and in German the Shakespeare of A. W. Schlegel. As for Fitzgerald, Omar became English—changed his Persian personality for an alluring dress of another land. But Maeterlinck loses naught of his full value.

It is to be deplored that we Americans miss so much of what is written about the English stage—and the foreign also. William Archer's "year books" are not as full as they should be, and in America, outside of the theatrical journals, there is no yearly record of the drama easily accessible for the library. And after a season's work are there not some criticisms worth preserving? It would take comparatively little trouble to systematize our dramatic records for future reference. Where look for something concerning Alfred Sutro? We need a dramatic guide. Apropos of this subject it is a welcome announcement that comes to us concerning George Bernard Shaw. Nowhere has he been more brilliant than in the dramatic criticisms he used to write some years ago; and nowhere were they accessible save in the files of the London *Saturday Review*. They have now been gathered together and will soon be issued in book form.

IT is a curious thing that the American issue of Swinburne's poems should not include the trilogy dealing with Mary Stuart. It is, perhaps, not too much to claim for them the high-water mark of the poet's psychological achievement. These dramas have a robustness about them too often lacking in Swinburne's work. His incomparable preciosity too frequently submerged his intellectuality, and he gave to his listeners the rhythmical clamor of poetry without its substance. But in the Mary Stuart plays, character after character appears in full stature, with enigmatic soul made lucid, and placed properly in that dark tangle of ambitions and hates and passions which gave to Scotland one of the most sinister and fascinating of her historical dramas.

WHEN Miss Cather, author of "The Troll Garden," was not quite nine years old her father moved from the Shenandoah Valley to a ranch in the southwestern part of Nebraska about ten miles north of the Kansas line. The years when she first began to notice surroundings at all were "pretty much devoted," she says, "to discovering ugliness. . . . You can't imagine anything so bleak and desolate as a Nebraska ranch of eight or nine years ago." Most of the Cathers' neighbors were Swedes and Norwegians; and she remembers being taken to a Christmas entertainment at the Norwegian church, where the Christmas tree was "a poor, little, naked box elder wrapped in green tissue paper cut in fringes to look like foliage." From 1890-1894, while she was at the state university at Lincoln, there was a steady drouth over the country which plunged the Norsemen into a grim and dreadful despair, and brought forth only suicides and broken households. Miss Cather said once that no matter how great may be its prosperity, whenever she revisits the country she sees in the background the old tragedies that she knew so intimately. She has been out there this summer working on a novel which a friend who has seen it declares to be of a rather dark cast,—shadowed, it may be, by the "old tragedies."

MARY STEWART CUTTING
Author of "Little Stories of Courtship," etc.

MR. RANDALL PARRISH is to the front with another novel—his third. "A Sword of the Old Frontier" is the characteristic title. Pontiac's conspiracy is the subject, and it is one sufficiently thrilling to suit even Mr. Parrish, that lover of excessive danger and true love gone wrong. Raoul de Coubert, sometime captain of hussars in Languedoc, is the adventurous hero, whose indomitable struggles and marvelous escapes are said to hold the reader's attention to the end. Mr. Parrish's previous novels have proved to be extraordinarily popular. It is prophesied that "A Sword of the Old Frontier" will prove to be as fascinating as its predecessors.

Another novel to be published by the same house—A. C. McClurg—is "Ben Blair," by an author new and untried, Will Lillibridge, in whom the publishers have great confidence. It is the story of a cowboy handicapped in life and love, who wins out, as a good cowboy should. The atmosphere and the incidents, the character of the hero and the nature of the victory which concludes a story of love and adventure, all recommend themselves to the judicious lover of romance, so it is said. Both of these novels are finely illustrated.

ONE result of the centralizing of the circus business and the enlarging of the shows has been the elimination of the old-time fun of the clown, who now finds the tents too large in which to make his voice carry to the thousands of auditors, and has to resort to the pantomime art of long ago. Time was when pantomime was almost as popular in this country as it was in England, France or Italy, where it was considered the basis of all stage acting, and where aspirants for dramatic honors learned it as the first step toward their goal. There are those still alive who remember with keen delight the remarkable pantomimic art of George L. Fox and his astonishingly clever imitations and caricatures of the great actors of his day. Tony Denier, one of his associates, is living yet, we believe, forgotten by the generation which enjoyed his silent comedy and unknown by that which now leans to other forms of amusement. After these men the Kiralfy brothers introduced slight touches of pantomime in their productions, and the Hanlons went a little farther, but were more acrobats than real pantomime actors. Even in England the taste for pantomime survives only in the annual productions at Christmas time. That an appreciation of pantomime still exists in America was proved by the success which attended the visit here several years ago by a French company of great ability.

IT is interesting to read the comments made upon the spiritual inheritance of Secretary of the Navy Charles J. Bonaparte. His name is one which summons swift recollection of the good little adage, "blood will tell," but our American editorial writers are jealously claiming for an American mother the honor of transmitting to Mr. Bonaparte those qualities of fearlessness, decision and civic rectitude which have caused him to be appointed to his present high place. That he is the grandson of a king seems to them, in view of certain acts of that evanescent monarch, to be a fact best honored in the forgetting. But the down-east Yankee mother of Mr. Bonaparte, a woman of sufficient strength of opinion to sustain her northern principles in spite of her alliance with a Baltimorean, is accredited—justly, no doubt,—with having passed on to her son those characteristics which have made him an aggressive reformer and a politician of impeccable honor. He knows how to go down with the right and to make a victory out of the defeat, as was shown in his long fight with the forces of corruption in the municipal politics of Baltimore. He is a man of sufficient independence to excoriate the members of his own party when he finds them running counter to the ideals which they are supposed to cherish. He has given the prestige of his name and his character to a party which, in the section from which he comes, suffers from being in a negligible minority, socially inconspicuous and pining from a merciless stigma. He has been with the under dog, and has contrived, by methods which commend themselves to all honest men, sometimes to get the under dog on top. He is an intense American in his ideals and principles, notwithstanding the ease with which he could lay claim to aristocratic advantages. "A good citizen," he declares, "needs no grandfather." This remark was

not, it must be noted, made with copybook obviousness, but was spoken spontaneously and wittily in connection with the disfranchising act for Maryland, which contains a "grandfather" clause.

AFTER a protracted period of apparent inactivity M. Rostand has appeared in Paris with the manuscript of a new play. It is called "Chanteclair," and all the characters are birds. Coquelin is to represent *Chanteclair,* and he and the other sixty personages in the play will appear dressed as birds. The play, as usual, is in the familiar couplet form of French verse, and it is satirical in character. It is to be produced at Coquelin's theater after three months of rehearsals, a provision on which M. Rostand is said to have insisted. One may reasonably expect something charming and piquant from a theme like this handled by such a master, although it is almost too whimsical to promise extended life. Talented as M. Rostand is, it is noticeable that he is prone to use ideas already exploited, although his apparent appropriations may be more or less unconscious. The controversy over the authorship, or perhaps priority of idea, of "Cyrano" is well known, and his indebtedness to previous authors for his "L'Aiglon" was still more apparent. The conceit of this new play is as old as Aristophanes, and even in America within a year we have had a comic opera in which all the characters were dressed as birds, and the stage was made to represent a huge bird-cage.

PAUL Elmer More is one of those fortunate journalists who has the happy distinction of combining a high quality of scholarship with a facile pen. There is a certain timeliness in what he writes that is journalistic; there is also a leisurely vein which suggests the easy chair. It is not incompatible that a journalist's work should have in it the element of permanence; what we mean by timeliness, however, is in contradistinction to such essays as those comprised by W. C. Brownell in his "Victorian Prose Masters," which are estimates intended for the library rather than for readers of the magazine or the newspaper. Mr. More's latest volume of "Shelburne Essays" is witness to what we mean. His "Elizabethan Sonnets" is apropos of Sidney Lees's recently compiled volumes on the subject; his "Lafcadio Hearn" appeared soon after the death of that author in 1904; his "Hazlitt" and "Lamb" were both called forth by those exhaustively personal editions of the essayists which the publishers

PAUL ELMER MORE

have been issuing within the past months, and so on through the book. Mr. More has a wide knowledge of English and classical literature, and his duties as literary editor of the New York *Evening Post* afford him ample opportunity for using it in the right direction.

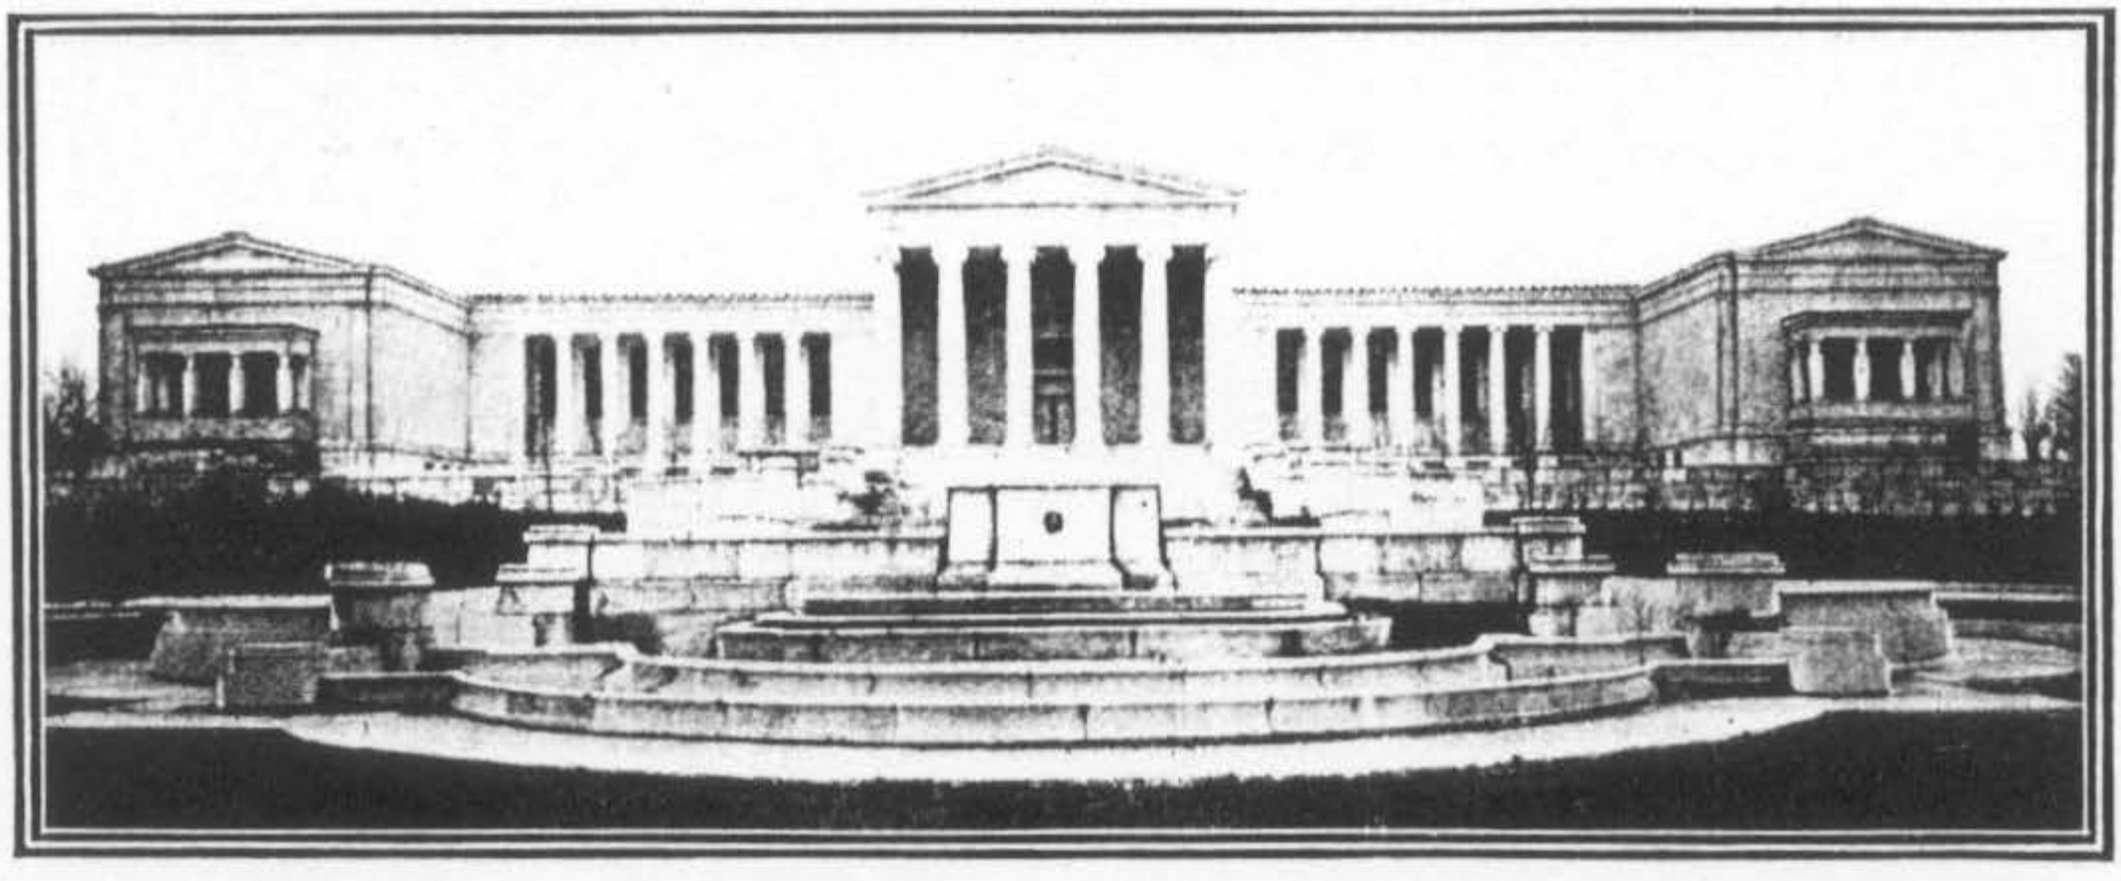
MR. Hamlin Garland is off again to the mountains. He has with him the same guide who accompanied him to the Yukon, and who on this occasion will lead him over twelve hundred miles of wild mountain travel, the destination being some lofty and splendid peak of the Rockies in Montana. On such an expedition Mr. Garland himself performs the more arduous tasks, such as loading and unloading the pack train, pitching the tents, cooking the

meals, etc. For a man who has been so acutely conscious of the pain of labor, Mr. Garland seems willing to assume a disproportionate amount. But he would probably say that there is a world of difference between the toil of a man who is tied to it like Ixion to his wheel and the *insouciant* assumption of labor because of the zest it gives to life.

IT seems to be the consensus of opinion that Mr. Swinburne's novel, "Love's Cross-Currents," written in the poet's youth and exhumed by Mr. Theodore Watts-Dunton, is a "school-girlish performance." The characters are trivial gossips, the ideas are conspicuous by their absence, and the book drags its slow length along without sweetness and without light. Mr. Swinburne's luscious lyricism has won for him a high place among poets. So enchanting has been his melody that the comparative absence of ideas has been overlooked; but the puerilities of this novel of his youth throw another light upon his character, his culture and his dreams.

IS Mr. George Ade going to become a dramatist? That is the question his friends are asking with a good deal of eagerness and expectancy. At the beginning of his composition for the stage his pretensions were accepted lightly. It was taken for granted that he would do a few popular pieces, make a snug fortune, reform and live a better life. But it is not to be denied that the young man develops. "A College Widow" has proved to be an innocuous, engaging satire, amusing enough to divert even the middle aged, and full of situations and characters that delight the young. It breathes, indeed, the spirit of youth. The thought is young, the story very, very young; the joy is of the young variety, and there is no sorrow. No more charming, innocent and gay satire has ever been put on the American stage, or, one might venture to say, upon the stage anywhere. Satire is usually written for the sophisticated. Even the delightful libretti of Gilbert revealed sophistication. But Mr. Ade's plane of thought as indicated by "The College Widow," hardly goes beyond adolescence—and is all the better for it, too. Young folk adore the drama, but there is not, once in a blue moon, anything to which it is an undefiled pleasure to take the growing inmates of the household. Mr. Ade's play is an exception. It is within the realm of possibility that Mr. Ade may not consider this praise. But why should he not? So many have written dramas for the sinful, the tempted, the learned, the sophisticated, that he, at least, may be willing and proud to write for that large constituency of innocent and lighthearted persons and for that yet larger company who, knowing of the pain, the struggle and the sin of the world, are quite willing to forget it for one pleasant hour in which their youth attains a partial recrudescence.

Down at his fine farm in Indiana Mr. Ade has completed two more plays, which will be presented this winter, one to be called "The Bad Samaritan," and the other "Just Out of College."



IT may not be recognized among the non-musical, but it is a fact nevertheless, that the number of musical festivals is continually increasing in the United States. Several villages, both North and South, have their spring or mid-winter festivals, their seasons of oratorio or concert-opera, and Scotch-Americans, Irish-Americans, Welsh-Americans and German-Americans, all have their respective singing societies. Among the leaders in work of this class is Tali Esen Morgan, who has organized and who trains and leads at least six fine choruses. The largest of these is at Ocean Grove, where four hundred voices are trained and supplemented by orchestral accompaniment; another is at New York, where the chorus consists of three hundred and fifty; the one at Philadelphia includes three hundred voices; that at Cumberland, Maryland, two hundred and fifty; that at Thousand Isles two hundred and fifty, and the one at Pittsburg one hundred.

All the best in oratorio, cantata and song cycle, with orchestral accompaniment, has been presented by Mr. Morgan's choruses. Mr. Morgan frankly avows himself the advocate of popular musicianship. These ideas he brought with him from the old world, to find that in America they were at a decided discount. Sight reading was an unknown art, and he can felicitate himself on having

taught at least five thousand singers the art of sight reading. It is, therefore, no formidable undertaking for him to produce a new work, and it is not too much to say that the existence of such choruses as his acts as an incentive to composers to prepare musical works for their production. Seven years ago, when Mr. Morgan began his work, there were no musical bodies outside of the Apollo clubs of the large cities capable of presenting such works as the "Messiah" and "Elijah." At Ocean Grove, this summer, Mr. Morgan's chorus has presented these oratorios, and Stainer's "Crucifixion," Dr. Adam Geibel's "The Nativity," Gaul's "Joan of Arc," and Cowen's "Rose Maiden." Mr. Morgan has, it is said, a winning personality. He is a modest man, and one that can talk about something else besides music when the occasion demands.

WHEN Clyde Fitch rests it means that he goes off somewhere and writes hard and persistently. This very quality of untiring effort on his part is perhaps his greatest weakness. Mr. Fitch has remarkable cleverness as a practical playwright; in many of his plays he has come very near permanent satire; his dialogue is usually crisp and ofttimes brilliant. His enemy is his haste; he often writes before the idea has crystallized, and this is not so with Henry Arthur Jones or Pinero. Yet Mr. Fitch rarely ever fails to interest. When he returned from abroad this year he brought with him a play of George IV's era, for Viola Allen, called "The Comedy Mask," and also a revised text of "His Grace De Grammont" for Otis Skinner, though we hope this actor has not abandoned his intention of playing Richepin's "Don Quixote." Mr. Fitch has also written "Her Great Match" for Maxine Elliott, and helped turn Alfred Henry Lewis's "Wolfville" into a play. Naturally Mr. Fitch leads in the productiveness of the American dramatist; he is closely seconded by Augustus Thomas, who generally conceals the names of his plays until the last moment; then follows George Ade, whose pieces are stamped all over with American humor, even to their titles, such, for instance, as the new ones, "Just Out of College" and "The Bad Samaritan." Ella Wheeler Wilcox has essayed a drama, which she calls "Mizpah;" and "The Letters of a Self-Made Merchant to his Son" has not escaped the stage, for "Old Gorgon Graham" is announced for early production.

ROBERT Hitchens is to follow "The Garden of Allah" with "The Black Spaniel." No doubt the worshipping admirers of the former will approach the latter with some apprehension, for they must know that only a remarkable production could interest them as vigorously as did "The Garden of Allah."

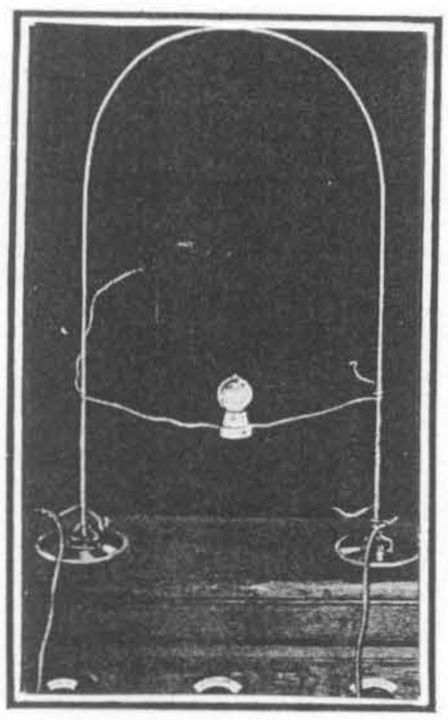
NICOLA TESLA MUST PAY UP



C. J. DUFFNER GETS JUDGMENT AGAINST FAMOUS INVENTOR IN THE DISTRICT COURT.

Judge Robert Kerr in the county court yesterday sustained the attachment of the plaintiff in the case of C. J. Duffner vs. Nicola Tesla, and entered judgment for the plaintiff for the sum of $789.59, together with $100.63 interest to the commencement of the action and $29.35 to the date of trial, making a total of $928.57.

HIGH-POTENTIAL DISCHARGES.

BY A. FREDERICK COLLINS.

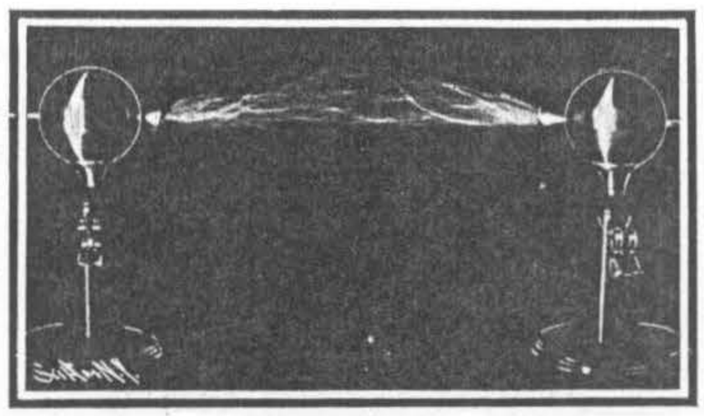
The various manifestations of high-frequency and high-potential discharges offer a fertile field of research, especially for the amateur investigator, since it is a subject that has received comparatively little attention considering its significance as revealed in its recent applications to electrotherapy, radiography, and wireless telegraphy.

LIGHTING AN INCANDESCENT LAMP SHORT-CIRCUITED WITH HEAVY COPPER.

The current has the choice of two paths—an easy one through the copper bar and a path of higher resistance through the lamp—and it chooses the latter. Ordinary currents would take the easier path.

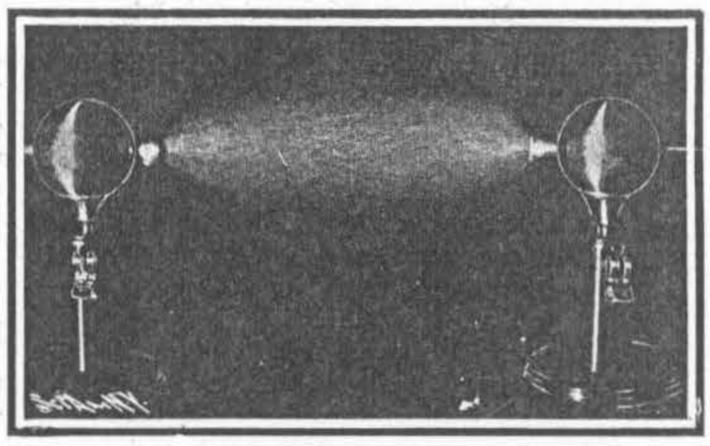
The term "electric discharge" is understood to include all modes of equalization of differences of potential between the terminals of a source of electrical energy on their connection by a conductor, by the removal of their charges by a stream of electrical particies of air, or by a sudden discharge that breaks down the air or other intervening dielectric. These are the three chief methods of restoring the electrical equilibrium, and are known respectively as the conductive, the connective, and the disruptive discharge.

The various forms may be further subdivided into alternating, arc, brush, brush and spray, dead-beat, flaming, glowing, lateral, oscillating, periodic, streaming, stratified, impulsive, and periodic discharges, and these may be produced by utilizing a source of direct or alternating current of low voltage, as for instance a commercial generator; a high-potential apparatus as an induction coil, or a high-potential, high-frequency arrangement, as a Tesla coil, depending upon the requirements of the various cases.



In this review we are concerned only with disruptive and connective discharges, the former in its application to wireless telegraphy and the latter in its relation to the human body. Since only potentials such as can be obtained with an ordinary induction coil are needed for disruptive discharges, these will be described first.

In the production of a discharge of this nature there are two diametrically opposite conditions involved, the first representing an oscillator and spark-gap in an unenergized and non-conductive state, and the second when it is energized and rendered highly conductive, thus completing the circuit. To bring about this result the arms of the oscillator are charged with high-potential energy impressed upon them, which is set up in the secondary of the coil in the form of currents. This kinetic energy is then converted into electrostatic energy, and when the static charge is maximum for a given resistance offered by the dielectric between the surfaces of the spark-gap electrodes heat is evolved in consequence, and when a certain critical temperature is reached the positive electrode volatilizes, and it is this effect that forms the initiative in breaking down the dielectric of the spark-gap.



The law relating to the heat evolved states that it is proportional to the square of the charging current and to the resistance of the dielectric between the positive and negative electrodes forming the boundaries of the spark-gap. The energy that is emitted from the positive electrode is proportional to the potential difference impressed on the oscillator system and the specific inductive capacity, while it is inversely as the distance separating the spark-gap electrodes. The length of the spark that passes depends also largely on the following factors, namely, the difference of potential between them, the character of the medium that separates them, and on the density or pressure of the dielectric through which the discharge passes.

A decrease in the pressure of the medium serves to increase the distance through which a spark will pass, but a point is quickly reached wherein a further decrease has the effect of cutting down the length of the spark, and hence where a low vacuum will permit the passage of high-potential currents over longer distances than in air, a high vacuum retards them even though the potential may be considerably increased. Then again the metal of which the electrodes are made determines the sparking capacity to a certain appreciable extent since some retard and others assist the process of volatilization, and finally the size and shape of the spark-gap-electrodes also have their effect upon the discharges.

From these considerations it will be observed that when the electrodes are placed closely together the strength of the charging current is increased, and hence the heat developed causes the temperature to rise. When the sparking distance is greater than the maximum difference of potential can easily break down, a faintly luminous discharge will be seen issuing from the positive electrode, especially if it should present any sharp points. This phenomenon occurs in virtue of the fact that metallic points are more easily heated than those in the form of spheres.

HIGH-FREQUENCY ARC DISCHARGE.

HIGH-FREQUENCY STREAMING DISCHARGE.

When the charge and temperature reach a critical value a conducting microscopic thread of gaseous vapor is developed and this is attracted to the negative electrode, to which it passes by the path of the least resistance. When this filament bridges the gap its diameter is very greatly increased, the resistance that was previously enormously high becomes minimum, and the current surges forth and back until the energy of the system is damped out by the sum of the resistances.

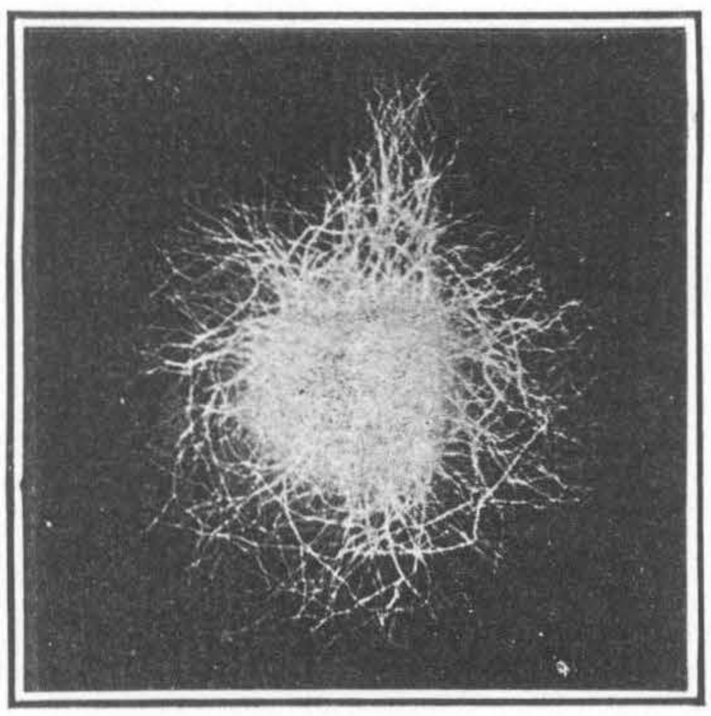
While Tesla was not the first to produce the varied and beautiful forms of convective discharges he was probably the first to systematically investigate them. Though convective discharges may be frequently observed from a pointed positive electrode of an induction coil, they are much more intense and brilliant when the potential and frequency of the oscillations are stepped up by means of a secondary transformer.

The compact apparatus for obtaining high-frequency and high-potential discharges shown in the illustrations was designed by Prof. Ovington, who repeated many of Tesla's experiments and introduced several new ones during the recent electrical exhibition at the Madison Square Garden.

With high potentials and high frequencies the electrostatic field is collapsed more easily than when those of lower value are reached, while the oscillations increase the temperature developed by the transition of static into kinetic energy and for this reason the volume of vapor is increased and an arc discharge results.

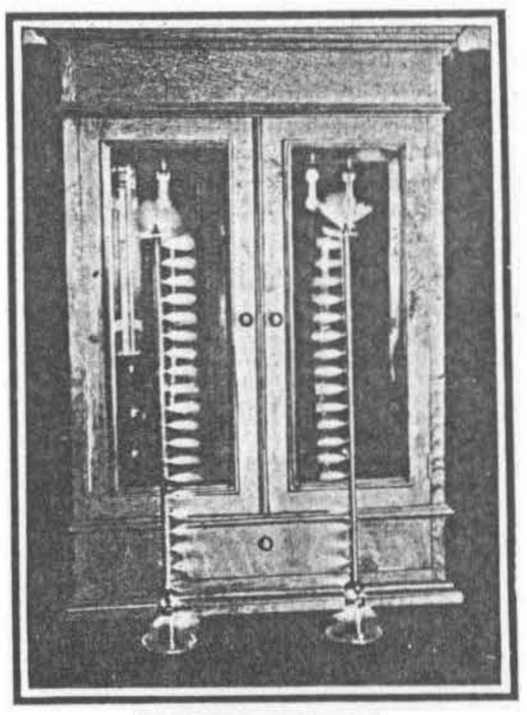
The flaming and streaming discharges which are forms of the connective discharge are closely allied and occur when the frequency and potential is increased beyond a certain value; under these conditions the discharge assumes definite characteristics wholly different from those of the disruptive discharge. In these

BURNING PLATINUM WIRE WITH CURRENTS PASSING THROUGH THE BODY.



A platinum wire is held in the fingers and near one terminal of the machine. The spark jumps to the body and through the wire.

forms of discharge the energy passes between the electrodes as luminous streams. Such discharges obtained with high-frequency coils are different from those obtained with electrostatic machines, as they lack in the violet color developed by the positive static electrode as well as the bright glow of the negative electrode.



When the frequency and potential necessary to produce the flaming and streaming discharges is increased new phenomena result and a brush and spray discharge is obtained. With suitable electrodes comprising a large number of small points the emanations resemble jets from a gas-flame escaping under high pressure. According to Tesla "they not only resemble but they are veritable flames, for they are hot. Certainly they are not as hot as a flame of gas, but they would be so if the frequency and potential would be sufficiently high."

If the frequency and potential is further increased, the discharge will pass through several inches of solid glass. Ordinarily glass is an insulator of electricity, and yet in this case the streams flow through it apparently with the greatest freedom. The flow of luminous energy has a tendency to stream out and to be dissipated to such an extent that when the brush is produced at the positive electrode no disruptive discharges will occur, even though the hand or any conducting object is held within the stream, and what is even more singular, the luminous stream is not at all easily deflected from its path by the approach of a conducting body.

Under these remarkable conditions the energy loses its property of producing sensation when it comes in contact with or passes through the human body, and a person may now be connected with the source of high-potential and high-frequency currents and be completely charged, though he will feel nothing; that he is a portion of an oscillator, however, can be readily determined, for if a vacuum tube is brought near any part of his body it will glow due to the electric waves emanating from him. To illustrate how absolutely devoid the sensory nerves are to these currents, a

THE AUTOGRAPH OF AN ELECTRIC SPARK, WRITTEN ON A PHOTOGRAPHIC PLATE.

ELECTRIC TESTS.

The current issues at an enormous voltage from a large number of small points, so that it seems like jets of burning gas escaping at high pressure.

vacuum tube may be held in the mouth, and a current passed through the lamp lights it and then continues on its course, passing through the membranes of the mouth, which are perhaps the most sensitive of any in the body, yet no sensation whatever is experienced. A half-dozen incandescent lamps may be lighted with current passing through the body and no sensation is felt although instant death would result were the rate of oscillation reduced within certain limits.

To show the impedance a copper bar of large diameter offers to a high-frequency current, an incandescent lamp is short-circuited across the former and the current is thus given the choice of two paths, an apparently easy one of small ohmic resistance and high impedance through the copper rod, or a seemingly more difficult one of large ohmic resistance and low impedance through the lamp. While an ordinary current would of course choose the former, the extraordinary current traverses the latter path.

The practical application of these discharges is found in radiotherapy. Their use is being extended more and more, and by many it is considered a rational method in therapeutic practice. Heat, light, and electricity when properly applied have accomplished surprising results. With the apparatus shown not only are all the various remedial manipulations of electricity available, but current is also supplied suitable for producing the X-rays, ultra-violet light, etc.

Tesla Split-Phase Patent Litigation.

On January 19 Judge Kohlsaat rendered an opinion in a suit on final hearing involving the validity of the 1893 Tesla split-phase patents, the parties to the suit being the Westinghouse Electric & Manufacturing Company, complainant, and the Electric Appliance Company, defendant. The defenses in the suit were, first, that the claims at issue in the two 1893 patents are void for double patenting by reason of the grant to the same inventors of an earlier patent dated April 16, 1889; and second, that each of the patents in suit expired in the year 1903 by the reason of the expiration in that year of two British patents granted in 1889.

The court in its opinion stated that according to established judicial precedents, if the difference between the claims of the 1893 patents and those of the 1889 patent are only colorable, then either the former patents are void or the latter patent is void, but in fact, the later American patents were entirely unlike the earlier American patent, the latter being on means and the former a method. Assuming that Tesla had taken out the 1893 patents in advance of the 1889 patent, he would in them have disclosed all the elements of the latter patent, but being the inventor in both cases he would have had a right to proceed in this particular manner. To hold the two 1893 patents in suit to be identical with the 1889 patent would be to do violence to the facts and the rule of law; the contention of double patenting does not apply since the earlier patent covers a method for operating a motor by the means disclosed in the later patents. This being so, the 1893 patents were also in no wise affected by the expiration of the English patents, since these were nothing more than improvements upon the 1893 patents. The finding of the court was for the complainants.

The Colorado Springs Gazette March 10, 1906

TESLA'S FIXTURES IN SHERIFF'S SALE

FAMOUS INVENTOR'S PARAPHERNALIA TO BE SOLD TO SATISFY A JUDGMENT FOR $928.

The sale of a quantity of personal property belonging to Nicola Tesla, the famous electric inventor, to satisfy an execution issued out of the county court in favor of C. J. Duffner, for $928.75 and costs, was scheduled to be held yesterday but was postponed by consent until 10 o'clock on the morning of March 22. The property held by the sheriff consists of 27 cases of goods and 10 coils of copper wire, all of which was levied upon in Tesla's experimental station on Nob hill.

Marconi Says—"Ten Years From Now We May Be Talking With the Inhabitants of the Planet Mars."

By Guglielmo Marconi.

In ten years, probably much less, the world will be able to send messages to Mars directly and unhesitatingly, without a hitch or a stop or a word lost in space. If there existed any accurate knowledge in relation to the possibility of Mars being populated by intelligent beings, and if there existed a commercial necessity for communication with that planet, and if such communication could be rebuilt into profit for a commercial organization, I am certain that the attempt would be made in even less time than I have indicated. That it is possible to transmit signals to Mars I know, as surely as if I had a gun big enough or powder strong enough to shoot there—more surely, in fact, for a gun might miss the mark, while my wireless will strike the entire solar system without aiming.

Attempts to communicate with that planet in the absence of any certain information that there are inhabitants there of sufficient intelligence to recognize our signals as such, and with knowledge sufficient to enable them to translate such signals into their own language, if they possess a language, would be without any certainty of results.

Mars and our earth lie in the same great unbroken bed of ether. We know this because all signals long the beams of the sun reflected from Mars's red surface stream down the astronomer's telescope.

Wherever these rays can travel the ether exists, for light is only a vibration or wave of the ether, and the electric disturbances caused by the wireless travels in the same way. If there were a gulf in the ether we would see it, perhaps like a crack in a great block of ice, and Mars and all on the other side of the crack would be invisible.

If our nearest planetary neighbor floating off yonder 35,000,000 miles away is inhabited, it will soon be fairly pelted with messages transmitted with as much certainty and accuracy as were the messages which I recently transmitted from the company's station at Poldhu, in Cornwall, to H. M. S. Renown, while en voyage to India, bearing the Prince and Princess of Wales. These messages were received on board the Renown until she was within one hundred miles of the Port Said entrance to the Suez Canal.

In order to reach the Renown at that place it was necessary that the messages cross the English Channel, over the Islands of Jersey and Sicily, over the entire width of France, crossing the Cote-d'Or Mountains, the cities of Orleans and Auxerre, the Alps, Mt. Blanc, town of Lausanne, Switzerland; Lake Geneva, the Italian cities of Milan, Parma, Modena, Bologna and San Martino, crossing almost the entire length of the Apennine Range, the Adriatic Sea, Turkey, the Rimbus Mountains, Greece, City of Athens, Mt. St. Elias, crossing the Grecian Archipelago, the Aegean Sea, Karpathos Island and a portion of the Mediterranean.

This feat of transmitting wireless telegrams over a combined route of land and water for a distance of 2,100 miles is even more difficult than sending messages through interstellar space where no obstacles intervene.

It is not within my province to say that Mars, Jupiter or any other planets are inhabited; but if they are, and their inhabitants have our senses, they may recognize the new and unnatural disturbances that will be caused about them.

During the past few months wireless telegraphy has progressed with such tremendous and gratifying strides that one might venture almost anything for it and yet be within the bounds of possibility and even probability.

This progress is best illustrated by my recent invention, by means of which I am enabled to direct my wireless messages to a given point with as unerring accuracy as we are now enabled to focus rays of light by means of the lens upon a given point. Recently from the Poldhu station, before referred to, in a test conducted by the British Admiralty, I sent messages to one of the squadron lying at anchor in the harbor of Gibraltar. The commander of the other ships composing the squadron were instructed by the Admiralty to intercept this message if possible; to confuse it if possible, and to divert it if possible. Nevertheless, under the rigorous conditions prescribed by the Admiralty I was able to communicate with the vessel selected. Messages were uninterrupted, uninterrepted, unconfused. None of the other vessels was able to receive those messages.

Subsequently I was able to follow the course of the vessel in question in its voyage through the Strait of Gibraltar, up the coast of France, back to its home station in British waters, all the while preserving the secrecy of the messages invisible from the attempts of other wireless installations to confuse and to intercept them. This was as severe a test as ever wireless telegraphy has been compelled to undergo. Those messages were transmitted across the English Channel, across the entire length of the Spanish peninsula, over the Cantabrian Mountain, over the Sierra Candrama, the Sierra Toledo, Sierra Moreno, Sierra Nevada and also over the important cities of Valladolid and Seville.

Martian Knowledge Will Overwhelm Us.

If we are able to send signals through space over such intervening obstacles as mountains, forests, cities, liberating vast quantities of electricity, and yet safely deliver them at the point of reception undistorted and unconfused, it follows as a natural deduction that it is merely a question of commanding sufficient power to set up the necessary disturbance in the ether where there are no obstructions intervening to send signals to even so distant a point as Mars.

If Mars answers and tells us his history, then, for the first time on earth, imagination and discovery will be of little use to humanity in the face of the flood of actual information which will roll in as fast as our intelligence can apprehend it.

Had any one in his sober senses predicted a generation ago that Europe and America would today be communicating with each other without any material agency between the sending and receiving points he would have been adjudged insane or would have been ignored as a crank.

Yet today wireless telegraphy has progressed to such an extent that it is actually accomplishing that very thing. Within a very short time it will be accepted as an ordinary fact—a matter of daily commercial routine. Instruments which I have perfected, sending messages at the rate of 200 words per minute, will enable us to send as many words in twenty-four hours through the medium of these two stations—one near Sidney, N. S., and the other on the west coast of Ireland—as are now transmitted by all the cables connecting Europe and America.

Why, then, should it appear preposterous to venture that within a decade, or even half the time, wireless instruments will be so developed and perfected that it will be possible to transmit a message through 50,000,000 miles of space? It is not only possible, but very probable.

It is likely, so far as the system has been evolved, that the first agency capable of rationally reaching as far as Mars, for example, will be the heliograph. And this is only natural.

Why? Because it is an accepted scientific fact that light carries a much greater distance than sound or its equivalent. But, while the heliograph will be the pathfinder through the immensities of space, there is every reason to believe that it will simply be the utilization of wireless telegraphy as it is now being developed.

It may surprise many people that Mars may not be inhabited by intelligent creatures who could understand in every major instance, our earth before they could travel here if not in a condition to be introduced to the people of other planets.

As a look for an answer to Professor Lowell, an astronomer of note and in good standing in his profession. Quite recently he succeeded in photographing the many Martian canals.

From these photographs it is certain they are not natural builders but instead intelligent beings. Their stupendous canal construction proves that the degrees are neither very small nor likewise and strength, but infinitly skilled and trained to the use of mechanical devices of a nature that could most easily and quickly convert allowing them to visit our planet.

Should the United States ever engage in war with another nation, New York could be made absolutely impregnable for the first time. How? By means of torpedoes operated and discharged by wireless telegraphy.

A Whitehead torpedo, properly equipped, can be launched, timed, and then, while under both water and ship, can be accurately discharged by wireless. It also has been proved conclusively in the course of a series of tests by the British Admiralty that cannon can be fired and all manner of signals given at long distance by the same method.

We have more real substantial information about Mars, our nearest neighbor, than of any other of the planets. Taken altogether, we know that Mars is very much like our earth.

When the southern pole is directed toward the sun it is Summer for the southern hemisphere of Mars; and Winter for the northern. The northern pole can be seen growing bigger and whiter, while the southern shrinks and darkens.

It is in connection with the melting ice caps that the famous Martian canals appear. As Mars has little rain and much sun, the globe would be a desert of ice at the poles, and dry land between, without some stupendous system of irrigation. And this is just what appears.

A network of fine lines running from the ice caps to the equator appears clearer and clearer as the warm season advances on each hemisphere and grows fainter during the cold. A ruddy brown area shows dark and spreading about the canals until toward the Fall of the season it changes the entire color of the hemisphere. This, most astronomers agree, can be nothing else than vegetation following the flow of water from the melting ice caps.

The canals are too straight and methodically arranged for nature or accident, according to the latest astronomical belief. An object to be visible in Mars must be at least twenty miles in diameter. As these canals were observed long ago with inferior instruments they must be much more than twenty miles across.

Even the heaviest and fattest human specimen would be an acrobat on Mars. He would vault lightly into second story windows and would find no difficulty in climbing the waterspout or the lightning rod. But the chances are he would feel very insignificant in the presence of the native Martian.

Mars, being smaller and lighter, one would think of pigmy inhabitants to correspond. According to Sir Perceval Lowell, Sir William Ramsay, M. Flammarion and other great authorities the Martians are giants. Their reasons are based on force of gravity, which is about a third on Mars of what it is on earth.

Supposing the Martian to be three times as large as a man. If he were on earth he would weigh 27 times as much as a man, and would be unable to support his weight, as the cross section of his muscle would only be nine times as great. But on Mars he would weigh only nine times as much as a man, and with his nine times greater muscles he would be able to support his mighty frame with as little fatigue as a man on earth. In performing work he would be twenty-seven times as efficient as a man were it not that Mars's lightness makes physical work only one-third as hard. Therefore, the work of a laborer on Mars is variously estimated at from fifty to eighty-one days' work of a man.

Professor Gregory thinks all Martian creatures have enormous chests to adapt themselves to the rarefied Martian atmosphere. Gills like those of a fish would be necessary to give such great volumes of air a short cut to the lungs.

Sir Robert Ball has conceived a Martian with a prolonged nose, or proboscis, and long, slender arms reaching to his feet.

These arms would be strong enough on Mars to carry him up the side of a house from window to window, or up the branches of a tree, without touching the feet at all.

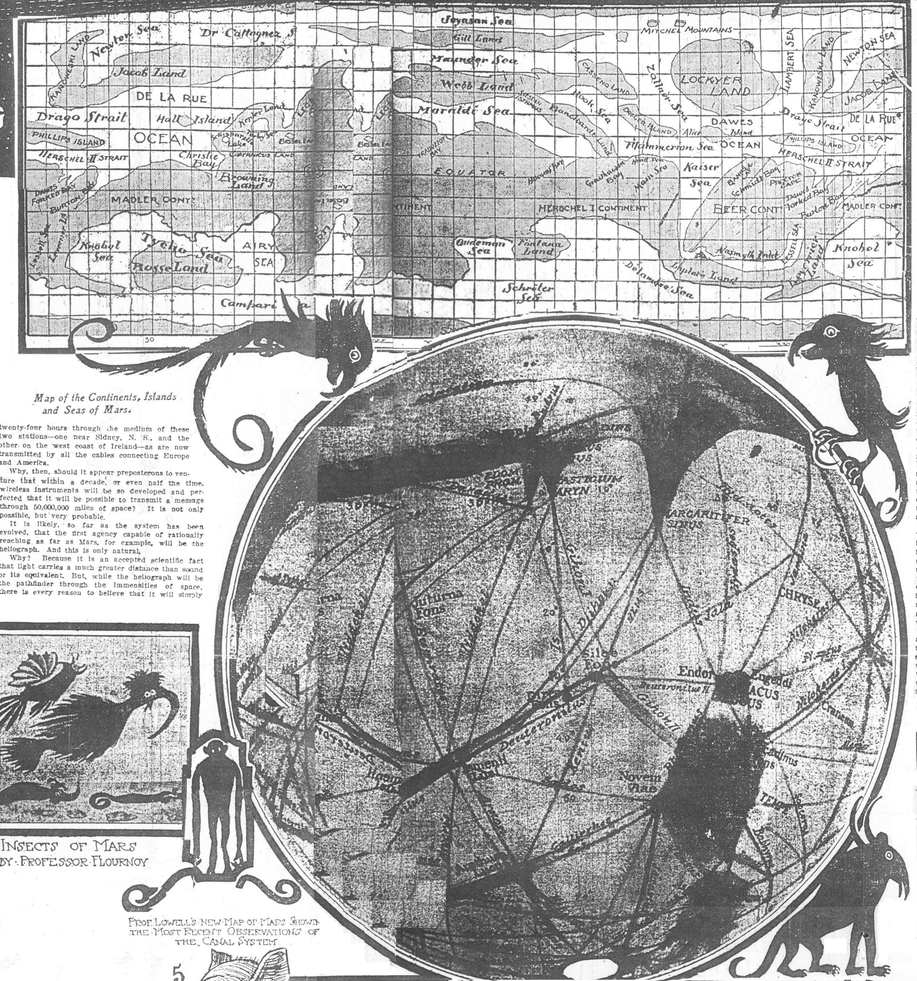
Perhaps the strangest of all attempts to picture the beings on the red planet are those by Professor Flournoy, of the University of Geneva, who drew his ideas from Miss Elise Muller, of Geneva, a medium, who believed herself transported to Mars during her hypnotic trances, and reported what she saw on Mars' and 's strange, unknown planet called Ultramars. Professor Flournoy put her utterance into scientific shape. She saw strange, huge insects, with feathers and long necks, flying about in the dim twilight of Ultramars. Her Martian man is very human, save for his great size.

Emanuel Swedenborg, the great Northern mystic, believed he saw a Martian. The creature was much like a man. His face had a Mark's area about the lower part which looked like a board, yet he was hairless. He had no chin.

But all this is tributary to the vaster problem of interplanetary communication. If wireless, or the heliograph, proves Professor Lowell to be correct in surmising the Martians to be such a formidable race, we may be thankful that our red neighbor is so distant. Whoever succeeds in mastering the problem will alone be able to say with the poet, "I stole the secret from the stars."

How the Inventor of Wireless Telegraphy is Planning to Find Out if Mars is Inhabited and What Sort of People They Are

"Mars is Surely Inhabited," says Prof. Camillé Flammarion.



By CAMILLE FLAMMARION.

It is forty years since I began to study the possibilities of certain planets as habitations. Personally, I am certain that the planet Mars is inhabited. But how shall I prove this to you in a few words? Ah!

The question is much more serious, more vast and more complex than certain minds, even scientific ones, seem to consider it. This is largely so because the practical utility of such knowledge is small, and our present generation, brought up to consider only the worth of material interests, wishing primarily to earn money, are content to ignore unknown marvels. But there is an intellectual minority who are not satisfied to remain ignorant.

This intelligent minority know that the terrestrial manifestations of life do not set a limit to its possible forms, and that, elsewhere, our epoch is only a wave in the ocean of ages. As to what constitutes life, we usually recognize only that which exists about us. We believe that an atmosphere identical to ours is everywhere necessary to life; that there must be water composed exactly of two parts of hydrogen to one part of oxygen; a temperature neither too cold nor too hot. Such reasoning by human beings is the sort that fish may imagine in if they are capable of reasoning—unable to understand life out of the waters in which nature's resources are infinite.

In the first place, it would be difficult for any human species to be less intelligent than ours, since we do not even know how to live. Then, again, progress is an absolute law which nothing may resist. Therefore the inhabitants of Mars, older than we, may represent what our humanity will become in several millions of years. Another of their advantages is that they are better placed than we are to throw off more quickly the heaviness of matter. They weigh less, their years are twice as long as on our moving island. To conclude, their climatic conditions seem to be much more agreeable than ours.

PROF. LOWELL'S NEW MAP OF MARS FOUND THE MOST RECENT OBSERVATIONS OF THE CANAL SYSTEM

How Various Modern Scientists Have Figured

That a Dweller on the Planet Mars Would Probably Look.

1—Prof. Lowell's Idea of a Martian of immense size and great muscular power.
2—Prof. Gregory's idea that the Martians have great chests and gills like fishes.
3—The strange kind of giant Prof. Ball thinks the Martian is.
4—Another conception by Sir Robert Ball.
5—Emanuel Swedenborg's vision of a Martian.

"Only a Matter of Patience Now," Says Tesla.

By NICOLA TESLA.

With a billion horsepower drawn from Niagara I am going to signal Mars, and think for mankind.

My message will reach not only that nearby planet, but one hundred times farther, even to Neptune, which is so distant that day nor moon looks little bigger than a star.

Our generators will soon be complete, and the waters of Niagara Falls will supply me with a billion horsepower in the form of electricity. My tower at Wardenclyffe, L. I., will receive as much of this power as is needed. Only one one-hundredth part will be necessary to reach Mars.

Whether we get an answer or not depends on who is there. More than likely the first answer from our neighbor will be:

"Well—well—at last. We have been calling you the last ten thousand years."

Astounding as this prediction is—a prediction that is also a boon fully promised—it becomes even more astonishing when translated into plain terms capable of human comprehension. For it means that we are on the eve of sending communications into space for a distance of 4,800,000,000 miles. In other words, no planet within the solar universe will be outside the range of communication promised.

It will be as simple as telephoning from one part of a city to another after the preliminary attuning of instruments on the two planets and the study and interpretation of each other's codes and languages are done.

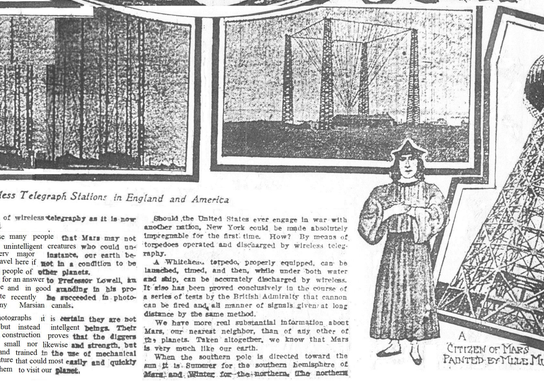
As the Martians are probably the most advanced and skilled they will take our code and language and learn it first and then teach us theirs in plain English. Difficult as this fact would seem, it in reality would not be comparable with the achievement of teaching a deaf, dumb and blind child to understand. Yet this is only a matter of patience.

Mars Would Learn English.

By using a little more power than is necessary to transmit a message to Mars, it will be possible to project a message across or through the 2,900,000,000 miles between ourselves and Jupiter. By using one-fifth of the Niagara Falls voltage, a message may be sent to Saturn floating off yonder 850,000,000 miles from the sun, or 735,000,000 miles from the earth. Even Neptune, the most distant planet in the solar system, will not be able to hide longer behind the 2,800,000,000 miles separating it from the earth.

Realizing the far-reaching importance of the stupendous riddle of universal communication, I have been proceeding slowly and carefully, but I have now reached the point where I am absolutely convinced of my ability to make the greatest dream of humanity come true.

My first step was to develop the magnifying transmitter. This met with such success that it is hard to form an adequate conception of the marvelous power of the unique appliance, by the aid of which the globe will be transformed. The electromagnetic pulsations being minimized and proper conditions of resonance maintained, the circuit acts like an immense pendulum, storing indefinitely the energy of the primary existing impulses and impressing upon the earth and its conducting atmosphere uniform harmonic oscillations of intensities which actual tests have shown to be capable of surpassing those attained in the natural displays of static electricity.

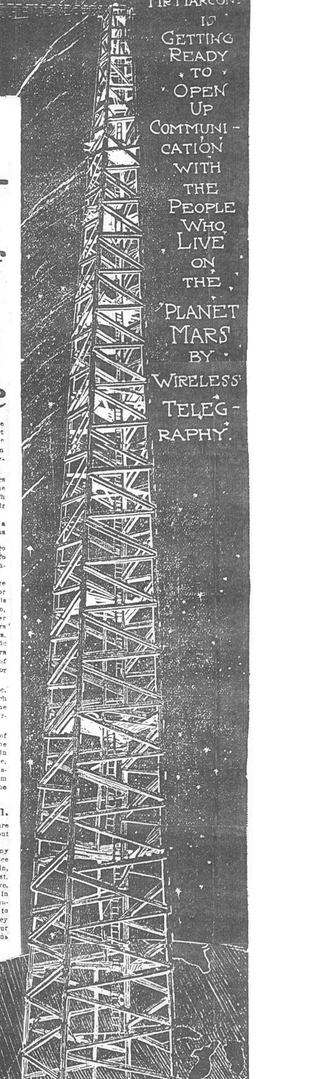


Briefly explained, my method, when fully inaugurated, will permit of a direct wireless service of thousands and millions of electric volts from the Niagara Falls plant to the great Wardenclyffe Tower, which is now practically completed, on Long Island. Wardenclyffe will be the main distributing point for sufficient wireless power, not only to illumine all of Greater New York, but to operate its elevated and subway trains and surface cars; to supply motive power to factories, automobiles, vans, ferryboats; to wind and regulate timepieces and to do nearly everything but think for mankind.

So stupendous is the capacity of the Wardenclyffe Tower, as compared with the Niagara Falls generators, that messages may be dispatched from it to Mars and millions of leagues beyond the red-named planet.

Other tributary towers are to be erected within a radius of three hundred miles of Niagara Falls, which will likewise supply them with electrical energy, each tower to distribute about ten thousand horsepower of wireless electricity under a tension of approximately one million volts or more, as occasion may demand, to cities, factories and private residences within a radius of thirty miles of each distributing station.

Eventually it is proposed to extend the system until the entire North American continent is fairly freckled with tower stations, about sixty miles apart, capable of operating the motive and stationary machinery of the United States, Canada, Mexico and Central America.



NICOLA TESLA.

Wireless Telegraph Stations in England and America

TESLA'S TOWER ON LONG ISLAND.

A CITIZEN OF MARS PAINTED BY HELENE MULLER.

The New York Herald March 11, 1906

TO SELL TESLA'S STATION.

[SPECIAL DESPATCH TO THE HERALD.]

COLORADO SPRINGS, Col., Saturday.—The experimental station which Nikola Tesla, electrical expert, established here six years ago, will be sold at auction by Sheriff Grimes on March 22, to satisfy a judgment for $928.57, in favor of C. J. Duffner, the caretaker. After a year of experiments with wireless telegraphy in high altitudes, Tesla went to New York, saying he would return in two weeks.

LEFT PROPERTY HERE; SKIPS; SHERIFF'S SALE

TESLA, FAMOUS INVENTOR, ENDS COLORADO CAREER.

EXPERIMENTS AT NOB HILL NOT SUCCESSFUL.

The beginning of the end of Nicola Tesla and his experiments in power transmission in the rarefied air of the Pike's Peak region, was witnessed by a curious crowd of electricians and the usual "sidewalk committee," at the sheriff's sale of the Nob hill station equipment, at the court house this morning.

From a business point of view, the sale cannot be chronicled as a success, for property said to be worth $4,000 failed to sell for enough to cover the judgment of approximately $1,100 standing against it. A specimen of the slaughter in values can be seen in the disposal of one of the articles, an electrical transformer, which went for about $10, or one-tenth its market value. The apparatus was bidden in by C. J. Duffner, who held the judgment on which the sale was based. The sheriff's hammer had hardly fallen, however, when the transformer was attached by an officer, under instruction from County Treasurer C. A. Pollen, who claimed $80 in taxes. This throws the taxes on the purchaser, but still leaves a good margin of profit.

The Duffner judgment was secured for services as caretaker. Tesla came in Colorado Springs in May, 1899, and remained until the following January, when he returned to New York. He expected to return to this city however, but soon after reaching New York became interested in a new station on Long Island and never came to the city. His actions would indicate that Colorado Springs and his work here dropped from his memory, for he allowed his property to go at sheriff's sale and failed to pay his bills, or even the accruing taxes.

The New York Tribune May 17, 1906

TESLA ASKS CHANGE OF VENUE.

Nikola Tesla's attorney yesterday applied to Justice Bischoff, of the Supreme Court, for a change of venue to Suffolk County in a suit brought by Frank W. Clark, a machinist, employed at one time by Tesla in his laboratory at Wardenclyffe, in that county, to recover $889 24 alleged to be balance due in wages, the suit having been brought in the City Court, Manhattan. Tesla said in an affidavit, after reciting that he had employed the plaintiff and paid him $743 76 in full, that he had never employed him for the services named in the suit, asserting that at the time of the alleged services at Wardenclyffe Clark was actually in the employ of Frederick C. Griswold at Port Jefferson. Decision was reserved.

WIRELESS AERIAL NAVIGATION.

Mr. Tesla's Experiments Antedating Those of Professor Bell.

TO THE EDITOR OF THE SUN—*Sir:* I am an assiduous reader of THE SUN, but somehow I overlooked a report contained in a recent number, which has just been forwarded to me through the courtesy of the *Electrical Review* and interests me keenly. During the last few days I have run across a number of newspaper comments and was wondering what had called them forth, until the clipping received enabled me to understand and trace to your columns of August 27 the origin of the disturbance.

I refer to an experiment supposed to have been performed by Professor Alexander Graham Bell, the inventor of the telephone, which consisted in propelling an aerial vessel by power transmitted without wire. This could have been practically accomplished only by the use of some of my inventions, and should I have been forestalled in this one of their many applications I shall have the satisfaction of knowing that it is by a man whose name is already linked with an immortal achievement. But if Professor Bell has undertaken this just to satisfy the world that an airship can be operated by power transmitted without wires he has gone to quite unnecessary trouble, for long ago I made a much better and further reaching demonstration. His experiment would only show that such can be done close to the source of electrical energy, but my experiments have established the fact that an aerial vessel or flying machine can be propelled with the same facility and efficiency either near the transmitter or at the antipodes.

The problem of aerial navigation was solved in the most satisfactory manner imaginable when, in the fall of 1899, I produced stationary terrestrial waves and passed a current equivalent to that of several hundred incandescent lamps around the globe. In a carefully prepared statement, which appeared in the *Century Magazine* of June, 1900, I have announced this advance in popular language, but clear and unmistakable. In my patents and technical articles, however, I have fully exposed my methods and appliances and given an account of my experiments; and the transmission of electrical energy without wires is no longer a secret to electricians.

NIKOLA TESLA.

NEW YORK, September 3.

The New York Herald November 26, 1906

TESLA ADMITS HE'S GREAT.

He Testifies in Court That He Is One of the Foremost Men of the Age.

PATCHOGUE, L. I., Sunday.—Nikola Tesla testified yesterday that he considers himself one of the greatest men of the age before Supreme Court Justice Jaycox, while defending himself in a suit for wages brought by a workman.

Frank N. Clark, of Port Jefferson, was employed by Tesla at his plant at Wardenclife as a machinist. Tesla said he had paid Clark all that was due him, but Clark claimed $389.24 balance due. Tesla admitted offering to settle by paying Clark $50 down and $12 a week. Clark won his case.

The New York Tribune November 26, 1906

NIKOLA TESLA'S IDEA OF HIMSELF.

Testifies in Suit That He Is One of the Greatest Men of the Age.

Patchogue, Long Island, Nov. 25.—Nikola Tesla considers himself one of the greatest men of the age, and so testified yesterday before Justice Jaycox, of the Supreme Court, in a suit brought by a former workman for wages due. Frank N. Clark, of Port Jefferson, formerly employed by Tesla at his plant at Wardencliffe as a machinist, sued the inventor for $889 25 for wages alleged to be due. Tesla admitted having offered to settle by paying Clark $50 down and $12 a week.

Clark's counsel asked Tesla if he was an inventor and promoter. Tesla said he was not a promoter and never received a fee, but that he was an inventor and could take rank among the foremost men of the age. Clark won his case.

The Patent Factory.

By George Ethelbert Walsh.

Contrary to a rather widespread impression an invention is generally a growth rather than a sudden inspiration. Moreover, it is often the product of several minds working along parallel lines, each contributing its quota of experimental knowledge. Forecasting an invention is not an impossible feat. The need of some sort of time-saving or labor-saving device is felt in an industry. Experts are called in and the ground thoroughly canvassed, impracticable methods eliminated, and the most feasible systematized and described. Then the work of developing the invention is turned over to experts, or rather to professional inventors, who can roughly forecast what they will do.

The conditions of modern industry demand the elimination of chance and uncertainty so far as possible. Inventions have upset business and manufacturing interests more than any other factor in the last ten years. The installation of expensive machinery is a costly undertaking if some inventor comes along with a patent six months later which practically makes the machinery ancient and obsolete.

"Last year," confessed a leading manufacturer of novelties, "my plant was practically knocked out by the invention of a device which makes it possible for my rivals to save $50,000 a year. I must either go out of business or invest in new machinery and pay big royalties to the inventor. This periodical revolutionizing of conditions by new inventions is one of the disturbing features of manufacturing. Is it any wonder that big concerns keep a sharp lookout for patents and even employ an army of experts to watch the applications for new patents?"

The professional inventor works better in cooperation with others interested in similar subjects, the deficiencies of one thus often being supplied by another. Associations of inventors have therefore become important organizations in this industrial age, and most of our great patents are products of one of these "patent factories" rather than of a single individual.

Edison's patent factory is not an exception to this rule, for while his personality dominates the establishment over which he presides, and credit is given to him for the inventions, he has surrounded himself with experts whose labors contribute to the general cause. Not only is the great "wizard" relieved of a great mass of detail work by his assistants, but suggestions and experiments are constantly coming to him from his associates. In his "patent factory" he employs some of the best chemists and mechanical experts in the country. Work of an experimental nature is intrusted to them which would require years of patient toil from a single inventor without the equipment of the modern plant.

Tesla is another great inventor who conducts his own "patent factory." With one of the best-equipped electrical and experimental laboratories in the world, he has surrounded himself with bright young men who have succeeded in chemistry, electrical sciences, mechanics and physics, and his labors of inventing are systematized to the point of simplicity. Most of Tesla's important discoveries in electrical science were predicted years ahead of their ultimate perfection, and the work of making good his promises has established for this inventor a unique position in the world of electricity.

Another important "patent factory," which differs from these two in some important respects, is the Ampere Electrochemical Company of Niagara Falls. Instead of a single dominating mind heading this plant, half a dozen inventors compose the company and direct its affairs. The company is not an operating concern, but purely an experimental organization or association of inventors. The object of the "patent factory" at Niagara Falls is to delve into the mysteries of electrochemistry for the purpose of discovering new processes for commercial application; but when a new patent is developed it is turned over to an operating company for exploitation. The inventors themselves have no interest in the applications of their patents.

The founders of this strange "patent factory" are men well known in the world of electrochemistry. Professor F. B. Crocker, C. A. Doremus, S. S. Wheeler and C. S. Bradley were the original organizers of the experimental plant, and later they had associated with them A. H. Buch, D. R. Lovejoy, H. E. Knight, N. Thurlow and Charles B. Jacobs. The results of this patent factory are evident in a hasty glance at some of the most important electrochemical industries which have grown up around Niagara, where a vast amount of electric current can be had at small cost.

To this "patent factory" can be traced the discovery of the present method of making artificial corundum by fusing bauxite by a patented process; the work of obtaining nitric acid from nitrogen and oxygen by electrical methods; the different processes of utilizing and producing barium sulphate and barium salts for the purification of our drinking water, and the production of artificial camphor from turpentine at Port Chester, which a few years ago failed after a short experimental test.

The large industrial and manufacturing companies have in recent years established "patent factories" of their own, where experts conduct tests and experiments along certain well-defined lines for mutual interests. These commercial "patent factories" are equipped with the best laboratories in the world, and men of genius and experience preside over them. The association of half a dozen experts in such a plant tends to make the work of discovery and invention simpler and more practical.

The General Electric Company spends tens of thousands of dollars every year in supporting its "patent factory." The presiding genius of this plant is Dr. C. P. Steinmetz, an inventor of world-wide fame. He has to his credit a long list of patents which have helped to bring the generation, transmission and application of electricity up to their present-day efficiency. With him are associated men of almost equal gift for invention and specialists in certain fields. The total output of this factory averages scores of new patents and improvements upon old ones every year. Any employe of the company who has a promising idea is encouraged to present it to the head of the patent factory, and if considered of value it is exhaustively tested and tried by experts. While the company holds all the patents developed by any of its employes, proper remuneration is made to the inventors, so that each one is stimulated to make suggestions and improvements. Frequently the development of a patent is more dependent upon the opportunities of the inventor to make exhaustive experiments with costly machinery and tools than upon the initiative impulse of the individual. Thus many valuable patents of today would never have been perfected had the inventors been forced to rely upon their individual means and work.

The Westinghouse Electric and Manufacturing Company is another representative concern which has a well-equipped "patent factory" in operation in connection with its manufacturing plant. Many valuable patents are taken out by this company, and most of them are traceable to the energy and foresight of the professional inventors employed by the company.

Another important "patent factory" is that of the Western Electric Company, which has to do largely, although not exclusively by any means, with telephone patents.

The various large concerns owning their own "patent factories" are rapidly specializing the work of inventing. The electrical manufacturers confine their attention to inventions in their industries, and the makers of special machines limit their tests and experiments to machinery in their particular line. The Ampere Electrochemical Company makes no efforts to invent dynamos and motors and equipents, but studies only the field of electrochemistry. Iron and steel mills find it more convenient and economical to confine their labors to the perfection of details of their plants and rarely branch out into other industries. In this way inventions are becoming specialized, and the professional inventor devotes his time and genius to certain departments of work.

The possibilities of inventions are probably greater in the electrical and electrochemical fields than in any other to-day. The electrochemist, in particular, has many untrodden paths ahead of him. By the aid of the electric current changes have been effected in the sugar and paint trades which make for efficiency. Electrochemists are to-day working with promise of success toward the manufacture of starch from by-products. Artificial rubber of fair value has also been produced, and the cyanides, silicides and ammonia are all promising products for the electrochemist. Synthetic electrochemistry is generally recognized as one of the greatest future businesses of the world; and that the Falls of Niagara were created for this purpose is the opinion of the workers in this field.

While the individual inventor may find his opportunities somewhat circumscribed by these changes, the gain obtained through the organization of professional inventors is great. Greater results flow therefrom, and the young man associated with a modern "patent factory" secures in time a training which makes his inventive gift of far greater value to himself and the world. In the field of discovery and invention of to-day expensive and elaborate tools and laboratory equipment are frequently essential to success, and the modern "patent factory" supplies these requirements.

"Tuned Lightning," Mysterious New Energy, to Turn Every Wheel on Earth.

FLEET ocean liners without steam or any other visible means of generating power; airships furnished with wireless energy, and telephone and telegraph stations connected by wireless ether waves only, are among the projected products of "tuned lightning," a marvellous new species of energy.

Poulsen, the Danish inventor, known as the Edison of Europe, predicts that tuned lightning will make wireless lighting, transatlantic wireless telephoning and telegraphy commercially possible very soon. Wireless ocean liners and airships will follow in due course.

At a remarkable demonstration in London lately before Prof. Silvanus Thompson, Sir William Preece and other distinguished scientists, Poulsen succeeded in lighting a series of arc lamps by means of his new and marvellous energy, which first passed through his own body. By means also of his wonderful electric waves sent into the atmosphere he fused a piece of copper suspended in midair without contact with wires or conductor of any kind.

The lighting of electric lamps without wires by energy passing through the human body opens up a wonderful vista of scientific accomplishment. By means of properly installed generating stations Poulsen will soon be able to effect electric lighting at great distances; and this absolutely without wires.

From his Danish generating station near Copenhagen he is to-day sending most powerful charges of what is practically nothing but raw tuned lightning between points separated by long distances.

Modern warfare will undergo a complete revolution when the Poulsen generating stations come into working order. If he can light a town by wireless energy conveyed through the air alone, it will be a simple matter to explode at long range an enemy's mines, or even burn up his ships and armies.

Owing to these startling possibilities the British war office through its most skilled electricians and scientists is manifesting considerable interest in Poulsen's experiments. Up to the present, however, the Poulsen power is only utilized for improvement and convenience; not for destruction. Lord Armstrong, the famous cannon manufacturer, one of the wealthiest men in England, has evinced his faith in the new energy by undertaking to finance Poulsen to an almost unlimited extent. A big company has just been formed with Lord Armstrong as chairman, and it is anticipated that it will soon be possible to send wireless messages across the Atlantic as rapidly and cheaply as ordinary telegrams.

But this is not all. Wireless trans-Atlantic telephones will be installed before very long; while wireless electric lighting has passed the experimental stage.

It will even be possible—and that perhaps before the end of two years—to build ships that will receive their motor power from shore stations. This will result in immense saving of space, for the great amount of room at present taken up by the bunkers and machinery of a modern liner will be available for passengers and freight. If Poulsen can direct his electric waves with sufficient energy to operate an electric lighting station miles away the supplying driving power to ships should be a mere question of detail. This will also apply to air ships, which so far have been failures owing to the weight of their motors. With Poulsen's tuned lightning, however, the problem will be solved.

Some of Poulsen's recent inventions have been quite Edisonian in their marvellous character. He invented the "telegraphone," an instrument somewhat on the order of the phonograph, but far more perfect. The telegraphone can be attached to any telephone and will receive messages mechanically, recording the voice on flat sheets of magnetized steel. The records are made simply by magnetism, and the steel sheet shows no indentations or markings of any kind.

A singular attribute of the telegraphone consists in the fact that one can talk upon one of the steel sheets, enclose it in an envelope and mail it for two cents, just as anyone would mail an ordinary letter. The receiver of this steel letter inserts the thin sheet into his telegraphone and the letter is spoken, with every inflection of voice of the sender.

Poulsen says it will be the only form of correspondence before very long.

In order to efface the record one has only to pass a magnet over the surface of the steel sheet, and it is ready for another message. Kelvin, Tesla, Graham Bell, Preece, Marconi and all the most noteworthy scientists of the day have attested their high appreciation of the merits of this wondrous instrument. Poulsen has many other inventions of a similar character.

Associated with Poulsen in his work is P. O. Pedersen, a mathematical genius. It is said that Pedersen thinks in figures. He can tell, without leaving his laboratory, just what is wrong with an installation, and his calculations are so marvellously accurate that they virtually amount to intuition.

It is these two men, working in harmony, who have brought wireless telegraphy to a state of final perfection.

Hitherto the sending of wireless messages has only been a scientific accomplishment. So far as the man on the street was concerned, wireless telegraphy may as well never have existed. Of course, between ships at sea under favorable weather conditions wireless has proved more or less effective.

Herr Poulsen long ago recognized the unsatisfactory nature of the spark principle. He has been working for years trying to find some wireless energy that could be made continuous and accumulative—that is, instead of using pistol shots for signalling, he has eben able to send through the air a continuous stream of energy in a given direction. This stream, by means of a receiving instrument, can be used just as an ordinary current of electricity would be. Poulsen calls it tuned lightning. Not only can he send his energy hundreds of miles in a certain direction, but his instruments are so perfect that he can utilize the same stream of energy for conveying two or more messages at the same time in opposite directions, just as is done in duplex and multiplex telegraphy to-day. Sir William Preece, speaking of the Poulsen wireless discovery, recently said that "it sounded the death knell of spark telegraphy."

WALDEMAR POULSEN The EDISON of DENMARK

The LETTER of the FUTURE. A STEEL DISK and VALVE

WIRELESS LIGHTING OF ARC LAMPS BY POULSEN'S SYSTEM

[1238.]—**Tesla Coil.**—The oils generally used for such are those of high insulating power, such as heavy petroleum (fluid vaseline) and boiled linseed oil. Resin oil is also excellent. The reason for boiling linseed oil is to drive off any moisture, which would tend to lower its insulating properties.

S. BOTTONE.

WONDERFUL PRANKS of the "NEW ELECTRICITY"

NIKOLA TESLA

NIKOLA TESLA Describes for the Sunday World a Spectacular Electrical Experiment, and Says We Will Soon be Able, Without Wires, to Talk Across the Ocean and Light a Lamp Anywhere on Earth.

THE announcement that Thomas A. Edison is tired of hard work—no American has worked harder—and that he is going to give himself more time for play, finds Mr. Edison's distinguished rival, Nikola Tesla, more than ever in the midst of strenuous labors that give no hint of cessation for many years to come.

A Sunday World representative has found Mr. Tesla deep in new experiments as well as in current construction associated with highly important electrical improvements having a world-wide significance.

The following statement by Mr. Tesla takes for its text a recent article on "Tuned Lightning" printed in the Sunday World.

BY NIKOLA TESLA.

I READ with interest an article in the Sunday World of Jan. 20 on "Tuned Lightning," described as a mysterious new energy, which is to turn every wheel on earth, and is supposed to have been recently discovered by the Danish inventors Waldemar Poulsen and P. O. Pedersen.

From other reports I have gathered that these gentlemen have so far confined themselves to the peaceful production of miniature bolts not many inches long, and I am wondering what an account of their prospective achievements would read like if they had succeeded in obtaining, like myself, electrical discharges of 100 feet, far surpassing lightning in some features of intensity and power.

In view of their limited Jovian experience, the programme outlined by the Danish engineers is rather extensive, Lord Armstrong's vast resources notwithstanding. Naturally enough, I shall look with interest to their telephoning across the Atlantic, supplying light and propelling airships without wires. *Anch'io sono pittore.* (I, too, am a painter.) In the mean time it may not be amiss to state here, incidentally, that all the essential processes of, and appliances for the generation, transmission, transformation, distribution, direction, storage, regulation, control and economic utilization of "Tuned Lightning" have been patented by me, and that I have long since undertaken and am sparing no effort to render these advances instrumental in insuring the welfare, comfort and convenience, primarily, of my fellow-citizens.

There is nothing remarkable in the demonstration reported to have been made before Sir William Preece and Prof. Sylvanus P. Thompson, nor is there any novelty in the electrical devices employed. The lighting of arc lamps through the human body, the fusing of a piece of copper in mid-air, as described, are simple experiments which by the use of my high-frequency transformers any student of electricity can readily perform. They teach nothing new and have no bearing on wireless transmission, for the actions virtually cease at a distance of a few feet from the source of vibratory energy. Years ago I gave exhibitions of similar and other much more striking experiments with the same kind of apparatus, many of which have been illustrated and explained in technical journals. The published records are open to inspection.

Regardless of all that, the Danish inventors have not as yet offered the slightest proof that their expectations are realizable, and before advancing seriously the claim that an efficient wireless distribution of light and power to great distances is possible, they should, at least, repeat those of my experiments which have furnished this evidence.

A scientific audience cannot help being impressed by a display of interesting phenomena, but the originality and significance of a demonstration such as that referred to can only be judged by an expert possessed of full knowledge and capable of drawing correct conclusions. A novel effect, spectacular and surprising, might be quite unimportant, while another, seemingly trifling, is of the greatest consequence.

To illustrate, let me mention here two widely different experiments of mine. In one the body of a person was subjected to the rapidly alternating pressure of an electrical oscillator of two and a half million volts; in the other a small incandescent lamp was lighted by means of a resonant circuit grounded on one end, all the energy being drawn through the earth electrified from a distant transmitter.

The first presents a sight marvellous and unforgettable. One sees the experimenter standing on a big sheet of fierce, blinding flame, his whole body enveloped in a mass of phosphorescent cloud. From his ears, nose and hair issue iridescent wriggling streamers like the tentacles of an octopus. Bundles of light stick out from his spine. As he stretches out the arms, thus forcing the electric fluid outwardly, roaring tongues of fire leap from his finger tips. Objects in his vicinity bristle with rays, emit musical notes, glow, grow hot. He is the centre of still more curious actions, which are invisible. At each throb of the electric force myriads of minute projectiles are shot off from him with such velocities as to pass through the adjoining walls. He is in turn being violently bombarded by the surrounding air and dust. He experiences sensations which are indescribable.

A layman, after witnessing this stupendous and incredible spectacle, will think little of the second modest exhibit. But the expert will not be deceived. He realizes at once that the second experiment is ever so much more difficult to perform and immensely more consequential. He knows that to make the little filament glow, the entire surface of the planet, two hundred million square miles, must be strongly electrified. This calls for peculiar electrical activities, hundreds of times greater than those involved in the lighting of an arc lamp through the human body. What impresses him most, however, is the knowledge that the little lamp will spring into the same brilliancy anywhere on the globe, there being no appreciable diminution of the effect with the increase of distance from the transmitter.

This is a fact of overwhelming importance, pointing with certitude to the final and lasting solution of all the great social, industrial, financial philanthropic, international and other problems confronting humanity, a solution of which will be brought about by the complete annihilation of distance in the conveyance of intelligence, transport of bodies and materials and the transmission of the energy necessary to man's existence. More light has been thrown on this scientific truth lately through Prof. Slaby's splendid and path-breaking experiment in establishing perfect wireless telephonic connection between Naum and Berlin, Germany, a distance of twenty miles. With apparatus properly organized such telephonic communication can be effected with the same facility and precision at the greatest terrestrial distance.

The discovery of the stationary terrestrial waves, showing that, despite its vast extent, the entire planet can be thrown into resonant vibration like a little tuning fork; that electrical oscillations suited to its physical properties and dimensions pass through it unimpeded, in strict obedience to a simple mathematical law, has proved beyond the shadow of a doubt that the earth, considered as a channel for conveying electrical energy, even in such delicate and complex transmissions as human speech or musical composition, is infinitely superior to a wire or cable, however well designed.

Very soon it will be possible to talk across an ocean as clearly and distinctly as across a table. The first practical success, already forecast by Slaby's convincing demonstration, will be the signal for revolutionary improvements which will take the world by storm.

However great the success of the telephone, it is just beginning its evidence of usefulness. Wireless transmission of speech will not only provide new but also enormously extend existing facilities. This will be merely the forerunner of ever so much more important development, which will proceed at a furious pace until, by the application of these same great principles, the power of waterfalls can be focussed wherever desired; until the air is conquered, the soil fructified and embellished; until, in all departments of human life, distance has lost its meaning and even the immense gulf separating us from other worlds is bridged.

Nikola Tesla

WIRELESS ACHIEVEMENTS BY TESLA

NIKOLA TESLA, the wizard of electricity, believes that he has at last found the secret of driving dirigible balloons through the air. This discovery Mr. Tesla ranks as the very climax of his active, fruitful life.

The wireless and at the same time absolutely limitless transmission of electric power has been the one problem to the solution of which Mr. Tesla has given all of his time and energy during the past few years. And now he believes that he has solved it.

Mr. Tesla has perfected a transmitter that he believes is destined to revolutionize the world. It will enable him to throw hundreds, and, if necessary, thousands, of volts of electricity, producing unlimited horse-power, to airships in any part of the world; it will enable him to drive an airship to the North Pole and back; it will enable him to drive ocean liners back and forth across the Atlantic without coal or any material conductor of electric power aside from the air; it will enable him not only to telephone to Europe without wires or cables; it will enable him to run our trolley cars, light our houses, operate our elevators and cook our meals without wires or third rails.

It is the perfecting of this transmitter that Mr. Tesla believes to be the greatest achievement of his life.

Mr. Tesla was one of the first modern inventors to devote his great mind to practically utilizing electricity. He first recognized the limitless power of Niagara Falls, and sought the means to harness it. Long before the public had become accustomed to the marvels of the trolley car, the telegraph and telephone, Mr. Tesla was seeking to do away with the primitive wires and cables used to transmit the electric power and to accomplish the same results with no other conductor than the air.

Bound, fettered and restrained by wires, Mr. Tesla felt the great value of electricity to mankind was lost. The enormous loss of power in its transmission over miles of wires, Mr. Tesla believed, made the apparent value of electricity as nothing to its actual worth. It was to save this loss that Mr. sought the wireless transmission of electric power.

And it is the solution of this problem that Mr. Tesla now offers the world.

To-day the wireless transmitter has accomplished what, ten years ago, would have been pronounced impossible. Its practicability has been thoroughly demonstrated.

This strange picture, showing the effect of Mr. Tesla's extraordinary experiment, was made by Dan Smith after a personal visit to Mr. Tesla at his laboratory.

SIGNALLING TO MARS—A PROBLEM OF ELECTRICAL ENGINEERING.

BY NIKOLA TESLA.

In the early part of 1900, still vividly impressed by certain observations I had made shortly before, and feeling that the time had come to prepare the world for an experiment which will soon be undertaken, I dwelt on the practicabilty of interplanetary signalling in an article which appeared in the June number of the *Century Magazine* of the same year. In order to correct an erroneous report

which gained wide circulation, a statement was published in *Collier's Weekly* of Feb. 9, 1901, defining my position in general terms. Ever since, my thoughts have been centred on the subject, and my original conviction has been strengthened both by reflection and suggestion.

Chief among the stimulating influences was the revelatory work of Percival Lowell, described in a volume with which the observatory, bearing his name, has honored me. No one can look at his globe of Mars without a feeling of profound astonishment, if not awe. These markings, still imperfectly discerned and incomprehensible, but evi...tly intended for a useful purpose, may they not contain a record of deep meaning left by a superior race, perhaps extinct, to tell its young brethren in other worlds of secrets discovered, of life and struggle, of their own terrible fate? What mighty pathos and love in such a gigantic drama of the universe! But let us hope that the astronomer has seen true, that Mars is not a cold grave, but the abode of happy intelligent creatures, from whom we may learn. In the light of this glorious possibility, signalling to that planet presents itself as a preëminently practical proposition which, to carry out, no human sacrifice could be too great. Can it be done? What chance is there that it will be done?

These questions will be answered definitely the moment all doubt as to the existence of highly developed beings on Mars is dispelled. The straightness of the lines on Lowell's map, their uniform width and other geometrical peculiarities, do not, themselves, appeal to me as strong proofs of artificiality. I should think that a planet large enough not to be frozen stiff in a spasm of volcanic action, like our moon, must, in the course of eons, have all its mountains leveled, the valleys filled, the rocks ground to sand, and ultimately assume the form of a smooth spheroid, with all its rivers flowing in geodetically straight lines. The uniform width of the waterways can be consistently explained, their crossings, however odd and puzzling, might be accidental. But I quite agree with Professor Morse, that this whole wonderful map produces the absolute and irresistible conviction, that these "canals" owe their existence to a guiding intelligence. Their great size is

Nikola Tesla.

not a valid argument to the contrary. It would merely imply that the Martians have harnessed the energy of waterfalls. We know of no other source of power competent to explain such tremendous feats of engineering. They could not be accomplished by capturing the sun's rays or abstracting heat imparted to the atmosphere, for this, according to our best knowledge, would require clumsy and inefficient machinery. Large falls could be obtained near the

polar caps by extensive dams. While much less effective than our own, they could well furnish several billions of horse-power. It should be borne in mind that many Martian tasks in mechanical engineering are much easier than the terrestrial, on account of the smaller mass of the planet and lesser density, which, in the superficial layers, may be considerably below the mean. To a still greater degree this is true of electrical engineering. Taking into account the space encompassed by Mars, a system of wireless transmission of energy, such as I have perfected, would be there much more advantageously applied, for, under similar conditions, a receiving circuit would collect sixteen times as much energy as on the earth.

The astonishing evidences furnished by Lowell are not only indicative of organic life, but they make it appear very probable that Mars is still populated; and furthermore, that its inhabitants are highly developed intelligent beings. Is there any other proof of such existence? I answer, emphatically, yes, prompted both by an instinct which has never yet deceived me, and observation. I refer to the strange electrical disturbances, the discovery of which I announced six years ago. At that time I was only certain that they were of planetary origin. Now, after mature thought and study, I have come to the positive conclusion that they must emanate from Mars.

Life, as a great philosopher has said, is but a continuous adjustment to the environment. Similar conditions must bring forth similar automata. We can have no idea what a Martian might be like, but he certainly has sensitive organs, much as our own, responsive to external stimuli. The indications of these instruments must be real and true. A straight line, a geometrical figure, a number, must convey to his mind a clear and definite conception. He ought to think and reason like ourselves. If he breathes, eats and drinks, he is moved by motives and desires not very different from our own. Such colossal transformation as is observable on the face of Mars could not have been wrought except by beings ages ahead of us in development. What wonder, then, if they have maps of this, our globe, as perfect as Professor Pickering's photographs of the moon? What wonder if they are signalling to us? We are sufficiently advanced in electrical science to know that their task is much easier than ours. The question is, Can we transmit electrical energy to that immense distance? This I think myself competent to answer in the affirmative.

TUNED LIGHTNING.

By NIKOLA TESLA.

I READ with interest an article in the *Sunday World* of Jan. 20 on "Tuned Lightning," described as a mysterious new energy, which is to turn every wheel on earth, and is supposed to have been recently discovered by the Danish inventors Waldemar Poulsen and P. O. Pedersen.

From other reports I have gathered that these gentlemen have so far confined themselves to the peaceful production of miniature bolts not many inches long, and I am wondering what an account of their prospective achievements would read like if they had succeeded in obtaining, like myself, electrical discharges of 100ft., far surpassing lightning in some features of intensity and power.

In view of their limited Jovian experience, the programme outlined by the Danish engineers is rather extensive, Lord Armstrong's vast resources notwithstanding. Naturally enough, I shall look with interest to their telephoning across the Atlantic, supplying light and propelling airships without wires. *Anch' io sono pittore.* (I, too, am a painter.) In the mean time it may not be amiss to state here incidentally that all the essential processes of and appliances for the generation, transmission, transformation, distribution, direction, storage, regulation, control, and economic utilisation of "tuned lightning" have been patented by me, and that I have long since undertaken, and am sparing no effort to render these advances instrumental in insuring the welfare, comfort, and convenience, primarily, of my fellow-citizens.

There is nothing remarkable in the demonstration reported to have been made before Sir William Preece and Prof. Sylvanus P. Thompson, nor is there any novelty in the electrical devices employed. The lighting of arc lamps through the human body, the fusing of a piece of copper in mid-air, as described, are simple experiments which by the use of my high-frequency transformers any student of electricity can readily perform. They teach nothing new, and have no bearing on wireless transmission, for the actions virtually cease at a distance of a few feet from the source of vibratory energy. Years ago I gave exhibitions of similar and other much more striking experiments with the same kind of apparatus, many of which have been illustrated and explained in technical journals. The published records are open to inspection.

Regardless of all that, the Danish inventors have not as yet offered the slightest proof that their expectations are realisable, and before advancing seriously the claim that an efficient wireless distribution of light and power to great distances is possible, they should, at least, repeat those of my experiments which have furnished this evidence.

A scientific audience cannot help being impressed by a display of interesting phenomena, but the originality and significance of a demonstration such as that referred to can only be judged by an expert possessed of full knowledge and capable of drawing correct conclusions. A novel effect, spectacular and surprising, might be quite unimportant, while another, seemingly trifling, is of the greatest consequence.

To illustrate, let me mention here two widely different experiments of mine. In one the body of a person was subjected to the rapidly-alternating pressure of an electrical oscillator of two and a half million volts; in the other a small incandescent lamp was lighted by means of a resonant circuit grounded on one end, all the energy being drawn through the earth electrified from a distant transmitter.

The first presents a sight marvellous and unforgettable. One sees the experimenter standing on a big sheet of fierce, blinding flame, his whole body enveloped in a mass of phosphorescent cloud. From his ears, nose, and hair issue iridescent wriggling streamers like the tentacles of an octopus. Bundles of light stick out from his spine. As he stretches out the arms, thus forcing the electric fluid outwardly, roaring tongues of fire leap from his finger-tips. Objects in his vicinity bristle with rays, emit musical notes, glow, grow hot. He is the centre of still more curious actions, which are invisible. At each throb of the electric force myriads of minute projectiles are shot off from him with such velocities as to pass through the adjoining walls. He is in turn being violently bombarded by the surrounding

air and dust. He experiences sensations which are indescribable.

A layman, after witnessing this stupendous and incredible spectacle, will think little of the second modest exhibit. But the expert will not be deceived. He realises at once that the second experiment is ever so much more difficult to perform and immensely more consequential. He knows that to make the little filament glow, the entire surface of the planet, two hundred million square miles, must be strongly electrified. This calls for peculiar electrical activities, hundreds of times greater than those involved in the lighting of an arc lamp through the human body. What impresses him most, however, is the knowledge that the little lamp will spring into the same brilliancy anywhere on the globe, there being no appreciable diminution of the effect with the increase of distance from the transmitter.

This is a fact of overwhelming importance, pointing with certitude to the final and lasting solution of all the great social, industrial, financial, philanthropic, international, and other problems confronting humanity, a solution of which will be brought about by the complete annihilation of distance in the conveyance of intelligence, transport of bodies and materials, and the transmission of the energy necessary to man's existence. More light has been thrown on this scientific truth lately through Prof. Slaby's splendid and path-breaking experiment in establishing perfect wireless telephonic connection between Naum and Berlin, Germany, a distance of twenty miles. With apparatus properly organised such telephonic communication can be effected with the same facility and precision at the greatest terrestrial distance.

The discovery of the stationary terrestrial waves, showing that, despite its vast extent, the entire planet can be thrown into resonant vibration like a little tuning-fork; that electrical oscillations suited to its physical properties and dimensions pass through it unimpeded, in strict obedience to a simple mathematical law, has proved beyond the shadow of a doubt that the earth, considered as a channel for conveying electrical energy, even in such delicate and complex transmissions as human speech or musical composition, is infinitely superior to a wire or cable, however well designed.

Very soon it will be possible to talk across an ocean as clearly and distinctly as across a table. The first practical success, already forecast by Slaby's convincing demonstration, will be the signal for revolutionary improvements which will take the world by storm.

However great the success of the telephone, it is just beginning its evidence of usefulness. Wireless transmission of speech will not only provide new but also enormously extend existing facilities. This will be merely the forerunner of ever so much more important development, which will proceed at a furious pace until, by the application of these same great principles, the power of waterfalls can be focussed whenever desired; until the air is conquered, the soil fructified and embellished; until, in all departments of human life distance has lost its meaning, and even the immense gulf separating us from other worlds is bridged.

SCIENTISTS DOUBT THE HUMAN SOUL WAS WEIGHED.

Nikola Tesla Considers the Statement Made by Five Boston Physicians Too Absurd for Discussion.

DR. I. K. FUNK, IF DYING, WOULD WELCOME TEST.

Dr. Carleton Simon Thinks Deflation of the Lungs May Have Caused Phenomenon.

A subject of widespread discussion during the past week was the statement published in The World that five Boston physicians of the highest standing have attained what they hold to be decisive results in establishing the weight of the human soul.

Dr. Isaac K. Funk was intensely interested, but he said to a World reporter:

"I cannot accept this experiment or series of experiments as decisive. I should like to see a thorough investigation made by other scientists. Mind you, I do not say that it is impossible. I only say that it is not conclusive; I have no doubt that there are other formations so fine that our grosser senses do not take cognizance of them.

"It all becomes a question of vibrations. To make myself more clear, I cannot do better than quote Sir William Crookes, who when elected President of the British Association said in his remarkable address that all of the phenomena of the universe are presumably waves and vibrations.

"I personally, if I were dying, would not in the least mind doctors making the experiment. My bed might be placed on delicately adjusted scales, and any difference after making all scientific allowances carefully noted."

Prof. John D. Quackenbos said: "I do not attach any importance to it.

"The experiment is subject to so many errors that it is not dependable. The weight of the human body varies all the time. Sometimes your clothes feel tight and at others loose, so, for that reason alone, the conclusion arrived at is erroneous.

"We must get a clearer definition of what is meant by the soul. I do not for one instant believe that the astral body has any weight.

"In my opinion if this experiment were true there would be a difference of weight when a man is asleep, for I believe that during his sleeping hours there is a temporary disconnection of the soul and the body."

No Loss of Weight, Says Tesla.

Nikola Tesla, discussing the subject said:

"That an aggregation of impressions, thoughts and feelings having no materiality, and vaguely designated as mind, or soul, should be a substance susceptible of quantitative determination is altogether too absurd for discussion.

"The change, however, which takes place in the human body during its awful transition from life to death is a great subject for scientific investigation which may possibly lead to important results. If the experiments of the Massachusetts physicians are to be at all seriously considered, it is only in this respect.

"I could not help being struck by the fact that men of a scientific calibre sufficiently large to undertake measurements requiring the greatest delicacy and skill, should not be correspondingly resourceful in divising the apparatus for the purpose. A scale responding to the weight of one-tenth of an ounce is not a fit instrument for weighing the human soul.

"It is not less astonishing that such trained observers should have overlooked a trivial cause responsible for the seeming lightening of the body. I use this term designedly, for excepting the exudations which have been taken into consideration there was no loss of substance in death.

"When rigor mortis sets in there is an increase of volume for various reasons. Just to give a rough idea I shall assume that the living body, weighing say 150 pounds, had filled a space of three cubic feet. The air in a sick room may weigh about fourteen ounces per cubic foot. Half an ounce of the air would consequently occupy a space of sixty-two cubic inches, and that would be only one per cent. of the original volume of three cubic feet. As will readily be seen, a very slight general deformation of the body, scarcely perceptible, is adequate to explain the puzzling observation. The sudden tipping of the scale demonstrates nothing except the coarseness of the instrument. Had the balance been very sensitive, owing to the resistance of the air, the platform would have ascended slowly."

Absurd, Says Dr. Simon.

Dr. Carleton Simon said: "If these experiments were performed honestly—that is to say if they were genuine, there can only be one conclusion, and that is that the loss of weight is due to the fact that the lungs are deflated.

"During life there is always a certain amount of air held in suspension in the lungs, that is, outside the air that is regularly inhaled and exhaled, and there must necessarily be a great difference in weight when this air leaves the body.

"If this difference in weight after death is seriously attributed to the loss of the soul, I can only qualify the whole conclusion as absurd."

Dr. Hereward Carrington, who is an associate of Prof. James H. Hyslop, and has been prominently identified with psychical research, on the other hand, was enthusiastic, and described the experiment as the most important addition to science the world has ever known. He, however, suggested that the experiment was not conclusive, as the subjects were ill and practically moribund, and therefore decomposition might set in the instant after death.

Scales May Have Been Influenced.

A well-known Newark scientist who does not wish his name published, said:

"The difference in weight, even of an ounce, in the several subjects' bodies immediately after death certainly appears remarkable if not attributable to some other physical influence, but such a phenomenon per se seems ill-adapted to dispel what to very many people is an article of faith, namely, the conviction that their souls, while being real and substantial, are nevertheless immaterial and therefore non-susceptible to space or scales.

"Just precisely what calculations and deductions based on physical agencies have been made by the medical experimenters, it is difficult to conjecture, but it seems safe to presume that in six at least of the seven cases mentioned, the counter action of these highly sensitive scales might be directly attributed to the cessation of the heart's beating, or in other words that the pulsation itself acted as an independent factor in influencing the balance until the moment when death intervened.

"As to the case of No. 7—termed the phlegmatic—if life had really ceased at the precise moment it is supposed to have, is it not possible that the mechanism of these highly sensitive scales may have been influenced by some physical agency apart from the subject under experiment that escaped the attention of the observers, or being phlegmatic, was the body slower to emit the gases than that of the others?

"However that may be, one cannot readily become reconciled to the rather singular theory put forward by Dr. Duncan MacDougal in regard to this latter case, viz.: that the soul remained 'suspended' in the body after death. Surely if death means pure and simple 'the separation of soul and body' the idea of this particular soul being suspended in this particular body is to the ordinary individual inconceivable."

The New York Times March 19, 1907

WIRELESS CAUSED IENA DISASTER?

French Expert Thinks Outside Current Communicated High-Tension Spark.

LOCAL SCIENTISTS' VIEWS

They Say If the Theory Is Correct It Indicates Gross Carelessness on the Vessel.

TOULON, March 18.—M. Naudin, the wireless telegraph expert, has advanced a new theory regarding the cause of the disaster to the battleship Iéna, whose afterpart was destroyed by the explosion of a magazine on March 12.

M. Naudin says that at the time of the explosion it was noted that powerful wireless currents were passing and he believes that the vessel's isolation in the dry dock here resulted in the accumulation of secondary Hertzian waves in the "B" powder magazine from the ship's wireless apparatus and that an outside current communicated a high-tension spark.

Prof. Michael I. Pupin of Columbia University, who has been deeply interested in the development of wireless telegraphy and has made many experiments with various apparatus, said last night:

"If explosives are kept in metallic cases and grounded there could be no explosion caused by wireless waves, but if explosives are not kept in metallic cases and grounded, it might happen. Failure to store explosives on a battleship in any other way would be the highest degree of carelessness, I should say. Of course, I have no information about the conditions on the Iéna at the time of the disaster."

Dr. Lee De Forest told a TIMES reporter last night that he considered the theory of M. Naudin as to the cause of the Iéna disaster improbable, but admitted ,that under certain conditions it might be correct. He said:

"The thinnest sheet of metal completely inclosing a space is an absolute barrier to electrical waves, no matter how intense. It is absurd to suppose, then, that any spark could have been caused within the magazine of the Iéna by waves sent out from some wireless transmitter outside the ship.

"It is, however, possible that high-potential, high-frequency currents could be induced in the electric light wires on board from the 'kick-back' of a powerful induction coil or transformer feeding an oscillating circuit and supplied from the same source of electric current. It is also conceivable that from such electric light wires faultily insulated from the steel walls of the magazine and not protected in iron conduits, sparks could jump."

Dr. De Forest added that it was almost inconceivable that such an explosion should occur unless the French were grossly negligent in their method of wiring the Iéna. While it was possible, he said, that a defectively insulated wire was in close contact with the powder, it was highly improbable.

He recalled the experiments of Nicola Tesla with a dirigible torpedo about the time of the Spanish-American war. Tesla then considered the problem of the use of wireless telegraphy for directing torpedoes and discharging them. It was Tesla's theory that a torpedo's movements could be controlled by means of waves of electrical energy, and he made many experiments to this end, but with no practical results.

At that time Tesla made the statement that in the same manner he could project a wave of sufficient intensity to cause a spark in a ship's magazine and explode it. That statement was ridiculed by other electrical experts.

The New York Times March 20, 1907

TESLA'S WIRELESS TORPEDO.

Inventor Says He Did Show That It Worked Perfectly.

To the Editor of The New York Times:

A report in THE TIMES of this morning says that I have attained no practical results with my dirigible wireless torpedo. This statement should be qualified. I have constructed such machines, and shown them in operation on frequent occasions. They have worked perfectly, and everybody who saw them was amazed at their performances.

It is true that my efforts to have this novel means for attack and defense adopted by our Government have been unsuccessful, but this is no discredit to my invention. I have spent years in fruitless endeavor before the world recognized the value of my rotating field discoveries which are now universally applied. The time is not yet ripe for the telautomatic art. If its possibilities were appreciated the nations would not be building large battleships. Such a floating fortress may be safe against an ordinary torpedo, but would be helpless in a battle with a machine which carries twenty tons of explosive, moves swiftly under water, and is controlled with precision by an operator beyond the range of the largest gun.

As to projecting wave-energy to any particular region of the globe, I have given a clear description of the means in technical publications. Not only can this be done by the use of my devices, but the spot at which the desired effect is to be produced can be calculated very closely, assuming the accepted terrestrial measurements to be correct. This, of course, is not the case. Up to this day we do not know a diameter of the globe within one thousand feet. My wireless plant will enable me to determine it within fifty feet or less, when it will be possible to rectify many geodetical data and make such calculations as those referred to with greater accuracy.

NIKOLA TESLA.

New York, March 19, 1907.

The New York Times March 26, 1907

WIRELESS ON RAILROADS.

Nikola Tesla Says It Is Perfectly Practical and Will Soon Be In Use.

To the Editor of The New York Times:

No argument is needed to show that the railroads offer opportunities for advantageous use of a practical wireless system. Without question, its widest field of application is the conveyance to the trains of such general information as is indispensable for keeping the traveler in touch with the world. In the near future a telegraphic printer of news, a stock ticker, a telephone, and other kindred appliances will form parts of the regular wireless equipment of a railroad train. Success in this sphere is all the more certain, as the new is not antagonistic but, on the contrary, very helpful to the old. The technical difficulties are minimized by the employment of a transmitter the effectiveness of which is unimpaired by distance.

In view of the great losses of life and property improved safety devices on the cars are urgently needed. But upon careful investigation it will be found that the outlook in this direction is not very promising for the wireless art. In the first place the railroads are rapidly changing to electric motive power, and in all such cases the lines become available for the operation of all sorts of signaling apparatus, of which the telephone is by far the most important. This valuable improvement is due to Prof. J. Puley, who introduced it in Germany eight years ago. By enabling the engineer or conductor of any train to call up any other train or station along the track and obtain full and unmistakable information, the liability of collisions and other accidents will be greatly reduced. Public opinion should compel the immediate adoption of this invention.

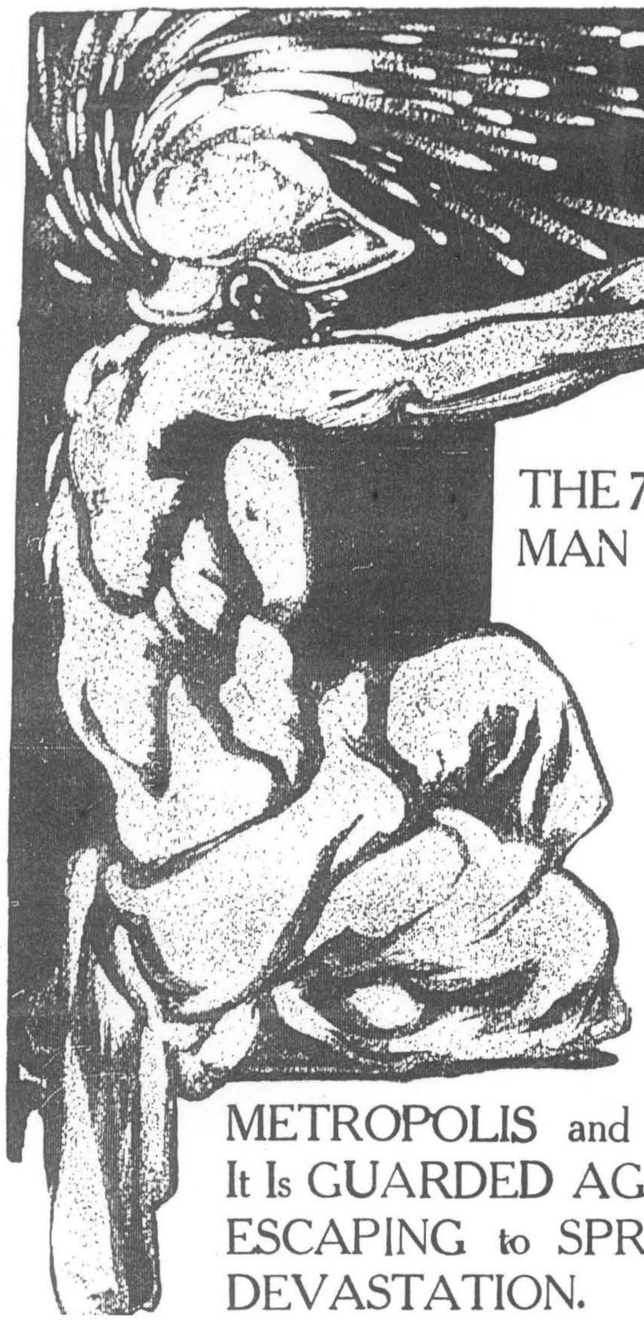
Those roads which do not contemplate this transformation might avail themselves of wireless transmission for similar purposes, but inasmuch as every train will require in addition to a complete outfit an expert operator, many roads may prefer to use a wire, unless a wireless telephone can be offered to them.

NIKOLA TESLA.

New York, March 25, 1907.

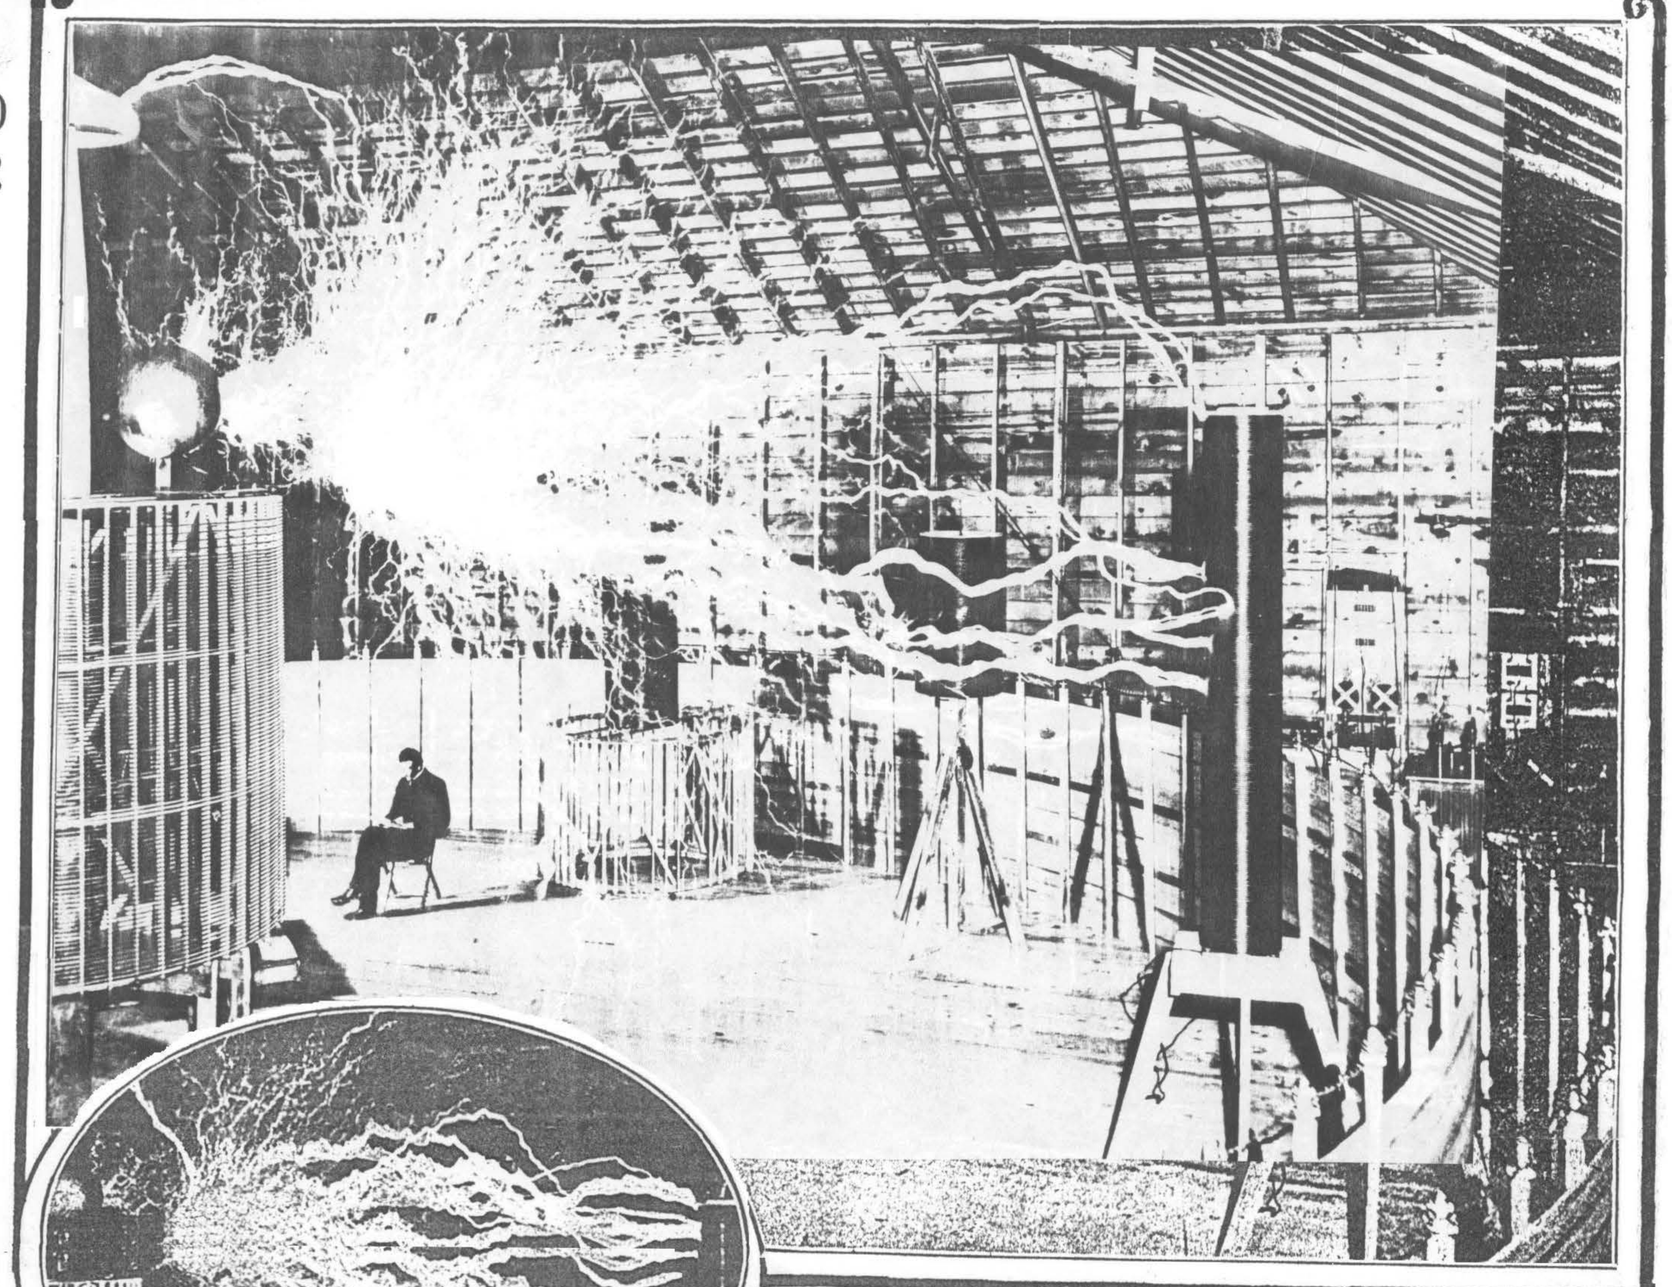
The New York Times March 28, 1907

A Positive If Not Expert Opinion.



To the Editor of The New York Times:

The undersigned, not a proper electrician but only a student of applied mathematics, cannot refrain from setting the public right apropos of Mr. Tesla's letter in this morning's TIMES concerning wireless telegraphing on moving trains. If the reader will try a wireless receiver while he is shaking it violently, though moderately in the distances involved, he will understand a little of the simplicity of Mr. Tesla's suggestion. And if he will, moreover, have his room filled with fine, minute dust, of which many of the particles are magnetic and all are particularly handsomely minute, he will appreciate the delicacy of this precious discovery of Marconi, capable of all things perhaps, but certainly not within the compass of a fanning mill such as a moving train resembles.



M. W. HARRINGTON.

New York, March 28, 1907.

THIS GIANT could WRECK NEW YORK

THE 7,000,000 MAN POWER ELECTRIC FORCE Running Through the Wire VEINS of the METROPOLIS and HOW It Is GUARDED AGAINST ESCAPING to SPREAD DEVASTATION.

These photographs of Nikola Tesla's magnifying transmitter were made under Mr. Tesla's supervision at his Long Island laboratory. The upper picture shows the results of a double exposure, one made to record the leaping electric flame, forty feet long, the second to impress on the plate the seated figure of Mr. Tesla himself. The potentiality of this remarkable exhibition of electrical force has been estimated at 25,000,000 horse-power—five times the power of Niagara.

WHOEVER has been upon a street car when a fuse burned out, have no doubt wondered what would happen if all the electricity in this most electric city of the world got loose.

There is an immediate exodus from the car. Often all of the car that is combustible is consumed by flame before the nearest fire engine can be brought to the spot. Between the first startling sharp report and the ignition of woodwork and the melting of insulation the period is short. But only one car is involved—or a train of cars, as one day last year in the Subway. In the event of a simultaneous breaking of bounds all over town by this marvellous agent which we hold to slavery by shackles confessedly weak, what would it do to Manhattan?

Manhattan and the Bronx has seised and harnessed and put to labor electricity to the total of 1,000,000 horse-power. The strength of a million horses! It does the equivalent of the work of 5,000,000 men—indeed, two and one-half times that number, for it sustains its power not for eight or nine hours but for twenty-four—adding to New York's industrial output nearly six times that of all the males in this tremendous city.

Here are the capacities of the power stations:

	Horse-Power.
Rapid Transit Subway	130,000
Metropolitan Railway	98,000
Manhattan Railway	180,000
New York City Railway	96,000
New York Central Railway (by July)	100,000
Edison Company	216,000
United Company	90,000
Pennsylvania Railroad	95,000
Private plants	125,000
Municipal lights	20,000
Total	1,070,000

In addition, there are the Edison light storage batteries in twenty different buildings on Manhattan, holding 75,000 horse-power for emergency. This, more than a million electric horse-power—practically all in Manhattan—is three times what there was in the entire United States seven years ago. In the Greater City two-million-man power may be added to the figures.

When Electricity Does Escape.

Electricians assert that in electrical science there is no such term as "breaking loose." Yet electricity does escape from third rails and light wires and wanders about town, eating copper roofs, corroding bridges and the steel frames of buildings.

At a recent hearing on the cost of gas, sections of iron pipe were shown in which vagrant electricity had bored immense holes. At a moment of puncture, if air were present, it is conceded that a spark would result and an explosion follow. Many a mysterious explosion has been caused by the wearing off of the insulation of wires and the instant ignition of leaked gas.

"The leakage of electricity is undeniably considerable," declared the editor of the Electrical Age the other day, "and the problem how to stop it is now the object of anxious research and experiment. In some cities electric railways are seriously troubled by the quantity that gets free. Conduits are made of fire-clay, and all known precautions are taken, but it is true that electrolysis is acting into the steel frames of modern buildings and iron structures generally — 'electrolysis' being the decomposition caused by errant electricity."

A definite impression exists that in relation to this subtle power, the nature of which we do not know, we may be dwelling in a false security.

Most of us know from photographs, at least, what electricity looks like when it leaps from one grounded pole to another. It streams across the intervening space in weird dazzling undulations. White tatters of ribbons—broken gleams, radiations, streaks—wave more erratically than strands snapping in a gale.

On this page you may see such a photograph, with a man calmly reading a newspaper a few feet beyond. Of course the man was not really there. Short time he would have lasted! By a well-known trick of photograph-making the picture of the man calmly reading was superimposed upon a picture of electricity darting from pole to pole.

Supposing all the electricity produced continuously in Manhattan were thus to disport itself? What could it do? Suppose it possible that this giant which we have set to drive wheels, make heat and supply light—which in this city we have compelled to operate the biggest artificial light system and the busiest transportation lines the world ever saw, at the same time subjecting its power to innumerable uses, even to curling a lady's hair, suppose all should escape, with its power of a million horses, what could it not do to Manhattan?

Dangers of a Short Circuit.

"Well, now," objects the practical electrician, "cables would be burned up by that escape—then the engines which drive the dynamos would stop. Engines stop on a short circuit. Remember that there are two electricities—the negative and the positive—which tend to unite, and in uniting produce the electric current. One punctured insulation makes no trouble. There's nothing doing unless there is a puncture on the other cable also. When one escapes it dashes for the other by the shortest route. Why should the engines stop? Because 10,000 horse-power becomes by such a crossing of cables equal to 100,000 horse-power, and the engine having only 10,000 capacity would be overwhelmed."

Sixty thousand volts is the present safety limit for power transmission. Anything more bursts through all insulators yet devised. At Niagara a plant with 10,000 horse-power, transmits its current under a pressure of 20,000 volts. On the Manhattan Elevated and Subway roads the pressure is 12,000 volts; on the lighting wires 240 volts.

Now, as at Sing Sing the voltage used to kill a man is only 2,000, the total voltage from Manhattan's horse-power could cause a very bad scene.

"Yes," assents the practical electrician, "it could kill everybody on the island.

"A little more than three amperes of current under pressure of 240 volts is furnished by one horse-power. If all the city used this pressure the amperage would be 3,000,000; and that would be able to fuse at a breath a steel column the thickness of 200 rails."

"Then suppose," the practical electrician was urged, "that some night all this mighty mystery threw off its man-made restraints and gathered itself into one super-Jovian thunderbolt?"

"Oh, the things it could do to Manhattan are beyond scientific estimating! They are only to be dealt with by fancy," he answered, ignoring every electric principle to suppose such an impossibility. Nothing merely earthly would be comparable with the monstrous happening. If all this New York electric power were condensed into one explosive cloud it would cause an explosion which would be heard around the world! However," he added, "electrical horse-power is not in an explosive condition. We can only put it in that state theoretically."

What Would Happen "Theoretically."

Putting it "in that state theoretically," it was fancied that this might happen.

Manhattan would be in its night pomp and splendor, "fabric of diamond and gold." The theatres would be letting out. Above, upon and below the surface the crowded cars would be hurrying people homeward. Suddenly every wheel would stop. The city's bright avenues would fall silent and black.

Then all that goes to light up the Great White Way would join the flashes leaping up from every Subway opening, and these would join the fantastic glares climbing down elevated road pillars, darting from buildings, lifting themselves from the crevice of the underground trolley; all signing-magging with enormous velocity.

Whatever was combustible would flash into flame at a touch.

Lead running like water; iron softened, and releasing the brick and stone it had upheld; glass melting, walls rushing asunder, "the noise of a thousand waters." There would be a rush from houses, apartments, tenements; a "tumult and gathering of feet." The Great White Way would be a roaring white furnace. Human beings thrillingly shocked, uttering those weird dying cries of the electrocuted, would clog the street.

"Electricity, awful sister of the air, would be walking in a kingdom of her own.

In plain sight she would exhibit a species of mad hilarity. Above the majestic copper and iron Liberty in the harbor the free atmospheric electricity would hover as always in great threatening density. Protecting the statue would be her seven pointed cap and her asbestos packing, insulating her exterior copper from interior iron. Diana, of Madison Square, being of copper gilded, would be a good conductress, and she would assist atmospheric electrons down to the ground to increase the forces. Diana's fatality would arise from the numerous illuminating wires and incandescents, which, overrunning tower and building—her underpinning—would drop her at last on a heap of bricks.

Manhattan a Gray Waste.

In this preposterous wild ritual of sacrifice and fiery strife the whole island would have glowed and smelled with luminous unbearable gaseous exhalations from burning casings, clothings, harnessings, seared flesh, exploded chemicals; until at last from the concentrated loose and reckless forces Manhattan would have suffered the ultimate dread eclipse. And the sun would rise over a sterile, gray waste of ashes.

Any feature would be recognizable except the Park Reservoir, whose storage of water might save it from the general sepulchral obliteration.

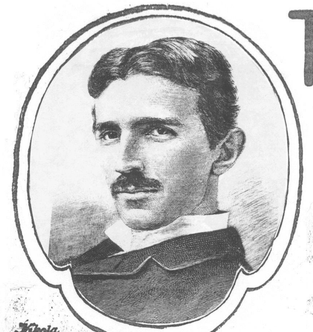
"You forget Wall Street," broke in the practical electrician lightly. "Its stock-water would preserve it from the cataclysm, no doubt."

What New York's Electricity Combined Could Do.

It would have the strength of 7,000,000 men, or 1,250,000 horses.

It could fuse at a breath a steel column the thickness of 200 rails.

It could leap in one continuous flame from shore to shore of Manhattan.



It is 625 times more powerful than the man-killing current of Sing Sing, and could kill every one in the city at a flash.

Its explosion would be felt around the world.

With one night of freedom it would leave the Metropolis a gray solitude of ashes.

Then he went on, after a moment's smiling consideration:

"As a matter of fact, you know, after this paroxysmic dream, you would wake up and learn that our million electrical horse-power could not heat to white heat one-hundredth part of the Waldorf. Also that, really, if all the electricity in Manhattan did escape, it would be no more than if you had a huge reservoir of air and it suddenly got out of its tank and mixed harmlessly with the outer atmosphere!"

TESLA'S TIDAL WAVE TO MAKE WAR IMPOSSIBLE

The New Wireless Wonder That Will Create Fleet-Destroying Convulsions in the Open Sea, Engulf the Heaviest Fighting Ships Like Toy Boats in a Tub and by Its Horrors Hasten the Day of Universal Peace.

BY NIKOLA TESLA.

TO urge peace was the dream of the Peace Conference. To compel peace is the newest dream of Science.

Representative men of many nations have been gathered in New York to plead the altruistic cause of international harmony. At this very juncture inventive Science comes forward to promise a device so terrible that, should it be perfected, and put into practice, sea battles will become impossible.

Nikola Tesla has devised a plan which will make navies as useless as the paper boats that babies float in bathtubs. Imagine a great navy approaching the coast of New York, battle-flags flying, decks cleared for action, guns shotted, lookouts peering westward in expectation of sighting the defending fleet. Then imagine a vast tidal wave suddenly rising from the ocean and swallowing up that hostile fleet, ships, guns, men and all, as Pharaoh's host was engulfed by the waters of the Red Sea. Imagine then the sea returning to its ordinary calm, with not a vestige of that vast armada left to tell the tale. Such is the unanswerable peace argument offered by Nikola Tesla.

The knowledge that any nation possessed the secret of creating such an invincible tidal wave would make that nation invulnerable. No other nation would dare attack it, at least by sea.

Wireless telegraphy is the force that Mr. Tesla will apply to the generation of such a tidal wave.

Wireless telegraphy, to-day but just out of its swaddling clothes, is destined to grow to be a giant Mr. Tesla describes below how it can be made to direct his "teleautomaton," which could be sent out against a hostile fleet, unmanned, steered from shore, its wave-crashing torpedoes discharged by electric waves impeled from shore. This invention would go far to make war too dangerous and too expensive to be undertaken by any nation; but the almost human messenger itself is a trifle in comparison with the annihilating tidal wave which Mr Tesla goes on to describe in this remarkable article written by him especially for The Sunday World.

JUST at this time, when all efforts toward peaceful arbitration notwithstanding, the nations are preparing to expend immense sums in the design and construction of monstrous battle-ships, it may be useful to bring to the attention of the general public a singular means for naval attack and defense, which the telautomatic art has made possible and which is likely to become a deciding factor in the near future.

A few remarks on this invention, of which the wireless torpedo is but a special application, are indispensable to the understanding and full appreciation of the naval principle of destruction.

The telautomatic art is the result of endeavors to produce an automaton capable of moving and acting as if possessed of intelligence and distinct individuality. Disconnected from its higher embodiment, an organism, such as a human being, is a heat—or thermodynamic engine—comprising: 1, a complete plant for receiving, transforming and supplying energy; 2, apparatus for locomotion and other mechanical performance; 3, directive organs, and, 4, sensitive instruments responsive to external influences, all these parts constituting a whole of marvellous perfection.

The ambient medium is alive with movement and energy, in a state of unceasing agitation which is beyond comprehension. Strangely enough, to most of this terrible turmoil the human machine is insensible. The automaton does not feel the weight of the atmosphere crushing him with a force of sixteen tons. He is unaffected by the shower of particles shooting through his body of cloud and the hurricane of finer substance rushing through him with the speed of light. He is unconscious that he is being whisked through space in the fearful rate of 10,000 miles an hour. But when gentle waves of light or sound strike him his eye and ear respond, his resonant nerve-fibres transmit the vibrations and his muscles contract and relax. Thus, like a float on a turbulent sea, swayed by external influences, he moves and acts. The average person is not aware of this constant dependence on his environment but a trained observer has no difficulty in locating the primary disturbance which prompts him to action, and continued exercise soon satisfies him that virtually all of his purely mechanical motions are caused by visual impressions, directly or indirectly received.

Using the Principles of Human Action.

A machine of such inconceivable complexity as the body of an organized being, capable of an infinite variety of actions, with controlling organs super-sensitive, responsive to influences almost immaterial, cannot be manufactured by man; but the mechanical principles involved in the working of the living automaton are also applicable to an inanimate engine, however crude.

An automobile boat was first employed to carry out the idea. Its storage battery and motor furnished the power; the propeller and rudder, respectively, served as locomotive and directive organs, and a very delicate electrical device, actuated by a circuit tuned to a distance transmitter, took the place of the ear. This mechanism followed perfectly the wireless signals or comments of the operator in control of the transmitter, performing every movement and action as if it had been gifted with intelligence.

The next step was to individualize the machine. The attunement of the controlling circuits gave it a special feature, but this was not sufficiently distinctive. An individuality implies a number of characteristic traits which though perhaps extant elsewhere, are unique in that particular combination. Here again the animated automaton, with its nerve-signal system, was coarsely imitated. The action of the delicate device—the ear—was made dependent on a number of sensitized receiving circuits each recognizable by its own free vibrations and all together by the character of their operative combination. Correspondingly the transmitter was designed to emit a wave-compound exactly matching the combination in the number and pitch of individual vibrations, the groupment and order of succession.

Wonders of the New Telautomaton.

That much is done, but more is to come the mechanism is being perfected which with the operator in control, left to itself, will behave as if endowed with intelligence of its own. It will be responsive to the faintest external influence and from these, unaided, determine its subsequent actions as if possessed of selective quantities, logic and reason. It will perform the duties of an intelligent slave. Many of us will live to see Bulwer's dream realized.

The reader for whom the preceding short explanation of this novel art is intended may think it simple and easy of execution, but it is far from being so. It has taken years of study and experiment to develop the necessary methods and apparatus, and five inventions, all more or less fundamental and difficult to practice must be employed to operate successfully an individualized telautomaton.

Such a novel engine of war—a vessel of any kind, submarine or aerial—carrying an agent of unlimited potency of destruction, with no soul aboard yet capable of doing all it is designed for, as if fully equipped with a fearless crew to command of its captain, must needs bring out a revolution in the present means of attack and defense.

Since ages human ingenuity has been bond upon inventing infernal machines. Of these the modern cannon has been so far the most remarkable. A twelve-inch gun charged with cordite is said to hurl a projectile of 850 pounds with the initial velocity of nearly 2,900 feet per second, imparting to it the energy of 110,000,000 foot-pounds. Were it not for the resistance of the air such a projectile would travel about fifty mile before striking the ground. It would take 3,300 horse-power more than a minute to accumulate its mechanical energy. Bear in mind, however that all this energy is imparted to the projectile while it is being urged through the gun-barrel with a mean force of 1,100 tons. If the barrel is fifty feet long and the average velocity through it 1,450 feet per second, the whole energy transferred to the moving mass in one thirty of a second, hence the rate of performance is 1,000 times the above—that is, about 6,000,000 horse-power. This seems wonderful indeed, but is nothing as compared with rates obtainable by other means. Electricity can be stored in the form of explosive energy of a violence against which the detonation of cordite is but a breath. With a magnifying transmitter, as diagrammatically illustrated, rates of 25,000,000 horse-power have already been obtained. A similiar and much improved machine, now under construction will make it possible to attain maximum explosive rates of over 800,000,000 horse-power, twenty times the performance of the Dreadnought's blindside of eight 12-inch guns simultaneously fired. some figures are so incredible that astronomers acquainted with the marvellous appliances have naturally doubted the practicability of signalling to Mars. In reality, by its means this seemingly visible project has been reduced to a rational enduring problem.

The time is not far distant when all the tremendous wastes of war will be stopped, and then, that there are battles, they will be fought with solar-power and electrical waves. That humanity is moving fast toward this realization is evident from many indications.

What is most to be regretted in the present day regime is that the effort of so many exquisite intelligences must be uneconomically applied, since it cannot be steadily directed toward a scientific truth, unalterable and of permanent usefulness, but must be entirely governed by the wavering struggle of opposing principles. This feverish applying to meet the instant demand, to create type after type, one to devour the other, to merge into one contrasting element, leads, like a nightmare, from one to another absurdity. Such a monstrosity is the latest creation of the naval constructor—the twenty-thousand-ton battleship. In theory it is condemned by competent authorities.

Everything points to the development of a small vessel with internal combustion engines, extreme speed and few weapons of great destructiveness. But the new leviathan is admirably adapted to be practical requirements of his day. In attack it could alone annihilate a nation's fleet. It is equally effective in defense. If equipped with proper acoustic and electric appliances it has little to fear from a submarine, and an ordinary torpedo will scarcely hurt it. That is why the first of these monsters, built in England, has been named Dreadnight. Now, there is a novel means for attacking a fortress of this kind, from shore or on the high seas, against which all its gun-power and prior resistance are of no avail.

This is the tidal wave.

What the Tesla Tidal Wave Will Do.

Such a wave can be produced with twenty or thirty tons of cheap explosive, carried to its destination and ignited by an inexpensive time estimation

The tidal disturbance, as here considered, is a peculiar hydrodynamic phenomenon, in many respects different from the commonly occurring, characterized by a rhythmical succession of waves. It consists generally of but a single advancing swell superceded by a hollow, the water if not otherwise excited being perfectly calm in front and very nearly so behind. The wave is produced by some hidden explosion or upheaval and is, as a rule, symmetrical for a large part of its course. Those who have encountered a tidal wave must have observed that the sea rises rather slowly, but the disturbance gains in violence as it progresses, and under the action of a varying force, great at first, but dying out quickly, while the raised mass is urged downward by the constant force of gravity. When produced by natural causes these waves are very dangerous to ordinary vessels, because the disturbance originates at a great depth. They give a very high idea of the efficacy of this novel means of destruction, particularly adapted for coast defenses, it may be assumed that thirty tons of nitro-glycerine compound, as dynamite, be employed to create the tidal disturbance. This material, weighing about twice as much as water, can be stowed in a cubical tank eight feet each way, or a spherical vessel of ten feet diameter. The reader will now understand that this charge is to be intrusted to a non-interferible telautomaton, heavily protected and partly submerged or submarine, which is under the perfect control of a skilled operator far away. At the propitious moment the signal is given, the charge sunk to the proper depth and ignited.

The water is incompressible. The hydrostatic pressure is the same in all directions. The explosion propagate through the compound with a speed of three miles a second. Owing to all this the whole mass will be converted into gas before the water can give way sensibly. Hence a spherical bubble ten feet in diameter will form. The immense pressure against the surrounding water will be twenty thousand atmospheres, or one hundred and forty tons per square inch. When the great bubble has expanded to twice its original volume it will weigh as much as the water it displaces, and from that moment on, its lower end tapering more and more into a cone, it will be driven up with a rapidly increasing force tending towards twenty thousand tons. Under this terrific impetus, it would shoot up the surface like a bullet were it not for the water resistance, which will limit its maximum speed to eighty feet per second.

Consider now the quantity and energy of the upheaval. The caloric potential energy of the compound is 2,800 heat units per pound, or, in mechanical equivalent, almost one thousand foot tons. The entire potential energy of the explosive will thus be sixty-six million foot tons. Of course, only a part of this immense store is transformable in mechanical effort. Theoretically 40 pounds of good smokeless powder would be sufficient to impart to the Dreadnought's displacement projectile the tremendous velocity mentioned above, but it actually takes a charge of 280 pounds. The tidal wave generator is a dynamic transformer much superior to the gun, its greatest possible efficiency being as high as 95 per cent. Taking, to be conservative, 25 per cent, instead, there will be of the total potential store about twenty-five million foot tons obtained in mechanical energy.

How the Enemy Would Be Engulfed.

Otherwise stated, 25,000,000 tons, that is, 800,000,000 cubic feet of water, could be raised, one foot, or a smaller quantity to a correspondingly greater elevation. The height and length of the wave will be determined by the depth at which the disturbance originated. Opening in the centre like a Volcano the great hollows will beak forth in a shower of ice. Some sixteen seconds later a valley of 800 feet depth, counted from normal ocean level, will form, surrounded by a perfectly circular swell, approximately of equal height, which will embrace in diameter at the rate of about 330 feet per second.

It is fair to consider the effect of such an eruption on a vessel situated nearby, however large. The entire navy of a great country, if massed around, would be destroyed. But it is instructive to inquire what such a wave could do to a battleship of the Dreadnought type at considerable distance from its origin. A simple calculation will show that when the outer circle has expanded to three-quarters of a mile, the swell, about 1,250 feet long, would still be more than 350 feet in height, from crest to normal sea level, and when the circle is one and one-quarter mile in diameter the vertical distance, from crest to trough will be over 180 feet.

The diagram on the right of this page shows the successive positions of the vessel in the gravity. The first impact of the water will produce pressures of three tons per square foot, which all over the submerged surfaces of, say, 20,000 square feet, may amount to 60,000 tons, eight times the force of the recoil of the broadside. That first impact may in itself be fatal. During more than one second the vessel will be entirely submerged and finally dropped into the hollow from a height of about seventy-five feet, the descent being effected, more or less like a free fall. It will then sink far below the surface, never to rise.

Nikola Tesla

The Earthquake Tidal Wave of Feb. 26, as Described by First Officer Brown, of the Steamship Planet Neptune

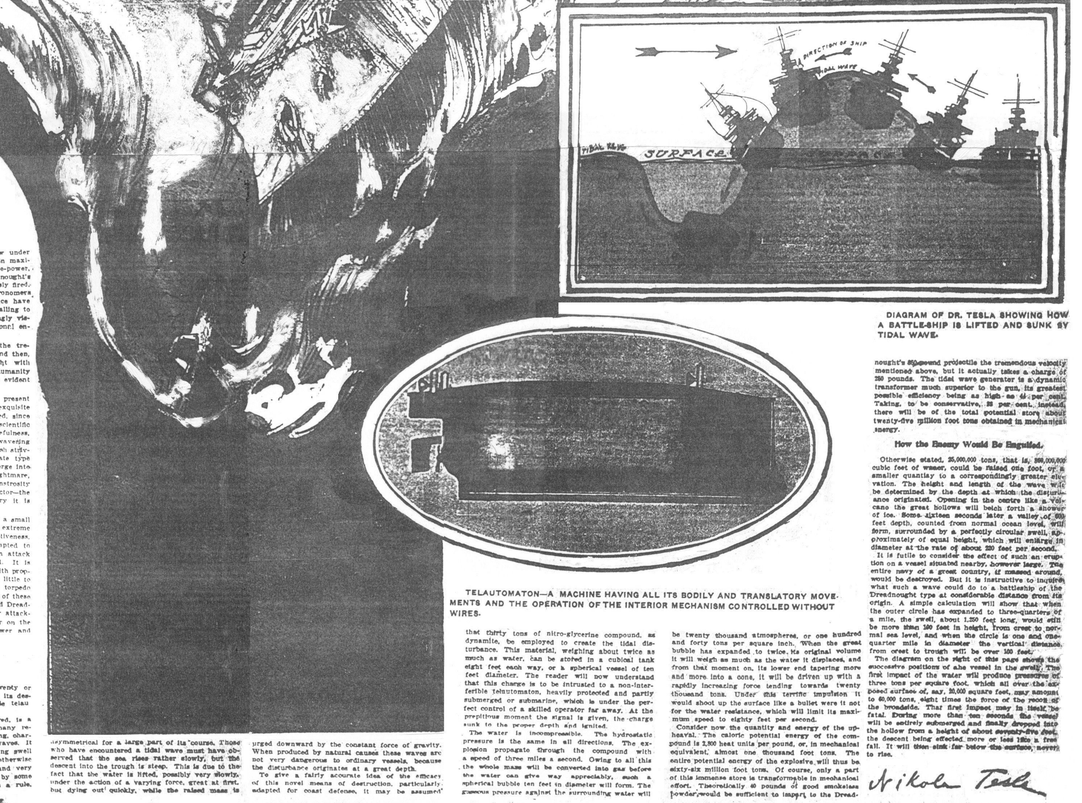


DIAGRAM OF DR. TESLA SHOWING HOW A BATTLE-SHIP IS LIFTED AND SUNK BY TIDAL WAVE.

TELAUTOMATON—A MACHINE HAVING ALL ITS BODILY AND TRANSLATORY MOVEMENTS AND THE OPERATION OF THE INTERIOR MECHANISM CONTROLLED WITHOUT WIRES.

Terrors of Tidal Wave Caused by an Earthquake at Sea.

Earthquakes on land are familiar, at least from hearsay, to everybody, but earthquakes in the depths of the sea are rarely heard of and even more rarely felt. They do take place, however, and sometimes cause tremendous tidal waves. The daily papers ten days ago contained a brief account of the experience of the steamship Planet Neptune in passing over the site of a submarine earthquake. The following account of it was written for the Sunday World by First Officer Vans Brown, who was on the bridge of that vessel when the awful thing happened.

BY VANS BROWN

First Officer, Steamship Planet Neptune.

I HOPE, as a seafaring man, that I shall never have to go through such an experience as we all had on the steamship Planet Neptune on the evening of Feb. 26. All hands thought their last hour had come.

The Planet Neptune had left Montevideo for New York a few days before. Everything went well for the first few days out. The sea was fairly calm. I was on the bridge with no thought that anything would happen. Most of the crew were below.

All of a sudden there was some mighty catclysm of the floor of the sea.

It could have been nothing less than a submarine earthquake. This is not uncommon, as a matter of fact. Several of my friends who have followed the sea have had the same experience, but none went through what we did.

There was no warning. It just seemed as if the bottom had fallen out of the sea. The big ship just dropped right down—there is no other way to describe it. It seemed as if we were going down into a bottomless pit. Actually we were falling into a great hole in the water.

It is hard to describe the sensation, for it seemed as though down, down, down we fell—I thought we should never stop, ship and all. I grabbed the flying bridge railing and held on for dear life. But we did stop. And then, to my horror, when I looked up there was a giant wave curling over us and ready to break.

A moment later it broke upon us, tons and tons of water. It seemed as if the ship had been lifted right up in the air and had fallen upon us.

Most of the loose gear on the deck was swept away. We had several coops of chickens on deck. They were carried away, of course. Two boats, all the deck gear, water butts—all were smashed and washed away. A dozen ports were smashed in, letting the water inside the ship. I thought we were all gone.

But the ship stood the shock. She shivered, her bows rose and up we popped as if she had been a toy boat in a bath tub. We were safe.

But poor Seaman Shalburg lay unconscious on the deck. He had been lookout and he was thrown against a stanchion. His leg was broken, he had concussion of the brain and internal injuries. I guess he will be a cripple for life.

The superstructure of the ship was well battered, too. But the ship proved her seaworthiness and it didn't affect our voyage north at all. Just as quickly, too, the sea calmed down again and the big wave died away in ripples.

But it was like your Niagara while it lasted. For thousands of yards round the great hole in the sea the waves were churned up into whitecaps. Yet there was no storm.

Give me a storm every time. There are no holes in the water then, and if you are a good sailor you can get out of it. But don't give me a submarine earthquake ever again.

The New York Times May 2, 1907

NICOLA TESLA OBJECTS.

Thinks He Should Receive Credit for His Own Inventions.

To the Editor of The New York Times:

I have been much surprised to read in THE TIMES of Sunday, April 21, that Admiral H. N. Manney, U. S. N., attributes a well-known invention of mine, a process for the production of continuous electrical oscillations by means of the electric arc and condenser, to Valentine Poulsen, the Danish engineer. This improvement has been embodied by me in numerous forms of apparatus identified with my name, and I have described it minutely in patents and scientific articles. To quote but one of many references, I may mention my experimental lecture on "Light and Other High-Frequency Phenomena," published under the auspices of the Franklin Institute and the National Electric Light Association, for which both of these societies have distinguished me.

I share with Admiral Manney in the gratification that we are in the lead, and particularly that wireless messages have been transmitted from Pensacola to Point Lorne. Inasmuch, however, as this feat could not have been accomplished except by the use of some of my own devices, it would have been a graceful act on his part to bring this feat to the attention of the wireless conference. My theory has always been that military men are superior to civilians in courtesy. I have not been discouraged by the refusal of our Government to adopt my wireless system six years ago, when I offered it, nor by the unpleasant prospect of my passing through the experiences described by Mark Twain in his story of the beef contract, but I see no reason why I should be deprived of a well-earned honor and satisfaction.

THE TIMES has hurt me grievously; not by accusing me of commercialism, nor by its unkind editorial comments on those letters I wrote, in condemnation of my system of power transmission in the Subway. It is another injury, perhaps unintentional, which I have felt most keenly.

The editor of THE TIMES may not have known that I am a student of applied mathematics when he permitted a fellow student of mine to insinuate in THE TIMES of March 28 that I avail myself of inventions of others. I cannot permit such ideas to gain ground in this community, and, just to illuminate the situation, I shall quote from the leading electrical paper, The London Electrician, referring to some wireless plants of Braun and Marconi: "The spark occurs between balls in the primary circuit of a Tesla coil. The air wire * * * is in series with a Tesla transformer. * * * The generating plant is virtually a Poldhu in miniature. Evidently Braun, like Marconi, has been converted to the high-potential methods introduced by Tesla." Needless to add that this substitution of the old, ineffective Hertzian appliances for my own has not been authorized by me.

My fellow-student can rest assured that I am scrupulously respecting the rights of others. If I were not prompted to do so by a sense of fairness and pride I would be by the power I have of inventing anything I please.

N. TESLA.

New York, April 30, 1907.

TESLA'S TIDAL WAVE TO MAKE WAR IMPOSSIBLE.*

By NIKOLA TESLA.

JUST at this time, when all efforts towards peaceful arbitration notwithstanding, the nations are preparing to expend immense sums in the design and construction of monstrous battleships, it may be useful to bring to the attention of the general public a singular means for naval attack and defence, which the telautomatic art has made possible, and which is likely to become a deciding factor in the near future.

A few remarks on this invention, of which the wireless torpedo is but a special application, are indispensable to the understanding and full appreciation of the naval principle of destruction.

The telautomatic art is the result of endeavours to produce an automaton capable of moving and acting as if possessed of intelligence and distinct individuality. Disconnected from its higher embodiment, an organism, such as a human being, is a heat—or thermodynamic engine—comprising:—(1) a complete plant for receiving, transforming, and supplying energy; (2) apparatus for locomotion and other mechanical performance; (3) directive organs; and (4) sensitive instruments responsive to external influences, all these parts constituting a whole of marvellous perfection.

The ambient medium is alive with movement and energy, in a state of unceasing agitation which is beyond comprehension. Strangely enough, to most of this terrible turmoil the human machine is insensible. The automation does not feel the weight of the atmosphere crushing him with a force of 16 tons. He is unaffected by the shower of particles shooting through his body of cloud and the hurricane of finer substance rushing through him with the speed of light. He is unconscious that he is being whisked through space at the fearful rate of 70,000 miles an hour. But when gentle waves of light or sound strike him his eye and ear respond, his resonant nerve-fibres transmit the vibrations and his muscles contract and relax. Thus, like a float on a turbulent sea, swayed by external influences, he moves and acts. The average person is not aware of this constant dependence on his environment, but a trained observer has no difficulty in locating the primary disturbance which prompts him to action, and continued exercise soon satisfies him that virtually all of his purely mechanical motions are caused by visual impressions, directly or indirectly received.

Using the Principles of Human Action.

A machine of such inconceivable complexity as the body of an organised being, capable of an infinite variety of actions, with controlling organs supersensitive, responsive to influences almost immaterial, cannot be manufactured by man; but the mechanical principles involved in the working of the living automaton are also applicable to an inanimate engine, however crude.

An automobile boat was first employed to carry out the idea. Its storage battery and motor furnished the power: the propeller and rudder, respectively, served as locomotive and directive organs, and a very delicate electrical device, actuated by a circuit tuned to a distant transmitter, took the place of the ear. This mechanism followed perfectly the wireless signals or comments of the operator in control of the transmitter, performing every movement and action as if it had been gifted with intelligence.

The next step was to individualise the machine. The attunement of the controlling circuits gave it a special feature, but this was not sufficiently distinctive. An individuality implies a number of characteristic traits which, though perhaps extant elsewhere, are unique in that particular combination. Here again the animated automaton, with its nerve-signal system, was coarsely imitated. The action of the delicate device—the ear—was made dependent on a number of sensitised receiving circuits, each recognisable by its own free vibrations, and all together by the character of their operative combination. Correspondingly the transmitter was designed to emit a wave-complex exactly matching the combination in the number and pitch of individual vibrations, their groupment and order of succession.

Wonders of the New Telautomaton.

That much is done, but more is to come. A mechanism is being perfected which without operator in control, left to itself, will behave as if endowed with intelligence of its own. It will be responsive to the faintest external influences and from these, unaided, determine its subsequent actions as if possessed of selective qualities, logic, and reason. It will perform the duties of an intelligent slave. Many of us will live to see Bulwer's dream realised.

The reader for whom the preceding short explanation of this novel art is intended may think it simple and easy of execution, but it is far from being so. It has taken years of study and experiment to develop the necessary methods and apparatus, and five inventions, all more or less fundamental and difficult to practise, must be employed to operate successfully an individualised telautomaton.

Such a novel engine of war—a vessel of any kind, submarine or aërial—carrying an agent of unlimited potency of destruction, with no soul aboard, yet capable of doing all it is designed for, as if fully equipped with a fearless crew in command of its captain, must needs bring on a revolution in the present means of attack and defence.

Since ages human ingenuity has been bent upon inventing infernal machines. Of these the modern cannon has been so far the most remarkable. A 12in. gun charged with cordite is said to hurl a projectile of 850lb. with the initial velocity of nearly 2,900ft. per second, imparting to it the energy of 110,000,000ft.lb. Were it not for the resistance of the air such a projectile would travel about fifty miles before striking the ground. It would take 3,300H.P. more than a minute to accumulate its mechanical energy. Bear in mind, however, that all this energy is imparted to the projectile while it is being urged through the gun-barrel with a mean force of 1,100 tons. If the barrel is 50ft. long and the average velocity through it 1,500ft. per second, the whole energy is transferred to the moving mass in $\frac{1}{300}$th of a second; hence the rate of performance is 1,800 times the above—that is about 6,000,000H.P. This seems wonderful indeed, but is nothing as compared with rates obtainable by other means. Electricity can be stored in the form of explosive energy of a violence against which the detonation of cordite is but a breath. With a magnifying transmitter, as diagrammatically illustrated, rates of 25,000,000H.P. have already been obtained. A similar and much improved machine, now under construction, will make it possible to attain maximum explosive rates of over 800,000,000H.P., twenty times the performance of the *Dreadnought's* broadside of eight 12in. guns simultaneously fired. These figures are so incredible that astronomers unacquainted with this marvellous appliance have naturally doubted the practicability of signalling to Mars. In reality, by its means this seemingly visionary project has been reduced to a rational engineering problem.

The time is not far distant when all the tremendous wastes of war will be stopped, and then, if there are battles, they will be fought with water-power and electrical waves. That humanity is moving fast towards this realisation is evident from many indications.

What is most to be regretted in the present war *régime* is that the effort of so many exquisite intelligences must be uneconomically applied, since it cannot be steadily directed towards a scientific truth, unalterable and of permanent usefulness, but must be entirely governed by the wavering struggle of opposing principles. This feverish striving to meet the instant demand, to create type after type, one to devour the other, to merge into one contrasting element, leads, like a nightmare, from one to another absurdity. Such a monstrosity is the latest creation of the naval constructor—a 20,000 ton battleship. In theory it is condemned by competent authorities.

Everything points to the development of a small vessel with internal combustion engines, extreme speed, and few weapons of great destructiveness. But the new leviathan is admirably adapted to the practical requirements of the day. In attack it could alone annihilate a nation's fleet. It is equally effective in defence. If equipped with proper acoustic and electrical appliances it has little to fear from a submarine, and an ordinary torpedo will scarcely hurt it. That is why the first of these monsters, built in England, has been named *Dreadnought*. Now, there is a novel means for attacking a fortress of this kind, from shore or on the high seas, against which all its gun-power and armour resistance are of no avail. It is the tidal wave.

What the Tesla Tidal Wave will Do.

Such a wave can be produced with twenty or thirty tons of cheap explosive, carried to its destination and ignited by a non-interferible telautomaton.

The tidal disturbance, as here considered, is a peculiar hydrodynamic phenomenon, in many respects different from the commonly occurring, characterised by a rhythmical succession of waves. It consists generally of but a single advancing swell succeeded by a hollow, the water if not otherwise agitated being perfectly calm in front and very nearly so behind. The wave is produced by some sudden explosion or upheaval, and is, as a rule, asymmetrical for a large part of its course. Those who have encountered a tidal wave must have observed that the sea rises rather slowly, but the descent into the trough is steep. This is due to the fact that the water is lifted, possibly very slowly, under the action of a varying force, great at first, but dying out quickly, while the raised mass is urged downward by the constant force of gravity. When produced by natural causes these waves are not very dangerous to ordinary vessels, because the disturbance originates at a great depth.

To give a fairly accurate idea of the efficacy of this novel means of destruction, particularly adapted for coast defence, it may be assumed that thirty tons of nitro-glycerine compound, as dynamite, be employed to create the tidal disturbance. This material, weighing about twice as much as water, can be stored in a cubical tank 8ft. each way, or a spherical vessel of 10ft. diameter. The reader will now understand that this charge is to be entrusted to a non-interferible telautomaton, heavily protected, and partly submerged or submarine, which is under the perfect control of a skilled operator far away. At the propitious moment the signal is given, the charge sunk to the proper depth and ignited.

The water is incompressible. The hydrostatic pressure is the same in all directions. The explosion propagates through the compound with a speed of three miles a second. Owing to all this, the whole mass will be converted into gas before the water can give way appreciably, and a spherical bubble 10ft. in diameter will form. The gaseous pressure against the surrounding water will be 20,000 atmospheres, or 140 tons per square inch. When the great bubble has expanded to twice its original volume it will weigh as much as the water it displaces, and from that moment on, its lower end tapering more and more into a cone, it will be driven up with a rapidly-increasing force tending towards 20,000 tons. Under this terrific impulsion it would shoot up the surface like a bullet were it not for the water resistance, which will limit its maximum speed to 80ft. per second.

Consider now the quantity and energy of the upheaval. The caloric potential energy of the compound is 2,800 heat units per pound, or, in mechanical equivalent, almost 1,000ft.-tons. The entire potential energy of the explosive will thus be 66,000,000ft.-tons. Of course, only a part of this immense store is transformable into mechanical effort. Theoretically, 40lb. of good smokeless powder would be sufficient to impart to the *Dreadnought's* 850lb. projectile the tremendous velocity mentioned above, but it actually takes a charge of 250lb. The tidal wave generator is a dynamic transformer much superior to the gun, its greatest possible efficiency being as high as 44 per cent. Taking, to be conservative, 38 per cent. instead, there will be of the total potential store about 25 million foot-tons obtained in mechanical energy.

How the Enemy would be Engulfed.

Otherwise stated, 25,000,000 tons — that is, 860,000,000c.ft. of water, could be raised 1ft., or a smaller quantity to a correspondingly greater elevation. The height and length of the wave will be determined by the depth at which the disturbance originated. Opening in the centre like a volcano, the great hollows will belch forth a shower of ice. Some sixteen seconds later a valley of 600ft. depth, counted from normal ocean level, will form, surrounded by a perfectly circular swell, approximately of equal height, which will enlarge in diameter at the rate of about 220ft. per second.

It is futile to consider the effect of such an eruption on a vessel situated near-by, however large. The entire navy of a great country, if massed around, would be destroyed. But it is instructive to inquire what such a wave could do to a battleship of the Dreadnought type at considerable distance from its origin. A simple calculation will show that when the outer circle has expanded to three-quarters of a mile, the swell, about 1,250ft. long, would still be more than 100ft. in height, from crest to normal sea level, and when the circle is one and one-quarter mile in diameter the vertical distance from crest to trough will be over 100ft.

The first impact of the water will produce pressures of three tons per square foot, which all over the exposed surface of, say, 20,000sq.ft., may amount to 60,000 tons, eight times the force of the recoil of the broadside. That first impact may in itself be fatal. During more than ten seconds the vessel will be entirely submerged and finally dropped into the hollow from a height of about 75ft., the descent being effected more or less like a free fall. It will then sink far below the surface, never to rise.

* From the *New York World*.

TESLA'S TIDAL WAVE.

[383.]—To the man in the street these "high falutin'" descriptions of the Jules Verne order may be exciting: to the practical engineer they provoke a large amount of contempt. Some years ago Mr. Tesla propounded to the newspaper men that he had invented a new means of transmitting large amounts of horse-power across the world—New York to Paris I think. There was a lot of preliminary very tall talk, and one received queries from various sources as to the truth of this new American wonder. For my part I advised large doses of sodium chloride, and finally the "wonder" collapsed, and it appeared the H.P. was to be placed on board a boat in the form of a storage-battery, a means of conveying H.P. to Paris or elsewhere which has been in use (before Tesla was born or thought of) in the form of the old-time "Geordie" collier of our own Tyne, only it carried coal instead of storage-cells.

In the case in question the cells were used to drive or steer the vessel under the control of a director ashore with a wireless telegraph. Given the invention of the transmission of H.P. in a boat whether in the form of coal in a "Geordie" or accumulators in a submarine, or compressed air in a torpedo; given also the wireless telegraph, the use of the latter to steer the former was all that was left for Tesla to talk about doing. Whether even this has come into successful being, except in the smoke of an after-dinner cigar, I do not know; but I should like to. How, for instance, can the director ashore tell where the submarine is? With a crew on board, the ordinary submarine captain finds it difficult enough to locate his position when he has been diving for some time.

On page 296 this would-be wonder appears again. Now it is not carrying accumulators to Paris, but becomes an animated submarine mine. It carries 30 tons dynamite, the explosion of which is intended to create a tidal wave, and destroy the *Dreadnought* and the Navy generally massed together in the neighbourhood. [Before letting it off, all persons living in the same hemisphere will be warned by wireless or other telegraph not to leave "the baby on the shore," or, indeed, any other property, within 500 yards of the sea, otherwise the tidal wave starter could not be held responsible for its devastations. N.B.—This warning was no doubt omitted from the *New York World*, but it is only too obviously necessary.]

Let us consider the proposed destruction of the *Dreadnought*. If she were close over the explosion, we might agree with Tesla as to the nature of the result. If, however, she were, as in the case he describes, a three-quarter mile off, she would encounter the wave of the explosion about 100ft. high, say about twice the height of the usual ocean wave storms, and 1,250ft. long, a comparatively gentle slope of water up and down, as anyone may see who draws it to scale, say 6in. long by ⅛in. high, coming at a speed of 220ft. per second. [Airy, and also Scott, give a considerably lower velocity, especially in deep water.] Tesla does not say what depth he takes, but we accept his figure. The resulting action is simply the rising of the water about the ship 100ft. in three seconds, and then sinking in the same time. The question as to whether her buoyancy would overcome her inertia so as to raise her at this rate may be left to the mathematicians. Supposing, however, she were immersed during the passage of the wave—i.e., for some fraction of six seconds, possibly three seconds, it is not necessary to suppose she will not "bob up serenely" afterwards. Ordinary vessels on ordinary tidal waves do so. An old skipper told me of a case where he and his mate on a little coaster, hearing the roar of an enormous wave approaching, sprang into the rigging. The whole hull becoming deeply immersed, the mate yelled, "She's down!" My friend replied: "Not so long as you can see the masts." And she rose trembling out of the depths.

Be that as it may, there are other consequences not considered; for instance, the after-effects of this tidal wave. Whatever fate would befall the *Dreadnought* would depend partly on the state of her preparedness, which would probably be complete when artificial tidal waves were raging around. What about merchant vessels within a few miles? Also, what about low-lying shores and their inhabitants? For we must remember that when such waves get into shallow water they rise in height and then break and sweep long distances inland in a solid rush of water. Fancy such a wave in New York Harbour, or the bore of one rushing up the Mersey or Belfast Lough, or any estuary, and the millions of innocent New Yorkers or coast dwellers anywhere that would be drowned. No, no: international law would step in, and public opinion would class tidal-wave starters with dynamitards, pirates, assassins, Guy Fawkes, and all the other vermin that have disgraced the human race.

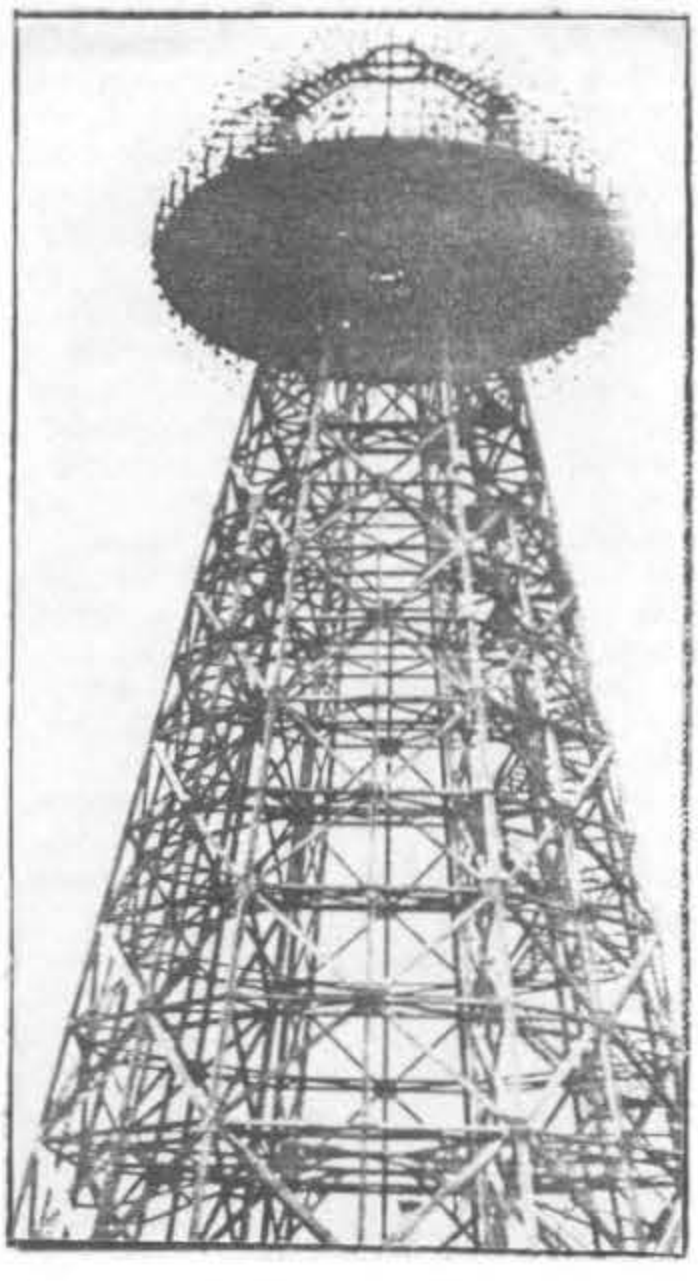
The Brooklyn Daily Times June 12, 1907

TESLA'S BIG TOWER TO BE SOLD FOR DEBT



GREAT INVENTOR'S PET SCHEME SEEMS TO HAVE RECEIVED A BLOW

JUDGMENT IS FOR $1,108.20

Structure Was 150 Feet High in Air and 150 Feet Shaft in Ground— Has Been a Mystery Ever Since It Was Built— Magnificent Ideas.

(Special to the Brooklyn Times.)

Riverhead, L. I., ~~June 12.~~ ~~The Tow~~er of Wonders at Wardencliffe, where Nikola Tesla, the inventor, preserved such mystery and where it was whispered scientific experiments were to be carried on greater in scope than any ever before attempted, is for sale. The Sheriff of Suffolk County to-day advertised the entire property to be disposed of to satisfy a judgment held by Dr. James S. Warden. The Tesla property consists of 200 acres and the wonderful steel tower 150 feet high and with a shaft sunk 150 feet in the ground. Tesla has spent a fortune in rearing the huge steel mass, which ever since its building has been the theme for discussion among the puzzled laymen of the Island.

TESLA TOWER AT WARDENCLIFF.

What did Tesla intend to do? This is the question that for a long time perplexed the people living in the Wading River and Wardencliffe neighborhood. It was at first believed that he intended experimenting with a project to store solar rays and transmit their power in some merchantable form. In a scientific treatise, he had promulgated the belief that it was possible to attract solar energy and find a market for the stored power. The height of the tower and its peculiar dome-shaped top readily lent substance to the belief that Tesla did, indeed, intend to utilize the sun's rays for motive power.

However, nothing has ever been learned of the Tower of Wonders. Tesla himself is a brave fellow, not seeking notoriety, and steadfastly holding to his belief, recently endorsed by Edison, that in regard to electricity the human race knows little or nothing. Just previous to building the tower, Tesla expounded the theory that messages could be transmitted between any points on the globe, using the earth as a medium, and there were not lacking people who asserted that his huge shaft was sunk 150 feet in the ground in order that messages might be transmitted through the earth's substance.

The tower itself is a bare steel structure. Near the base is a machine house of some kind. This is filled with intricate machinery. No one, so far as it known, has ever been able to find out from Tesla or his men just what the machinery is for and what was or is to be done with it. Visitors are not welcome and they are told very politely that the property is private and trespassing is not desired.

Niles and Johnson, of Wall street, are the attorneys for the sale. The judgment is for $1,108.20, and will probably be settled.

Nikola Tesla came into prominence many years ago as an inventor. In 1884 he took out citizenship papers and since that time has lived in America. He has of late years spent nearly all of his time on his scheme of world telegraphy and telephony and in designing plans for the transmission of power without a direct medium. He is a man of the most splendid visions and may prove to be as far ahead of the scientific world as Kepler was when his astronomical theories were scoffed at as dreams.

The Brooklyn Eagle June 13, 1907

TESLA WILL PAY UP.

Inventor Will Not Let His Wardenclyffe "Wonder Tower" Go Under the Hammer.

(Special to the Eagle.)

Riverhead, L. I., June 13—Under a judgment secured some time ago against Nikola Tesla, the inventor, Sheriff Wells has advertised for sale the Tesla property at Wardenclyffe, at Wading River, on which is located the big steel tower which has been so much of a mystery ever since it was built several years ago.

The "wonder tower," as it is called, is a huge structure of steel and cement, and no one appears to know exactly what it was intended for. That it was to be used to demonstrate his long-cherished theory of communicating with the Martians is popularly believed.

The judgment, which is for $1,108.20, is held by Dr. James W. Warden. The security is the two hundred acres owned by Tesla, upon which stands the tower, which is sunk into the ground a distance of 150 feet and is 150 feet in height.

Tesla is expected to satisfy the judgment and save his "wonder tower" from going under the hammer. The entire plant at Wardenclyffe is said to be valued at $350,000.

Colorado Springs, Col., June 13—Nikolai Tesla about ten years ago erected a laboratory and tower on Nob Hill, near this city, for experiments in the transmission of power without wires. This plant was valued at approximately $30,000. Shortly after he left this city the caretaker of the plant, a man named Duffmer, sued Tesla for about $1,000 salary. Subsequently the assessors' office levied upon the property for taxes, with the result that the building and machinery were sold under the judgment obtained by Duffmer, and the taxes were paid out of the proceeds of the sale.

TESLA'S TOWER LEVIED UPON.

Inventor's Mysterious Structure in Hands of Sheriff.

The steel tower, 216 feet high, erected by Nikola Tesla, the inventor, at the eastern end of Long Island, together with his entire property there, was advertised for sale by the sheriff of Suffolk County yesterday, to satisfy a judgment for $1,080. The judgment was obtained four years ago by Dr. James S. Warden and now belongs to his heirs. Mr. Tesla's tower has been a mystery for years. The public has never known the purpose for which it was erected. The property is at Wardencliffe, and consists of about 200 acres.

COLORADO SPRINGS, Col., June 13.—Nikola Tesla about ten years ago erected a laboratory and tower on Nob Hill, near this city, for experiments in the transmission of power without wires. The plant was valued at approximately $30,000. Soon after he left this city the caretaker of the plant, a man named Duffmer, sued Tesla for about $1,000 salary. Subsequently, the assessors' office levied upon the property for taxes, with the result that the building and machinery were sold under the judgment obtained by Duffmer, and the taxes were paid out of the proceeds of the sale.

The New York Sun June 13, 1907

SHERIFF TAKES TESLA'S TOWER

And the Inventor Guesses He'll Have to Pay a $1,080 Judgment Now.

The steel tower, 216 feet high, erected by Nikola Tesla, the inventor, at the eastern end of Long Island, together with his entire property there, was advertised for sale by the Sheriff of Suffolk county yesterday, to satisfy a judgment for $1,080. The judgment was obtained four years ago by Dr. James S. Warden and now belongs to his heirs.

Mr. Tesla, when seen at the Waldorf-Astoria last night, did not seem to be at all afraid that he would lose the tower, which has been a puzzle to the people of Long Island ever since it was erected four years ago. He was afraid, however, that he would have to pay the judgment.

"This is an old case which has been dragging in the courts for years," he explained. "I took an option on 400 acres of land down there at some distance from my property on which my plant is located. I intended to use this land for an agricultural experiment in fertilizing soil by means of electricity. I thought that by the use of certain electrical principles the productivity of the soil could be increased very much. I agreed to take a certain option, but subsequently discovered that the person who entered into the agreement had no right to make such a disposition of the property. I told him the option was off and paid no further attention to the matter. A year or so later a suit was brought and has been fought with varying results. The heirs of the owner have simply pressed the claim and it is very likely that it will have to be paid. It does not in the least affect my undertakings and the work at my plant."

Mr. Tesla said that altogether his plant was worth $350,000, but he refused to dispel the mystery surrounding the tower. At the time that work on this was begun it was reported that it was to send the human voice on wireless waves around the globe.

"I have no announcement to make now," sain Mr. Tesla. "In a few months I shall begin to manufacture new devices of mine at this plant and then I may have something of interest to say."

The Tesla property is at Wardencliffe and consists of 200 acres. The tower has a great mushroom top, from which there used to be blinding flashes of electricity at night some years ago.

CAN BRIDGE THE GAP TO MARS

Nikola Tesla on His Wireless System for the Transmission of Energy.

To the Editor of The New York Times:

You have called me an "inventor of some useful pieces of electrical apparatus." It is not quite up to my aspirations, but I must resign myself to my prosaic fate. I cannot deny that you are right.

Nearly four million horse power of waterfalls are harnessed by my alternating current system of transmission, which is like saying that one hundred million men—untiring, consuming nothing, receiving no pay—are laboring to provide for our wants, incidentally saving the waste of one hundred million tons of coal annually. In this great city the elevated roads, the subways, and street railways are operated by my system, and the lamps and other electrical appliances get the current through machinery of my invention. And as in New York so all the world over where electricity is introduced. The telephone and the incandescent lamp fill specific and minor demands, electric power meets the many general and sterner necessities of life. Yes, I must admit, however reluctantly, the truth of your unflattering contention.

But the greater commercial importance of this invention of mine is not the only advantage I have over my celebrated predecessors in the realm of the useful, who have given us the telephone and the incandescent lamp. Permit me to remind you that I did not have, like Bell, such powerful help as the Reis telephone, which reproduced music and only needed a deft turn of an adjusting screw to repeat the human voice; or such vigorous assistance as Edison found in the incandescent lamps of King and Starr, which only needed to be made of high resistance. Not at all. I had to cut the path myself, and my hands are still sore. All the army of my opponents and detractors was ever able to drum up against me in a fanatic contest has simmered down to a short article by an Italian—Prof. Ferraris—dealing with an abstract and physically meaningless idea of a rotating magnetic pole and published years after my discovery, months even after my complete disclosure of the whole practically developed system in all its essential universally adopted features. It is a publication, pessimistic and discouraging, devoid of the discoverer's virility and force, devoid of results, utterly wanting in the faith and devotion of the inventor, a defective and belated record of a good but feeble man whose only response to my whole-souled brother greeting was a plaintive cry of priority—a sad contrast to the strong and equanimous Schallenberger, a true American engineer, who stoically bore the pain that killed him.

A fundamental discovery or original invention is always useful, but it is often more than that. There are physicists and philosophers to whom the marvelous manifestations of my rotating magnetic field, the suggestive phenomena of rotation without visible connection, the ideal beauty of my induction motor with its contactless armature, mean quite as much as the thousands of millions of dollars invested in enterprises of which it is the foundation.

And this is true of all my discoveries, inventions, and scientific results which I have since announced, for I have never invented what immediate necessity suggested, but what I found as most desirable to invent, irrespective of time. Let me tell you only of one—my "magnifying transmitter," a machine with which I have passed a current of one hundred amperes around the globe, with which I can make the whole earth loudly repeat a word spoken in the telephone, with which I can easily bridge the gulf which separates us from Mars. Do you mean to say that my transmitter is nothing more than a "useful piece of electrical apparatus"?

I do not wish to enlarge on this for obvious reasons. To be compelled by taciturn admirers to dwell on my own achievements is hurting my delicate sensibilities, but as I observe your heroic and unceasing efforts in praising your paper, while your distinguished confreres maintain on its merits a stolid silence, I feel that there is, at least, one man in New York able to appreciate the incongeniality of this correspondence. Allow me to ask you just one or two questions in regard to a work which I began in 1892, inspired by a high tribute from Lord Rayleigh at the Royal Institution, most difficult labor which I have carried on for years, encouraged by the sympathetic interest and approval of Helmholtz, Lord Kelvin, and my great friends, Sir William Crookes and Sir James Dewar, ridiculed by the small men whose names I have seen displayed in vulgar and deceptive advertisements. I refer to my system of wireless transmission of energy.

The principles which it involves are eternal. We are on a conducting body, insulated in space, of definite and unchangeable dimensions and properties. It will never be possible to transmit electrical energy economically through this body and its environment except by essentially the same means and methods which I have discovered, and the system is so perfect now that it admits of but little improvement. Since I have accepted as true your opinion, which I hope will not be shared by posterity, would you mind telling a reason why this advance should not stand worthily beside the discoveries of Copernicus? Will you state why it should not be ever so much more important and valuable to the progress and welfare of man?

We could still believe in the geocentric theory and yet advance virtually as we do. The work of the astronomer would suffer, for some of his deductions would rest on erroneous assumptions. But, after all, we shall never know the intimate nature of things. So long as our perceptions are accurate our logic will be true. No one can estimate to what an extent the great knowledge he conveyed has been instrumental in developing the power of our minds and furthering discovery and invention. Yet, it has left all the pressing material problems confronting us unsolved.

Now my wireless system offers practical solutions for all. The aerial navigation, which now agitates the minds, is only one of its many and obvious applications equally consequential. The waterfalls of this country alone, its greatest wealth, are adequate to satisfy the wants of humanity for thousands of years to come. Their energy can be used with the same facility to dig the Panama Canal as to operate the Siberian Railway or to irrigate and fertilize the Sahara. The Anglo-Saxon race has a great past and present, but its real greatness is in the future, when the water power it owns or controls shall supply the necessities of the entire world.

As to universal peace—if there is nothing in the order of nature which makes war indispensable to the safe and sane progress of man, if that utopian existence is at all possible, it can be only attained through this very means, for all international friction can be traced to but one cause—the immense extension of the planet. My system of wireless transmission completely annihilates distance in all departments of human activity.

If this does not appeal to you sufficiently to recognize in me a discoverer of principles, do me, at least, the justice of calling me an "inventor of some beautiful pieces of electrical apparatus."

NIKOLA TESLA.

New York, June 21, 1907.

Tesla.

The following letter from Mr. Nikola Tesla appeared in the *New York Times* of Sunday, June 23:

"You have called me an 'inventor of some useful pieces of electrical apparatus.' It is not quite up to my aspirations, but I must resign myself to my prosaic fate. I cannot deny that you are right.

"Nearly 4,000,000 horse-power of waterfalls are harnessed by my alternating-current system of transmission, which is like saying that one hundred million men—untiring, consuming nothing, receiving no pay—are laboring to provide for our wants, incidentally saving the waste of one hundred million tons of coal annually. In this great city the elevated roads, the subways, and street railways are operated by my system, and the lamps and other electrical appliances get the current through machinery of my invention. And as in New York so all the world over where electricity is introduced. The telephone and the incandescent lamp fill specific and minor demands, electric power meets the many general and sterner necessities of life. Yes, I must admit, however reluctantly, the truth of your unflattering contention.

"But the greater commercial importance of this invention of mine is not the only advantage I have over my celebrated predecessors in the realm of the useful, who have given us the telephone and the incandescent lamp. Permit me to remind you that I did not have, like Bell, such powerful help as the Reis telephone, which reproduced music and only needed a deft turn of an adjusting screw to repeat the human voice; or such vigorous assistance as Edison found in the incandescent lamps of King and Starr, which only needed to be made of high resistance. Not at all. I had to cut the path myself, and my hands are still sore. All the army of my opponents and detractors was ever able to drum up against me in a fanatic contest has simmered down to a short article by an Italian—Prof. Ferraris—dealing with an abstract and physically meaningless idea of a rotating magnetic pole and published years after my discovery, months even after my complete disclosure of the whole practically developed system in all its essential universally adopted features. It is a publication, pessimistic and discouraging, devoid of the discoverer's virility and force, devoid of results, utterly wanting in the faith and devotion of the inventor, a defective and belated record of a good but feeble man whose only response to my whole-souled brother greeting was a plaintive cry of priority—a sad contrast to the strong and equanimous Schallenberger, a true American engineer, who stoically bore the pain that killed him.

"A fundamental discovery or original invention is always useful, but it is often more than that. There are physicists and philosophers to whom the marvelous manifestations of my rotating magnetic field, the suggestive phenomena of rotation without visible connection, the ideal beauty of my induction motor with its contactless armature, mean quite as much as the thousands of millions of dollars invested in enterprises of which it is the foundation.

"And this is true of all my discoveries, inventions and scientific results which I have since announced, for I have never invented what immediate necessity suggested, but what I found as most desirable to invent, irrespective of time. Let me tell you only of one—my 'magnifying transmitter,' a machine with which I have passed a current of 100 amperes around the globe, with which I can make the whole earth loudly repeat a word spoken in the telephone, with which I can easily bridge the gulf which separates us from Mars. Do you mean to say that my transmitter is nothing more than a 'useful piece of electrical apparatus'?

"I do not wish to enlarge on this for obvious reasons. To be compelled by taciturn admirers to dwell on my own achievements is hurting my delicate sensibilities, but as I observe your heroic and unceasing efforts in praising your paper, while your distinguished confreres maintain on its merits a stolid silence, I feel that there is, at least, one man in New York able to appreciate the incongeniality of this correspondence. Allow me to ask you just one or two questions in regard to a work which I began in 1892, inspired by a high tribute from Lord Rayleigh at the Royal Institution, most difficult labor which I have carried on for years, encouraged by the sympathetic interest and approval of Helmholtz, Lord Kelvin, and my great friends, Sir William Crookes and Sir James Dewar, ridiculed by the small men whose names I have seen displayed in vulgar and deceptive advertisements. I refer to my system of wireless transmission of energy.

"The principles which it involves are eternal. We are on a conducting body, insulated in space, of definite and unchangeable dimensions and properties. It will never be possible to transmit electrical energy economically through this body and its environment except by essentially the same means and methods which I have discovered, and the system is so perfect now that it admits of but little improvement. Since I have accepted as true your opinion, which I hope will not be shared by posterity, would you mind telling a reason why this advance should not stand worthily beside the discoveries of Copernicus? The Anglo-Saxon race has a great past and present, but its real greatness is in the future, when the water power it owns or controls shall supply the necessities of the entire world.

"As to universal peace—if there is nothing in the order of nature which makes war indispensable to the safe and sane progress of man, if that utopian existence is at all possible, it can be only attained through this very means, for all international friction can be traced to but one cause—the immense extension of the planet. My system of wireless transmission completely annihilates distance in all departments of human activity.

"If this does not appeal to you sufficiently to recognize in me a discoverer of principles, do me, at least, the justice of calling me an 'inventor of some beautiful pieces of electrical apparatus.'"

LETTER TO THE EDITORS.

Wireless Transmission of Energy.

To the Editors of Electrical World:

SIRS:—The writer has read with a good deal of interest the reprint in your issue of June 29, 1907, of Mr. Nikola Tesla's recent letter to the *New York Times.*

In this letter it is to be observed that Mr. Tesla is still harping on his system for the "wireless transmission of energy" and proclaiming it as a discovery deserving to rank with that of Copernicus. It occurs to the writer, however, that we have been hearing about this system (mostly from Mr. Tesla himself) for a number of years, but apparently the "system" has never progressed beyond the *paper* stage.

At the exposition in St. Louis in 1904, a very substantial purse was offered to anyone who would succeed in transmitting even one-tenth of a horse-power a few hundred feet without

wires, but there were no successful contestants. May I enquire why Mr. Tesla did not wade in boldly and carry off the prize? And if he will enlighten us as to how *many* air ships he has *in operation,* deriving their power from water-falls, it will be greatly appreciated.

No one appreciates Mr. Tesla's achievements in the electrical field more than the writer, but it certainly seems that it is incumbent upon the inventor to show why his "system" of wireless transmission has failed to materialize, practically.

WASHINGTON, D. C. J. HANSON BOYDEN.

Nikola Tesla writes to the New York Times under date of July 2d to say that he is receiving many notices and inquiries on the subject of Martian signaling, mentioned in his letter in the Times of Sunday, June 23d. He refers those who have taken occasion to comment on this feature of the letter to his recent article in The Harvard Illustrated Magazine, which is all he cares to say now despite "tauntings and temptations." For particular reasons, he says, that he reserves his full technical report, descriptive of the apparatus and results for the records of old institutions—academies of science—of which he is an honorary member.

The Brooklyn Eagle July 26, 1907

MAY KEEP HIS TOWER.

Tesla, Wizard of Wardenclyffe, Not to Be Sold Out.

(Special to the Eagle.)

Riverhead, L. I., July 26—Having settled the judgment against him by Dr. James S. Warden, Nicola Tesla, the wizard of Wardencylffe, may retain possession of his mysterious steel tower there. It was to have been sold by the sheriff on Monday, but the sale is off. The judgment has been paid.

The New York Herald July 29, 1907

TESLA SNEERS AT GLIDING CRAFT

Declares Hydroplane Invention of Peter Cooper Hewitt Is Old and Worthless.

HIS JEALOUSY CRITICISED

In Letter in New York Times Electrical Expert Takes Petulant Fling at Achievement.

Many persons were surprised yesterday at the following letter from Nicola Tesla, published in the New York Times, and which seems to have been inspired by jealousy of Mr. Peter Cooper Hewitt's invention and achievements with a hydroplane, described in recent issues of the HERALD:—

GLIDING CRAFT.

Nicola Tesla Says the Hydroplane is Neither New Nor Practical.

To the Editor of the New York Times:—

The science of engineering has become so positive and precise that practical results are generally in close agreement with theory, and pretty nearly everything turns out as expected. Naturally, then, the exercise of this profession is more or less tedious and uninteresting. Occasionally, though, life is infused into the apathetic community by the sudden announcement of some stunning scheme or puzzling travesty of some old discovery or invention.

Two weeks ago an enterprising journal of this city created quite a ripple of excitement in engineering circles by the news that a most novel and startling advance in marine propulsion had been made. It was a gliding craft or "hydroplane," which was to make a speed of 100 miles an hour possible. The discovery was indorsed by a great engineer and a naval officer of no mean attainments, both of whom preferred to remain incognito. For a good reason, I should think. When it comes to being identified with the "hydroplane" discretion is decidedly better than valor. As a matter of fact, it is an old and worthless idea, an illusion and a snare.

The Times has done some good service in dispelling the myth of novelty in its issue of the 17th inst., but the optimistic tone of the otherwise accurate report will only tend to add to the number of those who have fallen victims of the delusion.

NICOLA TESLA.

NEW YORK, July 26, 1907.

After reading the letter Mr. Hewitt dictated the following reply:—

"My attention has been called to a letter published in the New York Times and I feel compelled in fairness to the future of the art employed by devices using planes as a means of support, such as hydroplanes and aeroplanes, to state that the old idea is not 'worthless,' but that in a short time it will find its field of utility in the world's work. The gliding craft referred to was designed to demonstrate by performance some of the most interesting theories that have been from time to time forecast by great scientists and engineers. The performance of the gliding craft was so successful and so near to theory that it impressed others as well as myself with the great possibilities of the art in the future."

Mr. Hewitt declined to make any further comment upon the motives behind Mr. Tesla's letter, but several experts who have given the invention close study asserted that it gave promise of greater importance to the world generally than anything ever accomplished by Mr. Tesla.

Both Mr. Tesla and Mr. Hewitt are men of international reputation and by friends of both Mr. Tesla's petulant fling at the achievement of a brother scientist was a matter of much surprise.

Particularly was his sneer at the "great engineer and naval officer of no mean attainments" regarded as beneath the dignity of a man of Mr. Tesla's reputation.

Both the engineer and the naval officer referred to are men whose scientific opinions overbalance those of Mr. Tesla, and their names were withheld from publication because of the request of Mr. Hewitt.

Their indorsement of the possibilities of the hydroplane, following its performances, will count for a great deal more than Mr. Tesla's jealous and prejudiced slur based entirely upon theory.

The New York Herald July 30, 1907

MR. TESLA ON GLIDING BOAT

TO THE EDITOR OF THE HERALD

The imputation in a report contained in your issue of this morning that in condemning the old and fallacious idea of the gliding boat or "hydroplane" I was prompted by jealousy, must have provoked some mirth among those who are acquainted both with my friend Cooper Hewitt and myself and our respective endeavors and accomplishments. But there is nothing to laugh about in the assertion that this worthless thing promises to be more important to the world than anything I have done. Thousands of millions of dollars are invested in enterprises based on my inventions in the transmission of power alone, and yet they are less than twenty years old. Not one cent is invested in the "hydroplane," although it has been well known and tried again and again for the last fifty years.

My opinion is not founded "merely on theory," as you seem to believe. I always try to be as thorough as possible. It is a characteristic trait of my family. Permit me to give an example. Sometime in 1899, while I was carrying on my wireless experiments in Colorado, a special despatch appeared in your columns to the effect that I was afflicted with consumption. Nothing could be further from my mind than the thought that the injury was intended. A great newspaper is a big, complicated machine difficult to control. I was simply run down by a one million horse power automobile. It was a small consolation that the chauffeur—I mean the editor—did not intend to do it. Nearly everybody in such a case would rush into print to deny. But I am a peculiar man. It occurred to me that—perhaps—if I waited eight or nine years my denial would be more convincing to the HERALD'S readers, and so it comes that I am taking advantage of this agreeable opportunity.

I have observed the same attitude as regards the "hydroplane." It so happened that long ago I hit upon a much better scheme of marine propulsion which appeared revolutionary. The errors I discovered after careful study turned out to be of the same nature as those involved in the gliding boat. Believing that I might be of service to those who were laboring under an illusion, I wrote to your distinguished confrère of the New York Times, concluding my letter as follows:

"Every ill spent effort is to be regretted. Should you think it desirable I shall be glad to expose in a popular and easily understandable manner the fallacies and deficiencies of the gliding craft on some occasion at your pleasure in the near future."

I was evidently misunderstood, but through my own fault.

You have criticised statements not intended for publication, which once more proves the truth of the proverb, "Gouvent les apparences sont trompeuses."

NIKOLA TESLA.

NEW YORK, July 29, 1907.

The New York Herald July 31, 1907

HEWITT ASKS TESLA TO SHOW "FALLACIES"

Builder of Gliding Craft Thinks Inventor Should Point to Errors He Sees.

In a letter to the HERALD, printed yesterday morning Nikola Tesla repeated the assertion made previously by him that the hydroplane, or gliding craft, recently built and demonstrated by Peter Cooper Hewitt is worthless as an invention and based upon a false and disproved theory.

When Mr. Hewitt's attention was directed to the letter yesterday he dictated the following answer:—

"I stated in the HERALD that I believed the hydroplane theory practical. My reasons, as then stated, were based on the performance of an experimental craft built by me to embody the essential features required by theory for a device of the hydroplane type. This experimental device, designed for the special purpose of testing theories, operated practically, not only once, but many times. In fact, it is a practical craft and with a few structural alterations would be a satisfactory commercial craft.

"In your issue of to-day there is the following statement by Nikola Tesla:—'Every ill spent effort is to be regretted. Should you think it desirable, I shall be glad to expose in a popular and understandable manner the fallacies and difficulties of the gliding craft on some occasion at your pleasure in the near future.'

"If I am in error concerning the gliding craft, notwithstanding the photographs and facts announced in the HERALD of July 14, and if I am misleading the public because of inherent 'fallacies and deficiencies of the gliding craft,' I regard it as his duty to the public to point out what these 'fallacies and deficiencies' are."

Engineers who have witnessed the performances of Mr. Hewitt's gliding craft said yesterday they believed it to be based upon a theory quite as substantial and profitable to the world as Mr. Tesla's latest theory of telegraphing to the planet Mars. These men insisted that they were basing their faith on what Mr. Hewitt had already done and not upon what he or Mr. Tesla or anybody else might dream to be false or substantial in theory. If the hydroplane theory had hitherto been held as an illusion, they said, it was greatly to Mr. Hewitt's credit to have proved the contrary.

SANTOS-DUMONT EXPERIMENT

TO THE EDITOR OF THE HERALD:—

The experiment which, according to a special cable in the HERALD, is to be performed by Santos-Dumont should yield very valuable and much needed engineering data. He succeeded in producing a remarkably light and powerful machine. If there is truth in certain old notions which have been strengthened by misleading experiments with gliding boats he would have no difficulty in attaining a speed of one hundred miles an hour, in view of the fact that Count Lambert reached twenty-five miles with a craft of this kind weighing sixty pounds to the horse power. It was a crude machine compared with the Dumont apparatus of 122-horse power, which, with operator and some fuel, will hardly exceed 600 pounds to the horse power. But the popular ideas in regard to the hydroplane and also the aeroplane are not in agreement with practice. It takes much more power to glide on the water or to soar than generally assumed.

There is a simple way of accomplishing this feat which Santos-Dumont has undertaken which absolutely precludes failure. Let him construct a shell resembling that of a Whitehead torpedo. The central part may contain the engine. Fuel and other necessaries may be put between the motor and the propeller. In the front part the operator should place himself in a reclining posture with the controlling levers conveniently at hand and looking out through a small glass window. Virtually the whole surface will thus be below the surface of the water. * * * The essence of this philosophy is that he cannot accomplish the feat if he attempts to glide, nor yet if he tries to soar, but he will without fail if he will change his plans and dive.

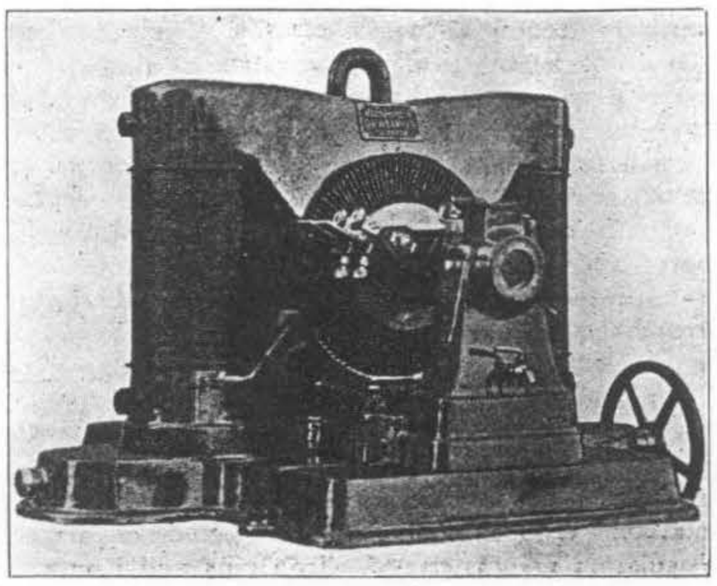
NEW YORK, Sept. 27, 1907.

Dynamo-electric Machinery and Its Evolution During the Last Twenty Years.

By B. A. Behrend,

Chief Engineer and Chief Designer, Bullock Works, Allis-Chalmers Company.

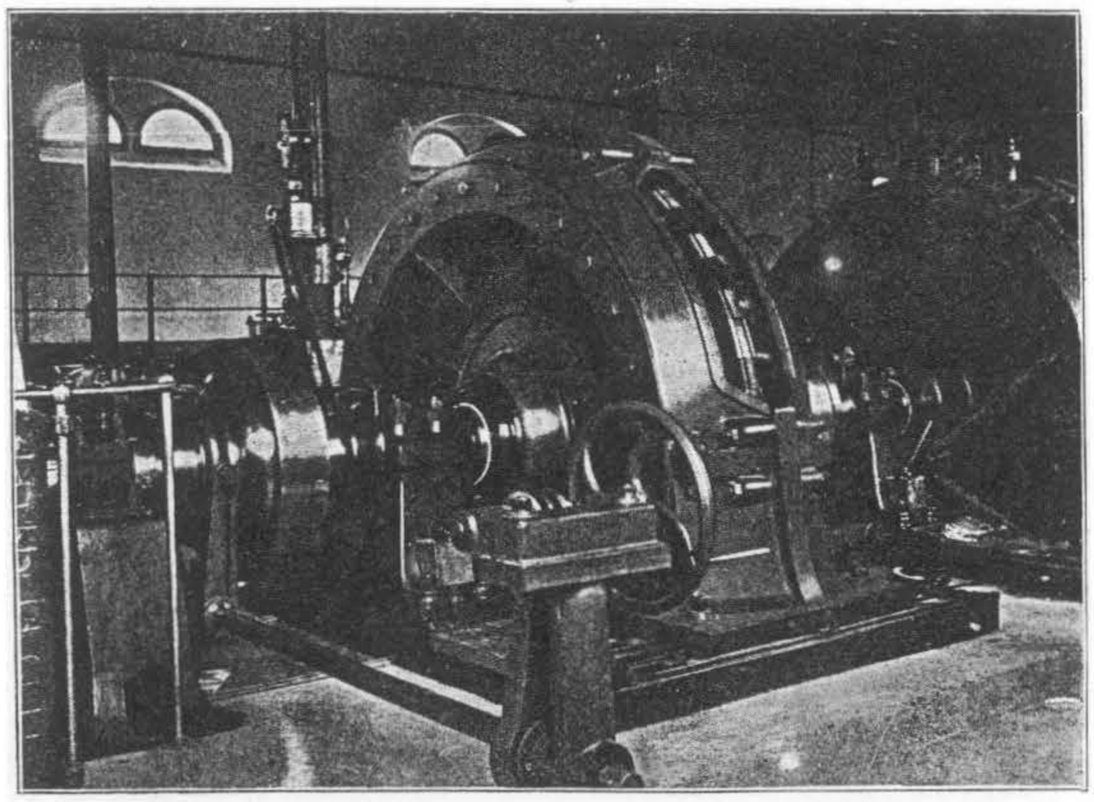


WHEN the historian-engineer writes upon the evolution of electric machinery during the last twenty years, he must needs write a story in which his own work and the work with which he has been associated form a more prominent part than is desirable in an impartial historical review. But every writer has the defects of his qualities, and the historian-engineer is prone to be either too much of a historian, or too much of an engineer, in relating the story of the growth and development of electric generating machinery and electric motors. No one who has ever carefully read history can deny that the bias of the author lends a peculiar color to his views and statements, and, in writing this article, I cannot plead guiltless of a similar bias.

BERNARD A. BEHREND.

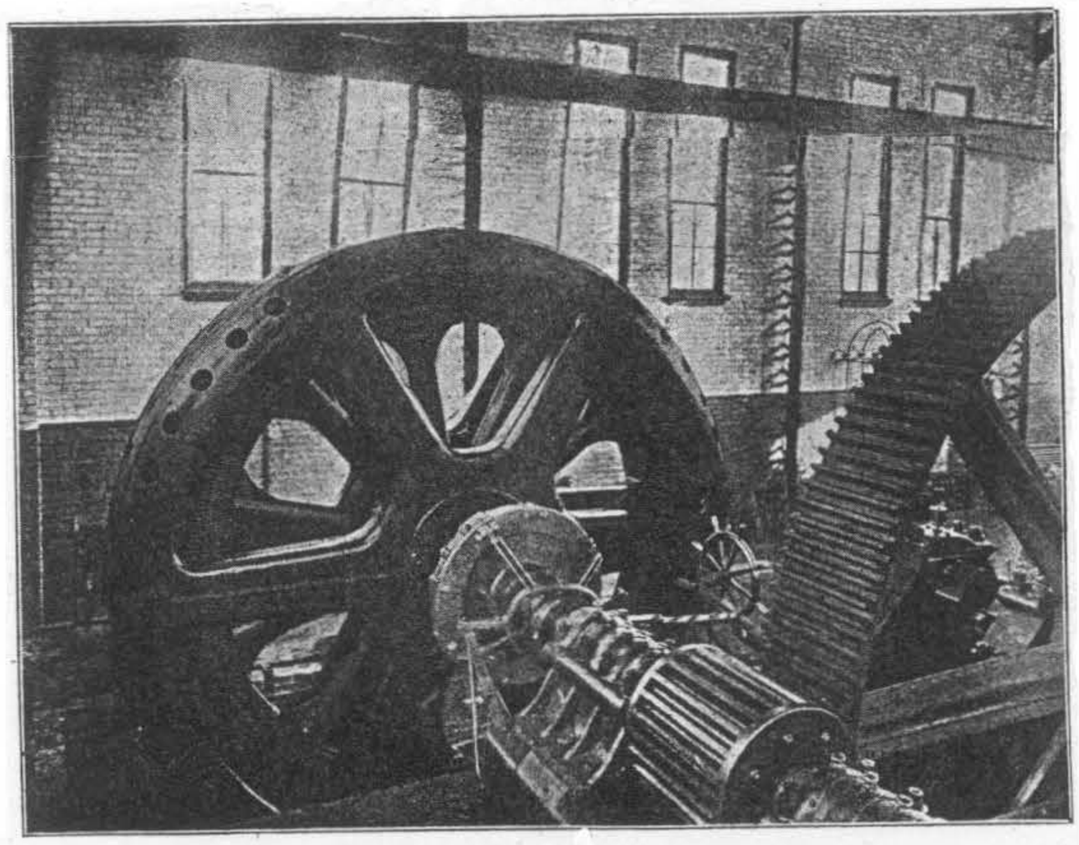
Twenty years ago we find a number of gifted physicists and engineers, the latter mostly of the telegraph type, engaged in fathoming the mysteries of electricity for the purpose of making machines which generate electric energy. Great masters of physical science, as Faraday, William Thomson and Maxwell, understood all about electromagnetic induction, but did not care to build dynamo-electric machinery, or, perhaps, heresy though it may be to say so, could not have done it. Here the engineer stepped in, a little lame, perhaps, in the mastery of theory, but with that creative imagination and poetic vision which form an important quality in the designing engineer.

There were dynamos built by Gramme, by Deprez, by Edison, by Elihu Thomson, by Siemens, and others whose names are beginning to fade from our memory. It must be irreverently stated, however, that our college boys would laugh to scorn these attempts and deem themselves greatly superior designers to the pioneers. The weakness of these early machines was not confined to the electrical design; in point of fact, it has always struck me that these early designers were more deficient in knowledge and experience in mechanical matters than in electrical. And there was much less excuse for this, as the mechanical art was developed and could be utilized without much difficulty. To this condition is to be attributed the deplorable patent situation in the electrical field, which has led to the protection by patent of mechanical features, known for many years, applied to electrical machinery because of the profound ignorance of the mechanical arts displayed by the electrical experts.



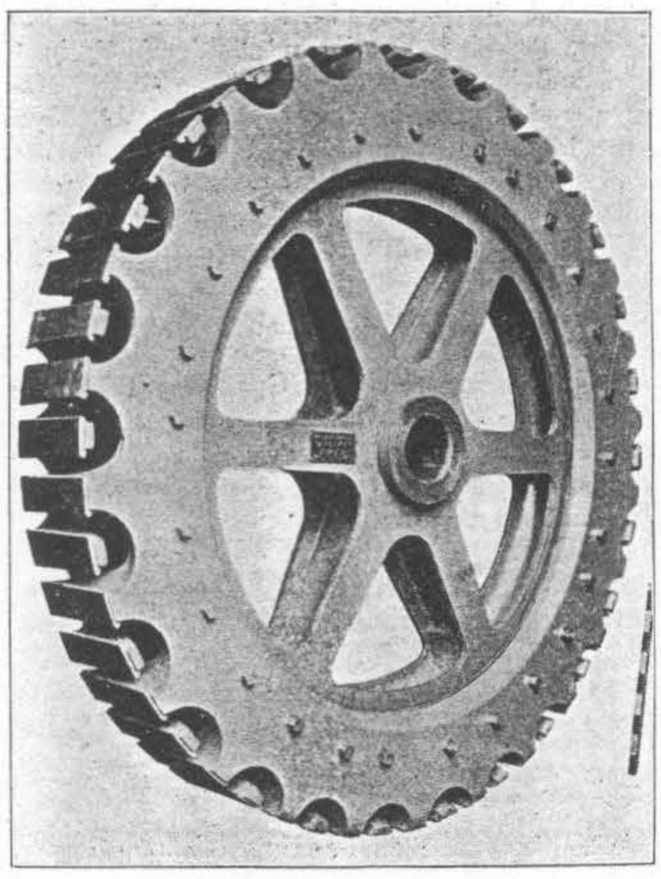
HIGH-VOLTAGE DIRECT-CURRENT DYNAMO OF 1887 (OERLIKON).

I have always contended that electrical designing is but a branch of mechanical engineering, as the design of heat engines is considered but a branch of the same field. That, of course, the electrical engineer should possess a thorough familiarity with the principles of electrical phenomena is as fundamental a requirement as that the steam engineer should know thermo-dynamics. These electrical machines which generated electricity but came to pieces in the process, burning out their bearings and being altogether nothing but toy machines turned over to a millwright, started the procession. And as any glaring faults are often made the starting point for improvements, so the dynamo-electric machine was taken out of the instrument makers' hands and placed with mechanical men in machine shops. In America I believe it was the Westinghouse & Schmidt Company, the precursor of the Westinghouse Electric and Manufacturing Company, which greatly improved the mechanical features of dynamo-electric machinery, while in Europe the Oerlikon Company made machines in which the art of mechanical engineering was utilized to the full.

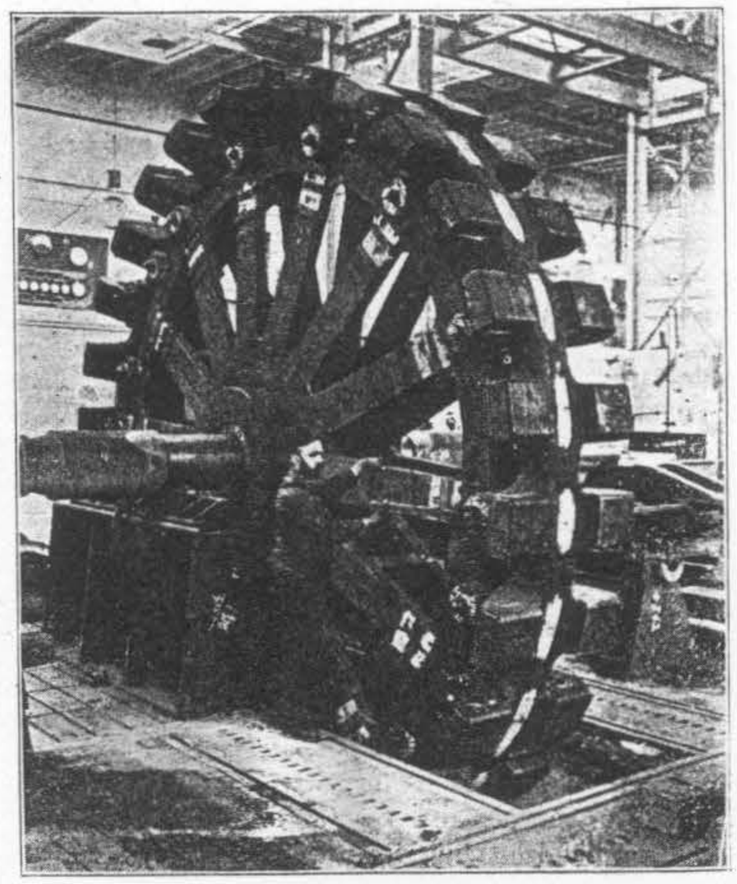


To all those who have followed the recent discussions about the relative merits of single-phase alternating currents and of high-voltage direct current for railway work it must be interesting to be reminded that the first electric generators of any account were direct-current machines of from 50 kilowatts to 150 kilowatts, generating from 1,200 volts to 3,000 volts, and being used for the transmission of power as series-wound machines. These machines were of the Manchester type, credited to Hopkinson, being bipolar and having copper brushes. Both the careful mechanical and electrical work which was put into these forerunners of modern electric machinery is testified to by the fact that a number of these plants are still in operation with commutators whose once cylindrical surfaces have been worn into bodies of revolution with fantastically curved outlines. The series winding of these machines was, of course, an essential condition; but we have in the interpole, which is over twenty years old, and which has recently been unearthed, a means of obtaining equally satisfactory results with shunt-wound generators.

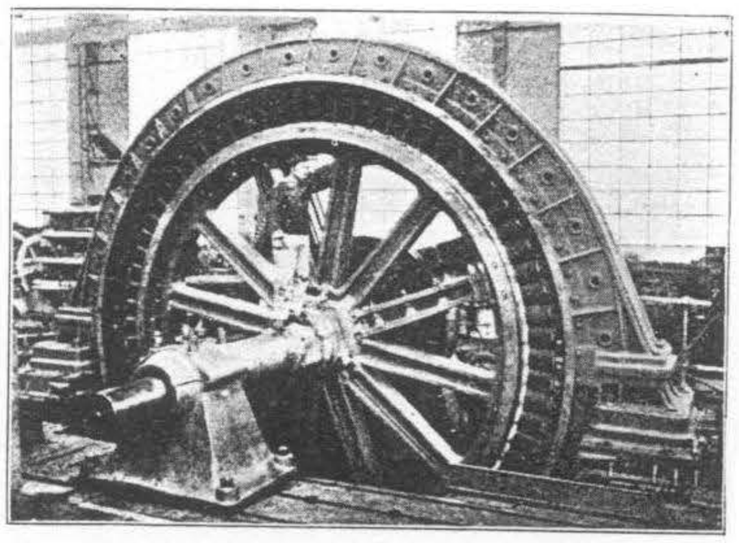
While intent upon the development and improvement of the direct-current machine, there came the startling work of Nikola Tesla, which prevented any further concentration of thought on anything excepting alternating currents and their combinations into polyphase currents. The work of Tesla has never been clearly understood or appreciated according to its intrinsic value by the majority of engineers. Mr. Tesla's early papers are classical contributions to the art of engineering and rank with the best that have been written. This statement is altogether independent of the validity of his patents—a matter which is not here under discussion.



Mr. Tesla is the victim of his friends. It is a peculiar trait of ignorant men to go always from one extreme to another, and those who once were the blind admirers of Mr. Tesla, exalting him to an extent which can be likened only to the infatuated praise bestowed on victims of popular admiration, are now eagerly engaged in his derision. There is something deeply melancholy in the aspect, and I can never think of Nikola Tesla without warming up to

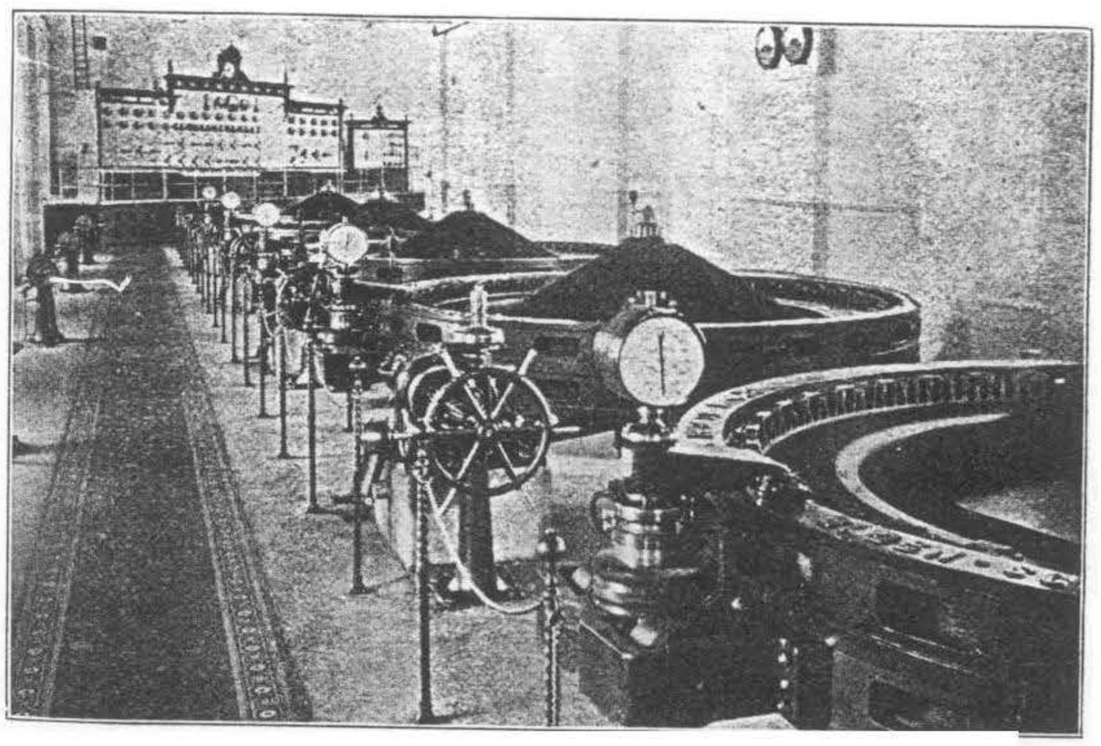


KAPP ALTERNATORS AT ZURICH, SWITZERLAND, 1890.



LOW-SPEED 500-HORSEPOWER INDUCTION MOTOR (BULLOCK) AT MONTREAL WATERWORKS

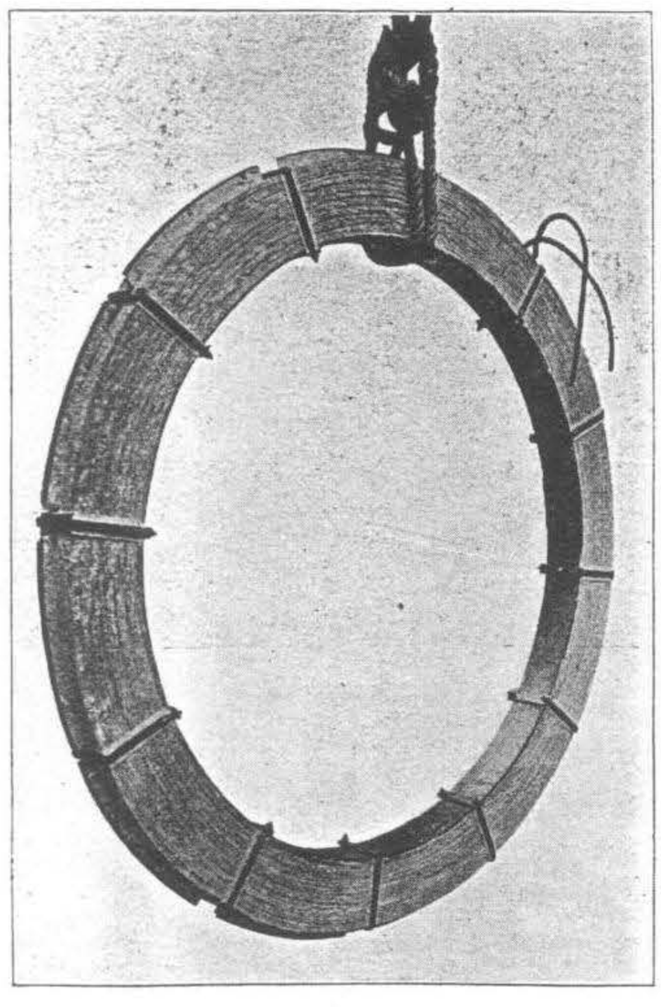
LAUFFEN-TYPE REVOLVING FIELD, 1893 (OERLIKON).



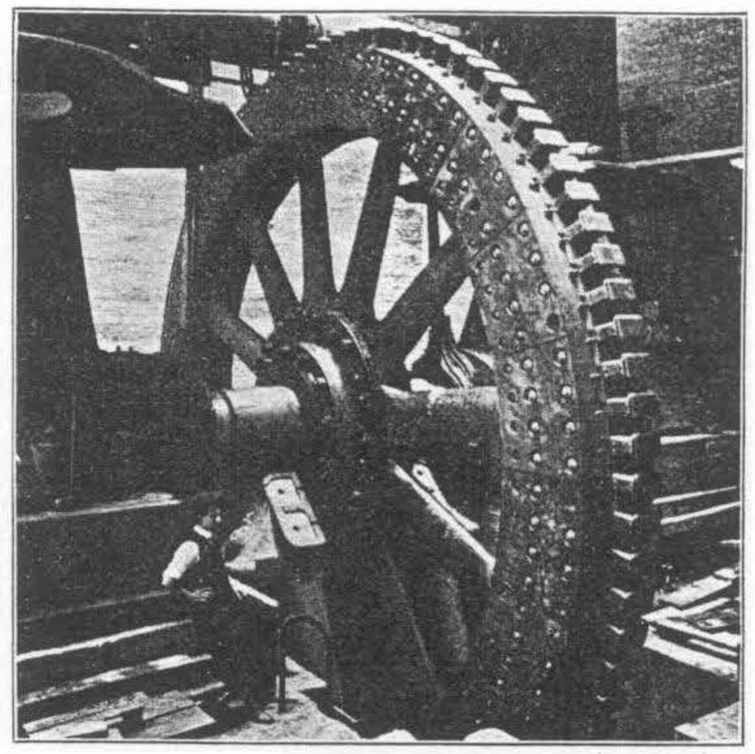
REVOLVING ELEMENT OF 1,000-KILOWATT INDUCTOR ALTERNATOR (OERLIKON), 1896.

LARGE REVOLVING-FIELD ALTERNATOR (OERLIKON, 1898.

my subject and condemning the injustice and ingratitude which he has received alike at the hands of the public and of the engineering profession. A child of genius, springing from a race not inured to the poisoning of flattery, he came to this country and did great and imperishable work. His admirers feted and celebrated him, and he took them seriously. It was only natural that his later work did not show the clearness and originality which characterized his work on polyphase machinery, and which made him famous. The engineering profession, unjustly and ungratefully ignoring his early work, labeled him a charlatan, and the public, always on the lookout for new sensations, dropped Mr. Tesla and forgot him. As my professional work for almost a score of years has had for its object the development and improvement of electrical machinery, for which Nikola Tesla has done much, I wish to take this opportunity to pay a tribute to his work done at the opening of the epoch which has culminated in the large industry of electrical engineering.



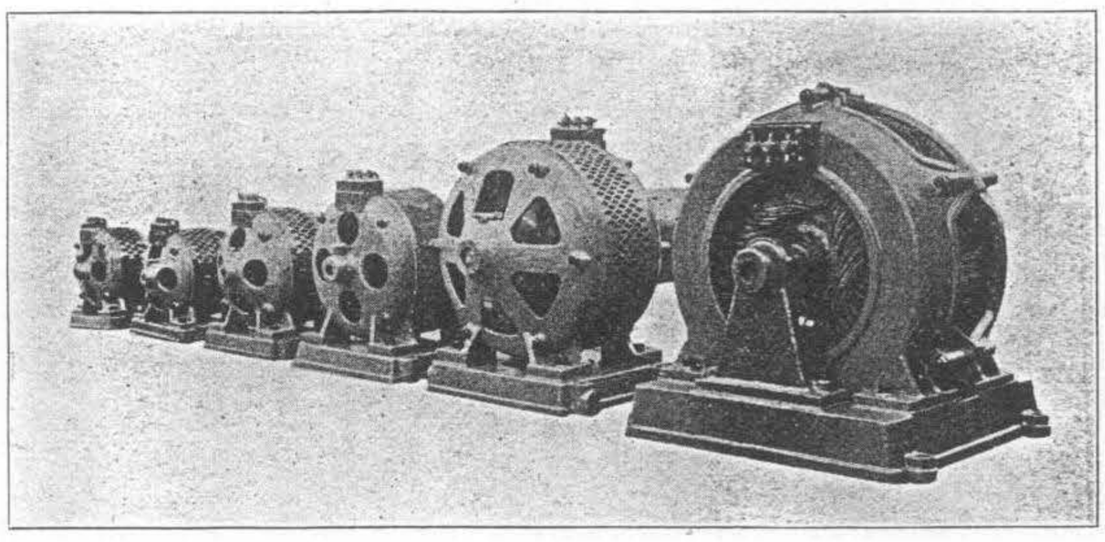
UMBRELLA-TYPE REVOLVING-FIELD ALTERNATORS (BROWN-BOVERI), 1897.



As the early direct-current machines were all wound as Gramme rings, there became established a preference for this construction in alternating-current generators. Besides the ironless types represented by Mordey, Ferranti and Siemens alternators, we notice the iron-core alternators of Kapp and of Schuckert, in which flat rings are wound with coils, in principle like the Gramme ring. The application of mechanical principles soon created reliable mechanical construction by using drum windings, and we record the next step in improvement of dynamo-electric machines when we refer to the direct-current generators built by the Westinghouse & Schmidt Company and the Thomson-Houston Company in America for railway work. Mr. Sidney H. Short, of the Walker Company, should here receive honorable mention for his pioneer work in this respect.

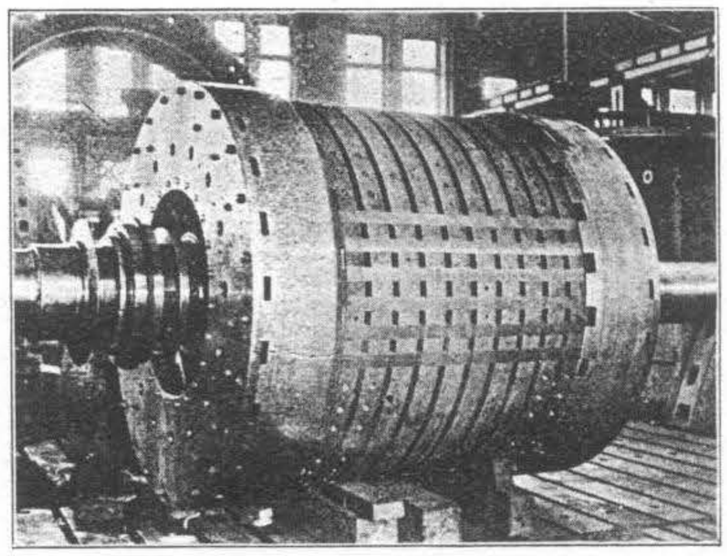
It has always seemed to me that the designs of electrical machinery in the early '90's lacked a clear recognition of underlying principles until the designing genius of C. E. L. Brown had done for the art what Corliss and Reynolds had been doing for the steam engine. Unity of plan enters into the field, and the present dynamo-electric machines become stereotyped. The direct-current generators have become multiple-wound multipolar units, with cross connectors in the armatures, and with commutators and brush-holders which we are all familiar with in present designs. The alternating-current generators are multipolar machines with internal revolving fields and external stationary armatures with windings arranged similar to those of drum-wound armatures. No more are we tempted from the straight path of engineering by such will-o'-the-wisps as Lauffen types, inductor types and other patent articles. The general design and construction have become established and will remain established until the introduction of entirely new principles which will relegate present dynamos to the past.

In reviewing the evolution of dynamo-electric machinery during the last twenty years, we must needs comment on the careful development of details and upon the adoption of rational processes for the manufacturing of this machinery. Fifteen years ago it was quite customary to manufacture the core plates by using circular shears and to build up the plates without slots, these being milled in the cores after the cores were built up. The manufacture of a large number of machines of the same size has made it possible to use dies and punchings for this operation, so that sectional plates completely slotted and dovetailed for fastening can be turned out with the greatest accuracy.



STATIONARY FIELD COIL OF INDUCTOR ALTERNATOR (OERLIKON), 1896.

REVOLVING FIELD OF 3,200-KILOWATT ALTERNATOR (BULLOCK), 1902.



Field coils which, in the early dynamos, were made of insulated wire, are made of copper strip bent on edge, and coils thoroughly mechanical and strong have thus been evolved.

A LINE OF RING-WOUND INDUCTION MOTORS (OERLIKON), 1893.

Instead of hand-wound armatures, the winding of which required great skill and patience, form-wound armature coils were introduced, leading to mechanical construction with easy possibility of repair.

The gradual evolution from step to step which is pursued by Nature is also pursued by engineers in the development of an art. Different steps are evolved by different designers in different parts of the world in almost exactly the same way, because this evolution is the product of the human brain, which is the same the world over. It appears, therefore, most preposterous to any thoughtful man of culture and knowledge to designate these intrinsically small steps as inventions, and to bewilder the mind with claims couched in words of ambiguity and prolixity which apply to the objects they are meant to describe as well as to the process of the creation of the world as related to us in the first chapter of Genesis.

FOUR-POLE RKVOLVING FIELD OF 10,000-HORSEPOWER TURBO-GENERATOR (ALLIS-CHALMERS), 1904.

Much yet has to be done to educate the public, and the engineering public in particular, to understand the philosophy of progress and invention and to appreciate a complex situation created by a well-meaning institution like the Patent Department, but here, as elsewhere, human institutions founded

with the best of intentions have defeated their own purpose. In an art which has hastily grown and whose principles have been considered mysterious, it may be excusable if certain means for mechanically fastening pole-pieces, for example, are represented to serve certain occult purposes conducting magnetism; but it seems pitiful that experts can be found to give their support to such humbug.

Though the perfection of the present dynamo-electric machines can be traced step by step from a modest beginning, yet there is a vast gulf between the first slow-speed machines and the present 7,500-kilowatt generators operating at 750 revolutions per minute. Yet little or nothing has had to be changed in the principles underlying the design of electric machinery, and the engineers must be filled with pride who, twenty years ago, recognized in the principles of Faraday and Maxwell the leading light of their art.

The New York Herald October 17, 1907

SUBMERGED VESSEL, HE SAYS, CAN GO 65 MILES

Mr. Tesla Comments on the Idea of Resistance Under Water Advanced by Lord Kelvin.

FASTER THAN ON SURFACE

Inventor Says Aeronauts Overlook Important Law in Their Attempt to Attain High Speed.

TO THE EDITOR OF THE HERALD:—

In the European edition of the HERALD of October 1, Santos-Dumont has credited me with a theory which is not my own, namely, that a higher speed can be attained in the water than by gliding on the surface. This idea was advanced long ago by Lord Kelvin and has been since accepted in all classical works as a manifest truth. A vessel completely submerged and creating no surface disturbance has nothing but skin friction to overcome.

In attempting to reach a speed of 100 kilometres, or 62½ miles, the aeronaut evidently places faith in the demonstrations of Pictet with the hydroplane, paralleled by those of Langley with the aeroplane. But in both of these an important law has been ignored, of which, however, no hint or suggestion can be found in the entire scientific literature from Newton's principia to the most modern treatises and which profoundly affects the results in gliding and soaring.

The experiment which, as reported in the HERALD, Santos-Dumont is to make will forever dispel the popular notions of the hydroplane, according to which, were it not for air resistance, a speed of 360 miles would be attainable with his remarkable craft. In the light of the law I have discovered that this gliding boat, weighing, with operator and fuel included, five pounds per horse power, will reach only a speed of forty-eight miles. To attain 100 kilometres the motor would have to develop much more than 120 horse power. What is true of the hydroplane likewise applies, with a slight modification, to the aeroplane. But a submerged vessel of the Whitehead torpedo type could be propelled at a rate of sixty-five miles.

NIKOLA TESLA.

NEW YORK, Oct. 16, 1907.

Through the Water? Or Over It?

Nikola Tesla says that Santos-Dumont's new hydroplane will not be able to travel sixty-two miles an hour, as expected by its ingenious constructor—that it will not exceed a speed of forty-eight miles.

It is in the column of letters from HERALD readers this morning that Mr. Tesla presents his views on the subject. He insists, in short, that higher speed can be made in the water than by gliding on the surface.

M. Santos-Dumont, through the European edition of the HERALD, recently replied to the first letter of Mr. Tesla and expressed a wish on the subject that the latter would put his theories to the test.

"If he cares to build a boat on the lines indicated in his letter," said M. Santos-Dumont, "I will give him half of the 50,000 francs I stand to gain." The communication from Mr. Tesla which we print this morning is very interesting, but makes no refereuce to this "sporting" challenge of the young Brazilian aeronaut and inventor.

SLEEP FROM ELECTRICITY.

Nikola Tesla Noted Narcotic Influences of Periodic Currents in 1898.

To the Editor of The New York Times:

I have read with interest the reports in THE TIMES of the 13th and 15th insts. referring to Prof. Leduc's discovery of causing sleep by electric means. While it is possible that he has made a distinct advance there is no novelty in the effect itself.

The narcotic influence of certain periodic currents was long ago discovered by me and has been pointed out in some of my technical publications, among which I may mention a paper on "High Frequency Oscillators for Electro Therapeutic and Other Purposes," read before the American Electro Therapeutic Association Sept. 13, 1898. I have also shown that human tissues offer little resistance to the electric flow and suggested an absolutely painless method of electrocution by passing the currents through the brain. It is very likely that Prof. Leduc has taken advantage of the same general principles though he applies the currents in a different manner.

In one respect, however, my observations are at variance with those reported. From the special dispatch in THE TIMES of the 13th inst. it would appear that sleep is induced the moment the currents are turned on, and that awakening follows as soon as the electrodes are withdrawn. It is, of course, impossible to tell how strong a current was employed, but the resistance of the head might have been, perhaps, 3,000 ohms, so that at thirty volts the current could have been only about 1/100 of an ampere. Now, I have passed a current at least 5,000 times stronger through my head and did not lose consciousness, but I invariably fell into a lethargic sleep some time after. This fact impresses me with certain arguments of Prof. Barker of Columbia University in your issue of Sept. 15.

I have always been convinced that electric anaesthesia will become practical, but the application of currents to the brain is so delicate and dangerous an operation that the new method will require long and careful experimentation before it can be used with certitude.

POSSIBILITIES OF 'WIRELESS.'

Nikola Tesla Says Distance Forms No Obstacle to Transmission of Energy.

To the Editor of The New York Times:

In your issue of the 11th inst. Edison makes statements which cannot fail to create erroneous impressions.

There is a vast difference between primitive Hertzwave signalling practicable to but a few miles, and the great art of wireless transmission of energy which enables an expert to transmit, to any distance, not only signals, but power in unlimited amounts, and of which the experiments across the Atlantic are a crude application. The plants are quite inefficient, unsuitable for finer work, and fatally doomed to an effect less than 1 per cent. of that I attained in my tests in 1899.

Edison thinks that Sir Hiram Maxim is blowing hot air. The fact is my Long Island plant will transmit almost its entire energy to the antipodes, if desired. As to Martin's communication I can only say, that I shall be able to attain a wave activity of 800,000,000 horse power and a simple calculation will show, that the inhabitants of that planet, if there be any, need not have a Lord Raleigh to detect the disturbance.

Referring to your editorial comment of even date the question of wireless interference is puzzling only becaus of its novelty. The underlying principle is old, and it has presented itself for consideration in numerous forms. Just now it appears in the novel aspects of aerial navigation and wireless transmission. Every human effort must of necessity create a disturbance. What difference is there in essence, between the commotion produced by any revolutionary idea or improvement and that of a wireless transmitter? The spectre of interference has been conjured by Hertzwave—or radiotelegraphy in which attunement is absolutely impossible, simply because the effect diminishes rapidly with distance. But in my system of energy transmission, based on the use of impulses not sensibly diminishing with distance, perfect attunement and the higher artifice of individualization are practicable. As ever, the ghost will vanish with the wireless dawn.

The New York Tribune October 25, 1907

LETTERS TO THE EDITOR

TESLA ON WIRELESS.

Electrical Inventor Thinks Marconi's Plants Inefficient.

To the Editor of The Tribune.

Sir: In so far as wireless art is concerned there is a vast difference between the great inventor Thomas A. Edison and myself, integrally in my favor. Mr Edison knows little of the theory and practice of electrical vibrations; I have, in this special field, probably more experience than any of my contemporaries. That you are not as yet able to impart your wisdom by wireless telephone to some subscriber in any other part of the world, however remote, and that the presses of your valuable paper are not operated by wireless power is largely due to your own effort and those of some of your distinguished confreres of this city, and to the efficient assistance you have received from my celebrated colleagues, Thomas A. Edison and Michael I. Pupin, assistant consulting wireless engineers. But it was all welcome to me. Difficulty develops resource.

The transmission across the Atlantic was not made by any device of Mr. Marconi's, but by my system of wireless transmission of energy, and I have already given notice by cable to my friend Sir James DeWar and the royal institution of this fact. I shall also request some eminent man of science to take careful note of the whole apparatus, its mode of operation, dimensions, linear and electrical, all constants and qualitative performance, so as to make possible its exact reproduction and a repetition of the experiments. This request is entirely impersonal. I am a citizen of the United States, and I know that the time will come when my busy fellow citizens, too absorbed in commercial pursuits to think of posterity, will honor my memory. A measurement of the time interval taken in the passage of the signal necessary to the full and positive demonstration will show that the current crosses the ocean with a mean speed of 625,000 miles a second.

The Marconi plants are inefficient, and do not lend themselves to the practice of two discoveries of mine, the "art of individualization," that makes the message non-interfering and non-interferable, and the "stationary waves," which annihilate distance absolutely and make the whole earth equivalent to a conductor devoid of resistance. Were it not for this deficiency, the number of words a minute could be increased at will by "individualizing."

You have already commented upon this advance in terms which have caused me no small astonishment, in view of your normal attitude. The underlying principle is to combine a number of vibrations, preferably slightly displaced, to reduce further the danger of interference, active and passive, and to make the operation of the receiver dependent on the co-operative effect of a number of attuned elements. Just to illustrate what can be done, suppose that only four vibrations were isolated on each transmitter. Let those on one side be respectively a, b, c and d. Then the following individualized lines would be ab, ac, ad, bc, bd, cd, abc, abd, acd, bcd and abcd. The same article on the other side will give eleven similar combinations, and both together twenty-two lines, which can be simultaneously operated. To transmit one thousand words a minute, only forty-six words on each combination are necessary. If the plants were suitable, not ten years, as Edison thinks, but ten hours would be necessary to put this improvement into practice. To do this, Marconi will have to reconstruct the plants, and it will then be observed that the indefatigable Italian has departed from universal engineering customs for the fourth time.

New York, Oct. 24, 1907. NIKOLA TESLA.

The New York Herald October 26, 1907

SANTOS-DUMONT'S SPEED.

TO THE EDITOR OF THE HERALD:—

I notice from the HERALD of even date (page 8) that Santos-Dumont managed to attain a speed of 32 miles instead of 48, as I calculated. I assumed an efficiency of 6[illegible] per cent for propeller and inclined plane combined. If his motor was driven at full power the efficiency was only 43 per cent, and it is more likely to be true than the highest theoretical figure I assumed. I wish that he had made a good test and come close to 48 miles, as I calculated to give my theory a better test. But you see that the old notions of the hydroplane cannot possibly be true. * * * Santos-Dumont can still win the bet if he will follow my suggestion.

The New York Times October 27, 1907

TESLA TOWER TO BE SOLD.

Property of Electrician to be Disposed of to Satisfy a Judgment for $199.31.

The tower erected by Nicola Tesla, the electrical inventor, at Wardencliffe Long Island, is advertised for sale, by Sheriff Wells of Suffolk County on Monday, Dec. 9, for a debt of $199.31. August Eisenmann, through his attorney, Ralph J. Hawkins, has obtained a judgment for this amount against the electrician.

This is the second time it has been advertised for a judgment sale within half a year. Dr. Warden, the founder of Wardencliffe, had it seized a few months ago to satisfy a small judgment. Mr. Tesla paid the judgment just before the time of sale.

The property is valuable and consists of about two hundred acres. The tower was built at great cost. It extends deep into the ground, and rises a great height in the air, and its equipment was expensive.

The New York Tribune October 27, 1907

TESLA'S TOWER FOR SALE AGAIN.

The tower erected by Nicola Tesla at Wardencliffe, Long Island, is to be sold by Sheriff Wells of Suffolk County on Monday, December 9, for a debt of $199 31. August Eisenmann is the creditor. This is the second time the tower has been advertised for sale to satisfy a judgment within half a year. The last time, Dr. Warden, founder of Wardencliffe, was the creditor. Mr. Tesla paid just before the sale. The Tesla property at Wardencliffe consists of about two hundred acres. The tower was built at great cost.

The New York World October 27, 1907

TO SELL TESLA'S TOWER.

Sheriff to Auction Costly Structure to Satisfy Small Claim.

For a debt of $199.31 the tower erected by Nikola Tesla at Wardenclitte, L. I., is to be sold by Sheriff Wells, of Suffolk County, on Monday, Dec. 9. Any one wishing to dabble in electrical oscillations preparatory to launching wireless messages to Mars will find the Tesla tower especially fitted for the purpose.

August Eisenmann, through his attorney, Ralph J. Hawkins, obtained a judgment of $199.31 against the inventor and handed it to the Sheriff to execute.

The Tesla property at Wardenclitte is valuable, consisting of about 200 acres of exceedingly desirable property. The tower was built at a cost, it is said, of many thousands of dollars.

The New York World October 29, 1907

Tesla's Wireless Patents.

To the Editor of The World:

As bearing intimately on the report in your issue of even date that my tower is to be sold for $199.31 on Dec. 9, which, to use Mark Twain's phrase, is "greatly exaggerated," your readers might be interested to know that, among others, the following patents on wireless transmission, transformation and utilization of energy have been granted to me in the United States: Nos. 568,176, 568,178, 568,179, 568,180, 577,670, 645,576, 649,621, 685,595, 685,954, 723,183, 725,605, 787,412.

These documents, most carefully drawn with the assistance of some of the ablest attorneys, set forth clearly my fundamental discoveries on which this novel art is based, and give a faithful description of my processes, apparatus and experiments, thus enabling experts not only to flash wireless telegraphic and telephonic messages to any distance, but also to transmit power in unlimited amounts and with the highest economy.

Copies of these specifications can be readily obtained by addressing a courteous request to the Honorable Commissioner of the Patent Office, Washington, D. C., inclosing $1.20 postage stamps.

NIKOLA TESLA.

New York, Oct. 27.

Narcotic Effects of Electricity.

Mr. Nikola Tesla in a recent communication to the New York *Times* says: "I have read with interest the reports referring to Prof. Leduc's discovery of causing sleep by electric means. While it is possible that he has made a distinct advance there is no novelty in the effect itself. The narcotic influence of certain periodic currents was long ago discovered by me and has been pointed out in some of my technical publications, among which I may mention a paper on 'High Frequency Oscillators for Electro Therapeutic and Other Purposes,' read before the American Electro-Therapeutic Association, Sept. 13, 1898. I have also shown that human tissues offer little resistance to the electric flow and suggested an absolutely painless method of electrocution by passing the currents through the brain. It is very likely that Prof. Leduc has taken advantage of the same general principles, though he applies the currents in a different manner.

"In one respect, however, my observations are at variance with those reported. From the special dispatch in the *Times* of the 13th inst. it would appear that sleep is induced the moment the currents are turned on, and that awakening follows as soon as the electrodes are withdrawn. It is, of course, impossible to tell how strong a current was employed, but the resistance of the head might have been, perhaps, 3000 ohms, so that at 30 volts the current could have been only about 1/100 of an ampere. Now, I have passed a current at least 5000 times stronger through my head and did not lose consciousness, but I invariably fell into a lethargic sleep some time after.

"I have always been convinced that electric anæsthesia will become practical, but the application of currents to the brain is so delicate and dangerous an operation that the new method will require long and careful experimentation before it can be used with certitude."

TO TALK TO MARS WITH NIAGARA'S VOICE

"With the Co-operation of Niagara Power Companies I Am Now Preparing to Project an 800,000,000 Horse-power Message Over the 100,000,000 Mile Gulf Between the Earth and Mars."—*Nikola Tesla*

"This Will be the Next Great Achievement of Science."—*Sir Hiram S. Maxim.*

WHEN Sir Hiram S. Maxim, the distinguished inventor and scientist, made his recent announcement to Peter Cooper Hewitt that the next great achievement of science would be the harnessing of the whole energy of Niagara and the sending of a message to Mars, he hit the nail, in the opinion of Nikola Tesla, squarely on the head.

Mr. Tesla announces to-day that with the co-operation of power-producing companies at Niagara Falls he is preparing to hail Mars with Niagara's voice. A way has been found at last for transmitting a wireless message across the gulf, varying from 40,000,000 to 100,000,000 miles, which separates this earth from Mars. Once that has been accomplished and Mars, which is considerably older and supposedly more advanced in science than us, has acknowledged the receipt of our signal and sent back flash for flash, it will remain to devise an interplanetary code through the medium of which the scientists of this world and of Mars will be able to understand what each is saying to the other.

Mr. Tesla has been quietly working for several years on a wireless power plant capable of transmitting 10,000 horse-power to any part of the world, or to any of our neighboring planets, for that matter. The mere matter of distance between despatching and receiving points is absolutely no object whatever. Wireless power, Mr. Tesla says, may be sent one million or more miles just as easily as one mile.

Several of the electric power companies with immense generating plants at Niagara Falls have agreed to co-operate with Mr. Tesla in an effort to reach Mars by wireless.

These Niagara power plants, Mr. Tesla declares, are now capable of producing electrical vibrations of such intensity that, if measured according to ordinary standards, the rate at which their energy is delivered could readily be advanced to a billion horse-power. But no such performance is necessary to produce strong electrical impulses on Mars. Mr. Tesla has estimated that a rate of a few hundred million horse-power is quite sufficient to establish wireless communication with that planet.

Mr. Tesla's wireless plant, which he has already equipped at Wardenclyffe, L. I., for the sending of long distance electric waves, will enable him to attain a rate of 800,000,000 horse-power—much more than is necessary to bridge the gulf of from 40,000,000 to 100,000,000 miles between this earth and Mars.

Now, it was explained by Mr. Tesla, if his magnifying wireless transmitter and corresponding receiver, or a somewhat similar apparatus, were installed on Mars it would be a very simple matter for the Martians to receive wireless flashes from the earth and to send us others in reply. And in sending messages to this earth the Martians would not need to use more than one-sixteenth the electrical energy needed to send flashes from the earth to Mars.

"It should be borne in mind," Mr. Tesla wrote, "that many Martian tasks in mechanical engineering are much easier than the terrestrial, on account of the smaller mass of the planet and lesser density, which, in the superficial layers, may be considerably below the mean. To a still greater degree this is true of electrical engineering. Taking into account the space encompassed by Mars, a system of wireless transmission of energy, such as I have perfected, would be there much more advantageously applied, for, under similar conditions a receiving circuit would collect sixteen times as much energy as on the earth.

"The astonishing evidences furnished by Lowell are not only indicative of organic life, but they make it appear very probable that Mars is still populated; and furthermore, its inhabitants are highly developed, intelligent beings."

"Is there any other proof of such existence?"

"I answer, emphatically, yes, prompted both by an instinct, which has never yet deceived me, and observation. I refer to the strange electrical disturbances, the discovery of which I announced six years ago. At that time I was only certain that they were of planetary origin. Now, after mature thought and study, I have come to the positive conclusion that they must have emanated from Mars.

"Such colossal transformation as is observable on the face of Mars could not have been wrought except by beings ahead of us in development.

"What wonder if they are signalling to us? We are sufficiently advanced in electrical science to know that their task is much easier than ours. The question is, can we transmit electrical energy to that immense distance? This I think myself competent to answer in the affirmative."

THE SUN MAY AID US IN SIGNALLING MARS.

By Prof. Garret P. Serviss.

IF the men of Mars—the majority of astronomers agree that the planet is probably inhabited—have telescopes comparable with ours, it is perfectly conceivable that they can see the great canals which are under construction on the vast, arid plains of the West. The so-called canals of Mars are at least sixty miles wide. Now, if we build a canal here in the western desert tapping some great lake which can readily be seen from Mars, and from this long canal there radiate many little canals for irrigation, bordering this giant waterway, there will be a long strip of bright green one hundred miles wide. Set in the gray of the desert, this could easily be seen. Then the flashing of the water in the sunshine would make it even more visible.

Very likely, too, should the Martians notice this sudden and remarkable change on the earth's surface, especially if the aspect assumed, even roughly, some geometrical shape, they would naturally suppose we were signalling to them. Then it would be not beyond the range of possibility that they might answer back.

WHY THE MARTIANS WILL ANSWER OUR SIGNALS.

By Nikola Tesla.

AS the Martians are probably more advanced and skilled than us, their first readable message to this earth will undoubtedly be, "We have been calling you for the last ten thousand years."

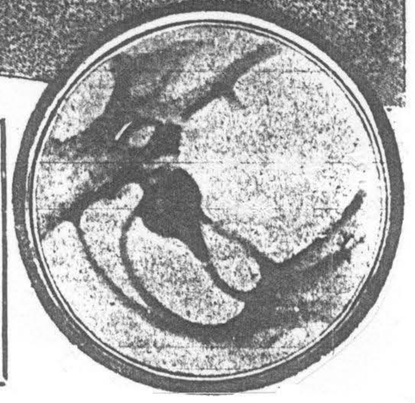
Once communication is established, the Martians will gradually take our code and language and learn it first and then teach us theirs in plain English. Difficult as this fact would seem, it in reality would not be comparable with the achievement of teaching a deaf, dumb and blind child to understand. To talk to Mars is only a matter of patience now.

Prof. David P. Todd of Amherst College.

New Evidence That Mars Is Inhabited.

By Prof. E. C. Slipper,
of the Flagstaff, Ariz., Observatory.

A PRELIMINARY inspection of the results of my recent observations of Mars, taken in the Andes, entirely corroborates Prof. Lowell's theory that there is intelligent life on that planet. Several new canals in addition to those already known have been discovered, and a great many double canals have been observed, indicating the employment of great intelligence and care in their construction.



If any reasonable doubt yet exists as to the existence of life on Mars the announcement of that very conservative astronomer, Prof. David P. Todd, of Amherst, that there is something like human life on Mars, may be taken as authoritative and conclusive. During six weeks' observation this spring with a specially constructed photographic telescope set up in the Andes Mountains, in Northern Chili, Prof. Todd took more than 2,000 remarkable photographs of Mars.

These pictures constitute a complete series of surface photographs of Mars, from pole to pole, from side to side, the enlargements of which will enable a new sphere to be made. To this sphere the lines and cross lines of the planet will be attached in raised edges, so that in three months' time we shall have an entirely new and most complete globe of the planet.

"Of course, the difficulty heretofore has been to trust the observations of the naked eye through the telescope," said Prof. Todd. "Prof. Lowell has made photographs of Mars, but the aerial and atmospheric conditions at Flagstaff have not been so advantageous as to secure so thorough an examination as the one we have just made.

"During the six weeks that we observed Mars the planet exposed its spherical surface completely, and although I base my conclusions that there is something like human intelligence at work up there purely upon inferential indications, I was much impressed with the possibility.

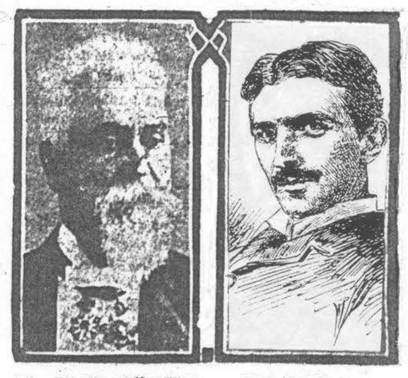
"Among the six or seven thousand photographs, however, which I was fortunate enough to obtain there is no illusive line, no questionable dot. What the camera saw is there, and what these pictures will reveal when they have been carefully examined I am sure will add a great deal to our knowledge of Mars."

How Mars Looked to Prof. Todd When Viewed from a Distance of 43,000,000 Miles. The Thin Lines Are Now Believed to Be Strips of Vegetation Fifty Miles Wide, Irrigated from Central Canals.

What the Martians Might Say to Us in Reply

By Edward Sylvester Morse, A.M., Ph.D.

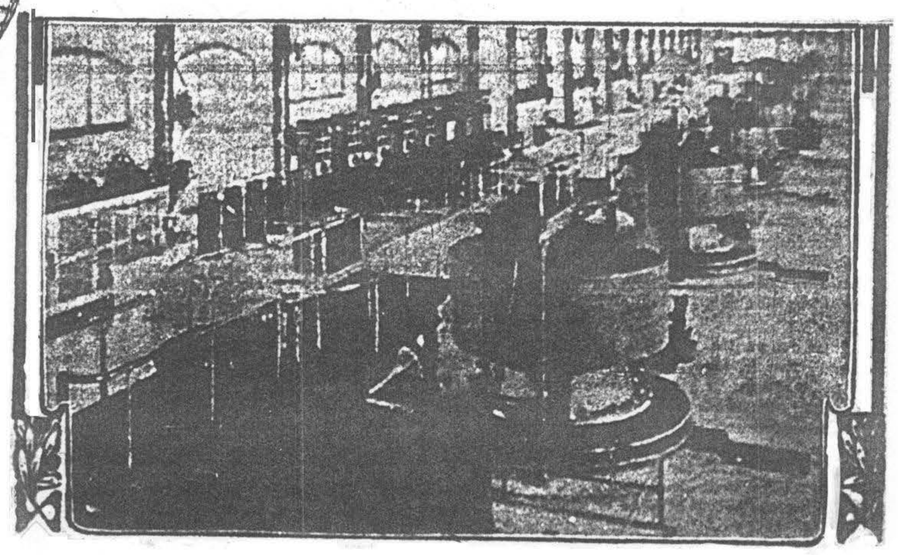
FOR every single perplexity of interpretation we encounter in our study of the surface workings of Mars the Martian would encounter a dozen perplexities in interpreting the various features on the surface of the earth. What must be the Martian interpretation of the surface features of this world? It is a perfectly fair inquiry, for by such means we may appreciate the attitude of some of our interpreters of Mars.



In examining the earth, then, as we have examined Mars, the Martian would find large yellow and reddish areas, extensive greenish areas, and, besides, large regions of varying shades of blue, possibly occupying three-fourths of the earth's surface. The yellow areas he would interpret as desert land; the greenish areas he might consider vegetation, but what would he make out of the larger regions of blue? This would certainly puzzle him, because, unfamiliar with oceans, he could not believe that such vast tracts could really be water. He would easily interpret the Polar snow caps and the waters at their edges, but the oceans would be impossible to solve. They form the basis for one of the first questions the Martian would ask us in seeking information about the earth.

The perennial character of the vegetation in the tropics would also be a puzzle requiring much explanation from us. Even if the Martian recognized oases in the deserts of America and Africa, the result of artesian wells or springs, he could not believe them to be vegetation, for he would detect no irrigating canals running into them. He would come to the conclusion that no creature could possibly exist on the earth, as the tremendous force of gravitation, with great atmospheric pressure, would forbid the existence of any organic forms.

The immense clouds veiling the surface of the earth must, in the probable opinion of the Martian, at times suffer condensation, and the impact of the rain drops would, from their velocity and weight, smash everything in the way of life. Life would apparently exist only in forms supported by stupendages, with legs of iron to sustain their weight and a turtle-like crust, to be impervious to rain drops; and this would be contrary to all Martian analogy.



The courses of rivers, if detected, would puzzle him from their irregularity, unless he dared to suggest or we explained to him, that these long, sinuous channels, extending for thousands of miles, are identical with the little rivulets he had studied near his own pole.

If Mars is an older sphere, we trust it has outgrown the superstitions which still hamper man in his interpretation of the inexorable phenomena of nature.

Sir Hiram S. Maxim. Nikola Tesla.

Great Generators Converting the Power of Niagara Falls Into Electric Force.

The New York Herald December 3, 1907

MR. TESLA'S INVENTION

TO THE EDITOR OF THE HERALD:—

In a special despatch in your issue of to-day a well known improvement of mine is referred to as if invented by German engineers. This is all the more disappointing to me as I have been virtually ridiculed for advocating the idea. I refer to the electric driving of propellers, which I have recommended as particularly suitable for ocean liners.

A common mistake of my critics was to assume that the adoption of the system would necessitate a great increase in weight, but it is not so. The turbo-generators would weigh much less than the equivalent marine engine, and the motors designed for very high peripheral velocity would be light. Numerous auxiliary engines, the special lighting plant, belts, shafting, pulleys, supports and miles of pipe could be done away with, thus diminishing the total weight and saving power besides. Much more energy could be obtained from the prime movers and the propellers could be made to work with the highest efficiency. In making this change on the existing vessels the boiler plant could remain intact. The gain in space would be considerable.

I cannot agree with the opinion unanimously expressed by the Association of Shipbuilders and Shipbuilding Engineers that "electric power transmission affords the only solution," for, as stated in a previous letter to the HERALD, I have discovered another and better one.

NIKOLA TESLA

NEW YORK, Nov. 30, 1907.

TESLA TO TALK TO MARS.

Mr. Tesla announces that, with the co-operation of power-producing companies at Niagara Falls, he is preparing to hail Mars with Niagara's voice. A way has been found at last, it is asserted, for transmitting a wireless message across the gulf which separates this earth from Mars. Once that has been accomplished, and Mars—which is considerably older and supposedly more advanced in science than us—has acknowledged the receipt of our signal, and sent back flash for flash, it will remain to devise an interplanetary code through the medium of which the scientists of this world and of Mars will be able to understand what each is saying to the other.

Mr. Tesla has been quietly working for several years on a wireless power plant capable of transmitting 10,000H.P. to any part of the world, or to any of our neighbouring planets, for that matter. The mere matter of distance between despatching and receiving points is absolutely no object whatever. Wireless power, Mr. Tesla says, may be sent one million or more miles just as easily as one mile.

Several of the electric-power companies with immense generating plants at Niagara Falls have agreed to co-operate with Mr. Tesla in an effort to reach Mars by wireless.

These Niagara power plants, Mr. Tesla declares, are now capable of producing electrical vibrations of such intensity that, if measured according to ordinary standards, the rate at which their energy is delivered could readily be advanced to a billion horse-power. But no such performance is necessary to produce strong electrical impulses on Mars. Mr. Tesla has estimated that a rate of a few hundred million horse-power is quite sufficient to establish wireless communication with that planet.

Mr. Tesla's wireless plant, which he has already equipped at Wardenclyffe, L.I., for the sending of long-distance electric waves is to be utilised.

Mr. Tesla seems to believe that Mars is already signalling to us:

"The astonishing evidences furnished by Lowell are not only indicative of organic life, but they make it appear very probable that Mars is still populated, and, furthermore, its inhabitants are highly-developed, intelligent beings."

"Is there any proof of such existence?"

"I answer, emphatically, yes, prompted both by an instinct, which has never yet deceived me, and observation. I refer to the strange electrical disturbances, the discovery of which I announced six years ago. At that time I was only certain that they were of planetary origin. Now, after mature thought and study, I have come to the positive conclusion that they must have emanated from Mars.

"Such colossal transformation as is observable on the face of Mars could not have been wrought except by beings ahead of us in development.

"What wonder if they are signalling to us? We are sufficiently advanced in electrical science to know that their task is much easier than ours. The question is, Can we transmit electrical energy to that immense distance? This I think myself competent to answer in the affirmative."

MARCONI NOT INFORMED.

"An Achievement of Far-Reaching Importance," If Claims Are Correct.

To the Editor of The New York Times:

GLACE BAY, N. S., Dec. 19.—As I am not familiar with the details of Prof. Poulson's wireless telephone I am not in a position to give a definite opinion thereon, but should he accomplish what he claims it would be an achievement of far-reaching importance. MARCONI.

MY APPARATUS, SAYS TESLA.

Confident, However, That Wireless Telephony Is Entirely Possible.

To the Editor of The New York Times:

I have read with great interest the report in your issue of to-day that the Danish engineer, Waldemar Poulson, the inventor of the interesting device known as the "telegraphone," has succeeded in transmitting accurately wireless telephonic messages over a distance of 240 miles.

I have looked up the description of the apparatus he has employed in the experiment and find that it comprises:

(1) My grounded resonant transmitting circuit; (2) my inductive exciter; (3) the so-called "Tesla transformer"; (4) my inductive coils for raising the tension on the condenser; (5) my entire apparatus for producing undamped or continuous oscillations; (6) my concatenated tuned transforming circuits; (7) my grounded resonant receiving circuit; (8) my secondary receiving transformer. I note other improvements of mine, but those mentioned will be sufficient to show that Denmark is a land of easy invention.

The claim that transatlantic wireless telephone service will soon be established by these means is a modest one. To my system distance has absolutely no significance. My own wireless plant will transmit speech across the Pacific with the same precision and accuracy as across a table. NIKOLA TESLA.

New York, Dec. 19, 1907.

DEADLY WAVE

Naval Battles of the Future to Be Fought by Water Power.

Cynamite, Discharged Beneath the Surface of the Sea, Will Create a Tidal Wave That Could Engulf a Fleet.

By NIKOLA TESLA.

THE time is not far distant when all the tremendous wastes of naval war will be stopped, and then, if there are battles, they will be fought with water power and electric waves. That humanity is moving fast towards this realization is evident from many indications.

What is most to be regretted in the present war regime is, that the effect of so many exquisite intelligences must be uneconomically applied, since it cannot be steadily directed toward a scientific truth, unaltered and of permanent usefulness, but must be entirely governed by the wavering struggle of opposing principles. This feverish striving to meet the instant demand, to create type after type, one to devour the other, to merge into one contrasting element, leads, like a nightmare, from one to another absurdity. Such a monstrosity is the latest creation of the naval constructor—a 20,000 ton battleship. In theory, it is condemned by competent authorities.

Everything points to the development of a small vessel with internal combustion engines, extreme speed, and few weapons of great destructiveness. But the new leviathan is admirably adapted to the practical requirements of the day. In attack it can alone annihilate a nation's fleet. It is equally effective in defense. If equipped with proper acoustic and electrical appliances, it has little to fear from a submarine, and an ordinary torpedo will scarcely hurt it. That is why the first of these monsters, built in England, has been named the Dreadnought. Now, there is a novel means for attacking a fortress of this kind, from shore or on the high seas, against which all its gun power and armor resistance are of no avail. It is the tidal wave.

Such a wave can be produced with 20 or 30 tons of cheap explosive, carried to its destination and ignited by a non-interferable telautomaton.

The tidal disturbance, as here considered, is a peculiar hydrodynamic phenomenon, in many respects different from the commonly occurring characterized by a rythmical succession of waves. It consists generally of but a single advancing swell succeeded by a hollow, the water if not otherwise agitated being perfectly calm in front and very nearly so behind. The wave is produced by some sudden sxplosion or upheaval, and is, as a rule, symmetrical for a large part of its course. Those who have encountered a tidal wave must have observed that the sea rises rather slowly, but the descent into the trough is steep. This is due to the fact that the water is lifted, possibly very slowly, under the action of a varying force, great at first, but dying out quickly, while the raised mass is urged downward by the constant force of gravity. When produced by natural causes these waves are not very dangerous to ordinary vessels, because the disturbance originates at a great depth.

To give a fairly accurate idea of the efficacy of this novel means of destruction, particularly adapted for coast defense, it may be assumed that 30 tons of nitro-glycerin compound, as dynamite, be employed to create the tidal disturbance. This material, weighing about twice as much as water, can be stored in a cubical tank eight feet each way, or a spherical vessel of 10 feet diameter. The reader will now understand that this charge is to be entrusted to a non-interferable telautomaton, heavily protected, and partly submerged or submarine, which is under the control of a skilled operator far away. At the propitious moment the signal is given, the charge sunk to the proper depth, and ignited.

The water is incompressible. The hydrostatic pressure is the same in all directions. The explosion propagates through the nitro-glycerin compound with a speed of three miles a second. Owing to all this, the whole mass will be converted into gas before the water can give way appreciably, and a spherical bubble 10 feet in diameter will form. The gaseous pressure against the surrounding water will be 20,000 atmospheres, or 140 tons per square inch. When the great bubble has expanded to twice its original volume, it will weigh as much as the water it displaces, and from that moment on, its lowering and tapering more and more into a cone, it will be driven up with a rapidly-increasing force tending towards 20,000 tons. Under this terrible impulsion it would shoot up to the surface like a bullet were it not for the water resistance, which will limit its maximum speed to 80 feet per second.

Consider now the quantity and energy of the upheaval. The caloric potential energy of the compound is 2,800 heat units per pound, or, in mechanical equivalent, almost 1,000-foot tons. Of course, only a part of this immense store is transformable into mechanical effort. Theoretically, 40 pounds of good smokeless powder would be sufficient to impart to the Dreadnought's 850-pound projectile the tremendous velocity mentioned above, but it actually takes a charge of 250 pounds. The tidal wave generator is a dynamic transformer much superior to the gun, its greatest possible efficiency being as high as 44 per cent. Taking, to be conservative, 33 per cent instead, there will be of the total potential store about 25,000,000 foot-tons obtained in mechanical energy.

Otherwise stated, 25,000,000 tons—that is, 860,000,000 cubic feet of water—could be raised one foot, or a smaller quantity to a correspondingly greater elevation. The hight and length of the wave will be determined by the depth at which the disturbance originated. Opening in the center like a volcano, the great hollows will belch forth with a roar. Some 15 seconds later a valley of 600 feet depth, counted from normal ocean level, will form, surrounded by a perfectly circular swell, approximately of equal hight, which will enlarge in diameter at the rate of about 220 feet per second.

It is futile to consider the effect of such an eruption on a vessel situated near by, however large. The entire navy of a great country, if massed around would be destroyed. But it is instructive to inquire what such a wave could do to a battleship of the Dreadnought type at considerable distance from its origin. A simple calculation will show that, when the outer circle has expanded to three-quarters of a mile, the swell, about 1,250 feet long, would still be more than 100 feet in hight, and when the circle is one and one-quarter miles in diameter the vertical distance from crest to trough would be over 100 feet.

The first impact of the water will produce pressures of three tons per square foot, which all over the exposed surface of, say, 20,000 square feet, may amount to 60,000 tons, eight times the force of the recoil of the broadside. That first impact may in itself be fatal. During more than 10 seconds the vessel will be entirely submerged and finally dropped into the hollow from a hight of about 75 feet, the descent being effected more or less like a free fall. It will then sink far below the surface, never to rise.

The New York World January 5, 1908

NIKOLA TESLA'S FORECAST FOR 1908.

Aerial and Sea Navigation and Wireless Telegraphy to Make Astounding Strides.

To the Editor of The World:

A forecast—not a prophecy!

Constant and careful study of the state of things in the particular sphere enables an expert to make a forecast fairly accurate of the next step. The seemingly isolated events are to him but links of a chain. As a rule, the signs he notes are so pronounced that he can predict the changes about to take place with certitude. The performance is a mere banality as compared with the piercing view of the inspired into the distant future. This is a forecast—not a prophecy.

The coming year will be great in thought and result. It will mark the end of a number of erroneous ideas which, by their paralyzing effect on the mind, have throttled independent research and hampered progress and development in various departments of science and engineering.

The first to be dispelled is the illusion of the Hertz or electro-magnetic waves. The expert already realizes that practical wireless telegraphy and telephony are possible only by minimizing this wasteful radiation. The results recently attained in this manner with comparatively crude appliances illustrate strikingly the possibilities of the genuine art. Before the close of the year wireless transmission across the Pacific and trans-Atlantic wireless telephony may be expected with perfect confidence. The use of the wireless telephone in isolated districts will spread like fire.

The year will mark the fall of the illusionary idea that action must diminish with distance. By impressing upon the earth certain vibrations, to which it responds resonantly, the whole planet is virtually reduced to the size of a little marble, thus enabling the reproduction of any kind of effect, as human speech, music, picture or character whatever, and even the transmission of power in unlimited amounts with exactly the same facility and economy at any distance, however great.

The next twelve months will witness a similar revolution of ideas regarding radio-activity. That there is no such element as radium, polonium or tonium is becoming more and more evident. These are simply deceptive appearances of a modern phlogiston. As I have stated in my early announcement of these emanations before the discovery of Mme. Curie, they are emitted more or less by all bodies, and are all of the same kind—merely effects of shattered molecules, differentiated not by the nature of substance but by size, speed and electrification.

The coming year will dispel another error which has greatly retarded the progress of aerial navigation. The aeronaut will soon satisfy himself that an aëroplane proportioned according to data obtained by Langley is altogether too heavy to soar, and that such a machine, while it will have some uses, can never fly as fast as a dirigible balloon. Once this is fully recognized the expert will concentrate his efforts on the latter type, and before many months are passed it will be a familiar object in the sky.

There is abundant evidence that distinct improvements will be made in ship propulsion. The numerous theories are giving place to the view that what propels the vessel is a reactive jet; hence the propeller is doomed to inefficiency at high speed. A new principle will be introduced.

The World is invited to test the accuracy of this forecast at the close of the year.

NIKOLA TESLA.

The New York Times January 28, 1908

WIRELESS AROUND THE WORLD.

Nothing Novel in the Accomplishment, Says Nikola Tesla.

To the Editor of The New York Times:

I read in your issue of to-day that, according to Lieut. Col. Ginsies, Director of Military Telegraphs of France, a wireless message "should theoretically go around the world." If you will take the trouble of perusing my French patent, No. 354,791, you will find that this has long since ceased to be a theory, for that document, while bearing the date of April, 1905, describes experiments which I made in the Fall of 1899, and one of which was to pass currents of 100 amperes around the globe; a mere breath in view of its immensity, but more than necessary to affect a sensitive receiver. You will also notice that in those tests I used "undamped" oscillations, one of my earliest improvements, which you seem to find pleasure in attributing to other electricians. These facts are mentioned incidentally, merely with the desire of informing you correctly.

What I wish to bring to your attention relates to certain provisions of the last wireless conference which are now being considered by the United States Senate. Some of the rules were undoubtedly proper and applicable to "radio-telegraphy" by electro-magnetic or Hertzian rays, in view of the impossibility of preventing interference and because many different forms of apparatus were employed. But since that time the Hertz waves have been abandoned by the more advanced experts and a uniform system adopted which permits the simultaneous transmission of any desired number of wireless messages without interference and with a precision and accuracy equal to, if not greater, than that practicable with cables. If international rules are to be established, they should be in reasonable harmony with existing conditions. Their consideration might be made the subject of another wireless conference, which it would be proper to hold here, as all the essential principles, processes, and devices have been discovered and perfected in this country.

You will probably agree with me that the contemplated compulsory exchange of messages is a measure not flattering to our enlightened age. We have no law compelling a person to go to the rescue of another in peril, and yet one who would fail to do so would be guilty of a crime insignificant as compared with that of ignoring a call of a vessel in distress. So ignominious a rule should not be permitted to go on record. Besides, the scheme is entirely impracticable. Even if sealed recording and controlling instruments were installed on the vessels, they would be of little use.

The trampling of rights granted to pioneers and attendant throttling of commercial undertakings, offering infinite possibilities, can be but hurtful to progress. As I have stated in a previous letter to THE TIMES, the wireless transmission of energy will ultimately insure the supremacy of the Anglo-Saxons, who are the fittest race to govern. Their interests and the world's peace are in the free and unhampered development of the art.

NIKOLA TESLA.

New York, Jan. 26, 1908.

Mr. Tesla Makes Further Disclosures.

Nikola Tesla, who has been making some rather remarkable assertions of late in letters printed in the New York Times, publishes another communication under date of January 26th. This is a part of it:

"I read in your issue of today that, according to Lieutenant-Colonel Chales, director of military telegraphs of France, a wireless message 'should theoretically go around the world.' If you will take the trouble of perusing my French patent, No. 354,791, you will find that this has long since ceased to be a theory, for that document, while bearing the date of April, 1905, describes experiments which I made in the fall of 1899, and one of which was to pass currents of 100 amperes around the globe, a mere breadth in view of its immensity, but more than necessary to affect a sensitive receiver. You will also notice that in those tests I used 'undamped' oscillations, one of my earliest improvements, which you seem to find pleasure in attributing to other electricians. These facts are mentioned incidentally, merely with the desire of informing you correctly.

"What I wish to bring to your attention relates to certain provisions of the last wireless conference which are now being considered by the United States Senate. Some of the rules were undoubtedly proper and applicable to 'radio-telegraphy' by electromagnetic or Hertzian rays, in view of the impossibility of preventing interference and because many different forms of apparatus were employed. But since that time the Hertz waves have been abandoned by the more advanced experts and a uniform system adopted which permits the simultaneous transmission of any desired number of wireless messages without interference and with a precision and accuracy equal to, if not greater than, that practicable with cables."

[89.]—TESLA COIL.—You will get better results by using a greater number of turns on an increased length of core. Of course, if you insulate every layer carefully, you may wind on several layers, both of primary and secondary; and, in order to prevent the insulation giving way, it would be better to stand the transformer bodily in an earthen vessel containing resinous paraffin oil of such a consistency that it will flow in between the layers of wire.

Arthur E. R. Bottone.

COMMUNICATION.

Mr. Tesla's Work.

To the Editor of the Western Electrician.

I note with interest the article in the issue of the Western Electrician of February 8th, entitled "Mr. Tesla Makes Further Disclosures." I have reason to believe that Mr. Nikola Tesla has already transmitted electrical energy without conducting wires to greater distances than any other inventor of "wireless" that the world has produced. In an interview with Daniel Drawbaugh, inventor of the telephone, some time ago he said that the Hertzian ray, or radio-telegraphy, is old. Mr. Drawbaugh said that the best transmission is through the earth. I have reason to believe that he is right. It seems very clear to me that some inventors are making use of some of Mr. Tesla's apparatus in modified forms.

J. HOLMES WILSON.

Carlisle, Pa., February 11, 1908.

The New York Herald March 11, 1908

TESLA WILL DESTROY AN ARMY A MINUTE

Twenty Million Horse Power Generator to Fight the Battles of the Future.

That present methods of warfare will be displaced by the use of electric waves projected through the air with effect sufficient to destroy an entire army in the space of a few minutes was the assertion of Nikola Tesla in an address delivered before the Entertainment Club at the Waldorf-Astoria last night. A twenty million horse power energy source will develop this electric force, he continued, its generating power in turn being drawn from the waterfalls of the country.

"With the age of great economies upon which we now are entering," he said, "it will be held wasteful to construct at great cost battle ships which are fit for active service only a few years. The battles of the future will be fought through the air. Further, there will be the creation of a system of wireless telephony which will render it possible to hold communication not only with every corner of the world, but with the other planets."

Commenting upon this picture of the future, Rear Admiral Charles D. Sigsbee said:—

"Well, all the naval and army officers of the future will have to do, evidently, in the light of the developments which Mr. Tesla promises, will be to sit down and fight their battles with kid gloves."

The New York Times March 11, 1908

AERIAL WARSHIPS COMING.

Also Wireless Telephony That Will Circle the Globe, Tesla Tells Diners.

Rear Admiral Charles Sigsbee and Nikola Tesla were guests of honor at a dinner and reception given by the Entertainment Club in the Waldorf-Astoria last night. Gen. J. Fred Pierson presided. Nikola Tesla spoke on the future of warfare. He said:

"Mankind will eventually harness the waterfalls and transform this enormous pressure into energy, and this will simplify warfare. Aerial vessels of war will be used to the exclusion of ships, and with 10,000,000 tons of energy this country will be equipped to rout the civilized world.

"I consider the greatest achievement of humanity will be wireless telephony, which may be operated throughout the globe. This will solve a thousand intricate features of our civilization. It is scientifically possible, and it will gradually become an actuality."

Admiral Sigsbee related his social activities during his long career in the navy. He told of a pork and beans dinner he ate with the family of Mme. Emma Eames in Shanghai in 1866.

TECHNICAL WORLD MAGAZINE April 1908

ENGINEERING PROGRESS

HOW TESLA WOULD DESTROY A NAVY

NIKOLA TESLA bears an honored name in electrical science and has done memorable work in oscillatory currents and in connection with Hertzian waves. A few years ago, it may be remembered, he stood in the theater of the Royal Institution with oscillatory currents of unheard-of voltage playing about his unharmed head, and this taste for the sensational appears to grow with increasing years, so that now Tesla's projects nearly always have a ring of the glaringly impossible, and are seldom anything more than plausible. His latest idea is that of creating an enormous tidal wave for purposes of coast defense in order to annihilate a hostile fleet. It may be assumed, remarks Mr. Tesla, that "thirty tons of nitroglycerine compound be employed to create the tidal disturbance. This material, weighing about twice as much as water, can be stored in a cubical tank eight feet each way or in a spherical vessel of ten feet diameter. . . . At the propitious moment the signal is given, the charge sunk to the proper depth and ignited. . . . The water is incompressible. The explosion propagates through the compound at a speed of three miles a second, so that the whole mass will be converted into gas before the water can give way appreciably, and a spherical bubble ten feet in diameter will form. The gaseous pressure against the surrounding water will be 20,000 atmospheres, or 140 tons to the square inch." At this point Mr. Tesla relapses into a maze of calculations of calories and power units, where it is difficult and unnecessary to follow him. He emerges presently with the resultant statement that 25,000,000 tons of water would be raised one foot, or a smaller quantity to a correspondingly greater elevation. The height and length of the wave will be determined by the depth at which the disturbance originated. Opening in the center like a volcano, the great hollows will belch forth a shower of ice. Some sixteen seconds later a valley of 600 feet depth, counted from normal ocean level, will form, surrounded by a perfectly circular swell, approximately of equal height, which will enlarge in diameter at the rate of about 220 feet per second. It is futile, concludes Mr. Tesla, pleasantly, to consider the effect on a neighboring vessel, however large. Even a navy would be destroyed.

WAR À LA TESLA

IT is suggested by Nikola Tesla that in the event of war a hostile navy could be swamped by a huge tidal wave created by the explosion at sea of a large quantity of nitroglycerin. Says a writer in *The Technical World Magazine* (Chicago, April):

"Nikola Tesla bears an honored name in electrical science and has done memorable work in oscillatory currents and in connection with Hertzian waves. A few years ago, it may be remembered, he stood in the theater of the Royal Institution with oscillatory currents of unheard of voltage playing about his unharmed head, and this taste for the sensational appears to grow with increasing years, so that now Tesla's projects nearly always have a ring of the glaringly impossible, and are seldom anything more than plausible. His latest idea is that of creating an enormous tidal wave for purposes of coast defense in order to annihilate a hostile fleet. It may be assumed, remarks Mr. Tesla, that 'thirty tons of nitroglycerin compound be employed to create the tidal disturbance. This material, weighing about twice as much as water, can be stored in a cubical tank eight feet each way or in a spherical vessel of ten feet diameter. . . . At the propitious moment the signal is given, the charge sunk to the proper depth and ignited. . . . The water is incompressible. The explosion propagates through the compound at a speed of three miles a second, so that the whole mass will be converted into gas before the water can give way appreciably, and a spherical bubble ten feet in diameter will form. The gaseous pressure against the surrounding water will be 20,000 atmospheres, or 140 tons to the square inch. At this point Mr. Tesla relapses into a maze of calculations of calories and power units, where it is difficult and unnecessary to follow him. He emerges presently with the resultant statement that 25,000,000 tons of water would be raised one foot, or a smaller quantity to a correspondingly greater elevation. The height and length of the wave will be determined by the depth at which the disturbance originated. Opening in the center like a volcano, the great hollows will belch forth a shower of ice. Some sixteen seconds later a valley of 600 feet depth, counted from normal ocean-level, will form, surrounded by a perfectly circular swell, approximately of equal height, which will enlarge in diameter at the rate of about 220 feet per second. It is futile, concludes Mr. Tesla, pleasantly, to consider the effect on a neighboring vessel, however large. Even a navy would be destroyed."

The New York Times April 21, 1908

MR. TESLA'S VISION.

How the Electrician's Lamp of Aladdin May Construct New Worlds.

To the Editor of The New York Times:

From a report in your issue of March 11, which escaped my attention, I notice that some remarks I made on the occasion referred to have been misunderstood. Allow me to make a correction.

When I spoke of future welfare I meant that it would be conducted by direct application of electrical waves without the use of aerial engines or other implements of destruction. This means, as I pointed out, would be ideal, for not only would the energy of war require no effort for the maintenance of its potentiality, but it would be productive in times of peace. This is not a dream. Even now wireless power plants could be constructed by which any region of the globe might be rendered uninhabitable without subjecting the population of other parts to serious danger or inconvenience.

What I said in regard to the greatest achievement of the man of science, whose mind is bent upon the mastery of the physical universe, was nothing more than what I stated in one of my unpublished addresses, from which I quote: "According to an adopted theory, every ponderable atom is differentiated from a tenuous fluid, filling all space merely by spinning motion, as a whirl of water in a calm lake. By being set in movement this fluid, the ether, becomes gross matter; its movement arrested, the primary substance reverts to its normal state. It appears, then, possible for man through harnessed energy of the medium and suitable agencies for starting and stopping ether whirls to cause matter to form and disappear. At his command, almost without effort on his part, old worlds would vanish and new ones would spring into being. He could alter the size of this planet, control its seasons, adjust its distance from the sun, guide it on its eternal journey along any path he might choose, through the depths of the universe. He could make planets collide and produce his suns and stars, his heat and light; he could originate life in all its infinite forms. To cause at will the birth and death of matter would be man's grandest deed, which would give him the mastery of physical creation, make him fulfill his ultimate destiny."

Nothing could be further from my thought than to call wireless telephony around the world "the greatest achievement of humanity," as reported. This is a feat which, however stupefying, can be readily performed by any expert. I have myself constructed a plant for this very purpose. The wireless wonders are only seeming, not results of exceptional skill, as popularly believed. The truth is the electrician has been put in possession of a veritable lamp of Aladdin. All he has to do is to rub it. Now, to rub the lamp of Aladdin is no achievement.

If you are desirous of hastening the accomplishment of still greater and further-reaching wonders you can do no better than by emphatically opposing any measure tending to interfere with the free commercial exploitation of water power and the wireless art. So absolutely does human progress depend on the development of these that the smallest impediment, particularly through the legislative bodies of this country, may set back civilization and the cause of peace for centuries.

PATENTS IN GERMANY.

Complaints of Ill Treatment of American Inventors.

To the Editor of The Sun—*Sir:* In a special cable despatch from Berlin in The Sun of May 3 the president of the Imperial Patent Office is reported as saying that he did not recall a case in which the rights of unexploited American patents have been withdrawn. That statement reminds me painfully of at least one such case, the annulment by a special act of the Reichsgeriche of my patents on the transmission of power, which deprived me of a great fortune. My discoveries in that field are the foundation of an immense industry in Germany, but it is of no benefit to myself or to the firm which undertook their introduction in that country. This, however, is not my only disappointing experience with the Imperial Patent Office. My application for my system of wireless transmission of energy, anticipating all others, is still locked up there, while German companies are exploiting the advances in the art it disclosed.

I could say more, but it would be nothing novel, for such has been the uniform experience of American inventors. The ablest patent attorneys here now advise their clients, almost as a rule, not to bother with German rights, and for good reasons. Ask any of the great inventors of this country, Bell, Edison, Thomson, Brush, Weston and others, what pecuniary benefits they have received from Germany, and the answer will be, none.

How much we have to fear from a patent war with Germany I leave it to yourself to infer. That the United Sates should adopt some measures for the protection of home invention is a perfectly obvious conclusion, particularly in view of the recent change in the British patent law. Nikola Tesla.

New York, May 5.

LITTLE AEROPLANE PROGRESS

So Says Nikola Tesla.—But He Is Working on One of His. Own.

To the Editor of The New York Times:

It was not a little amusing to read a short time ago how the "great secret" of the aeroplane was revealed. By surrounding that old device with an atmosphere of mystery one gives life and interest to the report; but the plain fact is that all forms of aerial apparatus are well known to engineers, and can be designed for any specific duty without previous trials and with a fair degree of accuracy. The flying machine has materialized—not through leaps and bounds of invention, but by progress slow and imperceptible, not through original individual effort, but by a combination of the same forces which brought forth the automobile and the motorboat. It is due to the enterprise of the steel, oil, electrical, and other concerns, who have been instrumental in the improvement of materials of construction and in the production of high-power fuels, as well as to the untiring labors of the army of skilled but unknown mechanics, who have been for years perfecting the internal combustion engine.

There is no salient difference between the dirigible balloon of Renard & Krebs of thirty years ago and that of Santos Dumont with which the bold Brazilian performed his feats. The Langley and Maxim aerodromes, which did not soar, were in my opinion better pieces of mechanism than their very latest imitations. The powerful gasoline motor which has since come into existence is practically the only radical improvement.

So far, however, only the self-propelled machine or aerial automobile is in sight. While the dirigible balloon is rapidly nearing the commercial stage, nothing practical has as yet been achieved with the heavier-than-air machine. Without exception the apparatus is flimsy and unreliable. The motor, too light for its power, gives out after a few minutes' run, the propeller blades fly off the rudder is broken, and, after a series of such familiar mishaps, there comes the inevitable and general smash-up. In strong contrast with these unnecessarily hazardous trials are the serious and dignified efforts of Count Zeppelin, who is building a real flying machine, safe and reliable, to carry a dozen men and provisions over distances of thousands of miles, and with a speed far in excess of those obtained with aeroplanes.

The limits of improvement in the flying machine, propelled by its own power, whether light or heavy, are already clearly defined. We know very closely what we may expect from the ultimate perfection of the internal combustion engine, the resistances which are to be overcome, and the limitations of the screw propeller. The margin is not very great. For many reasons the wireless transmission of power is the only perfect and lasting solution of the problem of aerial navigation. But even then it will scarcely be possible to reach very high speeds.

In this respect many experts are mistaken. The popular belief is that because the air has only one-hundredth of the density of water, enormous velocities should be practicable. But it is not so. It should be borne in mind that the air is one hundred times more viscous than water, and because of this alone the speed of the flying machine could not be much in excess of a properly designed aqueous craft.

The aeroplane of the Langley type, such as was used by Farman and others with some success, will hardly ever prove a practical aerial machine, because no provision is made for maintaining it in the air in a downward current. This and the perfect balance independently of the navigator's control is absolutely essential to the success of the heavier-than-air machine. These two improvements I am myself endeavoring to embody in a machine of my own design. NIKOLA TESLA.

WIRELESS TELEPHONY

BY R. A. FESSENDEN

Synopsis

A. Preface.
B. Brief history of the development of wireless signaling.
   1. Introduction.
   2. Period 1838–1897. Origin and development of old or damped wave-coherer method.
   3. 1898. Return to first principles and foundation, on lines antithetical to old, of new or sustained oscillation-non-microphonic receiver method.

During the course of this work, now extending over twelve years, since 1906, I have naturally incurred indebtedness on all hands. Amongst others to whom my thanks are due are: Professor Kintner for much valuable assistance in the experimental work; Mr. Brashear, for his kindness in making up a number of special pieces of optical and other apparatus for use in the work; Mr. H. W. Fisher, and to Professor Frost, for the loan of electrical apparatus. For the development of the high-frequency alternator, I have to thank Messrs. Steinmetz, Haskins, Alexanderson, Reist, Geisenhoner and Dempster, and Mr. Guy. For much valuable assistance in the construction of my transatlantic apparatus, I am obliged to Mr. Green. Especially am I indebted to the gentlemen who have acted as my assistants during the progress of the work, especially Mr. Stein and Mr. Mansbendel and Mr. Bennet, Mr. Davis, Mr. Hill, Mr. Kroeger, Mr. Boyle and Mr. Bryant, and to our shop superintendent, Mr. Williams.

In order to avoid repetition, patents covering inventions made and developed by the writer without assistance or coöperation are referred to by the patent number and date only. Where there has been co-operation on the part of an assistant the patent has been taken out and referred to under the joint names of the coöperators. All inventions made or developed by assistants are taken out and referred to by the assistant's name.

4. Fundamental differences between the old and new wireless schools.
5. Period 1898–1902.
   (a) Development and perfecting of sustained oscillation-non-microphonic receiver method.
   (b) Further development of damped wave-coherer method.
6. Period 1902–1908. General abandonment of old method and adoption of new method. Later developments.

C. Theory of wireless telephony.
D. History of development of wireless telephony.
E. Methods and apparatus.
F. Operation.
G. Possibilities.
H. How wireless development has been prevented by governmental action.
I. Considerations.
K. Appendix.

A. Preface

The discussion of the theory, practical operation, and possibilities of wireless telephony is facilitated by first briefly considering the history of the development of wireless signaling generally.

B. Brief History of the Development of Wireless Signaling

1. *Introduction.* In preparing this note it has been considered best, for the sake of accuracy, to refer to published results, such as scientific articles or theses or patent specifications. For the sake of brevity, references to work done in repetition of previously published work has as a rule been omitted. So far as possible, the expression of personal opinion has been avoided in this section of the paper, the object being to gather together in concise form the facts known in regard to the development of the art. With the exception of Munk's original paper, which could not be obtained, all references have been verified by consulting the original publications, a work of some labor, and if any omissions or mistakes have been made data for their correction will be much appreciated.

2. *Period* 1838–1897. *Origin and Development of Old or Damped Wave-coherer Method.* Joseph Henry, to whose work

the development of wire telegraphy owes so much, was the first (1838-1842) to produce high frequency electrical oscillations, and to point out and experimentally demonstrate the fact that the discharge of a condenser is under certain conditions oscillatory, or, as he puts it, consists "of a principal discharge in one direction and then several reflex actions backward and forward, each more feeble than the preceding until equilibrium is attained".[1]

This view was also later adopted by Helmholz[2] but the mathematical demonstration of the fact was first given by Lord Kelvin in his paper on "Transient Electric Currents".[3]

In 1870 Van Bezold discovered and experimentally demonstrated the fact that the advancing and reflected oscillations produced in conductors by a condenser discharge gave rise to interference phenomena.[4]

Professors Elihu Thomson and E. J. Houston in 1876 made a number of experiments and observations on high frequency oscillatory discharges.[5]

In 1883 Professor Fitzgerald suggested at a British Association meeting[6] that electromagnetic waves could be generated by the discharge of a condenser, but the suggestion was not followed up, possibly because no means was known for detecting the waves.

Hertz[7] discovered a method of detecting such waves by means of a minute spark-gap and before March 30, 1888, had concluded his remarkable series of researches in which for the first time electromagnetic waves were actually produced by a spark-gap and radiating conductor and received and detected at a distance by a tuned receiving circuit.

Hertz changed the frequency of his radiated waves by altering the inductance or capacity of his radiating conductor or antenna, and reflected and focused the electromagnetic waves, thus demonstrating the correctness of Maxwell's electromagnetic theory of light.

7. Hertz "Electric Waves".

Lodge later in the same year read a paper on the " Protection of Buildings from Lightning "[1], before the Society of Arts, in which he described a number of interesting experiments on oscillatory discharges.

Great interest was excited by the experiments of Hertz, primarily on account of their immense scientific importance. It was not long, however, before several eminent scientists perceived that the property possessed by the Hertz waves of passing through fog and material obstacles made them particularly suitable for use for electric signaling.

Professor Elihu Thomson in a lecture delivered at Lynn, Mass., on " Alternating Currents and Electric Waves ", in 1889, suggested this use.

Sir William Crookes in the *Fortnightly Review* for February, 1892, discussed the matter in some detail. I quote his statement in full as it shows what a clear conception he had of the possibilities and obstacles to be overcome:

> Here is unfolded to us a new and astonishing world, one which it is hard to conceive should contain no possibilities of transmitting and receiving intelligence.
>
> Rays of light will not pierce through a wall, nor, as we know only too well, through a London fog. But the electrical vibrations of a yard or more in wave length of which I have spoken will easily pierce such medium, which to them will be transparent. Here, then, is revealed the bewildering possibility of telegraphy without wires, posts, cables, or any of our present costly appliances. Granted a few reasonable postulates, the whole thing comes well within the realms of possible fulfilment. At the present time experimentalists are able to generate electrical waves of any desired wave-length from a few feet upwards, and to keep up a succession of such waves radiating into space in all directions. It is possible, too, with some of these rays, if not with all, to refract them through suitably shaped bodies acting as lenses, and so direct a sheaf of rays in any given direction; enormous lens-shaped masses of pitch and similar bodies have been used for this purpose. Also an experimentalist at a distance can receive some, if not all, of these rays on a properly constituted instrument, and by concerted signals messages in the Morse code can thus pass from one operator to another What, therefore, remains to be discovered is—firstly, simpler and more certain means of generating electrical rays of any desired wave-length, from the shortest, say of a few feet in length, which will easily pass through buildings and fogs, to those long waves whose lengths are measured by tens, hundreds, and thousands of miles; secondly, more delicate receivers, which will respond to wave-lengths between certain defined limits and be silent to all others; thirdly, means of darting the sheaf of rays in any desired direction, whether by lenses or reflectors, by the help of which the sensitiveness of the receiver

1. Lodge *Society* of *Arts*, 1888.

> (apparently the most difficult of the problems to be solved) would not need to be so delicate as when the rays to be picked up are simply radiating into space in all directions, and fading away according to the law of inverse squares.
>
> I assume here that the progress of discovery would give instruments capable of adjustment by turning a screw or altering the length of a wire, so as to become receptive of wave-lengths of any preconcerted length. Thus, when adjusted to 50 yards, the transmitter might emit, and the receiver respond to, rays varying between 45 to 55 yards, and be silent to all others. Considering that there would be the whole range of waves to choose from, varying from a few feet to several thousand miles, there would be sufficient secrecy, for curiosity the most inveterate would surely recoil from the task of passing in review all the millions of possible wave-lengths on the remote chance of ultimately hitting on the particular wave-length employed by his friends whose correspondence he wished to tap. By " coding " the message even this remote chance of surreptitious straying could be obviated.
>
> This is no mere dream of a visionary philosopher. All the requisites needed to bring it within the grasp of daily life are well within the possibilities of discovery, and are so reasonable and so clearly in the path of researches which are now being actively prosecuted in every capital of Europe that we may any day expect to hear that they have emerged from the realms of speculation into those of sober fact. Even now, indeed, telegraphing without wires is possible within a restricted radius of a few hundred yards, and some years ago I assisted at experiments where messages were transmitted from one part of a house to another without an intervening wire by almost the identical means here described.

The statement in the last paragraph of the quotation refers to the work of Professor David E. Hughes.[1]

Professor Dolbear also suggested the same thing in an article in Donahoe's Magazine, March, 1893.

In fact the idea of using Hertzian waves for wireless telegraphy seems to have been quite widespread in the years immediately following Hertz's publications.

Fairly efficient means of generating electromagnetic waves of any desired length had been made known by Hertz. Vertical antennas connected with the ground had been previously used for sending and receiving by Dolbear in 1882 in connection with his system for telegraphing by electrostatic induction[2] and also later by Edison and others.

Hertz's receiver, the minute spark-gap, was not suited for wireless telegraphy and before any telegraphic work could be done a suitable receiver had to be found.

1. For Report of this work see *Electrician*, May 5, 1899.
2. Dolbear U. S. patent 350,299, March 24, 1882.

The fact that tubes containing conducting powders had their resistance altered by the discharge of a Leyden jar and that the original resistance could be restored by tapping the tube was first noted by Munk in 1835.[1]

In 1890 Branly showed that such a tube would respond to sparks produced at a distance from it.[2]

In 1892, at the meeting of the British Association at Edinburgh, Professor George Forbes suggested that such a tube would respond to Hertzian waves.

In 1893 Professor Minchen demonstrated experimentally that such powders would respond to electromagnetic waves generated at a distance.[3] He used a battery and galvanometer shunted around the powder to detect the effect of the waves.

Sir Oliver J. Lodge on June 1, 1894, delivered a lecture before the Royal Institution.[4] In this remarkable lecture Lodge described among other things the following:

1. The filings coherer.
2. The filings coherer in hydrogen under reduced pressure (this in a note added July, 1894).
3. The automatic tapper back for the coherer.
4. The metallic reflector for focusing the waves.
5. The connection of the coherer to a grounded conductor; *i.e.*, a gas pipe system.
6. The method of making the coherer so connected respond by setting up oscillations in a separate grounded system, *i.e.*, a hot-water pipe system, in another part of the building.
7. The method of detecting distant thunder storms by connecting the coherer to a grounded gas pipe system.

In this lecture Professor Lodge stated that in his estimate the apparatus used would respond to signals at a distance of half a mile.

Early in 1895 Professor Popoff[5] of Cronstadt, Russia, constructed a very sensitive filings coherer, one form of which was used in some surveying experiments by the Russian govern-

ment,[1] consisting of iron filings suspended by a magnet and resting upon a metallic plate or cup. Other forms consisted of filings in glass tubes with platinum electrodes. He used early in 1895, the automatic tapping back mechanism, and substituted for the galvanometer an ordinary telegraphic relay. He operated this apparatus at a distance by means of a large Hertzian radiator. One terminal of his coherer was connected to a conductor fastened to a mast about 30 ft. high on the top of the Institute building and the other terminal of the coherer was grounded.

At the conclusion of his paper, which is dated December, 1895, Popoff made the following statement "In conclusion I can express the hope that my apparatus, with further improvements of same, may be adapted to the transmission of signals at a distance by the aid of quick electric vibrations, as soon as the source of such vibrations, possessing sufficient energy, will be found."

Among other experimenters who were working on this subject at the same time may be mentioned Captain Jackson of the British Navy, and Mr. A. C. Brown.

Marconi, on June 2, 1896, filed a provisional specification[2] showing two forms of apparatus, one similar to Lodge's 1894 apparatus using ungrounded aerials for both sending and receiving and the other for use "when transmitting through the earth or water" substantially identical with Lodge's 1894 and Popoff's 1895 apparatus, with tapper back etc., and the receiving antenna only being grounded.

Soon after, in July 1896, Marconi arrived in England and made a number of experiments for the English Post Office at Salisbury Plain and elsewhere, using ungrounded aerials and parabolic reflectors and succeeded in reaching nearly two miles.

On March 2, 1897, Marconi filed the complete specification in which was included a statement that the transmitting antenna also could be grounded.

Lodge filed a provisional specification[3] showing radiating spheres but no antenna on May 10, 1897. The complete specification filed on Feb. 5, 1898, shows as one form both antennæ

3. Lodge, Great Britain, patent, 11,575, 1897.

grounded and also the use of an inductance wound in the form of a coil for the purpose of diminishing the rate of damping of the waves.

So far as is known little work was done in America during this period. The writer made some experiments in 1896 and in conjunction with two of his students, Messrs. Bennett and Bradshaw, did considerable work on receivers of various type in the fall of 1896 and spring of 1897, the results of which were incorporated in a thesis.[1]

3. 1898. *Return to First Principles and Foundation, on lines Antithetical to Old, of New or Sustained Oscillation non-microphonic Receiver Method.* Up to the year 1898, as may be seen from the above, the development of wireless telegraphy had proceeded along a single line. In that year, however, an entirely new method of wireless telegraphy was developed, characterized by a return to first principles, the abandonment of the previously used methods and by the introduction of methods in almost every respect their exact antitheses.

While the coherer is of more or less interest theoretically it is not adapted for use for telegraphic purposes. Responding as it does to voltage rises above a certain limit it does not discriminate between impulses of different characters, and is therefore peculiarly susceptible to interfering signals and atmospheric disturbances, and the operation of coherer systems cannot be guaranteed during the summer months or in the tropics. Roughly speaking a coherer acts by starting an arc and making a short-circuit on the line every time a signal is received, which short-circuit persists until it is broken by a blow from an additional mechanism, and such a method of operation is obviously far from practical. In addition it is practically impossible to obtain sharp tuning in a local circuit containing a coherer; its action is always more or less erratic, its electrostatic capacity variable, and it is insensitive.

At the sending end the energy which can be liberated by the discharge of an antenna is limited and in the form used prior to 1897 the dampening is so great that there are only a few oscillations per spark.

Lodge[2] by placing a coil of large inductance in the antenna throttled down the amount of energy radiated per oscillation and so obtained with the same limited amount of energy derived from the charged antenna, an increase in the time of damping.

1. Western University of Pennsylvania, May, 1897.
2. Lodge, Great Britian, patent 11,575, 1897.

Braun[1] patented the method of using a local oscillatory circuit connected to an antenna, the local oscillatory circuit having a much longer period than the natural period of the antenna and of a different order of magnitude. Such a system, however, does not radiate energy appreciably, and produces a damped wave.

This dampening and the limited amount of energy obtainable by charging and discharging the antenna operates to prevent sharp tuning and working over long distances.

The coherer is well adapted for working with damped waves, but the coherer-damped wave method can never be developed into a practical telegraph system. It is a question whether the invention of the coherer has not been on the whole a misfortune as tending to lead the development of the art astray into impracticable and futile lines and thereby retarding the development of a really practical system.

The fact that no coherer-damped wave system could ever be developed into a practically operative telegraph system, and the fact that it was necessary to return to first principles and initiate a new line of development along engineering rather than laboratory lines was perceived in America in 1898[2] and a new method was advised which may be called the Sustained Oscillation-non-microphonic Receiver method as opposed to the Damped Oscillation-coherer method previously used.

4. *Fundamental Differences between the Old and New Wireless Schools.* The differences between the two methods are shown in tabulated form:

	Damped Oscillation-coherer Method		Sustained Oscillation-non-microphonic Method.
A1:	Damped oscillations are produced at the sending end.	A1:	Sustained oscillations are produced at the sending end.
2:	The energy transmitted is obtained by charging the antenna and discharging it.	2:	The energy transmitted is derived from a local source and fed into the antenna.
3:	A spark gap is used for producing the oscillations.	3:	An arc or high frequency dynamo is generally used for producing the oscillations.

1. Braun, German patent 11,578, Oct. 14, 1898.
2. *Electrical World*, July 29, Aug. 12, Sept. 16, 1899 and *Proceedings American Institute of Electrical Engineers*, Nov. 1899, p. 635 and Nov. 20, 1906, p. 781.

B1:	Imperfect or microphonic contact receivers are used.	B1: Non-microphonic contact receivers are used.
2:	The action of the receiver depends upon the voltage rise and is independent of the amount of energy received.	2: The receiver response is determined by the integral amount of energy received.
3:	An open tuned circuit is used for receiving.	3: A closed tuned circuit is used for receiving.
4:	The receiving circuit is tuned to the wave frequency only.	4: The receiving circuit may be tuned to a group frequency as well as to the wave frequency.
C1:	In transmitting messages the production of the electromagnetic waves is intermittent.	C1: The waves are preferably generated continuously and the transmission accomplished by changing the character of the wave.
2:	The wave energy flux is intermittent.	2: The wave energy flux is constant.
3:	A high voltage is used.	3: A low voltage is used.
4:	Comparatively short wave lengths are used.	4: Comparatively long wave lengths are used.
5:	The signals consist of dots and dashes, whose interpretation is fixed.	5: The signals may consist of dots only, whose interpretation depends on the station sending and receiving.
D1:	Antennæ are used adapted, roughly speaking, to utilize the electrostatic component of the electromagnetic waves.	D1: The antennæ are preferably arranged so as to utilize the other component of the electromagnetic waves instead of the electrostatic component.

The history of these two antithetical lines of development will be treated of separately.

5. *Period* 1898–1902 A. *Development and Perfecting of Sustained Oscillation-non-microphonic Receiver Method* (a) *The current-operated receiver.* The first essential for the development of the system was, of course, a quantitatively responsive receiver. Several forms of this were tried including the modification of the Boys' radio-micrometer (consisting of a light thermo couple suspended in the field of a permanent magnet

and heated by radiation from a wire which in turn was heated by the current to be detected) described by the writer at the Columbus meeting of the American Association in 1897.[1] This was abandoned in favor of Professor Elihu Thomson's alternating-current galvanometer[2] suitably modified for telegraphic work.[3]

Among other forms of current-operated receiver may be mentioned the following.

The *Hot-wire Barretter*,[4] consisting of a minute platinum wire a few hundred thousandths of an inch in diameter and approximately a hundredth of an inch in length. The term " barretter " was coined for this device for the reason that it differs essentially from the bolometer of Langley in that it is arranged to be affected by external sources of radiant heat as little as possible instead of as much as possible, and, to have an extremely small specific heat, an object not sought in the case of the bolometer.

The *Liquid Barretter*[5] in which the change of resistance is effected by heating a liquid, the concentration of path being obtained by means of a fine platinum wire point. Some question has been raised as to the theory of operation of this device but I think there is no question but that the effect is due to heat, though what per cent. of the effect is due to change in ohmic conductivity by heat and what per cent. is due to depolarization by heat is still, as originally stated by the writer,[6] uncertain. The facts that the device operates practically equally well irrespective of which terminal is connected to the local battery, and that the effect varies as the square of the alternating current (as a heat operated device should do) instead of directly with the alternating current as a rectifier would do, and that depolarization is produced by the heat, have been confirmed by Dr. L. W. Austin.[7] The writer has experimentally determined the fact that though the electrical impulses may have a duration of less than a millionth part of a second the change in resistance persists for approximately the ten thousandth part of a second, which would seem to show conclusively that the action is not a *direct* effect of the waves.

5. U. S. patent 727,331, April 9, 1903.
6. *Ibid.*
7. Austin, *Bulletin of the Bureau of Standards*, Vol. 2 No. 2.

The term electrolytic receiver has sometimes been applied to the liquid barretter. This is objectionable, as there are a number of electrolytic receivers. For example, the Neughschwender-Schaefer[1] receiver, in which a number of microscopic filaments are produced between two terminals by electrolysis, which filaments are ruptured by the wave produced oscillations, thus increasing the resistance; also the liquid coherer of Captain Ferrie, described by him as follows:[2]

> The same effect of self-decohering coherence has been determined for a contact of a metallic wire and a liquid conductor, acidulated water, contained in a glass tube of small diameter, and placed under the same conditions as the preceding. Always, the sensitiveness of this contact is very notably inferior to that obtained in the experiments disclosed above. The maximum sensitiveness was obtained when the resistance of the imperfect contact was about 2000 ohms and when the extremity of the metal wire scarcely grazed the meniscus of the liquid. The results obtained were better with a copper wire, attacked by the acidulated water, than with a platinum wire.

which probably acts through a chemical effect producing a thin film of gas and has never come into use, doubtless because, as Captain Ferrie points out, it is even less sensitive than the Marconi coherer. Also the rectifier of Pupin[3] in which the terminals are placed so closely together that practically no energy is absorbed in the receiver, in order that the rectified energy may be utilized outside in the external circuit, in opposition to the liquid barretter, where the position of the terminals is such that all the received wave energy is absorbed in the barretter for the purpose of producing a secondary effect, and so influencing the current in a shunted local circuit.

(b) *Methods of Obtaining Sustained Oscillations.* 1. *Spark-gap and Local Oscillatory or "tank" Circuit.* Professor Elihu Thomson discovered that by using a transformer without an iron core (the well known Elihu Thomson air-core transformer, later used by Tesla and others), and a spark-gap and condenser in the primary circuit and with the secondary circuit suitably tuned great resonant rises of potential could be obtained. In 1892 he constructed such a transformer giving discharges 64 inches long.[4]

The same method was later used by Tesla[5] in his experimental

1. Neughschwender German Patent 107843, Dec. 13, 1898, and Schaefer British Patent 6002, 1899.
2. Blondel, *L'Eclairage Electrique*, Sept. 29, 1900.
3. Pupin, U. S. Patent 713,044, January 4, 1898.
4. *Electrical World*, Feb. 20 and 27, 1892.
5. U. S. patent 645,516, Sept. 2, 1897.

researches and in his attempt to carry out Loomis'[1] method of transmitting a current through a hypothetical conducting stratum in the upper regions of the atmosphere.

The device, suitably modified for wireless telegraphic purposes, so as to give instead of a continuously cumulative rise of potential an initial rise of potential followed by a gradual feeding in of the energy from the local circuit to supply the energy lost from radiation, was made use of in 1898 for the purpose of producing prolonged trains of sustained waves.

Various types of connection between the antenna and the local oscillatory circuit were tested but it was found that the most efficient results were obtained by connecting the local circuit directly across the spark-gap.[2]

The results of some comparative tests are here given. The figures in the column "A" are for the local circuit connected directly to the terminals of the spark-gap, those in column "B" are for an auto-transformer, those in column "C" for a loose coupled primary and secondary.

	A	B	C
Frequency	212,000	212,000	212,000
Tank capacity	0.072 m.f.	0.072 m.f.	0.072 m.f.
Kilowatt output dynamo	30	30	30
Tank current	400 amperes	370 amperes	300 amperes
Antenna current	48.5	46.	48.

The large station at Brant Rock is operated with the local circuit directly connected across the spark-gap, partly because the efficiency is somewhat greater, but also on account of the great simplification of connections and the fact that the degree of sustainment of the wave train may be adjusted very simply, if desired, by sliding the lower terminal of the antenna along a few inches of the lead of the local oscillatory circuit.

Cooper Hewitt[3] in 1902 used a modification of his mercury lamp to obtain intermittent discharges each followed by a train of high frequency oscillations.

2. *Arc methods.* The worker with high frequency oscillatory currents will soon discover that we are indebted to the genius of Professor Elihu Thomson for practically every device of any importance in this art.

1. Loomis, U. S. patent, 129,971, July 30, 1872.
2. U. S. patents 706,735 and 706,736, Dec. 15, 1899.
3. Cooper Hewitt, U. S. patent 780,999, April 25, 1902.

The method of producing high frequency oscillations from an arc and continuous current was discovered by him in 1892.[1] Fig. 1, taken from his patent, shows the general form of his arrangement. If the directions given in the specification are followed no difficulty will be met with in obtaining frequencies as high as 50,000 per second.

Between 1900 and 1902 some experiments were carried out with the Elihu Thomson arc as a source of high frequency oscillations for wireless telegraphy and telephony.

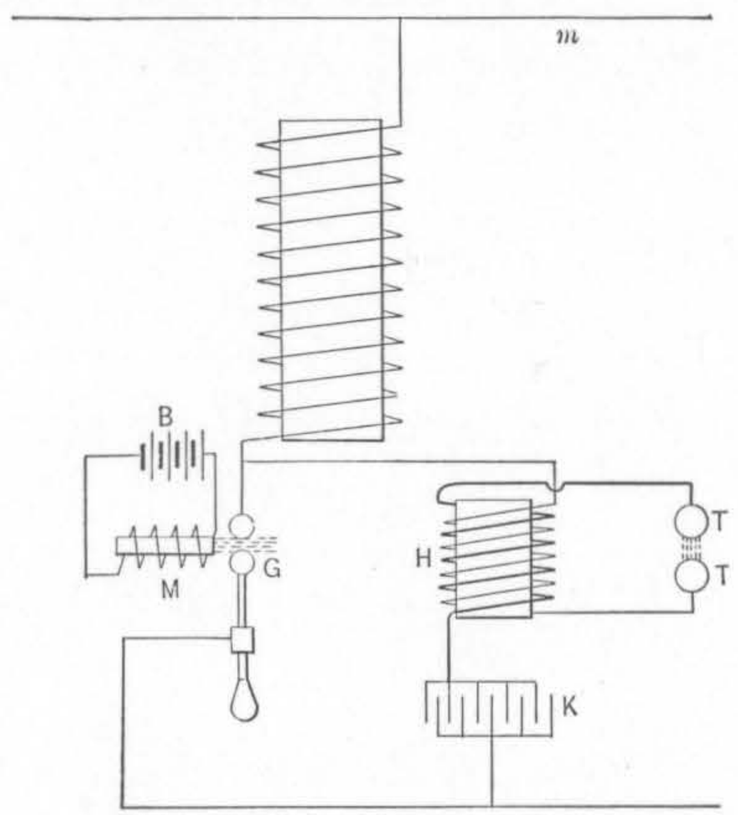

Fig.1

Some difficulties were found, for example the arc could not be started and stopped as quickly as was necessary for telegraphic purposes and the intensity of the oscillations and their frequency varied considerably. These were overcome by making some minor improvements, for example the difficulty in sending was overcome by permitting the arc to run continuously and using the key to change the electrical constants of the circuits.[2] The difficulty in keeping the intensity and frequency constant was

1. Elihu Thomson U. S. patent 500,630, July 18, 1892.

2. U. S. patents 706,742, July 6, 1902, 706,747, Sept. 28, 1901, 727,330, March 21, 1903, 730,753, April 9, 1903.

overcome by substituting resistance for a portion of the inductance, and also by using the arc under pressure.[1]

Tests made by Dr. Austin[2] show that with this method frequencies as high as 3,000,000 per second and efficiencies as high as 60% can be obtained together with an absolutely steady[3] generation of the high frequency currents and an absence of harmonic frequencies.

3. *High frequency alternator.* The first high frequency alternator was built by Professor Elihu Thomson in 1889. And it[4] was while experimenting with it in 1900 that Dr. Tatum made his very interesting discovery that high frequency currents of large amperage could be passed through the body without injury.[5]

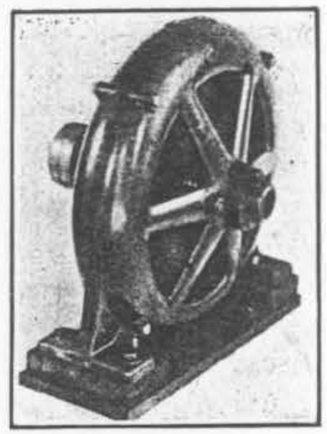

Fig. 2

From 1898 to 1900 numerous experiments were made on antennæ of large capacity and it was found that instead of using sheets of solid metal or wire netting, single wires could be placed at a considerable fraction of the wave-length apart and yet give practically the same capacity effect as if the space between them were filled with solid conductors.

From other investigations on the variation of radiation with

1. *Ibid* and U. S. patent 706,741.

2. Austin, *Bulletin of the Bureau of Standards*, Vol. 3, No. 2.

3. Austin assumed from the figure he obtained for the dampening, that the oscillations were not continuous; but the method used for determining the dampening is not applicable to this case, and a comparison of the currents and voltages with the frequencies given in Austin's experiments, shows that these oscillations must have been continuous.

frequency the result was arrived at that it should be possible to construct an alternating-current dynamo of sufficiently high frequency and output to give ample radiation for wireless telegraphic purposes.[1]

In 1900 a large American electrical manufacturing company kindly consented to take up the construction of such a dynamo. As a preliminary, a dynamo of 1 kw. output and 10,000 cycles (shown in Fig. 2) was built in 1902. By the summer of 1906 many of the difficulties had been overcome and a machine giving 50,000 cycles was installed at the Brant Rock station. Various improvements were made by the writer's assistants, and in the fall of 1906 the dynamo was working regularly at 75,000 cycles, with an output of half a kilowatt and was being used for telephoning to Plymouth, a distance of approximately 11 miles. In the following year machines were constructed having a frequency of 100,000 cycles per second and outputs of 1 and 2 kilowatts.

The credit for the development of this machine is due to Messrs. Steinmetz, Haskins, Alexanderson, Dempster, and Geisenhoner and also to the writer's assistants, Messrs. Stein and Mansbendel.

(*c*) *Closed tuned circuits.* In 1898 the open tuned circuits originally used were discarded for closed tuned circuits[2] and it was discovered that valuable selective effects could be obtained by placing the condenser in shunt to the inductance instead of in series with it.[3]

(*d*) *Combination of wave and group tuning.* The fact that if selectivity is obtained solely by tuning to wave frequencies, the number of stations is limited, was appreciated at an early date. In 1900[4] a new method was developed, the stations being tuned both to the wave frequency and to an independent or group frequency, so that stations might obtain selectivity by varying either the wave or the group frequency and thus have at their disposal a virtually unlimited number of combinations and be practically free from atmospheric disturbances. Fig. 3 shows a type of group tuner.

(*b*) *Further development of damped wave-coherer method.* Marconi by 1898 had carried the development of the filings coherer to its maximum point.

1. U. S. patent 706,737, May 29, 1901.
2. U. S. patents 706,735 and 706,736, Dec. 15, 1899.
3. *Ibid.*
4. U. S. patents 727,325, June 2, 1900, and 727,330 March 21, 1903.

Lodge in 1897[1] had disclosed the open secondary circuit for receiving.

Marconi in 1898[2] greatly improved this by adjusting the length of the secondary so as to tune it, and by the aid of this improvement was enabled to telegraph a distance of 35 miles[3] in October, 1899.

Lodge in 1902[4] invented what is perhaps the most perfect form of coherer, consisting of a thin steel disc dipping in oil

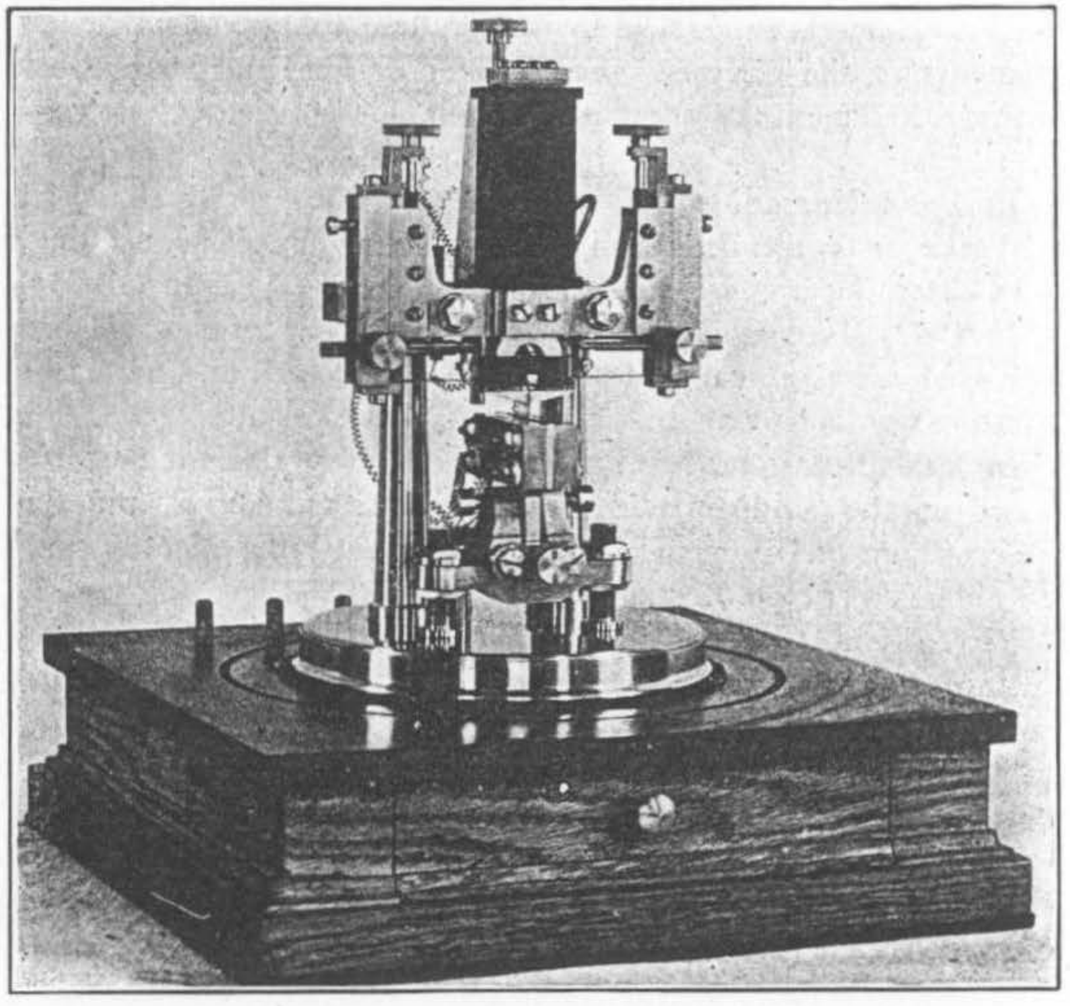

FIG. 3.

covered mercury and automatically decohered by being kept in continuous rotation.

A number of self-restoring coherers of which the Brown[5]

carbon coherer may be taken as a type, including the mercury carbon coherer of Solari, came into more or less extended use, and also modifications of the imperfect contact receiver of Neugschwender.[1]

The small progress made along these lines is to be explained by the fact that the damped wave-coherer system is essentially and fundamentally incapable of development into a practical system.

Period 1902-1908—*Later Developments.* Progress in Europe since 1902 has been marked by the gradual abandonment of the elements of the damped wave-coherer system and the substitution of elements of the sustained wave non-microphonic contact type.

In 1900[2] Marconi substituted for the plain aerial an aerial with the writer's tuned local circuit or tank circuit for sending, thus obtaining a considerable increase in range of transmission.

In 1902, Marconi invented a very ingenious form of current operated receiver, called the magnetic detector[3], and with this combination achieved some very remarkable results.

In 1905 Professor Fleming[4] invented a very efficient detector based on the " Edison effect " in incandescent lamps, and the observations of Elster and Geitel[5] on the rectifying effect of such an arrangement on Hertzian oscillations.

Virtually nothing was done in Europe in the way of producing sustained oscillations by the arc or high frequency method until recently, possibly because of Duddell's erroneous statement[6] to the effect that frequencies much above 10,000 could not be obtained by the Elihu Thomson arc method, and Fleming's statement[7] that an abrupt impulse was necessary and that high frequency currents, even if of sufficient frequency, could not produce radiation.

In 1903 Poulsen[8] invented an interesting modification of the Elihu Thomson arc, which consists in forming the arc in hydro-

gen instead of in air or compressed gas as previously done. This modification is not, however, so efficient as the older methods and gives oscillations varying in amplitude and intensity and accompanied by strong harmonics,[1] but I have considered it worth mentioning on account of the amount of interest it appears to have excited in Europe.

Some very important and interesting papers on electrical oscillations were published during these years by Oberbeck,[2] Wien,[3] Drude,[4] and Bjerknes.[5]

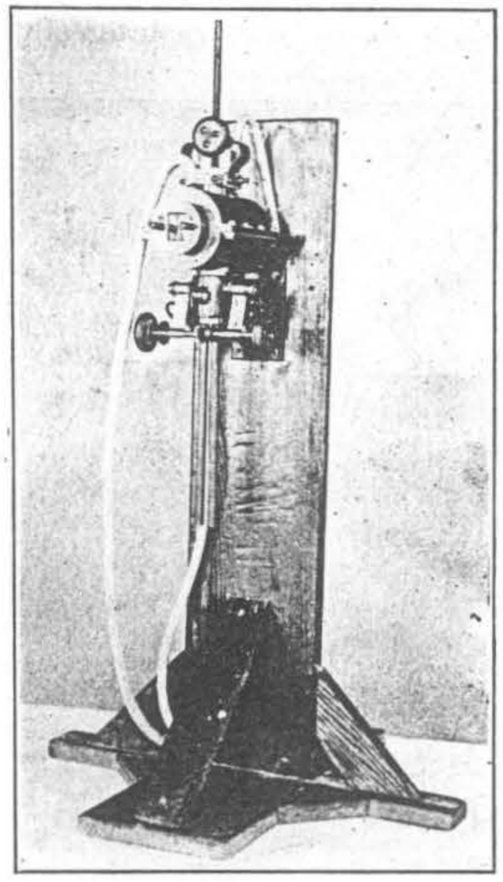

FIG. 4.

In America the development of the sustained oscillation non-microphonic system has proceeded steadily and it may now be said to have reached the stage of commercial practicability. On account of the amount of work which has been done it is impossible to refer to more than a few of the recent advances.

wound off from an insulating cylinder onto a cylinder of copper, and the cylinder of copper, forming a closed circuit secondary of the transformer, annuls the inductance of that portion of the wire wound upon the copper cylinder.

Fig. 9 shows an apparatus for determining the best shape of coil for use with the heterodyne receiver.

Fig. 10 shows a group-tuned call; that is, a vibration galvanometer which operates a selenium cell and rings a bell when a call is received.

C. THEORY OF WIRELESS TELEPHONY

For wireless telephony three things are necessary:

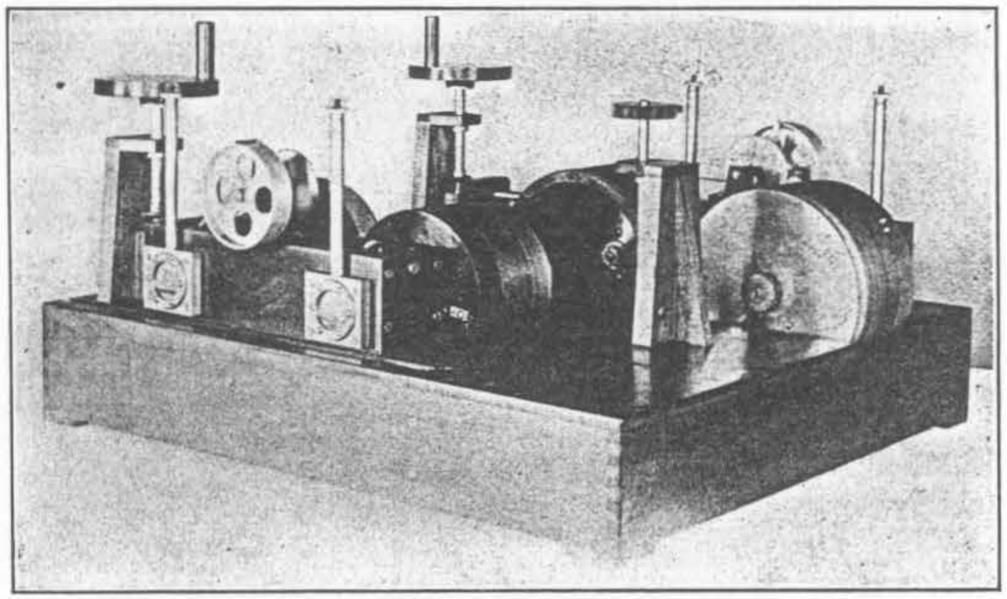

FIG. 8.

1. Means for radiating a stream of electrical waves sufficiently continuous to transmit the upper harmonics on which the quality of the talking depends.

2. Means for modulating this stream of waves in accordance with the sound waves.

3. A continuously responsive receiver giving indications proportional to the energy received, and capable of responding with sufficient rapidity to the speech harmonics.

Work on the wireless telephone was commenced before a satisfactory means was discovered for producing sustained oscillations.

To ascertain the number of sparks per second which was necessary to determine articulate speech, a phonograph cylinder

was taken and grooves were cut in it longitudinally. It was found in this way that practical transmission could be accomplished with 10,000 breaks per second. It is believed now that this number is unnecessarily high, possibly owing to the fact that it was impossible to cut the grooves on the cylinder without producing ridges. The lower limit may be fixed in another way.

Electrical circuits met with in actual working have resistance, self inductance capacity, and leakance. Heaviside gave the differential equations for the pressure and current over such circuits when alternating voltages were applied, but no method of solution being known the mathematical treatment of such

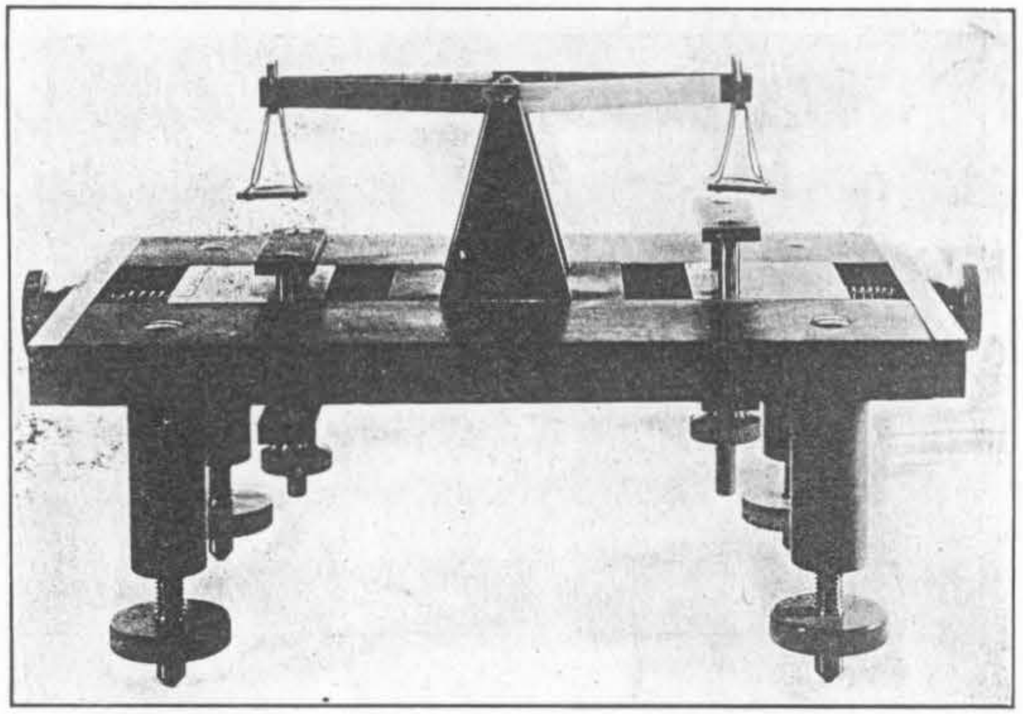

FIG. 9.

circuits was restricted to cases where one of the constants was neglected, until Dr. A. E. Kennelly in a masterly series of papers gave the complete solution.

The results were immediately found applicable to a great variety of problems, such as the transmission of signals through cables and of telephonic speech through various types of circuits.

In this way Dr. Kennelly[1] by comparing the results obtained by Dr. Hammond V. Hayes[2] in practical telephonic transmission

1. Kennelly, " Distribution of Pressure and Current over Alternating Current Circuits ", *Harvard Engineering Journal*, 1906, page 43.

2. Hayes, " Loaded Telephone Lines in Practice ", *Transactions International Electrical Congress*, St. Louis, Vol. 3.

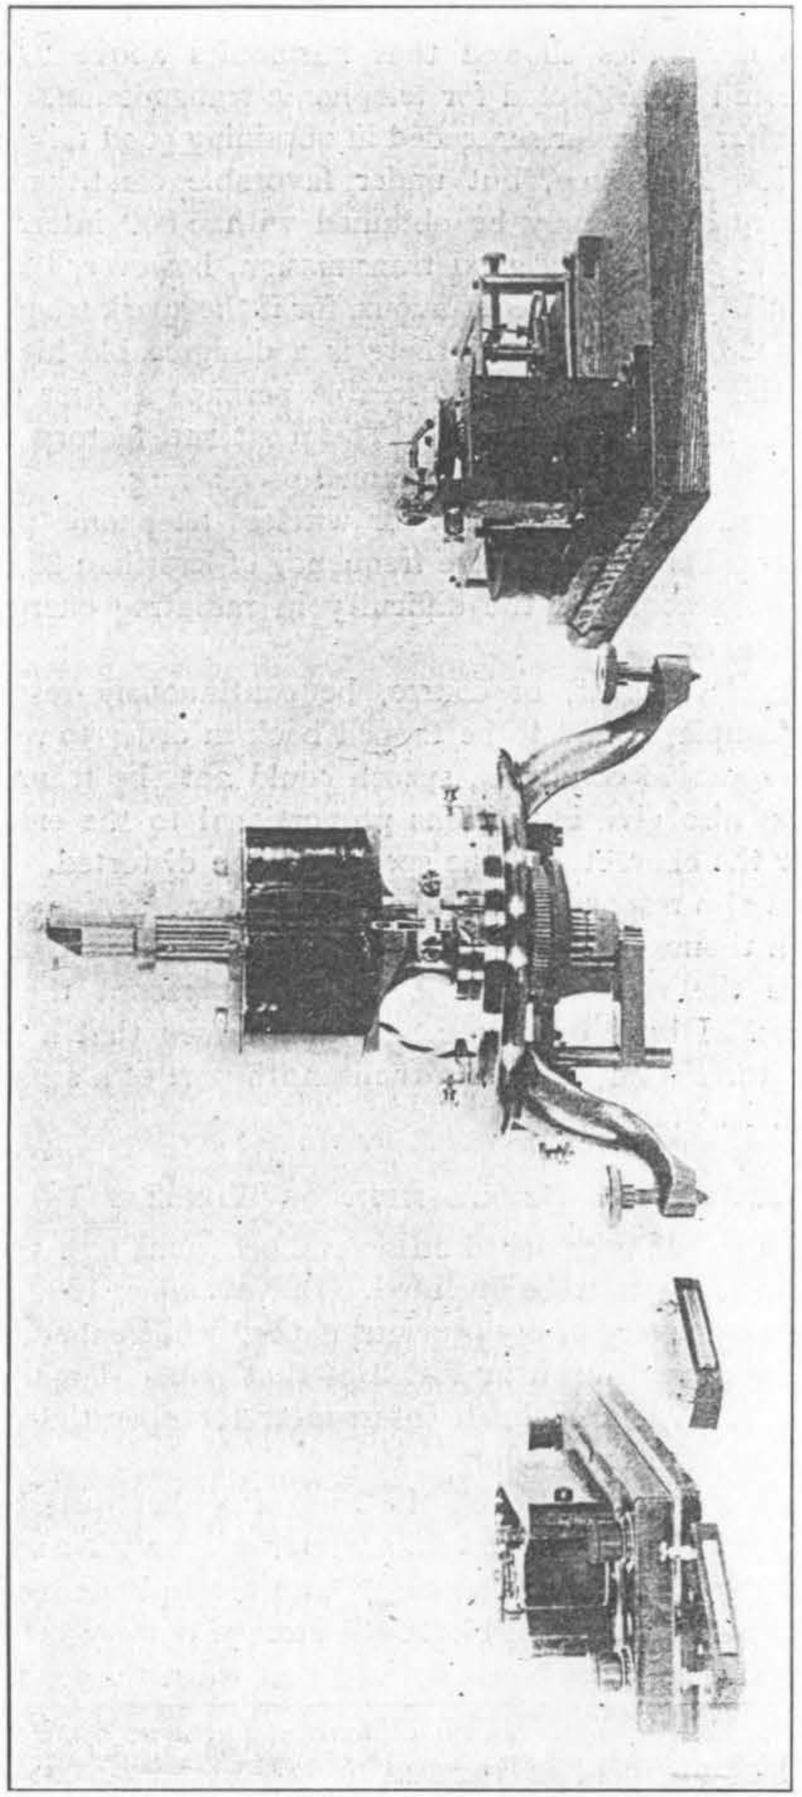

FIG. 10.

over loaded lines with the theoretical values of the current for different harmonics showed that harmonics above 2,000 per second could be neglected for telephonic transmission.

The writer has never succeeded in obtaining good talking with such a low frequency, but under favorable conditions fairly satisfactory speech may be obtained with 5,000 interruptions per second. For really good transmission, however, the radiation must be practically continuous, for if the spark frequency is less than 20,000 per second there is a disagreeable high pitch note in the telephone, not noticeable perhaps at first but apt to become annoying with use. The most satisfactory way is, of course, to use a source of sustained oscillations.

It fortunately happens that for wireless telephonic purposes it is inadvisable to use a wave frequency of less than 25,000 per second, on account of the difficulty in radiating energy with low frequencies.

The receiver must, of course, be continuously responsive. If, for example, it had to be tapped back in order to restore it to the responsive condition, speech could not be transmitted.

It must also give indications proportional to the energy received or the character of the speech will be distorted.

It must also respond with sufficient rapidity. If, for example, it takes a thousandth of a second to restore itself to its original resistance the receiver will obviously not record the higher harmonics. I have experimentally determined that a receiver which restores itself in the ten thousandth part of a second acts with sufficient rapidity.

D. History of the Development of Wireless Telephony

The writer has been asked on several occasions how the wireless telephone came to be invented. In November, 1899, shortly prior to the delivery of my previous paper,[1] while experimenting with the receiver shown in Fig. 3 of that paper, I made some experiments with a Wehnelt interrupter for operating the induction coil used for sending.

In the receiver mentioned the ring of a short-period Elihu Thomson oscillating current galvanometer rests on three supports, *i.e.*, two pivots and a carbon block, and a telephone receiver is in circuit with the carbon block. A storage battery being used in the receiver circuit[2] it was noticed that when the sending key

1. *Transactions American Institute Electrical Engineers*, Nov. 22, 1899.
2. U. S. patent, 706.736, December 15, 1899.

was kept down at the sending station for a long dash the peculiar wailing sound of the Wehnelt interrupter was reproduced with absolute fidelity in the receiving telephone. It at once suggested itself that by using a source with a frequency above audibility wireless telephony could be accomplished.

Professor Kintner, who was at that time assisting me in these experiments and to whose aid their success is very largely due, was kind enough to make the drawings for an interrupter to give 10,000 breaks per second. Mr. Brashear, the celebrated optician kindly consented to make up the apparatus and it was completed in January or February, 1900.

The experimental work was, however, delayed as the writer was at that time transferring his laboratory from Allegheny, Pa., to Rock Point, Md., and it was not until six months later that the stations at that point were completed and a suitable mast was erected for trying the apparatus.

The first experiments were made in the fall of 1900 with the above mentioned apparatus which was supposed to give 10,000 sparks per second but which probably gave less. Transmission over a distance of one mile was attained but the character of the speech was not good and it was accompanied by an extremely loud and disagreeable noise, due to the irregularity of the spark.

By the end of 1903 fairly satisfactory speech had been obtained by the arc method above referred to, but it was still accompanied by a disagreeable hissing noise. In 1904 and 1905 both the arc method and another method in which the 10,000 cycle alternator above referred to was employed, had been developed to such an extent that the apparatus could be used practically and sets were advertised and tendered to the U. S. Government.[1] The transmission was, however, still not absolutely perfect.

By the fall of 1906 the high frequency alternator had been brought to a practical shape and was used for telephoning from Brant Rock to Plymouth, a distance of 11 miles, and to a small fishing schooner,[2] this being the first instance in which wireless telephony was put in practical use. The transmission was perfect

1. Letter of July 8, 1905; see *The Electrician*, London, Feb. 22, 1907; also catalogue of 1904 and subsequent.
2. An amusing instance may be mentioned as illustrating the incredulity with which the wireless telephone was received. Some of the local papers having published an account of the experiments with the schooner above referred to the following appeared under the heading

and was admitted by telephone experts to be more distinct than that over wire lines, the sound of breathing and the slightest inflections of the voice being reproduced with the utmost fidelity.

As it was realized that the use of the wireless telephone would be seriously curtailed unless it could be operated in conjunction with wire lines, telephone relays were invented both for the receiving and transmitting ends and were found to operate satisfactorily, speech being transmitted over a wire line to the station at Brant Rock, retransmitted there wirelessly by a telephone relay, received wirelessly at Plymouth and there relayed out again on another wire line. On Dec. 11, 1906, invitations were issued to a number of scientific men to witness the operation of the wireless transmission in conjunction with the wire lines.[1] A report of these tests appeared in the American Telephone Journal of Jan. 26 and Feb. 2, 1907, the editor being one of the men present.

" Current News and Notes " in the columns of a prominent technical journal, Nov. 10, 1906.

" A New Fish Story.—It is stated from Massachusetts that the wireless telephone has successfully entered into the deep sea fishing industry. For the last week experiments have been conducted by the wireless telegraph station at Brant Rock, which is equipped with a wireless telephone, with a small vessel stationed in the fleet of the South Shore fishermen, twelve miles out in Massachusetts Bay. Recently, it is asserted, the fishermen wished to learn the prices ruling in the Boston market. The operator on the wireless fitted boat called up Brant Rock and telephoned the fishermen's request. The land operator asked Boston by wire and the answer was forwarded back to the fishermen. This is a rather fishy fish story ".

The doubt expressed was, however, only natural. I remember the astonishment displayed by one of the company's new operators some months previously on placing the receiving telephone to his head while the vessel was almost out of sight of land and hearing the operator at the land station call his name and begin to talk to him.

1. Brant Rock, Mass., Dec. 11, 1906.

American Telephone Journal, 100 William St., New York City.

Dear Sirs: A limited number of invitations have been issued to witness the operation of the National Electric Signaling Co's. wireless telephone system between Brant Rock and Plymouth, Mass., over a distance of between ten and eleven miles.

The tests will be as follows:

1. Transmission of ordinary speech, and also transmission of phonographic talking and music by wireless telephone between Brant Rock and Plymouth.

2. Transmission of speech over ordinary wire line to wireless station at Brant Rock, relaying the speech there automatically by telephone relay and automatically transmitting the speech by wireless to Plymouth,

In July 1907 the range was considerably extended and speech was successfully transmitted between Brant Rock and Jamaica, Long Island, a distance of nearly 200 miles, in daylight and mostly over land,[1] the mast at Jamaica being approximately 180 ft. high.

In 1907 several European experimenters succeeded in transmitting speech wirelessly, using some of the earlier forms of the writer's arc method, and some months ago the vessels of

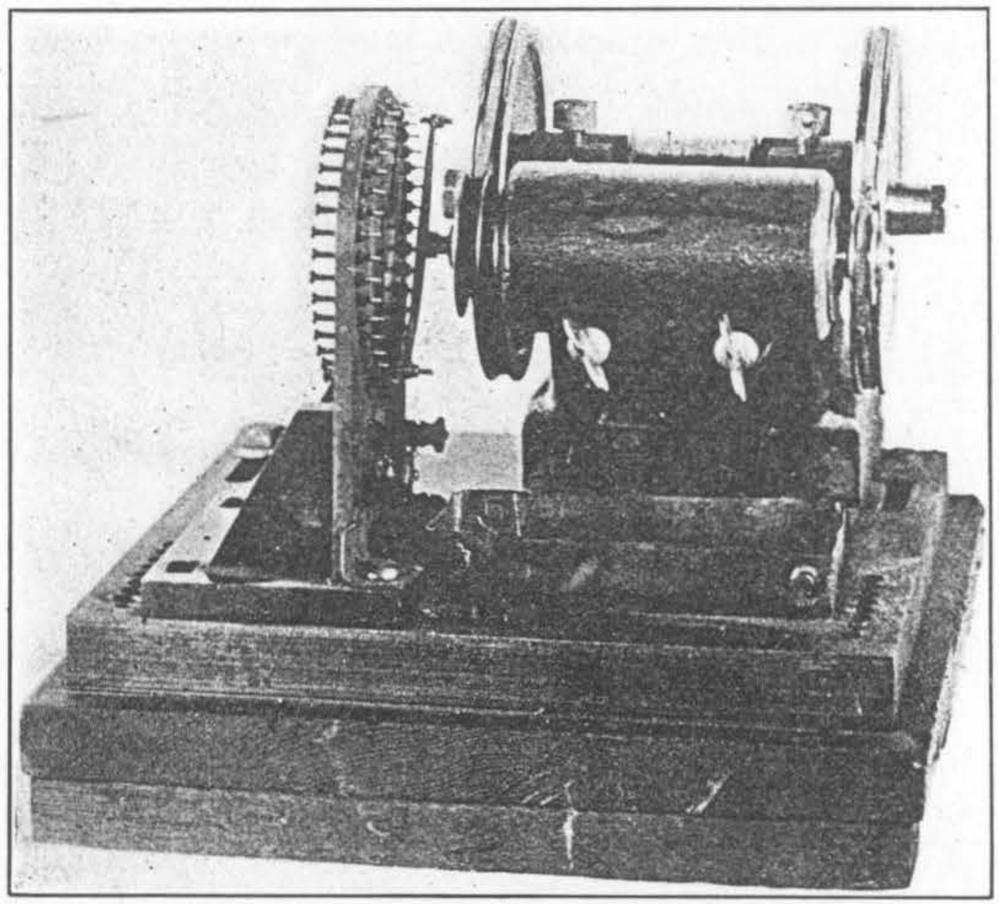

FIG. 11.

our Pacific squadron were equipped with wireless telephones, using this arc method, by another American company.

transmitting same at Plymouth automatically directly or by telephone relay over regular wire line.

Invitations have been issued to the following gentlemen, (here follows list of some of the guests, including Dr. A. E. Kennelly, Professor Elihu Thomson, etc., and a request to the company to send a representative).

Yours very truly,

National Electric Signaling Co.

E. Methods and Apparatus

1. *Methods and apparatus for producing the electromagnetic waves.* These have been already referred to. Fig. 11 shows a rotating spark-gap giving approximately 20,000 discharges per

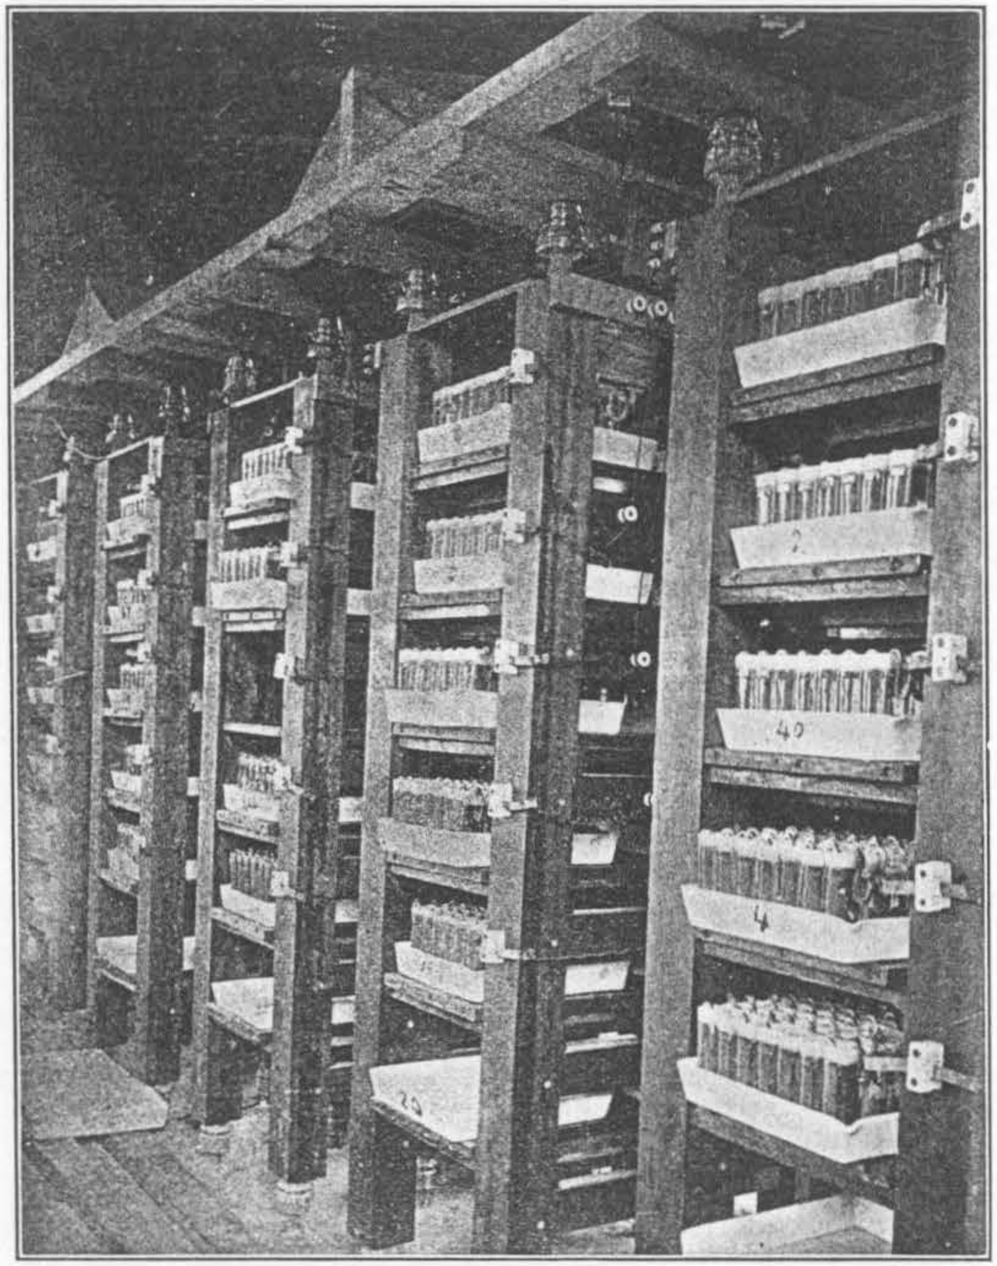

Fig. 12

second. This was connected to a 5,000-volt source of direct current. The terminals are of 40% platinum-iridium. In operation the apparatus is arranged to charge a condenser to a definite potential and discharge it.

Figs. 12 and 13 show forms of apparatus for operating the arc in a gas under pressure.

The apparatus of Fig. 13 is also used for the arc in vacuum and the critical distance arc.

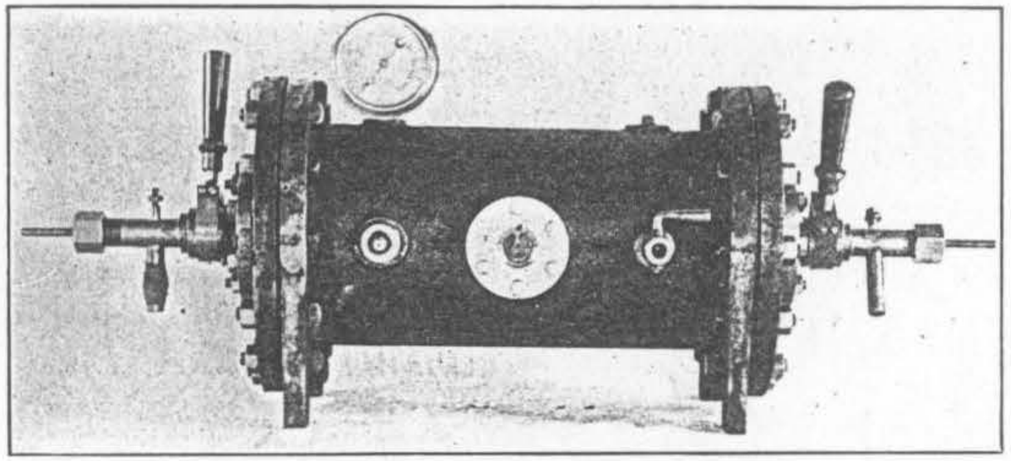

Fig. 13.

Fig. 14 shows a multiple gap with rotating electrodes, brass, amalgamated zinc and graphite being used.

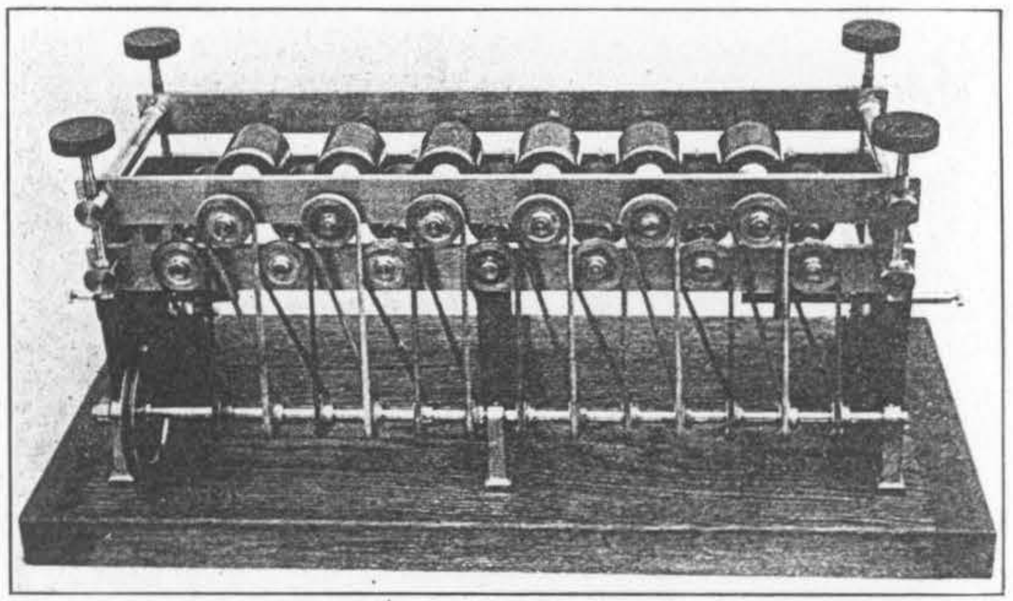

Fig. 14.

Fig. 15 shows a multiple arc gap with electrodes of different materials, the upper terminals being water cooled.

Fig. 16 shows a condenser dynamo.

Fig. 17 shows a general view of one type of high frequency alternator. It is driven by a motor and a DeLaval gear. It has been operated at 96,000 cycles per second, but is generally run at 81,700.

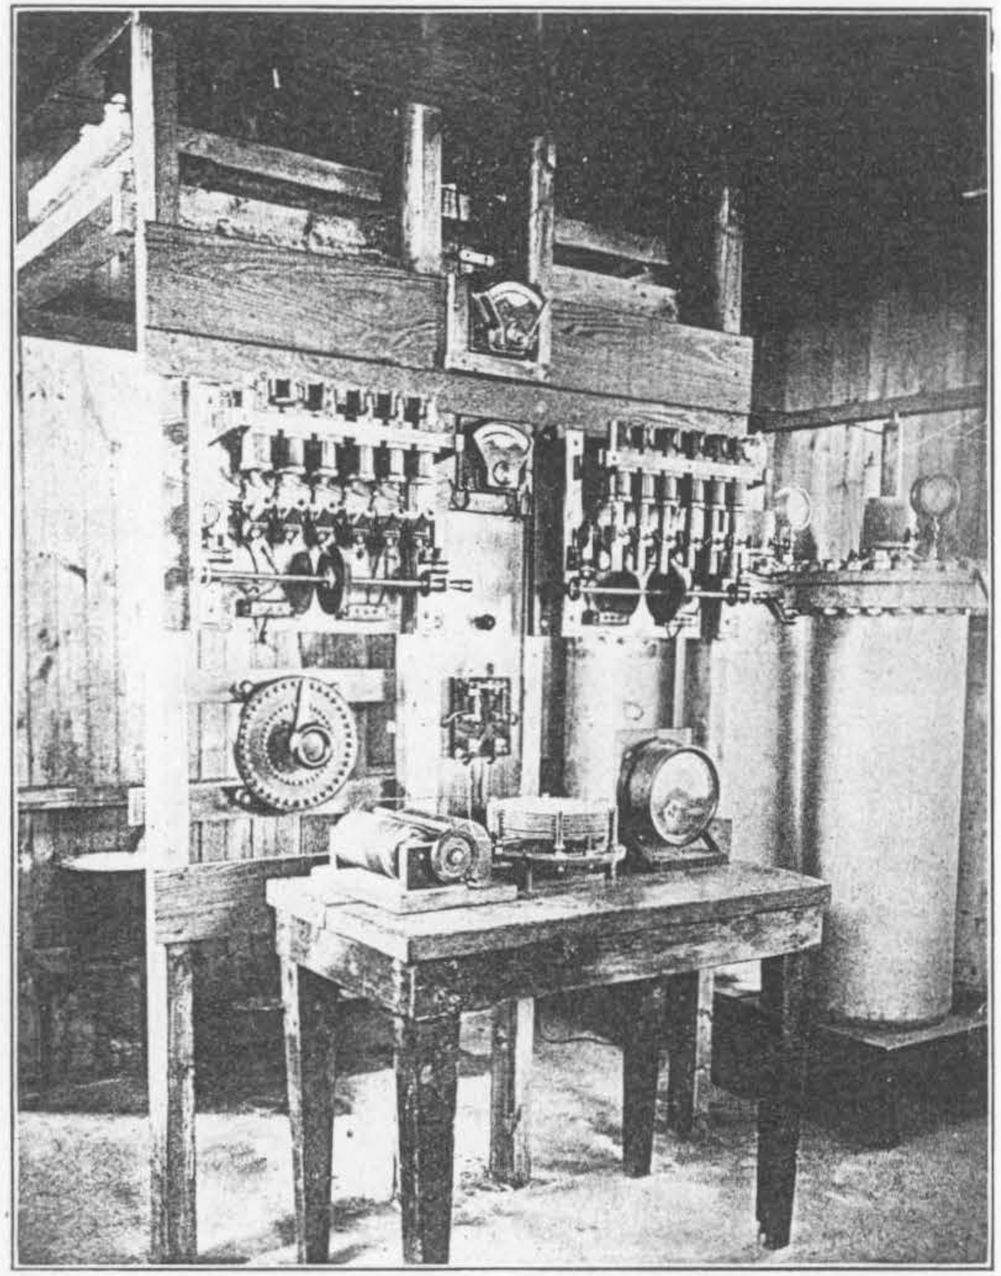

FIG. 15.

Fig. 18 shows a field disc; it is 12 inches in diameter and there are 300 slots on it.

Fig. 19 shows the armature and field coils. There are 600 armature slots each containing two turns of 13 mil wire. The

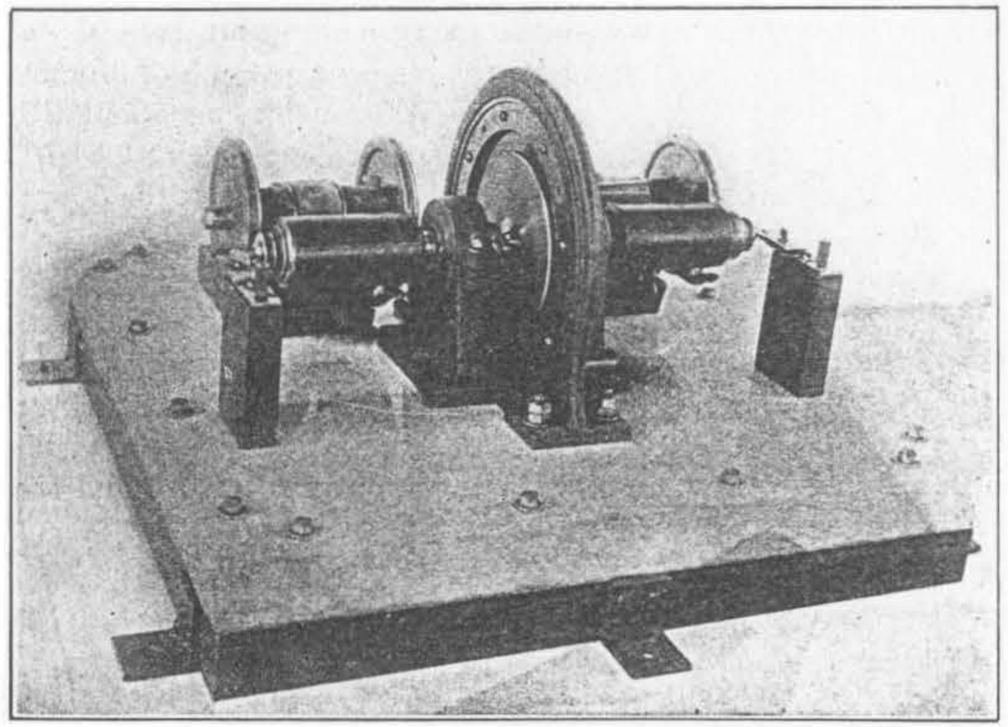

FIG. 16.

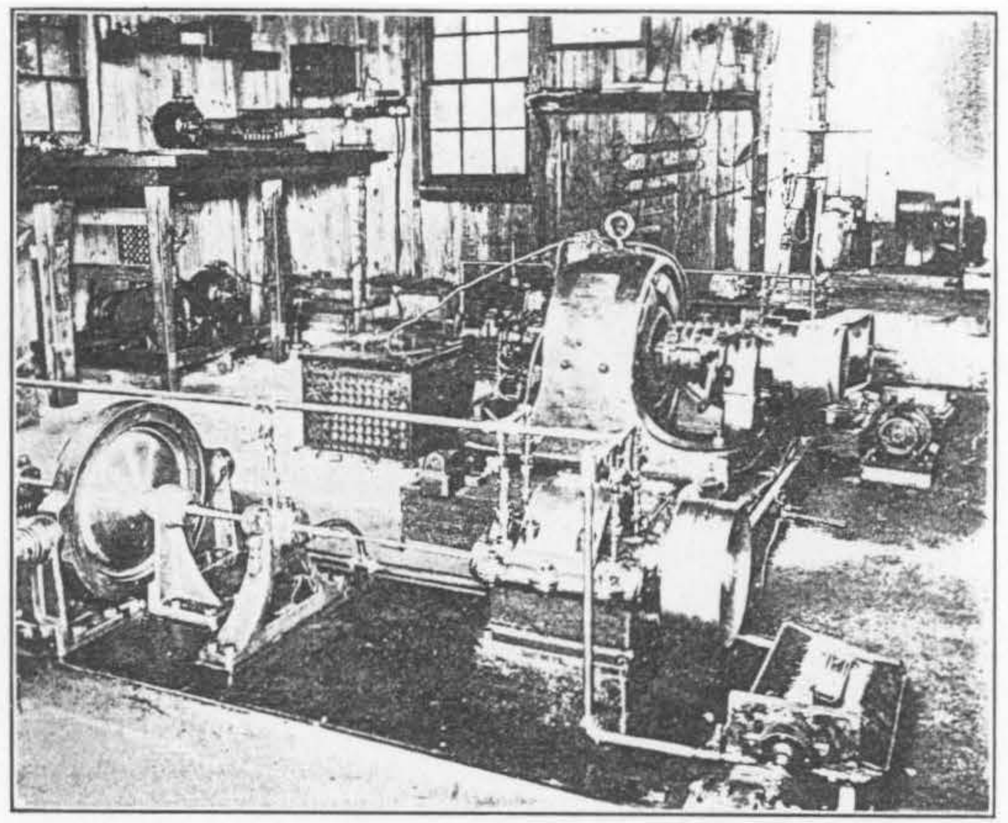

FIG. 17.

field current is 5 amperes. The resistance of the armature is 6 ohms; it gives 160 volts and about 7 or 8 amperes. Other armatures have been constructed having a resistance of 4 ohms. For some work double armatures are used giving about 270 volts. The output of the single armature machines at 81,700 cycles is approximately one kilowatt. The output of the double armature machine is approximately 2 kilowatts.

Other types of high frequency alternators are under construction. One type shown in Fig. 20 is designed for use on shipboard. The armature disc is 6 inches in diameter and two armatures are used. It is arranged to be mounted on gimbals and to be driven by a steam turbine connected to the steam pipe by flexible armored steam hose. The frequency is about 100,000 and the output about 3 kilowatts.

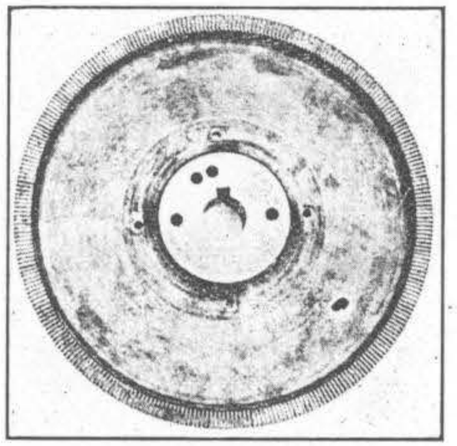

FIG. 18

Another type, which is at present being constructed by Mr. Alexanderson, to whose efforts the success of this type of generator is largely due, is designed to have an output of 10 kilowatts. Designs have been made for a generator of still larger size with a calculated output of 50 kilowatts and a frequency of 50,000. This machine is intended for transatlantic work.

For some of these machines, instead of driving by gear or steam turbine, a special two-cycle motor has been devised, to operate at a frequency of 500 cycles per second.

The high frequency alternator method is believed to possess a number of advantages over other methods, inasmuch as it is set in operation by merely opening a steam valve and has no complicated electrical apparatus or circuits of any kind. The

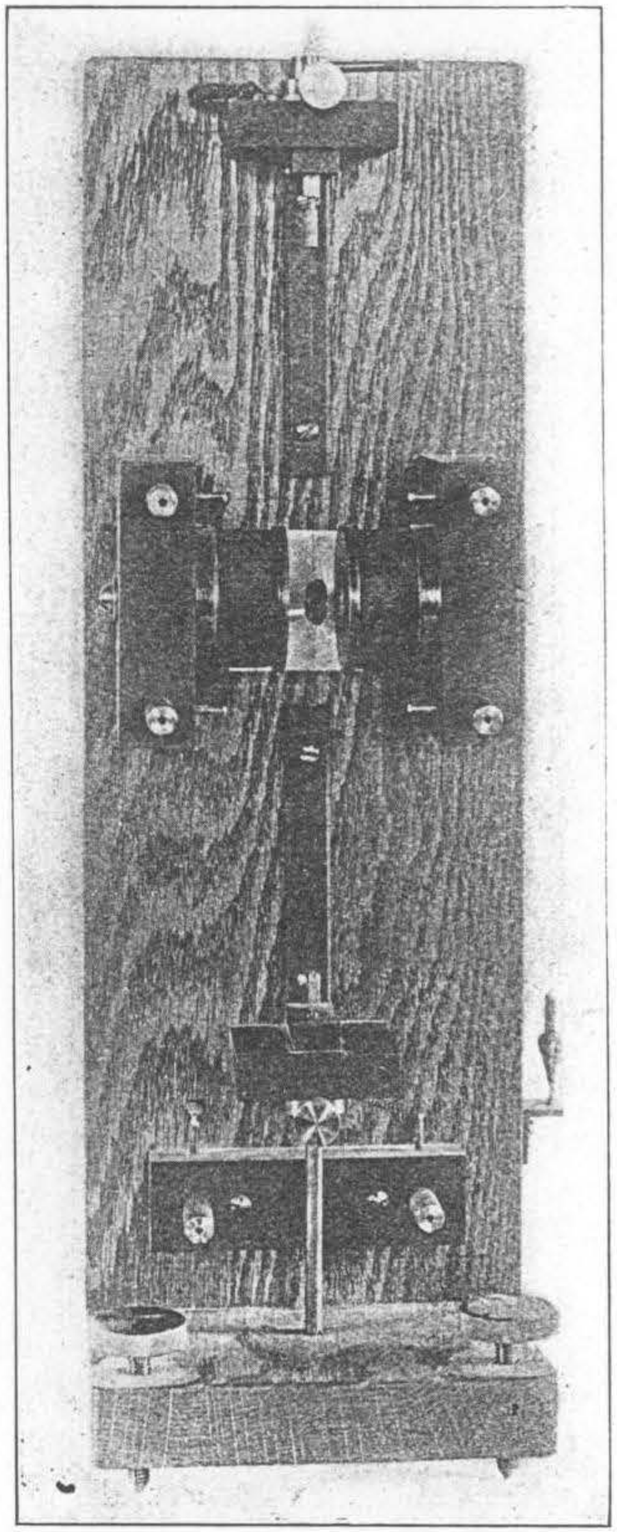

FIG. 21,

speed is regulated by the steam pressure, this being accomplished by an electrically operated reducing valve.

For measuring the frequency various speed indicators have been tried, but it has been found that the best way is to use a resonant circuit with an ammeter shown in Fig. 21 in it,[1] this being an extremely sensitive means of indicating the frequency and in addition affording a means of automatically keeping

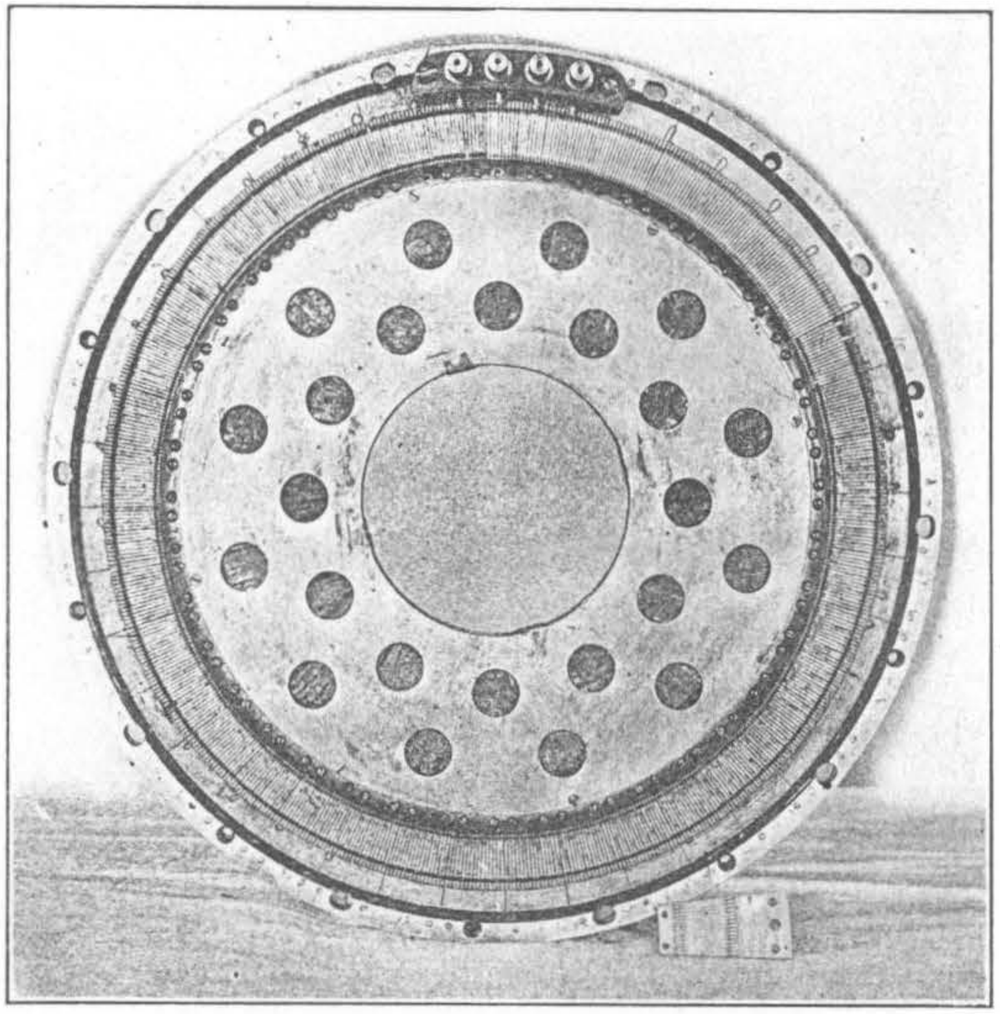

FIG. 19.

the speed constant to a small fraction of a per cent. The reducing valve is adjusted so that if left to itself the machine will run slightly above speed.[2] As soon as it reaches one-tenth of one per cent. higher than its designed speed the resonance begins to fall and a contact is opened which slightly throttles the steam. In

1. *Electrical World and Engineer*, Nov. 11, 1899.

2. Since writing the above, my attention has been called to the fact that the general method of governing by resonance was invented and patented by Kempster B. Miller, U. S. patent 559,187, Feb. 25, 1896.

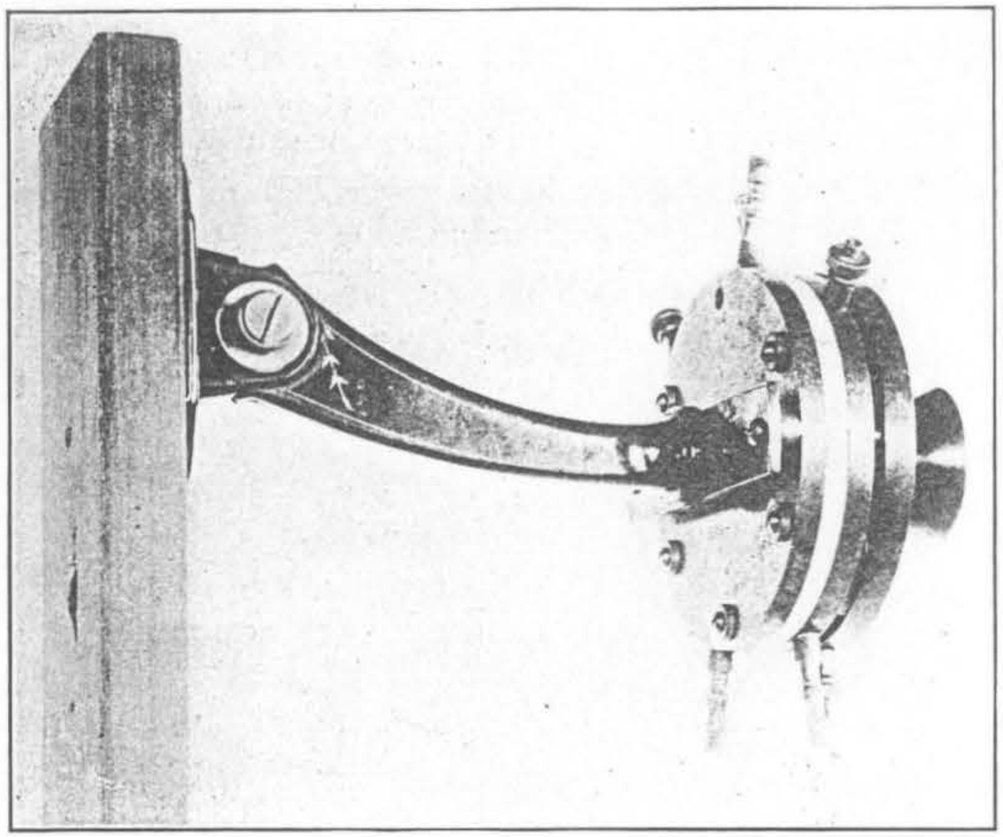

FIG. 20,

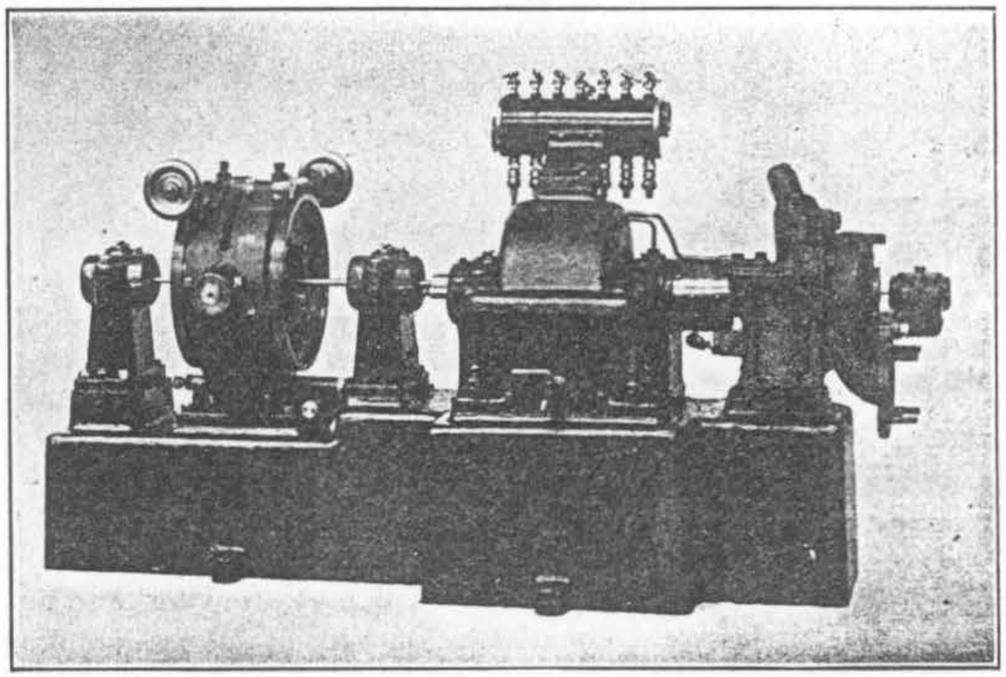

FIG. 22.

this way the frequency is kept varying between the limits of one-tenth of one per cent. above speed and one-tenth of one per cent. below speed. Where the drive is electric instead of by turbine, a storage battery is used to drive the two-phase generator and even better results may be obtained as regards regulation than with steam.

2. *Transmitters.* The types of transmitters most commonly

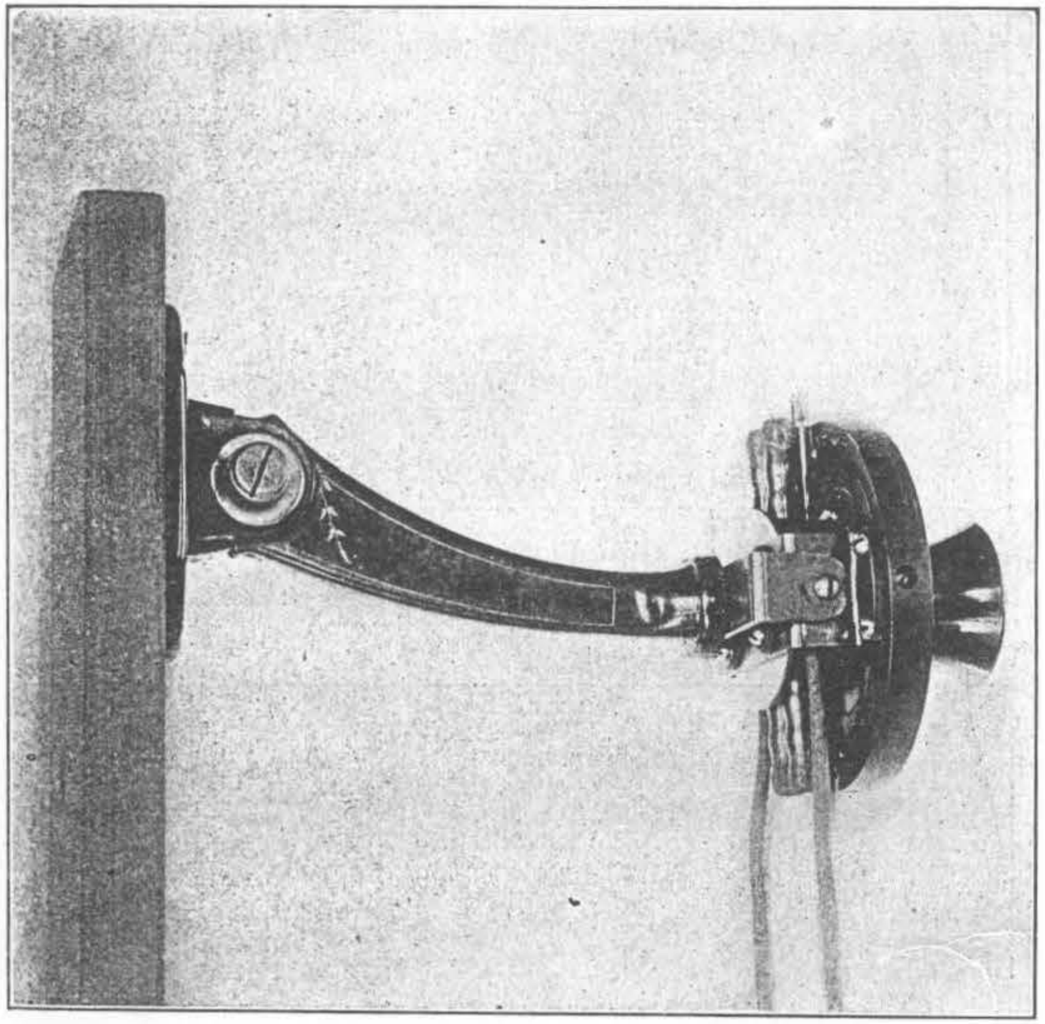

FIG. 23.

used are the carbon transmitter and static transmitter, and the carbon transmitter relay.

Fig. 22 shows the standard type of carbon transmitter.

It was found that the ordinary carbon transmitter was unsuited for wireless telephonic work on account of its inability to handle large amounts of power. A new type of transmitter was therefore designed which the writer has called the " trough "

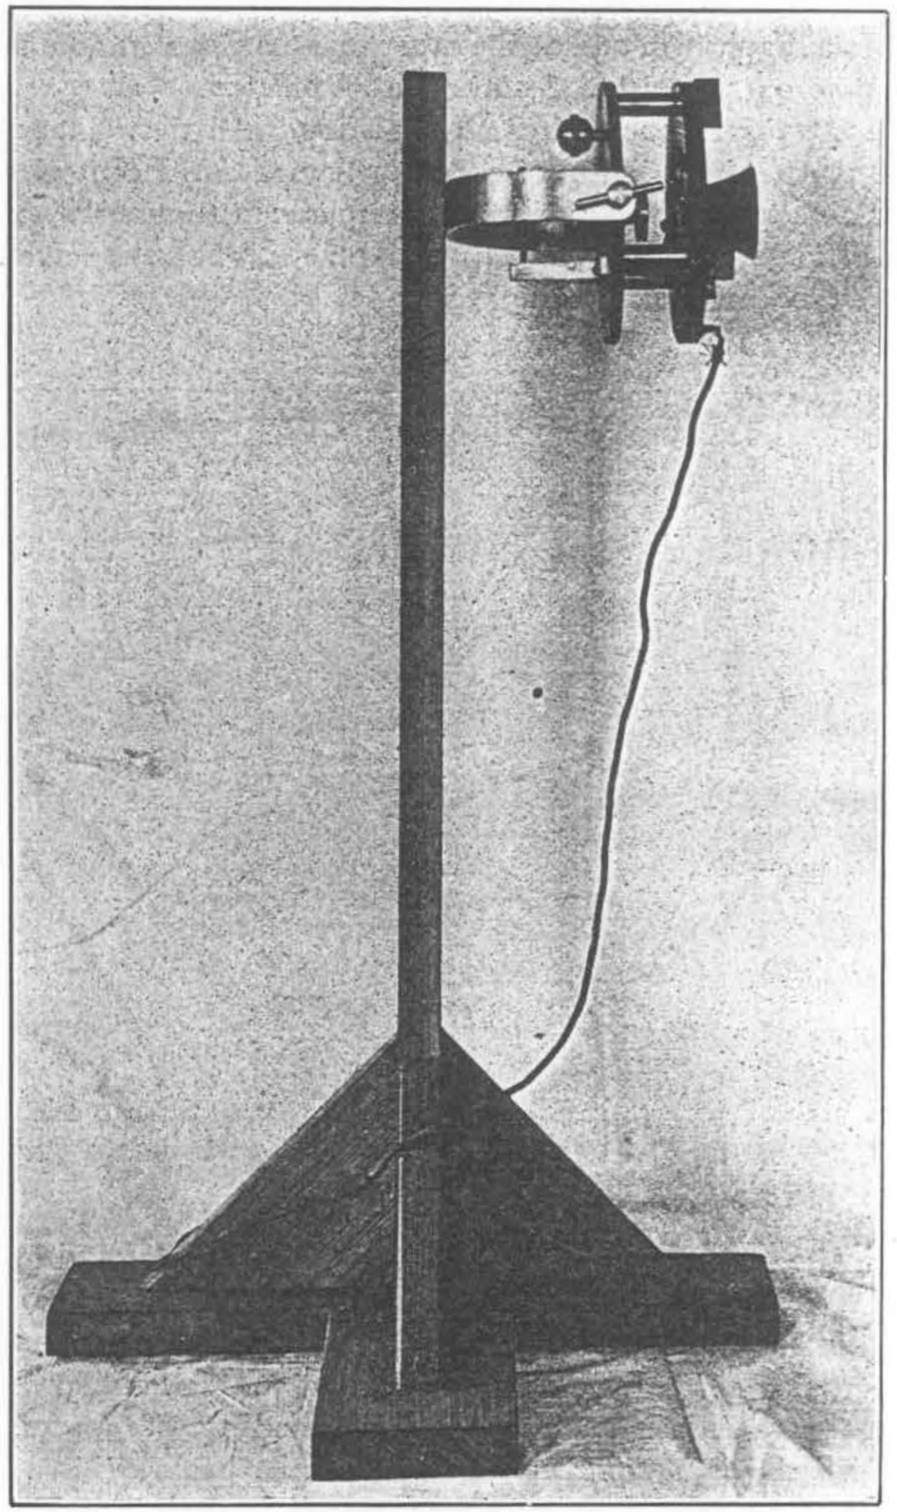

FIG. 24.

transmitter. It consists of a soapstone annulus to which are clamped two plates with platinum iridium electrodes. Through a hole in the center of one plate passes a rod, attached at one end to a diaphragm and at the other to a platinum iridium spade. The two outside electrodes are water-jacketed.

This transmitter requires no adjusting. All that is necessary is to place a teaspoonful of carbon granules in the central space. It is able to carry as much as 15 amperes continuously without the articulation falling off appreciably. It has the advantage that it never packs. The reason for this appears to be that

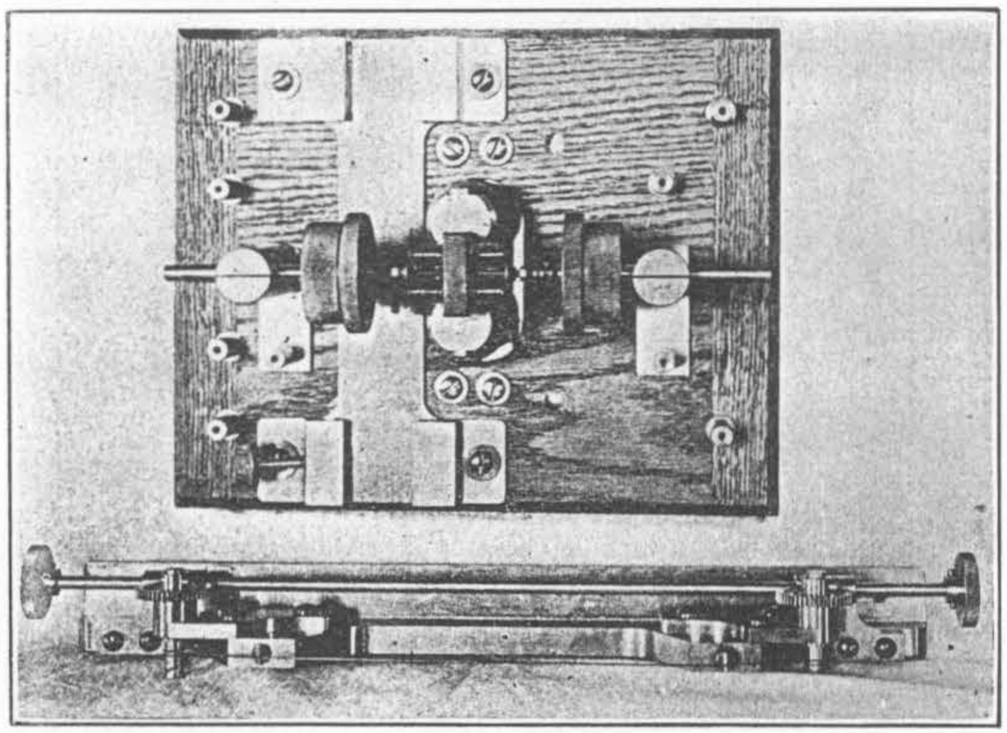

FIG. 25.

when the carbon on one side heats and expands the electrode is pushed over against the carbon on the other side. These transmitters have handled amounts of energy up to one-half horse power, and under these circumstances give remarkably clear and perfect articulation and may be left in circuit for hours at a time. Fig. 23 shows a modified form with split back.

Fig. 24 shows a type of condenser transmitter in which the vibration of the diaphragm alters the electrical capacity of the transmitter, thus throwing the circuit in and out of tune or spilling more or less energy through a leakage circuit.

Fig. 25 shows a transmitting relay for strong currents. The only thing noticeable about this is that the telephone magnet is a differential one.

Fig. 26 shows another type of transmitting relay, for amplifying very feeble currents. It will readily be understood that where a person in Albany, for example, wishes to talk to another person on board a ship off New York, the wireless station being located near New York, the volume of the transmission received at New York will not be very strong, and while it may be possible

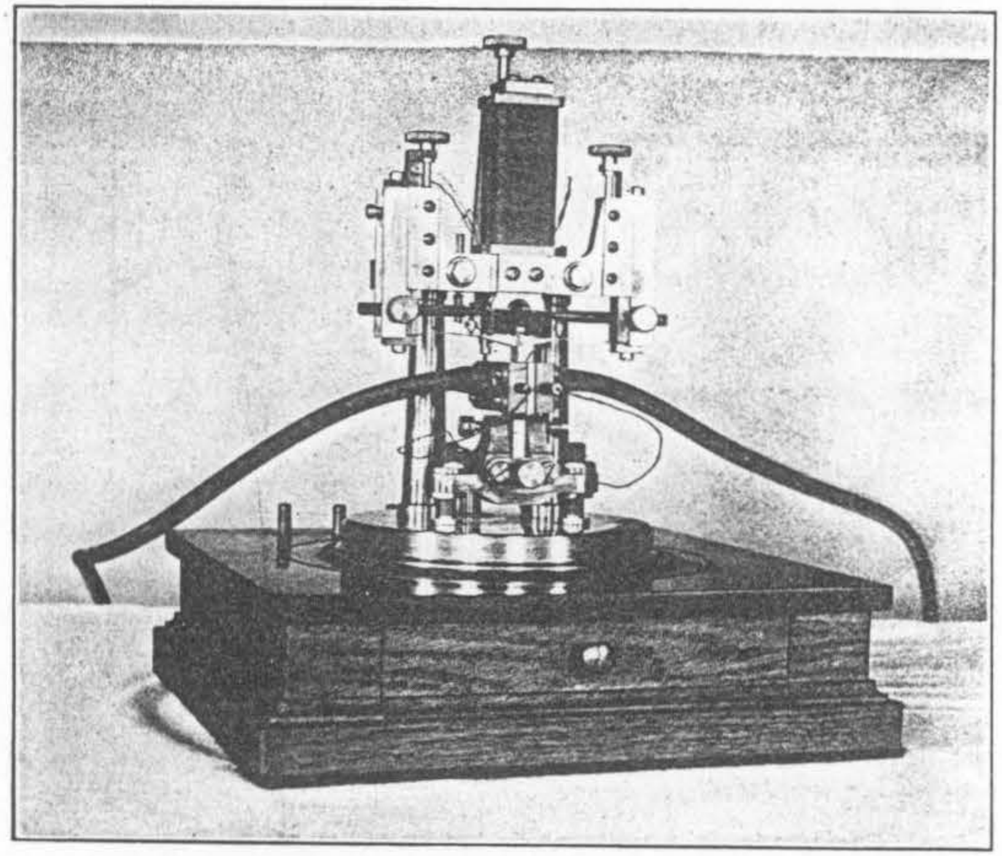

FIG. 26

to transmit it without amplification, amplification is advisable.

This receiver is a combination of the differential magnetic relay and the trough transmitter. An amplification of fifteen times can be obtained without loss of distinctness. The side electrodes of the trough are water-jacketed. The successful amplification depends upon the use of strong forces and upon keeping the moment of inertia of the moving parts as small as possible. Amplification may also be obtained by mechanical means but as a rule this method introduces scratching noises which are very objectionable even though comparatively faint.

Other types of transmitters have also been used, such as liquid jet transmitters, Fig. 27 transmitters operating by closing the air-gap in a magnetic circuit, and so changing the inductance of the oscillating circuit, etc.

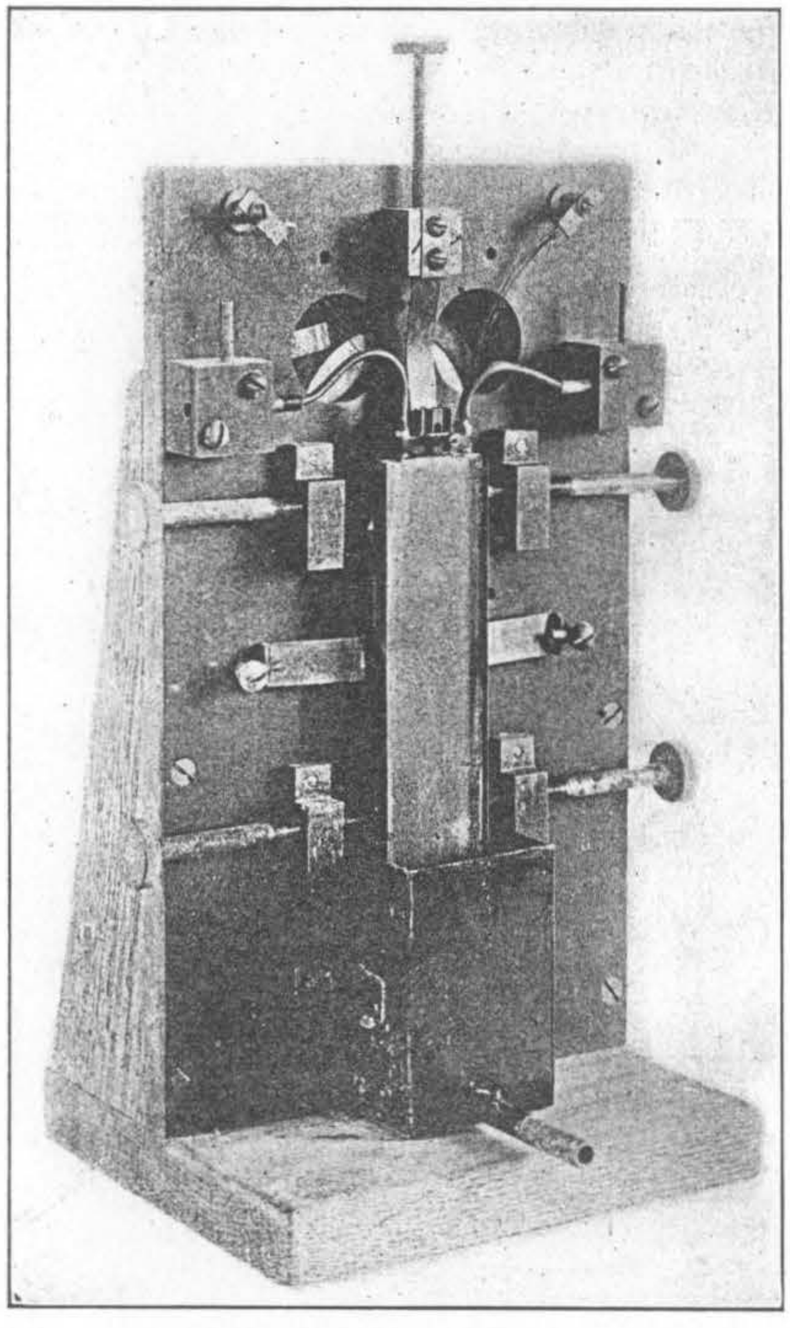

FIG. 27.

Fig. 28 shows a loud-speaking telephone receiver. A small iron disk is placed opposite a nozzle through which air at high pressure is blown. As is well known, this causes the disk to

be held close to the nozzle. The telephone magnets alter the position of the disk and thus produce very loud talking.

The transmitting relays are connected in the wire line circuit in the same way as the regular telephone relay, except that in place of being inserted in the middle of the line they are placed in the wireless station and an artificial line is used for balancing. There is no difficulty met with on the wireless side of the apparatus, but on the wire line side there are the well-known difficulties

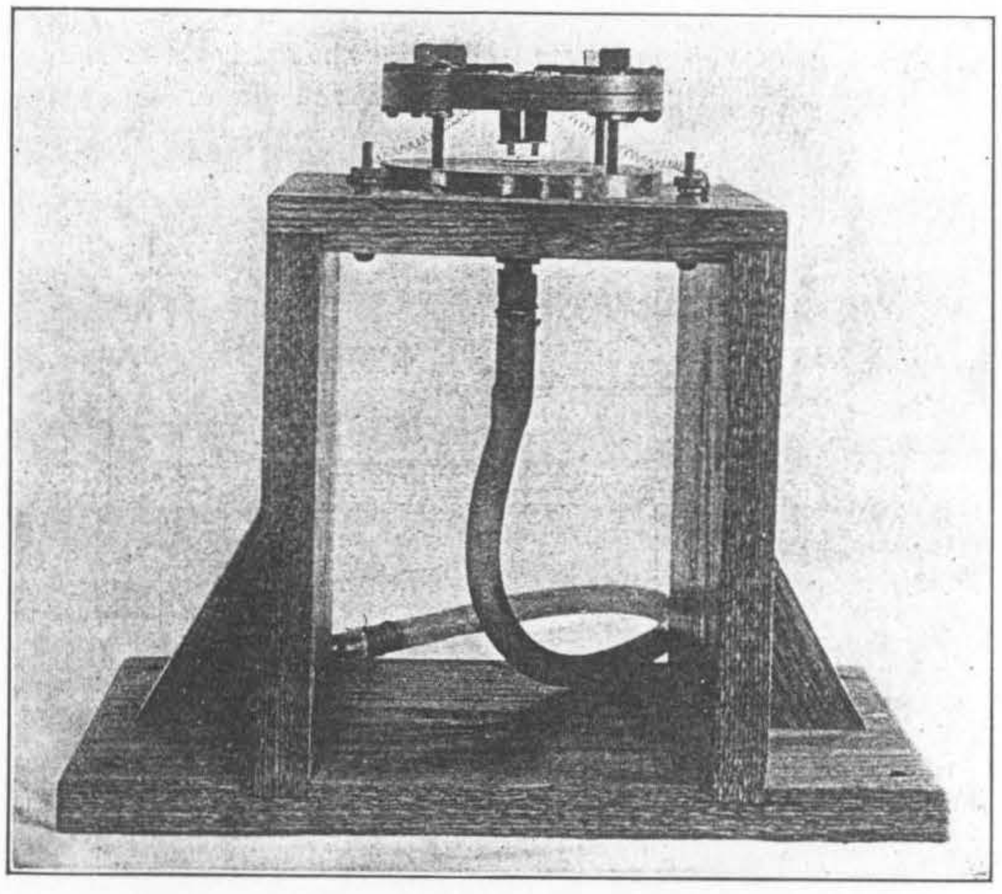

FIG. 28.

due to unbalancing which have not yet been entirely overcome. For the correction of these difficulties, therefore, we must look to the engineers of the wire telephone companies. At present the difficulties are if anything less than those met with in relaying on wire lines alone.

3. *Transmitting circuits.* Fig. 29[1] shows a type of arc circuit.

Fig. 30[2] shows a suitable type of connection for use with a high frequency alternator.

1. U. S. patents Nos. 706,742, June 6, 1902 and 730,753, April 9, 1903.
2. U. S. patent No. 706,742, June 6, 1902.

Fig. 31[1] shows a type of circuit for use with the condenser transmitter.

Fig. 32[2] shows a type of circuit in which the modulation is accomplished by changing the inductance of one of the oscillating circuits.

As a matter of fact the transmitter may be placed almost anywhere in the circuit between the arc or dynamo and the antenna, or between the arc or dynamo and ground, or in the transformer circuit, or in shunt to an inductance or capacity, the results obtained in all cases being indistinguishable. The sole criterion of success seems to be that the transmitter should be capable of handling the energy and the circuit should be

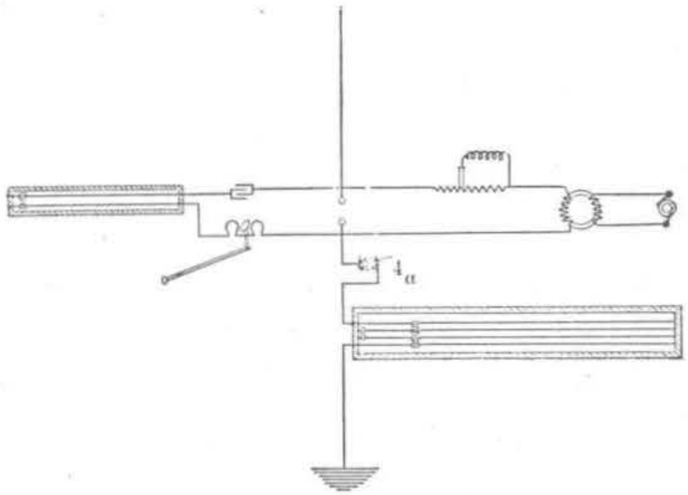

Fig. 29.

Fig. 30.

properly adjusted. Some success has also been attained by placing the transmitter in the field of the dynamo[3] but this method requires very careful designing of the field circuit.

4. *Receivers.* The receiver which the writer has found most satisfactory for general purposes is the liquid barretter. Fig. 33 and 34 shows this receiver. It consists of a fine platinum wire, about a ten thousandth of an inch in diameter immersed in nitric acid. Tests made with this receiver show that it responds without apparent loss of efficiency to notes as high as 5000 per second. Some very careful measurements recently made by my assistants, Messrs. Glaubitz and Stein, give the following results:

1. U. S. patent No. 706,747, Sept. 28, 1901.
2. U. S. patent No. 706,747, Sept. 28, 1901.
3. U. S. patent No. 793,649, March 30, 1905.

Voltage of high frequency circuit necessary to produce readable signals,	15×10^{-5} volts.
Ohmic resistance of receiver,	2,500 ohms.
Value of high frequency current necessary to produce readable signals,	6×10^{-5} amperes.
Electromagnetic wave energy required to produce audible note for period of one second,	1×10^{-4} ergs.

The telephone used for detecting the signals had a resistance of approximately 1000 ohms. Some measurements were made

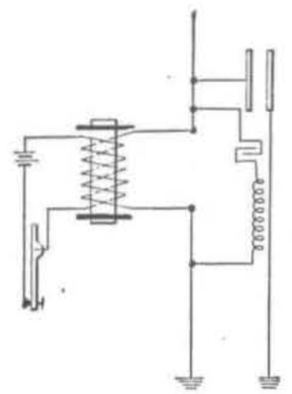

Fig. 31.

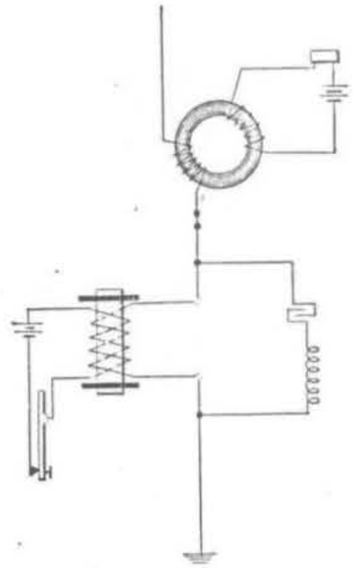

Fig. 32.

to determine the change of current in the telephone circuit by using a sensitive galvanometer in series with the telephone but the results obtained were obviously too low, possibly on account of the electrostatic capacity of the turns of the galvanometer with respect to each other. It will be noted that the amount of electromagnetic wave energy necessary to produce a signal is considerably less than that given in a previous note.[1] The difference is possibly to be attributed to improvements in adjustment and operation.

The above measurements were taken by shunting the barretter across a piece of straight resistance wire in series with a hot-wire ammeter, to determine the voltage necessary, and by intro-

1. *Electrical World and Engineer*, Oct. 31, 1905.

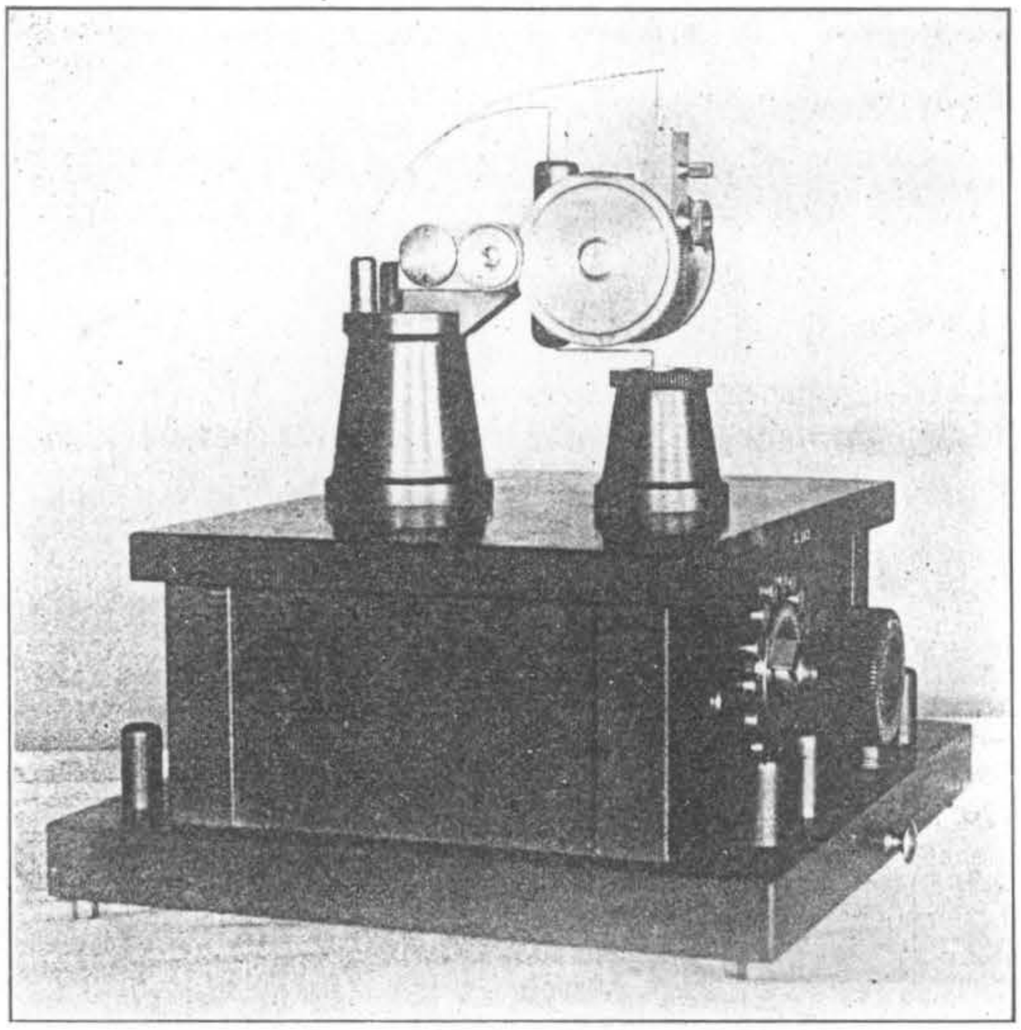

FIG. 33.

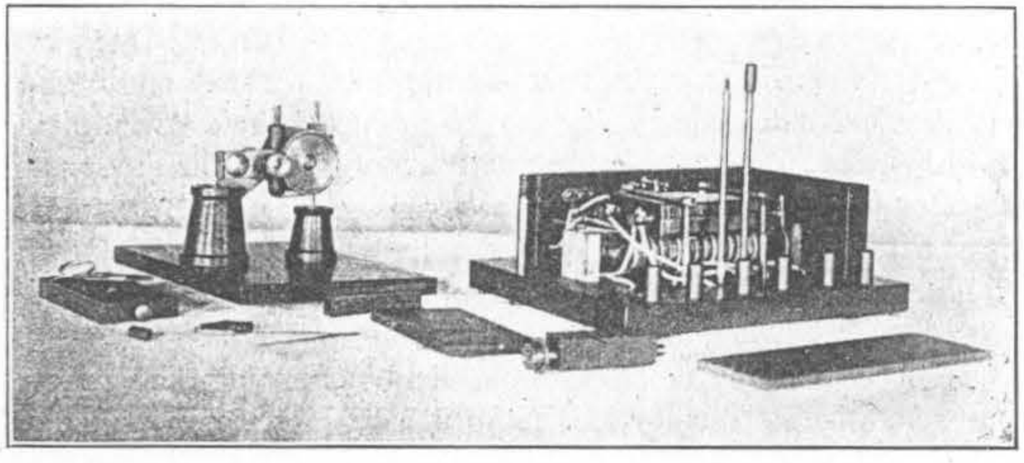

FIG. 34.

ducing resistance in series with the barretter to determine the resistance of the barretter. The figures were also checked in a number of other ways and very concordant results were obtained, so that it is believed they may be relied upon.

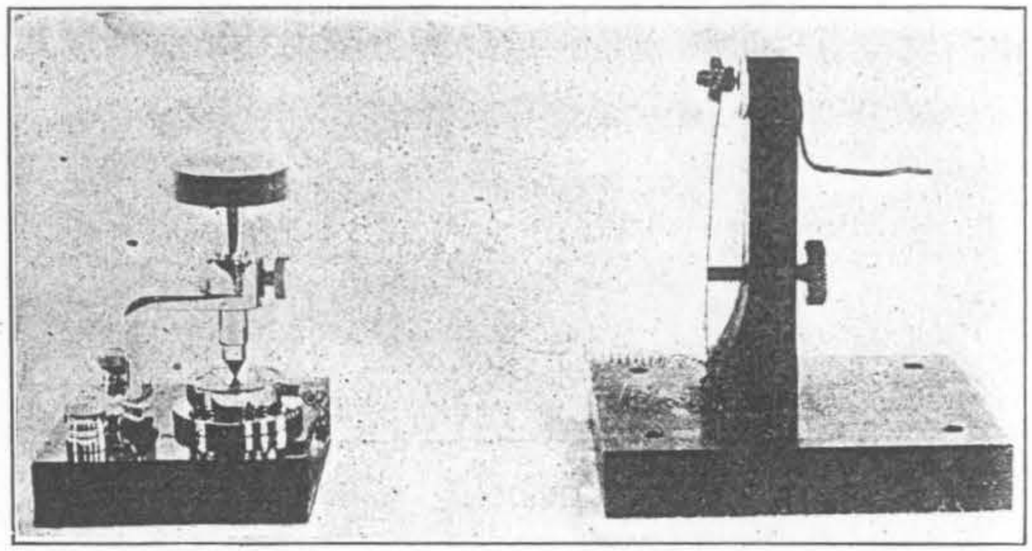

FIG. 36. FIG. 35.

The previously mentioned thermoelectric receivers or rectifiers of Dr. Austin and Mr. Pickard shown in Figs. 35 and 36 and the vacuum tube receivers of Fleming, deForest, and Cooper Hewitt also act very satisfactorily. The fact that the writer

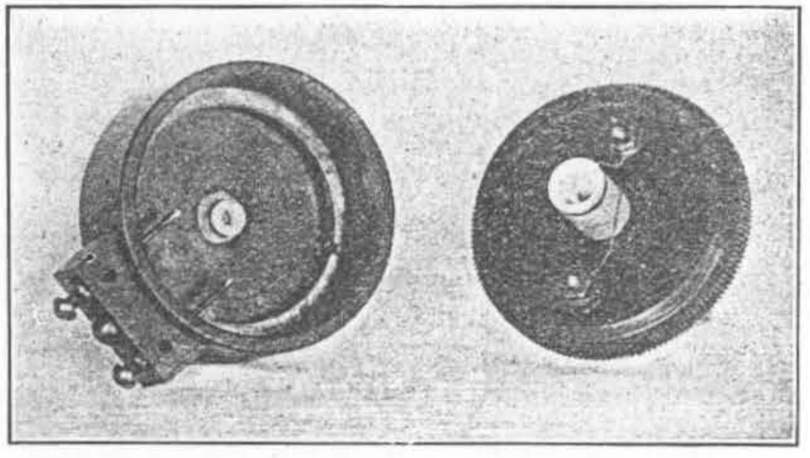

FIG. 37.

has not been able to get as good results from them may be due to greater familiarity with the liquid barretter and heterodyne receiver.

Figs. 37, 38, and 39 show forms of heterodyne receiver adapted for use for telephonic work.

5. *Receiver connections.* Where the wireless telephone is operated by first talking into the transmitter and then throwing a switch and listening, the usual wireless telegraphic connections

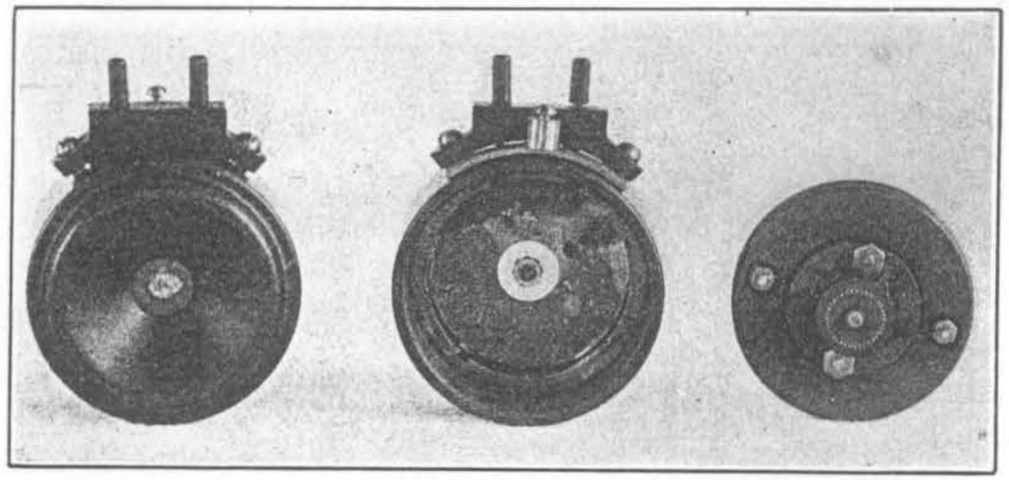

FIG. 38.

are used. This has been found in practice to be very inconvenient, however, and several methods have therefore been devised for talking and listening simultaneously, which methods

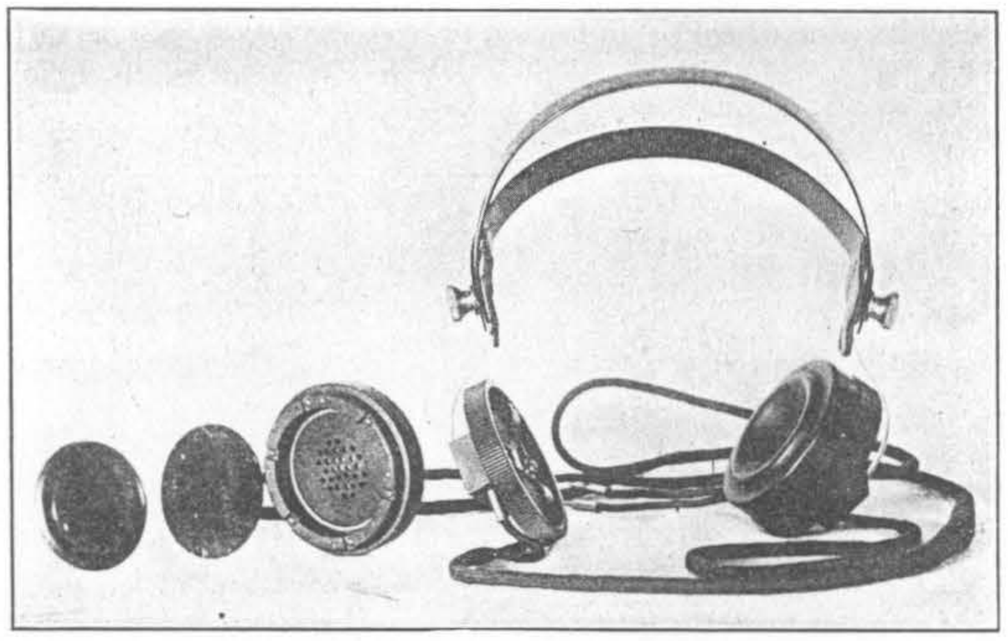

FIG. 39.

can, of course, also be applied to duplex wireless telegraphy. Among these methods may be mentioned the commutator method[1] and the balance method.[2]

1. U. S. application, 350,199, Dec. 31, 1906.
2. U. S. application, 366,528, April 5, 1907.

The former method is fairly well known and consists in rapidly connecting alternately the transmitter and receiver. The balance method consists in using a phantom aerial as shown in Fig. 40, where P is a phantom aerial, the circuit having such capacity inductance and resistance as to balance the radiating antenna. The apparatus is shown in Fig. 41.

In order entirely to cut out disturbances in the receiver while sending, an interference preventer, *I. P.*, the elements of which are shown in Figs. 42 and 43, is used in the receiving circuit.

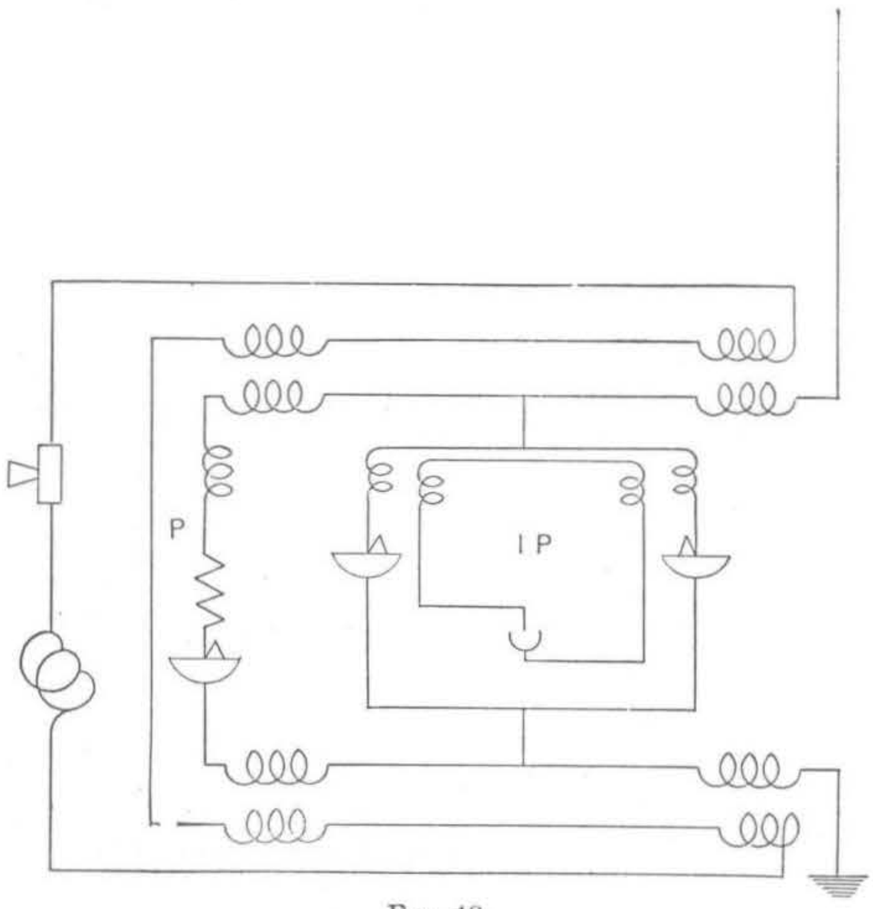

FIG. 40.

It may be here mentioned that balance methods work much better with wireless telephony and telegraphy than with line telephony and telegraphy, for the reason that the radiation resistance of an antenna is absolutely definite and is not affected by the weather, as are line circuits. Consequently, the balance can be made very sharp and once made does not need to be altered.[1] Of course, half the energy is lost but this is a matter

1. This method may, of course, be used for duplex working in wireless telegraphy. As some question has been raised in regard to the capacity of wireless telegraph lines the writer would say that he has received

of practically no importance, as the cutting down of the strength of a telephonic conversation to one-half is as a rule hardly noticeable, especially where there are no line noises or distortion of the speech through capacity effects.

6. *Receiving station relay.* The receiving station relay is similar to the transmitting relay shown in Fig. 26. The same

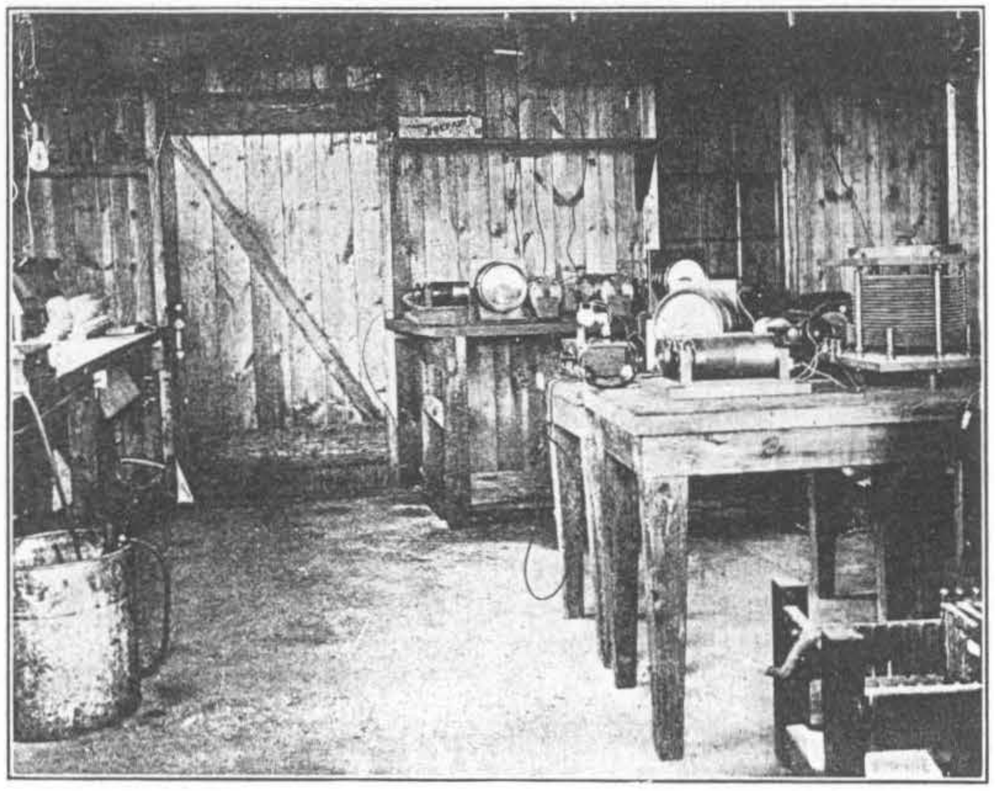

FIG. 41.

remarks apply to its use in connection with wire lines as to the transmitting relay.

messages at the rate of 250 words per minute by wireless and is now experimenting with apparatus designed to give 500 words per minute. With duplexing this gives 1,000 words per minute or 60,000 words per hour. The manager of one of the largest cable companies has stated (*London Daily Mail*, Sept. 24, 1907) that all the Trans-Atlantic cables together send 24,000 words per hour. It would appear, therefore, that if capacity alone be considered a single station on each side of the Atlantic can handle more traffic than all the present cables. It should be pointed out, however, that the mere ability to handle the messages is not sufficient and that unless the wireless telegraph companies obtain land facilities equal to those at present enjoyed by the cable companies they cannot handle the traffic as efficiency, *i.e.*, cannot deliver a message from New York to an individual in London and receive a reply in the same time. Fig. 44 shows a Wheatstone transmitter used for the test referred to.

F. OPERATION

As will be realized from the above, the operation of a wireless telephone system is very simple. The operator merely throws his switch to the position for telephoning and talks into an

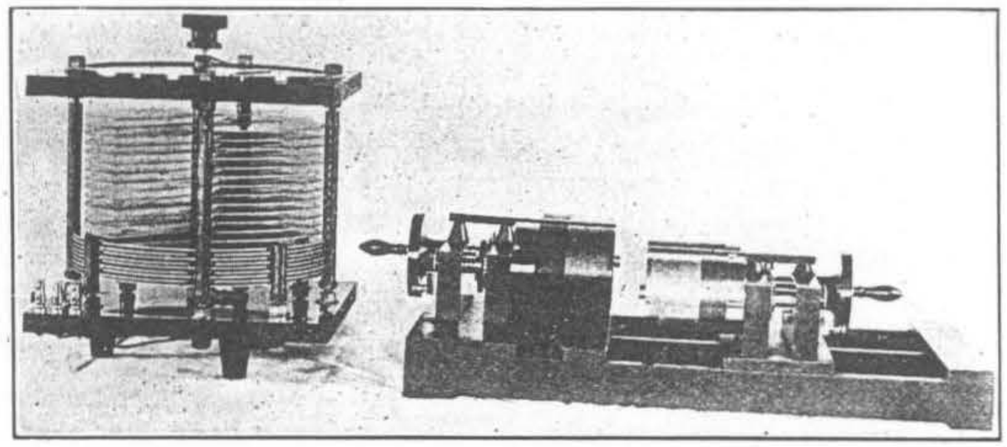

FIG. 42.

ordinary transmitter and listens in an ordinary telephone receiver. When the duplex method is used, as is always advisable, the conversation proceeds exactly as over an ordinary telephone line. Fig. 45 shows a phonograph transmitting music and speech wirelessly. Fig. 46 shows talking by relays from a local circuit.

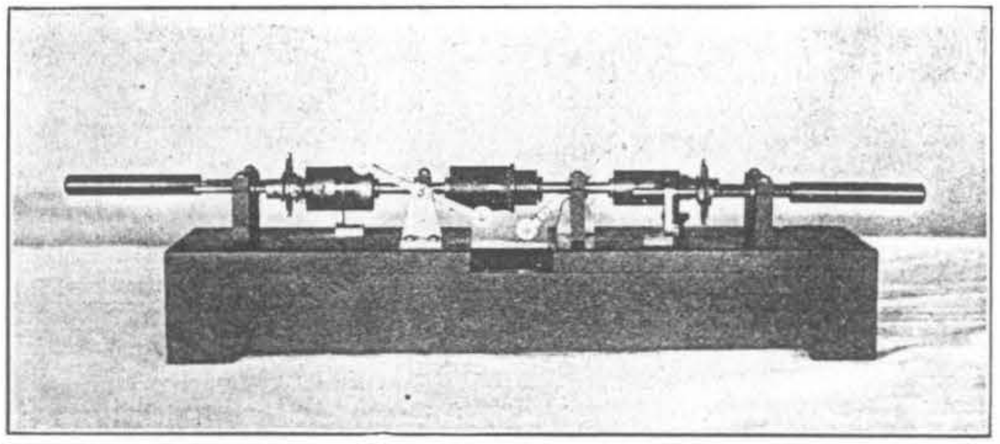

FIG. 43.

I believe I am correct in saying that the transmission by wireless telephone is considerably more distinct than by wire line and that the fine inflections of the voice are brought out much better. This, I presume, is due to the fact that there is no electrostatic capacity to distort the speech, as in the case of

wire lines, though I think the effect is also partly due to the absence of telephone induction coils with iron cores. Possibly some of the gentlemen present have witnessed the operation of the wireless telephone transmission between Brant Rock and Plymouth and between Brant Rock and Brooklyn. If so I think they will bear me out in saying that the transmission was clearer than over wire lines.

As a rule, there is absolute silence in the wireless telephone receiver except when talking is going on, though of course the usual noises may be heard if persons are walking across the room, etc. This makes listening in less of a strain than when talking over wire line. Even during severe atmospheric disturbances the talking is not interfered with to any noticeable extent, provided of course that an interference preventer is used.

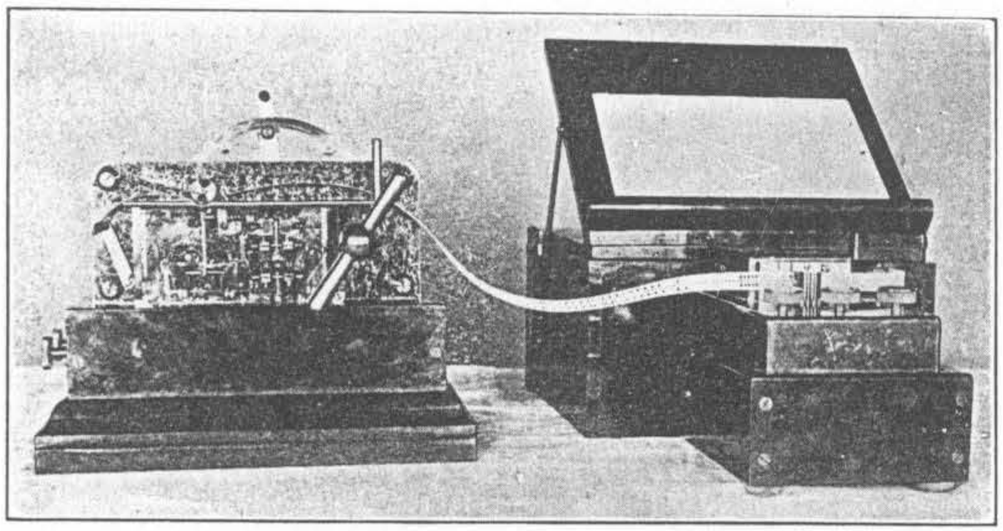

FIG. 44.

A comparative test was made with talking between Brant Rock and Brooklyn by wireless and by wire telephony. The talking over the wire line was done from a long distance station in Brooklyn. The wireless transmission was considerably the better. The fact that the wire line included in its circuits a cable from New York to Brooklyn was of course a disadvantage, but even allowing for this, practice and theory appear to be in agreement to the effect that transmission by wireless telephony over long distances is better than by wire line.

This method should be of especial value to independent telephone companies, which have their local exchanges, but no long distance lines, especially since no franchises or rights of way are necessary.

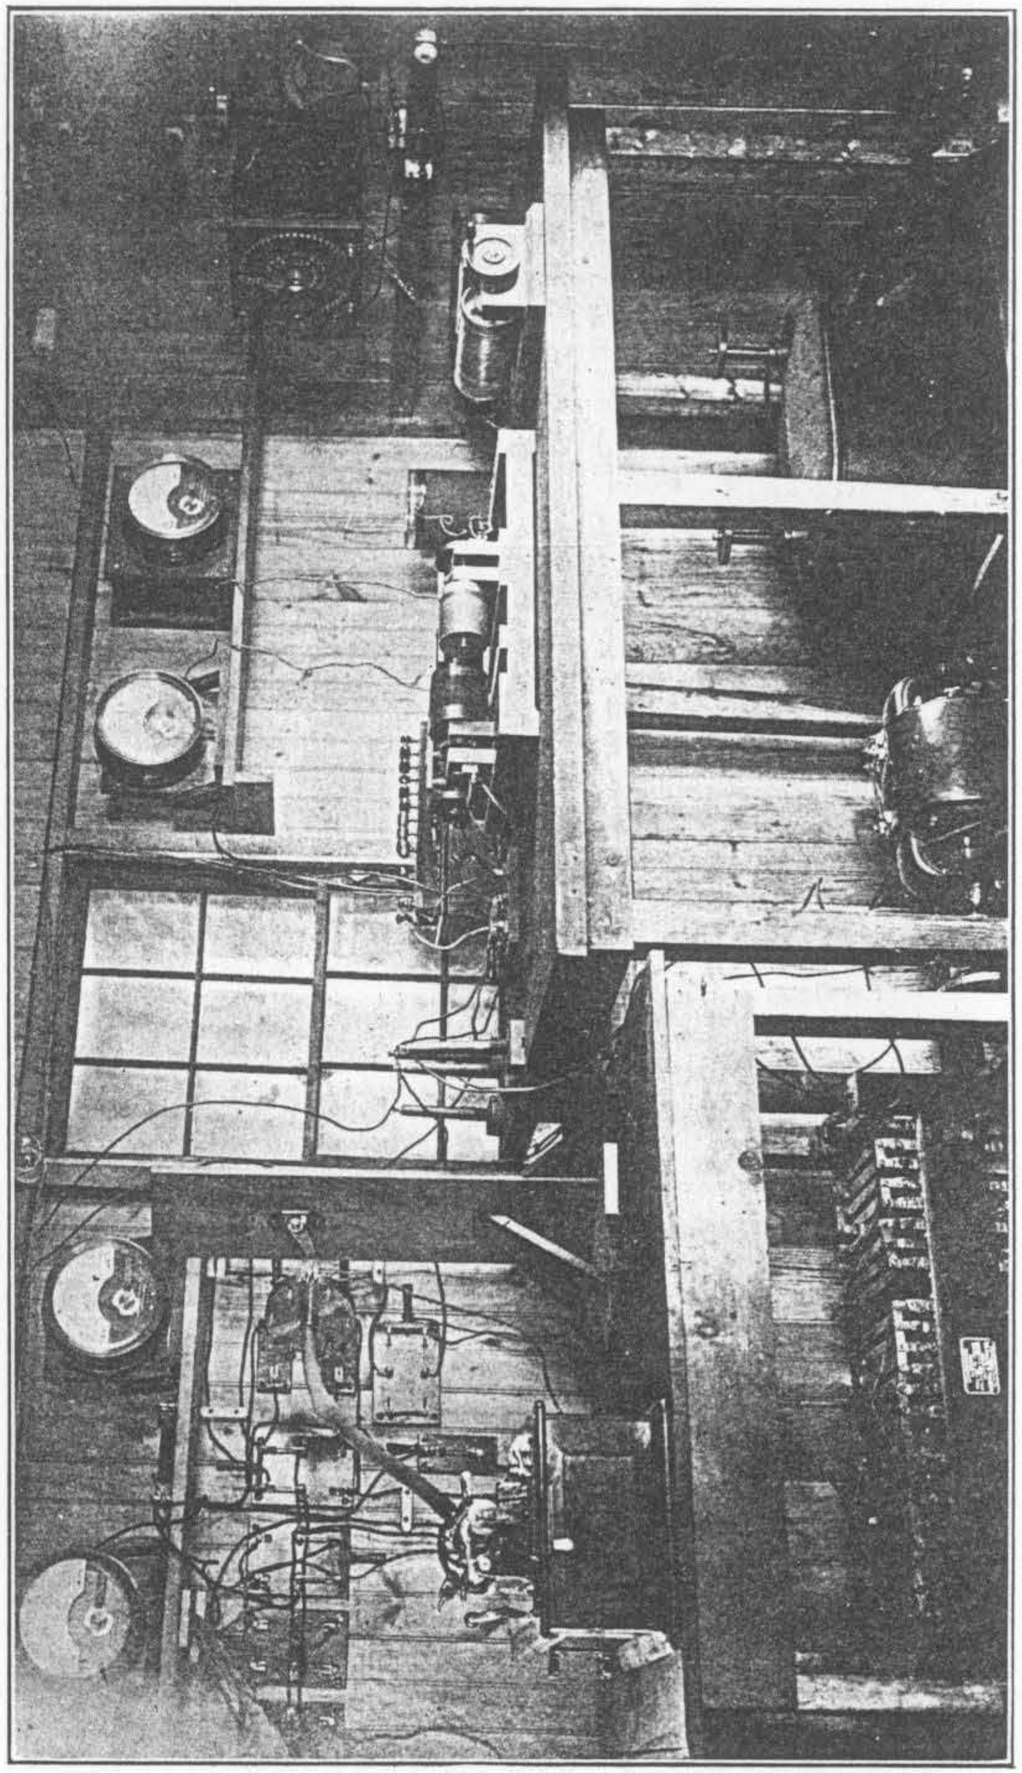

FIG. 45.

G. Possibilities

A. *Local exchanges.* There is no immediate prospect that wireless telephony will take the place of local exchanges. The difficulty in regard to the number of tunes can be overcome, but the fact remains that high frequency oscillations cannot be transmitted over wire and hence each subscriber must have his own generating station. At the present time no method is known which would be practical if placed in the hands of a subscriber. If such means should be found it would be very convenient to call up directly instead of through an exchange, but as I see it there are no immediate prospects of this.

B. *Long-distance lines.* I believe, however, that there is a

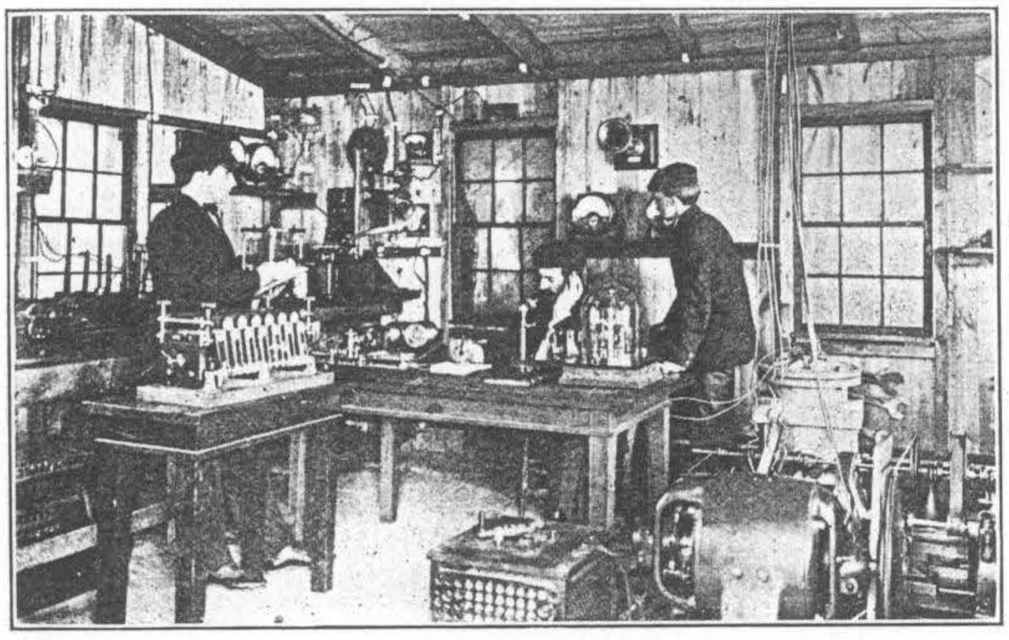

Fig. 46.

field for wireless telephony for long distance lines. The present long distance lines are very expensive to construct and to maintain, and a storm extending over any considerable section of country inflicts considerable loss on the telephone companies. Moreover, the distance of transmission is limited by the electrostatic capacity of the line, as I understand it. Wireless telephony would have the following advantages.

1. The initial cost would be very much less than that of wire lines.

2. The maintenance would be practically negligible in comparison.

3. In case of any breakdown, it would be right in the station and not at some unknown point outside on the line.

4. The depreciation would be comparatively small.

5. The number of employees required would be smaller.

6. The transmission is better, and as there is no distortion of the speech, the working distance is, it is believed, considerably greater.

7. The flexibility is greater. With wire lines a telephone company may not be able to give a Boston subscriber a line to New York, while having lines from Boston to Chicago and from Chicago to New York free. Operating wirelessly the wireless circuit normally used for operating between New York and Chicago and between Boston and Chicago could be used to operate from Boston to New York.

8. No right of way need be purchased and franchises it is believed, are not necessary.

It will be noted that I have not mentioned any disadvantages of wireless telephony for long distance work. I presume this is because I am not a telephone engineer. I hope the defects will be discussed by the experts who are familiar with telephone operation and therefore better able to point them out. Before leaving this part of the subject I would say that I think the question of interference has been worked out to such an extent that no serious difficulty need be feared in that direction.

C. *Transmarine Transmission.* Wireless telephony is peculiarly suited for this class of work. Pupin's ingenious and beautiful method has been successful at Lake Constance, Switzerland, I believe, but even assuming that deep-sea cables of this type could be laid and operated successfully, they would nevertheless be very much more expensive than wireless telephone stations. It is believed that wireless telephony will come into extended use for this purpose. Even without further development telephonic communication could be established between Norway or Denmark or Germany or Spain and Great Britain; between Sardinia and Corsica and France and Italy; between France and Algeria, between Australia and Tasmania and New Zealand; between the United States and Cuba and Porto Rico, etc, were it not that it is at present forbidden by law.

As regards telephonic communication between England and America, my measurements show that this should be possible with an expenditure of approximately ten kilowatts and suitably large towers say 600 feet high, or with some of the new forms of

antenna. Whether such a transmission would be commercially valuable or not is another matter. Personally I do not see that it would, but when I remember that at the time when the telephone was first being introduced a number of eminent business men decided that the house-to-house printing telegraph would be more of a success commercially than the telephone for the reason that no one would want to do business unless he were able to have a record of the transaction, I must admit that there is a possibility of my being mistaken in this.

D. *Wireless telephony from ship to ship.* Here, of course, wireless telephony occupies a unique position. Wireless telegraphy has the disadvantage that a telegraph operator must be carried. The additional expense is an objection in many cases. The proposition that the captain or mate should also be a telegraph operator has not met with favor. Anybody, however, can operate the wireless telephone and almost every vessel carries an engineer capable of repairing the electrical apparatus in case of accident. The final arrangement will, I believe, (if we can prevent the governments from carrying out their proposed laws, forbidding wireless telephony), be this; that passenger vessels will carry a telegraph operator and use the telephoning apparatus for ordinary work and for telegraphing where it is desired to communicate over long distances. Other vessels will use the telephone alone.

E. *Wireless telephone from ship to local exchange.* This also will, I think, have considerable value, as enabling the captain of a vessel to communicate, by relaying over the wire line, with the owner of the ship, or enabling a passenger on a vessel to communicate with friends on shore.

F. *Range of wireless telephony.* 1. *Atmospheric absorption.* The great obstacle to long distance wireless telegraphy and telephony is atmospheric absorption. For short distances up to 100 miles in the Temperate Zone there is little difference between the strength of the signals at one time of the day and another. As soon as the distance is increased much over 100 miles for the Temperate Zones and 40 or 50 miles for the Tropics the signals at night are very irregular and there is great absorption during the day time. The daylight absorption may be so great that less than a tenth of one per cent. of the energy transmitted gets through. Some nights will be as bad as day-time while on other nights there will be apparently no absorption.

Fig. 47 is a curve showing the strength of the messages transmitted between Brant Rock, Mass., and Machrihanish, Scotland, at night, during January, 1906. Nothing at all was received that month during daytime.

The change in the strength of the signals is very sudden. In working from Brant Rock to Porto Rico, a distance of 1700 miles, the strength of the signals with short wave lengths would fall off to one one-thousandth of their former value during a period of less than fifteen minutes, while the sun was rising.

Early experiments showed that the absorption was greater as the wave length was increased and the effect was at first attributed to absorption in the neighborhood of the sending

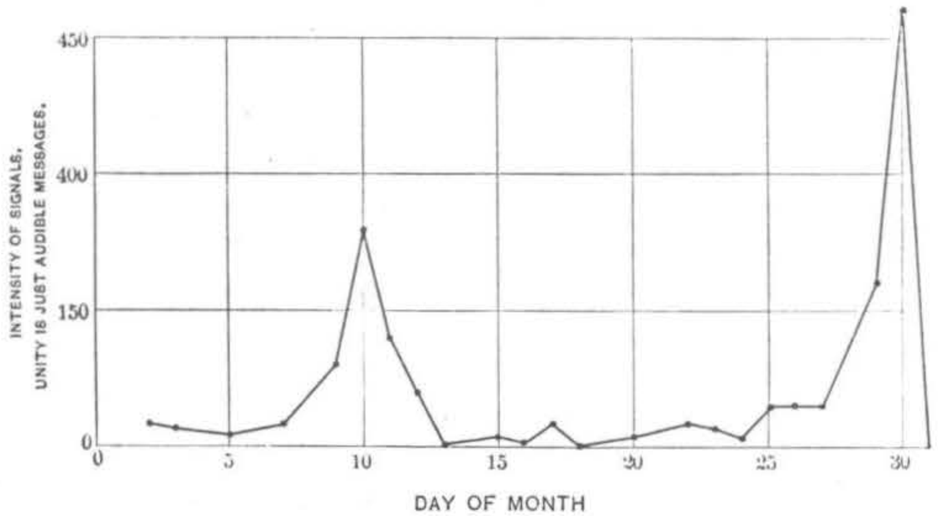

Fig. 47.—Curve showing variation of intensity of transatlantic messages for the month of January, 1906

station, and was thought to increase continuously with the wave length.[1] This fluctuating absorption at one time appeared to place a fundamental obstacle to commercial wireless telegraphy, as telegraph engineers will easily appreciate the impossibility of operating telegraph systems with circuits where the strength of the received signals may fall to one thousandth of its value

1. A mathematical explanation of this supposed fact was given by Dr. Fleming "Principles of Electric Waves Telegraphy" pages 617-618, 1906, the following conclusions being reached:

"Accordingly, the chief part of the weakening of the wave by sunlight is done in the neighborhood of the sending antenna, where the magnetic force H is greatest, and it is more sensible for long and powerful waves than for short and feeble ones. This agrees with the observations of Mr. Marconi".

or rise to a thousand times its value in the course of a few minutes.

It was therefore considered absolutely essential, in order to decide whether long distance wireless telegraphy was commercially possible or not, to investigate this phenomenon fully. As a preliminary the station at Brant Rock sent to four or five other stations at varying distances and comparative readings were taken. The following table shows the general character of the results obtained:

Station	Distance	Strength of signals received on worst nights (strength of unabsorbed signals being taken as 1000).
Company's cottage	200 yards	1000
Lynn	30 miles	1000
Schenectady	170 miles	500
Philadelphia	270 miles	300
Washington	400 miles	150
Machrihanish	3000 miles	1

These experiments proved conclusively that the absorption did not take place in the neighborhood of the sending station, because the strength of the signals received at nearby stations was the same during the day as during the night while there was great variation in the strength of signals received at stations further away.

It was also found that the absorption at a given instant was a function of the direction as well as of the distance, since on a given night the signals received by stations in one direction would be greatly weakened, while there would be less weakening of the signals received by stations lying in another direction, while a few hours or a few minutes later the reverse would be the case.

This was thought to be connected with the coming weather conditions but before this fact is proved a much larger amount of data must be collected. Through the kindness of the U. S. Weather Bureau I was enabled to obtain a chart of the magnetic variations and on comparison of these with the absorption between the Massachusetts and Scotland stations there appeared to be a quite definite relation, *i.e.*, the greater the absorption the greater the magnetic variation. Here also, however, much more data is needed before arriving at a definite conclusion. The fact that the absorption did not take place in the neighborhood of the sending station having thus been definitely settled

the next point to be investigated was whether or not there was any way of overcoming it.

The fact that variations in the absorption occurred with extreme rapidity, the absorption increasing sometimes a hundred fold in a single minute, and at night, when the effect could not be due to the sun directly, seemed to indicate that the body producing the absorption, whatever it was, was not in a state of continuity but was broken up into masses like clouds.[1] This also was in accordance with some experiments made in Brazil in 1905.

From optical theories it is known that where the absorption is produced by conducting masses of a more or less definite size the absorption is to a certain extent selective. The next point in the investigation was, therefore, to determine whether there

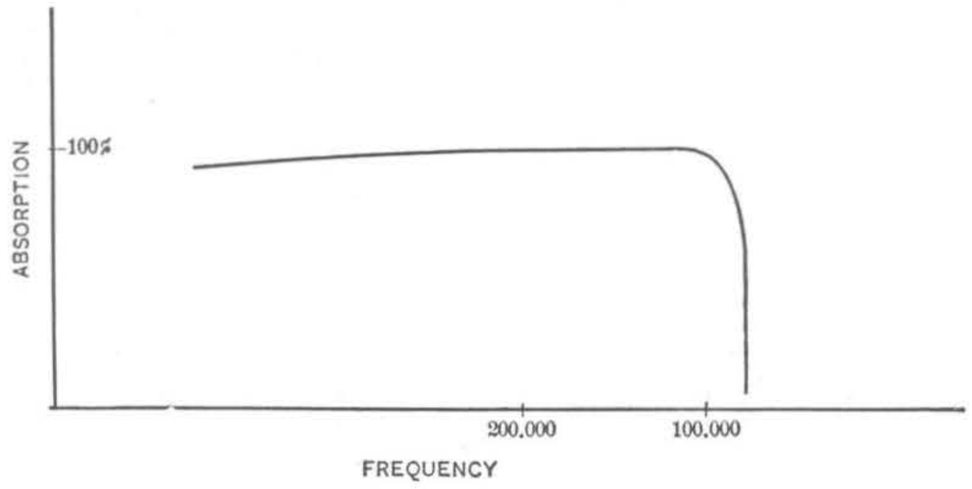

Fig. 47

was any possibility of this being the fact in the case of the absorption of wireless signals.

Comparative tests were therefore made of the absorption at night and during the day between Brant Rock and Washington, with wave lengths varying from a fraction of a mile up to four or five miles. It was found that the absorption did not increase continuously with the wave length but reached a maximum and then fell off with great suddenness.

Fig. 47 shows the general character of the curve, the ordinates referring to the amount of the absorption and the abscissas to the wave frequency.

1. *Electrical Review*, May 18, 1906.

It may be noted that the absorption is a maximum at a frequency of about 200,000 per second, nine hundred and ninety nine thousandths (0.999) of the energy being absorbed at this frequency during daylight, while for a frequency of 50,000 the absorption does not appear to be appreciable. Longer experiments, of course, might show some absorption, but in any case it is of a different order from the absorption for the shorter wave lengths.

Experiments were then made between Brant Rock and the West Indies, a distance of 1700 miles, during the spring and summer of 1907. It was found that the results were of the same character, *i.e.* that while there was greater absorption for frequencies of 200,000 there was comparatively little absorption for frequencies in the neighborhood of 80,000 and messages were successfully transmitted in daylight with this latter frequency. No messages were received in daylight with the higher frequency, though messages transmitted from the same station and with the same power and frequency were officially reported as having been received at Alexandria, Egypt, a distance of approximately 4000 miles.

The fact that these experiments were made during summer weather, and the receiving station was in the Tropics, and the fact that the distance, 1700 miles, was practically the same as that between Ireland and Newfoundland definitely settled the question as to whether long distance wireless telegraphy was a commercial possibility or not and the results were therefore published.[1]

Since the publication of the above results transmission has been accomplished by means of these long waves over still greater distances during daylight. Sig. Marconi early in October, 1907, abandoned the short-wave lengths previously used, and adopted one over two units in length, and immediately succeeded in operating between Glace Bay, Nova Scotia, and Clifden, Ireland a distance of more than 2000 miles, the frequency being approximately 70,000. The same messages were received at Brant Rock, Mass., a distance of nearly 3000 miles.

Still more recently Captain Hogg of the "Glacier" has written that during the southward passage of the Pacific fleet he received messages from the station at Brant Rock, Mass., while off Cape Ste. Roque, Brazil, S. A. The frequency used for sending was approximately 80,000, and the messages were

1. *The Electrician* (London), July 26, 1907.

received with the very interesting and sensitive silicon receiver invented by Mr. Pickard. This distance of 3000 miles is the greatest yet achieved by wireless transmission during daylight and would indicate that with the use of suitably high towers much longer distances can be reached.

2. *Range of wireless telephony and wireless telegraphy compared.* For the same power it is possible to telegraph to a further distance than to telephone. Distinct speech depends upon the presence of harmonics of a frequency as high as 1200 per second. The amplitude of these harmonics is according to some rough experiments made by the writer only about one per cent. of the fundamental frequency. Consequently, with a perfectly modulated transmitter 100 times as much energy would be necessary to telephone a given distance as to telegraph. It fortunately happens, however, that a carbon transmitter and also the circuits in which it is used, can be so constructed as not to modulate perfectly but can be arranged so as to accent the higher harmonics.

With transmitters arranged for the purpose good transmission has been obtained with thirty times the energy required to produce audible telegraphic signals. By still further modification the power required has been reduced to approximately ten times that necessary for telegraphing, curiously enough without noticeably distorting the character of the speech. There is one fact, however, which prevents the ratio from being as large practically as the instruments show, *i.e.*, speech can be satisfactorily understood with a less increase of power above a minimum audibility than telegraphic signals.

The amount of power necessary for wireless telephony may therefore be taken as approximately five to fifteen times that necessary for wireless telegraphy; *i.e.*, under the same circumstances and for the same power the wireless telegraph will carry two to four times as far. The difference in range would be very much greater also but for the curious fact that there is much less falling off with sustained oscillations than with intermittent groups of waves, even though the frequencies are identical.

This fact has been repeatedly determined by sending between Brant Rock and Brooklyn on the same frequency, using in the one case spark produced trains of waves and in the other the high frequency dynamo. The difference in the falling off for the same frequency and energy is very great but further work is necessary before anything very definite can be said about it or the reasons finally determined.

H. How Wireless Telegraphy has been Throttled by Governmental Action

The question has been asked why, if wireless telegraphy can compete with wire lines and cables, it is not put into operation. This is not an unnatural question. Ninety nine individuals out of a hundred would probably consider that if an inventor had perfected a system of wireless telegraphy or telephony so that it would operate reliably over long distances and would handle messages at a fraction of the cost of the present cables and without interfering with other stations, he would immediately pick out from an atlas half a dozen suitable points for operation, such as from France to Algiers, Italy to Egypt, Great Britain to Germany, New Zealand to Australia, Australia to Hong Kong, or Canada to Great Britain, and immediately commence commercial work, being perhaps delayed a few weeks on account of some slight formalities in connection with obtaining permits. The statement that nothing of the sort could be done would be received with incredulity, especially if it were known that the business men who would benefit by the reduced tolls were strongly desirous of having them put into operation.

This is a very important matter, not because the crushing out of a new system of telegraphy is so very important in itself, but because the prospects are that other branches of the electrical profession may have to face the same situation in the near future and it is, therefore, advisable to show in some detail just what governmental ownership means in its relation to the progress of civilization. I will, therefore, explain fully, but as briefly as possible how commercial wireless telegraphy is hindered by governmental action.

Examination of a chart of the world immediately suggests a number of points as suitable for the installation of wireless communication. For example the following:

1. United States to Cuba.
2. " " " Porto Rico.
3. " " " Jamaica and other West Indian Islands.
4. " " " Bermuda.
5. " " " Newfoundland.
6. " " " Great Britain.
7. " " " France.
8. " " " Azores.

9. Newfoundland " Great Britain.
10. Great Britain " Ireland.
11. " " " France.
12. " " " Spain.
13. " " " Germany.
14. " " " Denmark.
15. " " " Norway.
16. France " Algiers.
17. Italy " Egypt.
18. New Zealand " Australia.
19. Australia " Hong Kong.

The first fact to be noted is that these countries with the exception of Porto Rico are foreign countries and that in practically every one of these, Porto Rico is believed to be the only exception, there are stringent laws in force forbidding the erection of wireless stations without permits. The difficulty of obtaining these permits is shown by the fact that one wireless company within the writer's knowledge has been endeavoring for more than four years to obtain permits in the majority of the above mentioned foreign countries and has so far succeeded in obtaining only one permit and that for direct communication between the United States and Great Britain.

To take a specific illustration. In 1903 an American company was requested to install communication between Bermuda and the United States. The principal industry of Bermuda is the growing of produce of various kinds, which is exported almost entirely to the United States. The only present means of communicating is through Nova Scotia, and in winter especially, owing to the delays on the land lines, the service is often quite insufficient. Permission was asked of the Home Government by the Bermudian incorporators, but without success.

A petition was then signed by virtually every prominent business man in the islands and forwarded to the Home Government. The members of the New York Produce Exchange drew up a petition and forwarded it to the Secretary of State requesting him to use his influence in the matter. The Colonial Office stated in reply that it was favorable to the project but that the matter must be referred to other branches.

The Bermudian business men also sent several representatives to Great Britain to urge personally the granting of the permit. After a lapse of several years a definite reply was received to

the effect that the permit would not be granted. The Bermudians then took up the matter through a Canadian company which sent several representatives to interview the authorities in Great Britain but without success. The Lord High Commissioner of Canada, Lord Strathcona, finally was kind enough to interest himself in the matter and personally presented the case before the British authorities.[1] It is hoped by the Canadian company and the Bermudians that the permit will finally be granted, but this specific illustration will explain the difficulty in obtaining permits for operation.

As illustrating a different obstacle the case of Newfoundland may be taken. This is the natural point for establishing communication with Great Britain and the experiments previously referred to as having been made between Massachusetts and the West Indies showed conclusively that there would be absolutely no difficulty in operating commercially and with ease over this distance. On the other hand to operate directly from America is a much more difficult proposition for the reason that, as examination of a great circle chart will show, the whole of Newfoundland and Nova Scotia lies between any point in the United States north of Hatteras, and Great Britain.

If operation in Newfoundland were not forbidden by law half a dozen wireless stations would be at once erected, and the companies would be only too glad to pay into the Newfoundland treasury the ten or twenty thousand dollars per annum to be collected if they were put on the same footing as the cable companies in order to save the cost of the longer transmission. The Newfoundland government a number of years ago granted a monopoly of wireless telegraphy to one company, which company has never erected a transatlantic station in that island. While this monopoly has been very injurious to Newfoundland, on account of the loss of revenue entailed, it has been still more so to the wireless companies and to the public at large, which otherwise would have had cheap transatlantic telegraphy several years ago.

Another very formidable obstacle is the fact that in practically all the foreign countries referred to (and in Porto Rico) land telegraphy is a government monopoly. Consequently, the

1. Since the above was written a communication has been received from the colonial secretary stating that no decision will be given in the matter until the Wireless Company submits a plan for coöperating with the present cable companies (letter of Aug. 6, 1908).

wireless companies are entirely at the mercy of the government, are barred from collecting their own messages and must pay whatever tolls are fixed by the various governments. This, of course, also operates to prevent rapid service, since instead of communicating directly from Paris to London the messages would have to be sent from Paris by wire line to the French wireless station thence to the English wireless station and thence again by wire to London.

In a number of countries, the cable lines are also owned by their governments which makes them naturally averse to losing the invested capital or to permiting private companies to compete. It would be evident therefore that no matter to what perfection the art of wireless telegraphy is brought, years will elapse and the exercise of a great deal of political influence will be necessary before the public gets the advantages of the cheaper rates.

Ship communication. Here again the development of wireless working has been stifled by legislation. Vessel owners were at first rather slow to take up the matter of equipping their ships but after the system had proved its worth in several cases and some of the owners had had to pay large sums for salvage in cases where a wireless installation would have avoided the loss, its value began to be realized. It was at this point that the governments again stepped in with premature and injurious legislation. As a specific illustration, a United States company had arranged with the owners of some two hundred vessels to construct a line of stations from Maine to Texas, to operate with stations installed on the ships. The announcement was made that the administration proposed to recommend to Congress that wireless telegraphy be made a government monopoly.

A representative of the wireless company requested permission to submit some evidence to the effect that such a government monopoly was not necessary and that the various stations could operate without interference. A reply was received from the Administration that " information in regard to the subject was not desired ", and the administration recommended that wireless communication with ships should be made a government monopoly.[1]

It was proposed to carry this out as follows:

1. To establish Navy wireless stations at points along the coast

1. Recommendations of the Inter-departmental Board on Wireless Telegraph, 1904 submitted and approved by the Administration.

where wireless stations were needed by the merchant marine.[1-2]

2. To forbid the operation of private stations at these points.[3]

3. The Navy stations are to handle all messages to and from ships free of charge.

4. Wireless companies to be permitted, after obtaining a license from the Department of Commerce and Labor, to erect stations at points where there was no merchant marine business.[4]

The official approval and transmission of these recommendations by the Administration, although they were opposed and never went into effect, terminated, of course, all negotiations with vessel owners, since the owners would naturally not agree to contract for the transmission of their messages with the immediate prospect in view that the Government would transmit them free of charge. At the present time the masts ordered for the proposed line of stations are rotting at various points along the seaboard and the apparatus purchased for installation is deteriorating in storage.

The development of ship communication had just begun to recover from this blow when an International Wireless Telegraph Conference was arranged for by the various governments. In America no opportunity was afforded the wireless companies

1. *Ibid.* "That the maintenance of a complete coastwise system of wireless telegraphy by the Navy Department is necessary for an efficient and economical management of the fleets of the United States in time of peace and their efficient maneuvering in time of war."

2. *Ibid.* "As fast as the naval wireless telegraph stations are in operation the Navy Department shall receive and transmit through these stations free of charge all wireless messages to and from ships, providing such stations do not come in competition with commercial stations, until such time as Congress may enact the necessary legislation governing this subject". That the statement in regard to competition is disingenuous will be seen from examining the following extra Note 4, since only one station, and that a Navy one would be permitted at points where there was merchant marine business.

3. *Ibid.* "In asking for legislation on this point the board invites attention to the fact that where wireless stations are needed for the merchant marine, as a rule, the navy will also require them. The board believes it to be in the interest not only of governmental but of public economy and efficiency to permit the naval stations to handle the public service, for in the present state of the art but one station is desirable for the public interest in such places. It is admitted that there may be special cases where private stations can serve a useful purpose and the board believes that the Department of Commerce and Labor should have the duty of issuing licenses in such cases under such regulations as will prevent interference with stations necessary to the national defence."

4. *Ibid.*

of presenting the case to the delegates to the Conference, and a very stringent set of regulations was adopted. The Administration transmitted these regulations to the Senate.[1] The ratification of the treaty embodying these regulations was opposed by the Marconi Co., and by the National Electric Signaling Co. The following facts were pointed out:

1. That the proposed regulations virtually amounted to confiscation of the property of the wireless companies; that the working at present was carried on at a loss; that no wireless company was at the present time paying dividends; that the proposed rates would not permit of any return on the capital invested; and that the regulations would so limit the amount of business which it would be possible to transact that it would not pay to keep up the stations.

2. That the inventors in the art of wireless telegraphy had expended large sums of money in developing their systems, and such confiscation was therefore unjust and was thought to be unconstitutional.

3. That the regulations were impracticable in the following respects:

a. By requiring ships to use two tunes only[2] all stations were placed, so tc speak, on two-party lines, thereby producing a maximum of interference and preventing any one station working while any other was operating.

b. Allowing only five minutes per message and assuming only ten ships each with ten messages to be in the neighborhood of a given seaport, more than eight hours would have to elapse before the last station had transmitted its message. This time is believed to be underestimated, as the regulations provide that each ship before sending its message must call the coastwise station, have a number assigned to it, inform the coast station of its distance, its true bearing in degress, its true course in degrees, its speed in nautical miles, the number of words it has to transmit; must be informed how long it will have to wait, whether the transmission is to be in alternate order or in series, interrupt the sending after each 20 words, send an interrogation mark, wait for repetition of the last word, etc.[3] Hence it would be rather difficult to maintain the average time mentioned. This excessive delay would cut down the traffic to such an extent as to render it impossible for the stations to pay expenses of

1. Senate Document, Sixtieth Congress, first session.
2. Regulations II and III.
3. Regulations 19 to 26.

maintainance, and any telegraphic engineer will appreciate the difficulty of carrying on commercial business under such regulations.[1]

c. Placing all vessels on two-party lines introduces all the difficulties of the party line method and loses the only advantage, as it might easily happen that a ship in distress using one frequency might be within range of a number of vessels using the other frequency, but outside of range of any vessel using its own frequency. The obvious and practical method is legally to establish a single tune to be used exclusively for calling and distress signals but not for any other purpose; the transmission of messages to be continued by switching over to other tunes once the call has been received and accepted. In this way a ship in distress can always be sure of calling any vessel within range, while the transmission of messages can be carried on without interference and without one ship having to wait until the other is finished.

4. Its restrictions are of such a character as to prevent the future development of wireless telegraphy. For example.

a. The regulation[2] that all stations must carry a licensed wireless telegraph operator capable of receiving at twenty words per minute would prevent the installation of wireless stations on board the majority of ships since only the larger vessels can afford the additional expense of the operator. Many vessels would install wireless telephones which do not require a skilled telegraph operator, if it were not for this regulation.

b. The rules forbidding[3] the transmission of telegrams calling for repetition of messages, or for acknowledgement of receipt, or for telegrams to be forwarded, or for telegrams to be delivered by express or by mail, or for the transmission of money-order telegrams or for the transmission of telegrams with answer prepaid, or for the transmission of urgent telegrams are especially restrictive. By forbidding the transmission of telegrams of all the above classes the commercial field of wireless telegraphy is limited to such an extent as to deprive wireless telegraphy of its chief value.

1. As a practical illustration of this, on August 12, 1908, the Assistant Secretary of the Navy, on board U.S.S. Dolphin, had to wait two hours before an important message could be transmitted, as the two stations with which he was in range were occupied in sending a long message and the Dolphin was unable to cut in. Had a number of stations working on different times been available, this could not have happened.

2. Section 6, paragraph III.

3. Section XXXIII.

5. It expressly forbids the use of a number of the most important developments in wireless telegraphy. For example.

a. Section 3 in effect forbids long distance transmission in daylight. This section states that ships must not use wave lengths exceeding 600 meters. It is now well known that daylight absorption is very great for these wave lengths and that much longer wave lengths must be used during daytime. This rule therefore virtually forbids wireless telegraphy during daylight except within a very limited radius, and in case of an explosion or fire on shipboard during daylight the vessel would be unable to summon assistance unless by some fortunate chance another vessel happened to be within the radius limited by the restriction to the short wave length. It also virtually prohibits ships keeping in communication with the shore for more than twelve hours out of twenty-four.

b. Section 3 states that the system employed must be a syntonized system, thus forbidding the use of systems such as the heterodyne system which do not depend for selectivity on syntony. This would not be so injurious if it were not for the fact that the present indications are that syntony will in the near future be abandoned as a means of obtaining selectivity.

c. The rules of Section 2, 3, and 18 to 26, virtually forbid the use of duplex and multiplex systems. There is no reason why a number of ships should not communicate with the same station simultaneously, but the above rules forbid this by requiring only two wave lengths to be used and the messages to be taken one after the other.

d. It is premature. The expression "that an art is in its infancy" is a very hackneyed one but if it can be applied properly to any art it is to wireless telegraphy. The fact that the proposed regulations are unsuitable does not reflect in any way on the ability or conscientiousness of the delegates, though it would seem that it would have been advisable to consult the engineers of the various wireless telegraph companies before drafting the rules. The main difficulty, however, is that no one, no matter what his knowledge of the present state of the art, can foresee the future developments. The question of wave length and daylight absorption is an illustration of this, as is also the question of syntonized circuits. The time has not yet come for any such hard and fixed regulations as thus proposed.

6. It was also pointed out that the public had no rights in

regard to wireless telegraphy, since a patent differs from a franchise in that when the public grants a franchise it gives a right in respect to something which already exists and which it owns, and it therefore has a right to make what stipulation it chooses. In the case of a patent, however, the right is not given in respect to something which the public owns, but in regard to a new creation which exists merely in the mind of the inventor, to be called into being or not at the inventor's will, and therefore a thing in which the public has no right except as it obtains one by stipulation with the inventor. In the case of wireless telegraphy the companies invested their money under the patent law contracts with the various governments, and therefore the inforcement of regulations of the character proposed without the consent of the inventors is a breach of contract.

As a result of the hearing and of representations supporting the position of the wireless companies made by a very eminent electrical engineer the Senate Committee has decided to do nothing for the present in the matter. During the hearing the fact was brought out by the committee that the proposed regulations were passed upon the assumption that interference could not be kept out, and that the U. S. Navy had already made official reports on tests of interference preventers which showed that this was not the fact. On direct question by the Senate Committee the representative of the U. S. Navy present at the hearing freely admitted that it was a fact that interference could be kept out.

Still more recently another set of recommendations has been forwarded by the Administration to the Senate endorsing the recommendation of the Secretary of the Navy that a law should be passed[1] making it an offence punishable by imprisonment for one year of a fine of $2,000 or both for a private station to continue sending when called upon to discontinue by a Navy operator, or to produce interference with a Navy station when the latter is transmitting an official message. This recommendation was not accompanied by any recommendation to the effect that the Navy stations should use any means for keeping out interference. Before the transmission of this recommendation a conference was sought with the Navy officials with a view to drafting a form of regulation which would accomplish the results sought, without placing the wireless companies at the mercy of

1. *Congressional Record*, Feb. 14, 1908. Also H. R. bill 17719, 60th Congress, 1st Session.

the Government and without virtually confiscating their property but it was found impossible to obtain a hearing.[1]

The following memorandum of a portion of the interview between Secretary Straus of the Department of Commerce and Labor and the representative of the wireless company, asking for a hearing, will be of interest:

REPRESENTATIVE: " Will you not, Mr. Secretary, be willing to assist us in obtaining a treaty which, while giving the government all it desires in the way of intercommunication between different systems, reservation of wave-lengths for government purposes, etc., will, at the same time, avoid driving the wireless companies into bankruptcy? "

SECRETARY STRAUS: " The treaty was reported by the experts of the government departments, and we propose to carry it out, as it is the policy of the administration."

REPRESENTATIVE: " But, Mr. Secretary, these regulations virtually prevent the wireless companies from doing any commercial business. With everybody on one party line, even without the numerous other restrictions, it will not be possible to handle a sufficient number of messages to pay operating expenses, and the companies will necessarily be forced out of business."

SECRETARY STRAUS: That has nothing to do with this department. If you are injured you should go to the Congress and ask them to reimburse you.

REPRESENTATIVE: Mr. Secretary, you know that it would be practically impossible to get a bill to reimburse a private company through the Congress. Why should the government crush out a new and important method of communicating which will save the country millions of dollars yearly, when the government will gain nothing by the action. We feel that your department ought to assist us in this matter.

SECRETARY STRAUS: It has been decided by the administration that the treaty should be approved as it stands.

It will be noted that this conversation took place in the United States, and not in Russia, as might possibly be otherwise inferred. It will appear from this and the experience of others that the original object of the formation of the different government departments has been rather lost sight of in recent years.

It will perhaps be seen that the difficulties in the development of wireless telegraphy have not been wholly of a technical nature and more patience may perhaps in the future be extended to those engaged in the work.

In his book entitled " Public Ownership and the Telephone in Great Britain," Professor H. R. Meyer has treated specifically of the way in which the use of the telephone was opposed in Great Britain, by the English postal authorities with the object

1. See also appendix.

of, to quote the Postmaster General, Sir James Ferguson, "Guarding the Post Office monopoly." Professor Meyer shows how out of 77 companies which applied for licenses from 1882 to 1884 only 8 companies succeeded in obtaining permission to work, and how the various authorities prohibited the telephone companies from laying cables in the streets or from opening long-distance pay stations or from building trunk lines in order to force the public to use the telegraph instead of the telephone. It would appear that the same line of policy in a still more aggravated form has been adopted in connection with wireless telegraphy.

Considerations

The subject is, however, one which is bound to concern in the near future other branches of the engineering profession than those now affected and the present appears to be a suitable time for considering the matter more broadly.

Whatever the ultimate object of man's existence may be it is tolerably certain that it is not to occupy his entire mental activity with the question of how many grubs he can secure for food and where he can find a suitable hollow tree in which to spend the night. But whatever we have above this is due solely to the inventor (in which term I include not only the men who discovered how to produce fire and to build houses and steam engines and alternating current motors, and therefore all engineers whether they take out patents or not, but also those who discover how to distribute what is created in such a way as to make it available).

In the state of nature which Tolstoy so greatly lauds and so carefully avoids advance is impossible; all available energy of mind and body is necessarily employed in the problem of maintaining a bare existence. Before we can advance toward our goal, whatever it is, we must first have time and opportunity and a means of maintaining any advance. That we have this time and opportunity is due to the fact that by means of innumerable inventions we are rendered every day less dependent upon the accidents of nature. It would therefore appear, that whatever our ultimate goal may be, the first essential for reaching it is an increased control over the forces of nature.

This increased control can only be obtained through intense effort. When we see a performer at a circus contorting his body into apparently impossible positions we realize the peculiar aptitude and the many years of training which must have been

necessary. It is not generally realized, however, that a still more peculiar aptitude and many more years of still more intense training are necessary for those who would do useful work in any branch of mental achievement. We seldom think, in reading a mathematical paper for example, that the author has studied possibly for an average of ten or twelve hours a day for twenty or forty years before achieving sufficient proficiency in his subject to be able to accomplish the work.

To obtain results in a special line therefore a man with special aptitude and training is required. In addition to this there must be the opportunity. Hundreds of thousands, and in many cases millions of dollars are necessary for the development of an important invention. Such sums will not be furnished if there is no prospect of a return. As the success of an invention is always doubtful, the return from a successful invention must be sufficient to cover the losses from the much larger number of failures, for if the average return from one hundred inventions falls below that obtainable from mortgages or other forms of secure investment there will be no incentive.

The following question seem to me to be worthy of consideration:

1. Whether public officials, elected by the people, would consider themselves justified in expending millions of dollars on the development of inventions the success of which was uncertain.
2. Whether the best men to develop such inventions successfully would be found among the Government officials available.
3. Whether development can be expected in an art or industry entirely under Government control or ownership.
4. Whether universal Government control or ownership does not necessarily involve a fixed and non-progressive state as opposed to a state of progress and development.

Appendix

In the United States some additional hindrances on the part of the Government have been met with. For example, in the United States, and in Russia, as well, an inventor has no legal remedy in case the Government appropriates his invention.[1] It might be thought that the inventor could protect himself by suing infringing companies, but this is not so.

The wireless sets originally used by the United States Navy

1. Russel *vs.* United States, decided in 1900, 182 U. S. 516.

were imported from a country which was not at that time under the Patent Convention, and as they were purchased abroad no action could be taken. The then Secretary of the Navy, Mr. Moody, refused to require the foreign company to appoint a responsible representative in America. It was not until some years later, when, Mr. Morton being Secretary and the matter having been taken up by one of the Senators, this was done, and an injunction was obtained against the representative so appointed.

On further protest the next Secretary of the Navy, Mr. Bonaparte, stated that the patents could not be recognized as they had not been sustained. He was again approached but said that he had decided that he was not bound to respect them as he considered the price too high.[1] He declined, however, to allow the price to be fixed by arbitration, stating that he considered that the price should be fixed with reference to the cost of manufacture solely. It was pointed out that as the cost of labor and material of the particular device concerned amounted to less than a dollar and as a fair manufacturing profit on this would not be more than forty cents, this would afford no means whereby the company would be reimbursed for its expenditure of several hundred thousand dollars in developing the apparatus. To this Secretary Bonaparte replied that that was a matter which concerned the company and that his department had nothing to do with that. The principal infringing companies having been enjoined the Navy and Army began manufacturing the devices themselves in quantities.

Through the influence of one of the Senators the matter was again taken up and it was arranged that the Secretary of the Navy, Mr. Bonaparte, should obtain a legal opinion from the Attorney-General in regard to the matter. This opinion was prepared by one of the Attorney-General's assistants and proved to sustain the claims of the wireless company on every point. Before it was finally transmitted the Secretary of the Navy, Mr. Bonaparte, withdrew his request for an opinion.

The wireless company received a letter[2] from the Navy Department to the effect that by order of the Administration the patents had been turned over to the Navy Department. A written request[3] was forwarded to the Administration, pointing

1. Letter April 19, 1906.
2. Letter No. 137,244, July 11, 1906.
3. Letter April 3, 1907.

out that the above-mentioned property had been confiscated by the Government without a hearing and asking for a hearing. No reply was received.

The above is given as an illustration of the effect of the present law under which an inventor has no legal remedy against the confiscation of his patents by the United States Government. Among other recent instances of confiscation of inventions by the Government may be mentioned those of the Krupp and Armstrong Companies, the San Francisco Dry Dock, etc.

As the situation is not generally understood attention is here called to it. It should be remedied, as it operates very injuriously as regards the Government departments themselves. The Government is deprived of the services of American inventors who either place their talent at the disposal of other countries, as in the case of Hiram Maxim, or turn their attention to other lines. The general result is that the United States Government, instead of leading other nations, is obliged to follow after and copy, though the success of the United States Navy in developing submarine boats is an illustration of what can be accomplished in cases where the inventor has been able to develop his work without confiscation.

In 1906 President Roosevelt's attention was called to the above facts. He was asked if the administration would not introduce a bill to remedy this state of affairs. He replied that the administration had too many bills of its own to look after, but, on further inquiry, stated that if such a bill was introduced the administration would not oppose it.

On the strength of this promise a bill was introduced and unanimously reported, as follows:

HOUSE OF REPRESENTATIVES, 60TH CONGRESS, 1ST SESSION, REPORT No. 184

The Committee on Patents, to whom was referred the bill (H. R. 7653) to amend section 4919 of the Revised Statutes of the United States, to provide additional protection for owners of patents of the United States, and for other purposes, have considered the same, and recommend that the bill do pass with the following amendment:

In line 7, page 1, strike out the words " has been or," and insert the word " hereafter " after the word " shall."

A bill substantially the same as that now reported was passed by the Senate at the last Congress, and favorably reported to the House, but at too late a day in the session to receive consideration.

The object of the bill is to provide for owners of United States patents a remedy for the taking of their property by the United States for public use, when such taking occurs without the license or authority of such owners and without compensation.

In England and in practically all over civilized countries, except Russia and the United States, the Government can not appropriate an invention without paying a fair price for it. A regular tribunal is charged with the duty of determining what is a fair price for the use of an invention appropriated by the Government in case the Government considers the inventor's charge to be excessive. The United States habitually appropriates at its pleasure the patented inventions of its citizens and declines payment therefor. And this notwithstanding the fact that according to the decisions of the Supreme Court a patent of the United States is property within the meaning of the term as used in the Constitution and laws of the United States, and the use of a patented invention by the Government is a taking of private property, which can not be done lawfully without compensation to the owners. (Solomons *v.* United States, 137 U. S., 342, 346; McKeever *v.* United States, 14 Ct. Cls., R., 396; Affirmed S. C. 18 Ct. Cls., R., 745.)

But notwithstanding this right to protection which patentees and other property owners derive from Article V of the Amendments to the Constitution, it has been held by the Supreme Court that the owner of a patent can not restrain its infringement by the United States or an officer or agent of the Government. (Schillinger *v.* United States, 155 U. S., 163 (1894); Russell *v.* United States, 182 U. S., 516 (1900).)

In both of these cases the court held that in the absence of an express contract between the Government and the patentee, or transactions between them from which a contract may be implied, no court of the United States is vested with jurisdiction to entertain a suit or action by a patentee seeking to recover compensation for the use of his invention by the Government.

How next to impossible it would be to make a case of implied contract which would render the Government liable under the court's decision may be inferred from the following statement of the facts appearing in the Russell case just cited. It there appeared that at the Government's invitation Russell exhibited his patented invention to a board of officers appointed by the Secretary of War. The Government announced that it would adopt and use a device embodying his invention. Prior to the adoption and use of the device Russell communicated his patent to the War Department, showing that his patent covered the device and tended the use of his invention to the Government for reasonable compensation. The Government proceeded to use the device without denying Russell's right to compensation, but with the remark that he should seek his remedy by some means other than Executive action. And the Russell case is only a sample case; one of many.

It seems to be necessary and proper to provide for patentees a remedy, such as the passage of this bill will secure, for the invasion of their rights. Without such remedy, patentees are the only persons who are outside the protection of Article V of the Amendments of the Constitution. " Nor shall private property be taken for public use without just compensation."

Without such remedy a patent is not what it purports to be on its face. Many inventors have spent years of their lives and practically bankrupted themselves in developing inventions primarily of use to the Government, only to find in the end, after their property has been seized

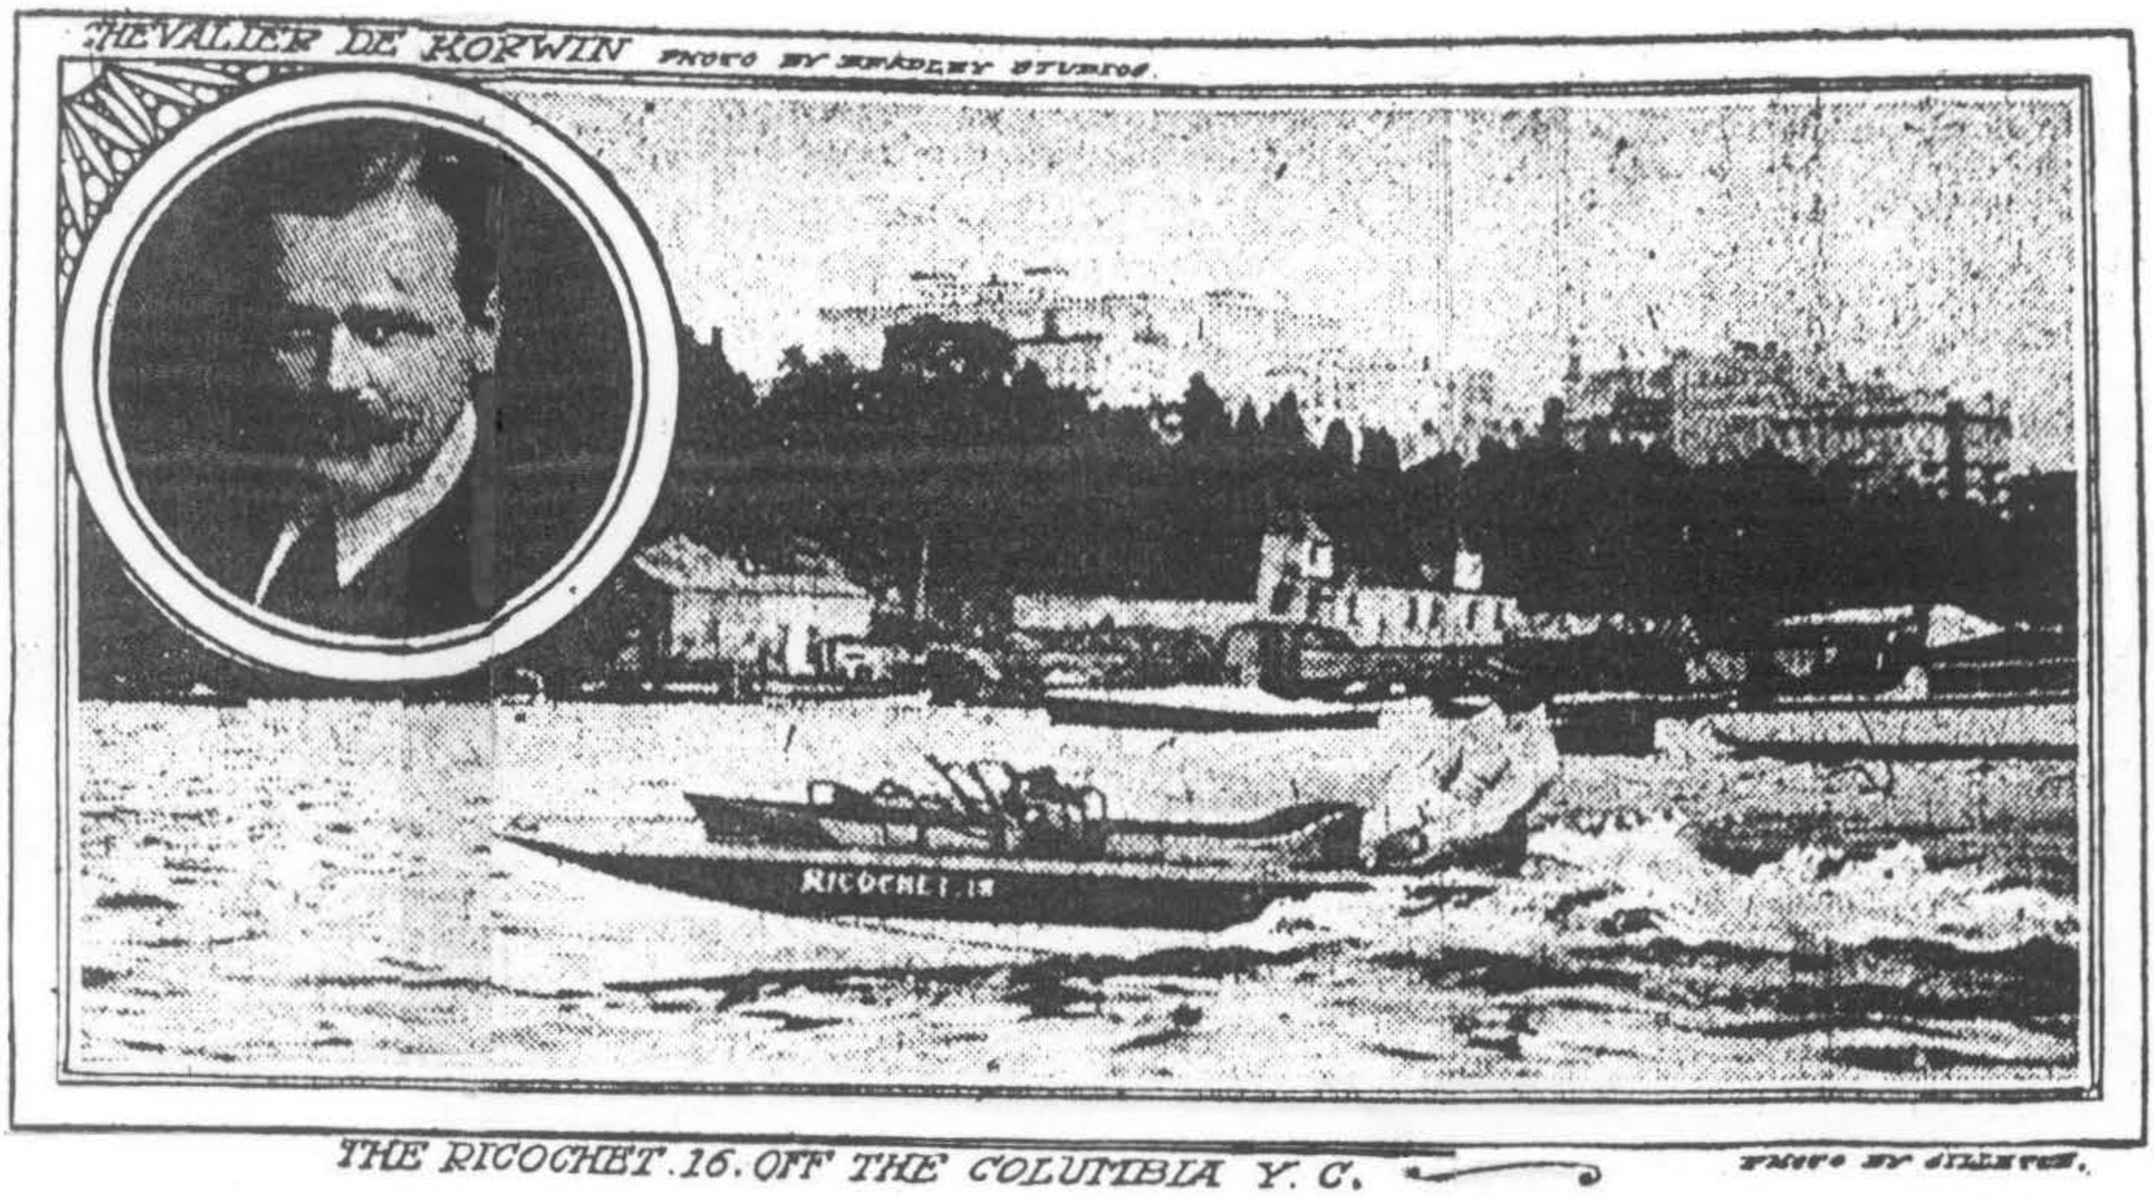
by the Government, that they have no legal means of redress, and that the governmental Departments will not recognize the decisions of the courts.

Without such remedy there is a ridiculous discrimination between inventors. The inventor of a children's game or of a new brand of chewing gum is protected by the courts. But the inventor of a device which may save the nation from an humiliating defeat in time of war, or reduce the cost of carrying the mails, or reduce the number of shipwrecks on the coast, is afforded no protection; the governmental Departments have the power to confiscate his property and habitually exercise that power. It may be a new type of breech mechanism, or a dry dock, or a method of communicating with ships at sea; if the invention is valuable the Government can and does seize it, though the inventor may have spent years of his life and bankrupted himself and his friends in developing it.

It may be conceded that the Government ought to have the right to appropriate any invention necessary or convenient for natural defense or for beneficent public use, and that, too, without previous arrangement or negotiation with the owner. Nevertheless, the appropriation having been made it would seem that justice to the citizen demands that in due time he should receive fair compensation for his property.

The claim is made by some that the Government, being the grantor of the patent, ought to have the right to use without compensation such inventions as are necessary for its purposes.

One answer to this is that there is no such limitation or reservation in the law governing the granting of patents; and another answer is that if that were the law there would be no time, brains, or money spent by anyone in inventing those things for which there would be no remuneration.



But it is useless to multiply reasons to justify the passage of the bill. The one fundamental reason already assigned is unanswerable—that no American citizen's property can be appropriated for public use by the Government or by anyone else without compensation being made therefor.

The amendment proposed, by striking out the words " has been or " and the use of the word " hereafter," in line 7, page 1, is deemed advisable, that there may be no question arising upon statutory construction that the law is not retroactive in its effect, but will apply only to future appropriations of patents by the Government.

It passed the House of Representatives by a large majority, the leaders of both the Republican and Democratic parties speaking in favor of it. It passed in the Senate unanimously. It did not become a law, however, as President Roosevelt declined to sign it, though its signature was strongly recommended by Secretary Taft, Senator Knox, and others. No reason was given by President Roosevelt for declining to sign the bill, but it is understood that his action was due to the fact that the ratification of the proposed wireless treaty had been opposed by one of those interested in the passage of this bill.

The New York Herald July 1, 1908

New Hydroplane Skims on the Hudson

THE RICOCHET 16 OFF THE COLUMBIA Y. C. PHOTO BY HADLEY.

Every one along the Hudson from Seventy-second street to Ninety-fifth street watched for an hour last night for a strange small craft that flew up and down the river at a rate varying from twenty-five to thirty miles an hour. It was not the speed of the device that attracted attention quite so much as its gait, which was more like that of a bucking bronco than of a motor boat.

The little craft was the Ricochet 16, a hydroplane, owned and driven by Chevalier Joseph de Korwin, chief of aeronautics of the Austrian army, who in the last year had devoted his attention to the development of a type of water vehicle that would make speed by skimming along the surface of the water rather than by driving through it. He arrived last week on the Provence with his hydroplane to try it in American waters, but it was not until yesterday that he succeeded in getting the craft through the Custom House.

At high speed it seemed as if the spray thrown up by the Ricochet would drench the operator, as he sat guiding the boat as much by the position of his body after the fashion of a cyclist turning a corner as by the twin rudders, the flat, scow shaped bow sending the spray high in the air at each bound. But the drenching was more apparent than real, for when after an hour's run he went aboard a yacht, the Nushka, his craft had not shipped a cup of water.

On the Nushka Chevalier de Korwin was entertained by Joseph H. Hoadley, who had as his guest Nikola Tesla, who of late has been devoting his attention to power boats, discovered that the Chevalier came from a short distance of his home in Austria and knew many of his relatives, after which they entered into a discussion of the value of relative types of propellers.

To him Chevalier de Korwin explained that his craft was twelve feet over all, four feet beam and at rest in the water drew only eight inches. In it is a 12-horse power gasolene engine, set well amidships at an angle of twenty degrees, which is also the angle at which the propeller is set. At high speed, as in all hydroplanes, this has the effect of pushing the boat upward and onward at the same time, which explains the skipping motion.

Before coming to New York Chevalier de Korwin took part in the motor boat races in the Adriatic from Fiume to Pola, a distance of 128 kilometres, for a trophy offered by the Prince of Monaco, finishing third in a heavy sea. In this race the winner had a 120-horse power engine, the second had five less and the fourth 100-horse power, as compared to his twelve.

In June two years ago the Chevalier made an attempt to go to Austria from England in a balloon and narrowly escaped being swept out over the Atlantic. After giving himself up for lost he made a landing near Dieppe, more dead than alive. Before making this trip he refused Oscar Lewisohn's offer of $50,000 to take him as a passenger, on the ground that he did not care to risk any life but his own.

Chevalier de Korwin will be in New York about a month, leaving for England to race at Cowes. He will do no racing while here.

"I came over for a chance to use the hydroplane on the Hudson," he said at the Plaza last night, "and I am glad I came, it is such a wonderful river.

"De Korwin is a wonderful fellow," said Nikola Tesla, after watching him run about the river, "and he gets every bit that is in his boat out of it, but that type will not develop the most speed. The resistance of the waves as he would strike them in a heavy sea would be greater than the resistance a boat would meet gliding through the water. He is a wonderful operator and knows every trick apparently. With my new propeller he could go twice as fast."

"Speed is largely a matter of power," said the Chevalier. "With a twenty-four horse motor in this type of boat I have travelled at the rate of mile a minute. I have made high speed in the roughest of weather; in fact, I rather like to have it some rough."

SIMPLE EXPLANATION OF HIGH FREQUENCY CURRENT.

Within recent years some very astonishing things have been done with high frequency electric current. It is extensively used by medical practitioners, for wireless telegraphy, etc., and seems to act in a manner widely different from the ordinary electric current now more or less familiar to all. The following explanation of high frequency current will be found perfectly simple and will enable the average person to understand the seemingly magical things done, which are often seen at electrical shows and like exhibitions.

When the current flows in one direction in a conductor and then reverses and flows in the opposite direction it is said to be an alternating current. The number of times per second that the current makes a complete change of the direction and comes back to its original direction of flow is called its frequency. The frequency of commercial alternating currents is seldom over a hundred per second, and generally less. A high frequency current is one in which the frequency is numbered in the thousands or millions per second, although there is no strict dividing line where high frequency begins and low frequency leaves off.

Machines that produce high frequency currents directly are called high frequency alternators. Very few of them have ever been made, other methods having been devised for changing ordinary low frequency currents into those of high frequency.

The general method used is as follows: What is known as a step-up transformer is used to raise the voltage of ordinary low frequency current to a pressure of several thousand volts. This current is used to charge a condenser which consists of either the common Leyden jar or its equivalent in plates of glass, ebonite or mica coated with tinfoil.

When such a condenser is discharged through a suitable coil, high frequency current is produced. A Tesla coil for this purpose consists of a primary winding of a few turns of heavy wire and a secondary of finer wire of many more turns spaced apart to prevent short circuits between adjacent turns. Coils of

this kind are often immersed in oil for insulation. There is no iron core of any kind in a Telsa coil. When the condensers are discharged through the primary of a Tesla coil in series with spark gap, which is simply a break in the circuit over which a spark jumps, a current of enormous voltage and frequency is produced in the secondary. With this current can be produced many interesting and peculiar phenomena. Fig. 1 shows at the left the transformer for raising the pressure or voltage of the ordinary current to several times its original value. Next is the glass plate condenser, and at the extreme right is the Tesla high frequency coil.

When one terminal of the Tesla coil is grounded, long specter like streams of sparks dart into space in all directions from the other terminal. If the capacity is increased these streams resolve themselves in flames making a striking display as shown in Fig. 2.

Nikola Tesla, while in Colorado carrying on a series of experiments, produced discharges 23 ft. in length, passing a current of 800 amperes at the tremendous pressure of 10,000,000 volts, producing a roar that could be heard for miles. At ordinary frequencies it is well known that current at a pressure of 1,000 volts and over will cause instant death. If, however, the frequency is very high, instead of producing death there is no sensation whatever and the current can be handled with impunity.

In the electrocuting of criminals a voltage of about 2,000 is used and only one-fourth ampere of current is sufficient to cause the death of any man. If an ordinary 16 c. p. lamp is held in the hand by one terminal and the other connected to only one terminal of the Tesla coil the lamp lights up brilliantly, consuming fully one-half an ampere or double the current used for electrocution, besides being painless. If any one doubts that the current passes through the body another method of holding the lamp will convince him. If the terminals of the lamp are connected to two persons and

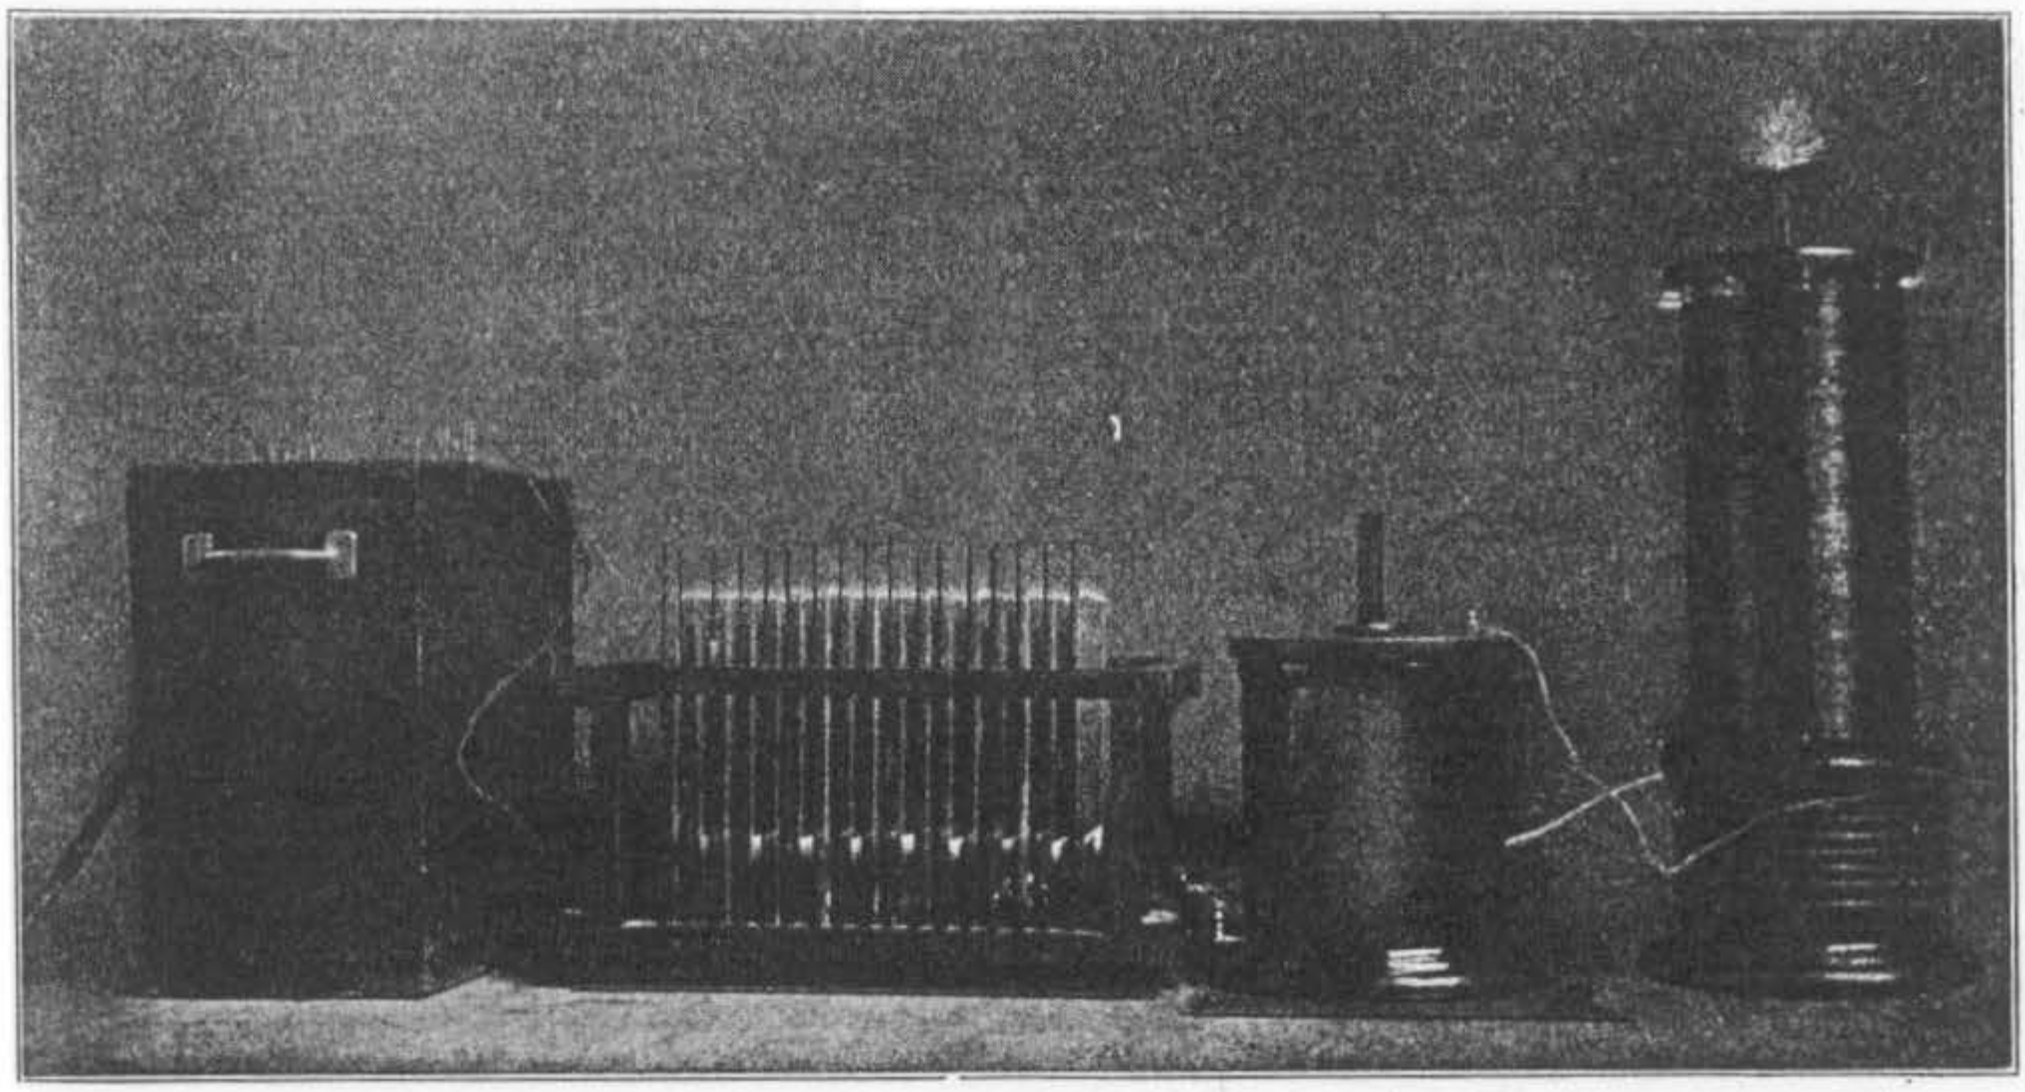


FIG. 1. APPARATUS FOR GENERATING HIGH FREQUENCY CURRENTS.

the terminal of the coil is connected to either one of them the lamp burns at full candle power. Even fine iron wire can be melted in two in the same way.

When the coil is in operation and is approached by a metal rod held in the hand the spark of the coil, which may be of over a foot long, will jump to the rod and entirely disappear if the terminal is touched, showing that all the current passed through the body.

With the pressure of this coil over 100,000 volts, if one person touches the terminal of the coil and another person comes near, sparks jump to the second person when several inches away. If a

vacuum tube is held in the hand in the vicinity of the coil it will glow with a soft white light, but if the coil is touched the effect is greatly enhanced, so that it is possible to read by it. Geissler tubes are affected the same way.

This current would rather jump a considerable distance through air than go through even a few turns of heavy wire on account of the choking effect. This effect can be shown in a remarkable manner by connecting an ordinary 16 candlepower lamp in series with a piece of heavy wire bent in a circle. This lamp, although short circuited, can be

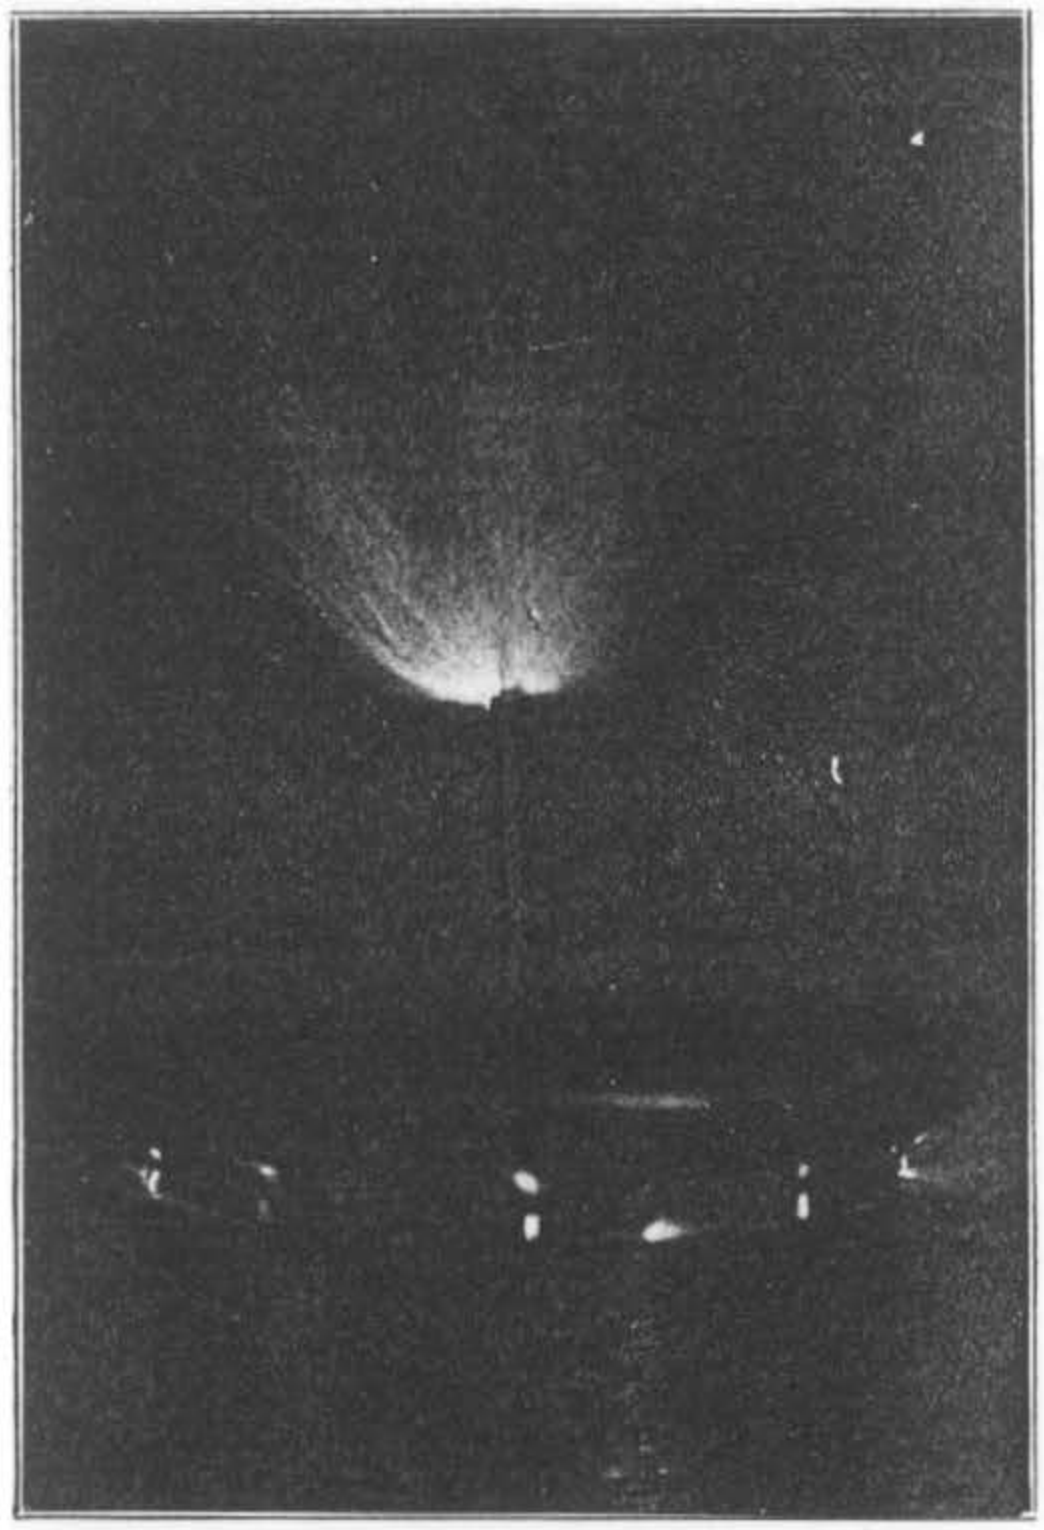

FIG. 2. DISCHARGE OF A TESLA COIL.

lighted to full candlepower by touching it to the coil, showing that the current would rather go through the lamp of high resistance than through the heavy wire whose resistance is negligible.

When a Tesla coil of considerable power is in operation sparks can be drawn from metal objects in the vicinity, although many feet away.

Wireless telegraphy is a practical application of high frequency currents.

In wireless telephony frequencies of from 100,000 to a million are used.

In electrotherapeutics the high frequency current is valuable.

Generally the source used to generate the high pressure necessary to charge the condensers is an X-ray coil, when used in electrotherapeutics.

It is held by many, Tesla among the number, that high frequency currents will work a revolution in the application of electric force, and that the electric power of the future will be produced in high frequency generating plants, will be sent out through space without transmission wires and will be collected at will at any point desired.

Problems of Aerial Motive Power.

Nikola Tesla.

PROGRESS in aerial navigation is essentially dependent on the perfection of a process of producing great mechanical effort with light machinery. Viewing the possibilities, near and remote, motive power is obtainable in four ways:—First, by transforming the heat energy of fuel in an internal combustion engine; second, by converting the electro-chemical energy of a primary or secondary battery in an electric motor; third, by harnessing, on the moving vessel itself, the energy of the surrounding medium and, fourth, by transmitting to it without wires the electrical energy of a distant source.

The first two methods are based on the use of a store of energy, which must be carried and periodically refilled, thus limiting the speed and duration of flight. The last two imply a flow of energy to the flying machine from without, the supply being continuous and inexhaustible. They are, therefore, immensely superior to the former.

Careful thought leads to the conclusion that the wireless method would be decidedly the best for the peace and welfare of men. But no matter how perfect the means for obtaining motive power, it will never be possible to go beyond certain rather narrow limits in aerial performance.

The atmospheric ocean is ideally adapted to travel, permitting, as it does, perfect freedom of movement in three directions, but the physical properties of the air make it rather unsuitable for navigation. It is a sticky or viscous substance, a hundred times more so than water,

NIKOLA TESLA

which means that it offers a relatively very great frictional resistance to a body in motion. Its small density is for many reasons detrimental to high efficiency of propulsion. Its compressibility, turbulence and perpetual unrest all cause additional specific losses of motive power. These properties forever preclude the possibility of excessive speed with reference to the surrounding air by the aeroplane as well as the dirigible balloon.

Making every allowance for future achievement, it is idle to expect that the record on land or water will be surpassed.

The question is frequently asked, Which of the two types, the heavier or lighter than air, is superior? No expert who has studied the subject thoroughly can be in doubt that the latter is by far the better of the two. The aeroplane has caught the public fancy, but such feats as those of Count Zeppelin will tell.

Many erroneous ideas relating to aerial flight have taken hold of the minds of the people. In view of this it may be useful to point out the following facts:—

1. The recent progress in aerial navigation is the direct and obvious result of the development of the internal combustion engine.

2. None of the latest flying machines, aeroplane or dirigible, contains a radically novel feature of importance.

3. The self-propelled balloon is by far superior to the aeroplane in carrying capacity, speed, cruising radius, safety and economy.

4. The aeroplane can never have more than half the propelling efficiency of the lighter than air machine.

5. The dirigible balloon is all the better the larger. The aeroplane gains nothing with size.

6. The inclined plane, that is, the rectilinear propeller, as a means of support is in all practical respects inferior to a vertical rotary propeller.

7. To produce an efficient high speed flying machine the screw propeller must be replaced by a better means for propulsion.

8. No machine, however perfect, supported in air against the force of gravity by buoyancy, dynamic effort or otherwise, can ever equal in speed a machine which derives its support from land or water.

9. The most pressing need in aerial navigation is unfailing protection against lightning.

The New York Times September 15, 1908

TESLA ON AEROPLANES.

Says Successful Heavier-Than-Air Flier Will Be Different.

To the Editor of The New York Times:

The chronicler of current events is only too apt to lose sight of the true perspective and real significance of the phases of progress he records. Naturally enough, his opinions on subjects out of the sphere of his special training are frequently defective, but this is inseparable from the very idea of journalism. If an editor were to project himself into the future and view the happenings of the present or of the past in their proper relations he would make a dismal failure of his paper.

The comments upon the latest performances with aeroplanes afford interesting examples in this respect. What is there so very different between a man flying half an hour and another, using a more powerful machine, an hour, or two, or three? To be sure, in one instance the supporting planes are larger and the gasoline tank bigger, but there is nothing revolutionary in these departures. No one can deny the merit of the accomplishments. The feats are certainly remarkable and of great educational value.

The majority of human beings are unreceptive to novel ideas. The practical demonstrator comes with forceful arguments which enlighten and convince. But they are nothing more than obvious consequences of what has preceded, steps in advance which, taken singly, are of no particular importance, but which, in their totality, make up the conquest of the world by the new idea. If any one stands out more strongly than the other it is merely because it chances to occur at the psychological moment, when incredulity and doubt are giving way to confidence and expectancy. Such work is often brilliant, never great, as some would make believe. To be great it must be original. Of such feature it is absolutely devoid.

Place any of the later aeroplanes beside that of Langley, their prototype, and you will not find as much as one decided improvement. There are the same old propellers, the same old inclined planes, rudders, and vanes—not a single notable difference. Some have tried to hide their "discoveries." It is like the hiding of an ostrich who buries his head in the sand. Half a dozen aeronauts have been in turn hailed as conquerors and kings of the air. It would have been much more appropriate to greet John D. Rockefeller as such. But for the abundant supply of high-grade fuel we would still have to wait for an engine capable of supporting not only itself but several times its own weight against gravity.

The capabilities of the Langley aerodrome have been most strikingly illustrated. Notwithstanding this, it is not a practical machine. It has a low efficiency of propulsion, and the starting, balancing and alighting are attended with difficulties. The chief defect, however, is that it is doomed if it should encounter a downward gust of wind. The helicopter is in these respects much preferable, but is objectionable for other reasons. The successful heavier-than-air flier will be based on principles radically novel and will meet all requirements. It will soon materialize, and when it does it will give an impetus to manufacture and commerce such as was never witnessed before, provided only that the Governments do not resort to the methods of the Spanish Inquisition, which have already proved so disastrous to the wireless art, the ideal means for making man absolute master of the air.

NICOLA TESLA.

New York, Sept. 13, 1908.

The St. Louis Republic November 15, 1908

ELECTRICAL CONTROL OF THE WEATHER WILL SOON BE AN ACCOMPLISHED FACT

—NIKOLA TESLA.

"For more than eighteen years I have experimented with the atmospheric effects of electrical discharges of tremendous strength. In my latest plant I expect to get a maximum rate of electrical discharge approximating 1,000,000,000 horse-power. While I am not familiar with the experiments along this line of anyone else, I have no hesitancy in declaring that the next step in the mastery of man over Nature will be the absolute control of the weather."

This statement, made by Nickola Tesla admittedly one of the greatest electricians of the age, when told of the recent experiments looking toward the control of the weather by electricity made by John A. Grahme.

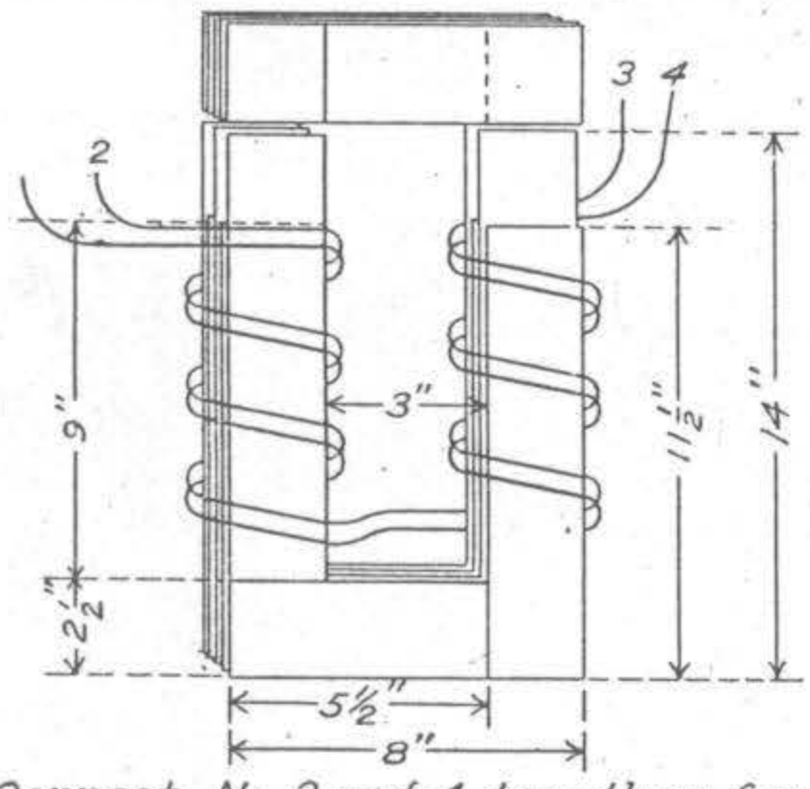
"Atmospheric effects, such as Mr. Grahme claims to be able to produce," continued Mr. Tesla, "necessitate the production of electrical discharges far beyond any that have yet been obtained by artificial means. That, however, is a mere detail. I am convinced that weather conditions are of electrical origin, and so must be susceptible of electrical control.

"I believe the day is near when man will not only forecast the weather with absolute accuracy, but will control it. Any one at all familiar with the fields opened up by recent experiments with high-tension electrical currents would hesitate to draw the line between the possible and the impossible.

"At present we are at the threshold of an era pregnant with tremendous possibilities. Every new discovery opens up new lines of thought and research; and despite the wonders that have been accomplished during the past half century, the surface has hardly been scratched.

"Of course, every man exploring in an undeveloped field is a butt for the ridicule of a skeptical public. Every announcement of a step forward in the fields of science and invention has been greeted with sneers and unbelief. Public opinion crucified Christ, imprisoned Galileo and branded Columbus a lunatic.

"I know nothing of the experiments of Mr. Grahme, but from my own work along similar lines, I am positive that the results he claims are possible of accomplishment and that this great problem will be solved in the very near future."



Popuular Electricity January 1909

HOW TO MAKE A HIGH FREQUENCY APPARATUS.

BY H. L. TRANSTROM.

Many readers of Popular Electricity have been interested in an article which appeared in August in which I described the general principles of an outfit producing high frequency currents, and in response to requests to give the details of construction of such an outfit this article has been written.

A transformer is needed, giving ten or 20,000 volts to charge the condenser. To construct one it is necessary to make a core from soft sheet iron strips, with a cross-section 2½ inches square, built in

Connect No.2 and 4 together for series connection and for parallel No.1 & 2, And also 3 and 4.

FIG. 1. TRANSFORMER FOR HIGH FREQUENCY WORK.

the shape of a rectangle 8 by 14 inches outside dimensions and 3 by 9 inches inside (see Fig. 1.)

Cut from the sheet iron, strips 2½ by 5½ inches and 2½ by 11½ inches, sufficient to make a mass five inches thick of each size when compressed in a vise.

Then take three strips at a time and build a core of the dimensions given in Fig. 1, leaving the top section unfinished until the secondary coils are placed in position.

To hold the core in shape after it is assembled, take two pieces of dry wood 12 by 3 by 1½ inches and bore a hole in the ends of each, nine inches apart. Put one board on each side of the bottom section and place in a vise, when the six-inch bolts can be drawn tight and then the core will be rigid.

On the vertical sections wrap tightly two or three layers of friction tape to within 2½ inches from the top. Over this wrap a couple of layers of Empire cloth.

The primary consists of 110 double turns wound in a single layer over the Empire cloth, the conductors being two No. 12 cotton-covered copper wires placed side by side, 55 double turns on each vertical section (see Fig. 1.)

Over the primary winding next wind tightly 15 layers of No. 7 Empire cloth 9 inches wide and we are ready for the secondary winding.

In winding the secondary much care must be exercised, as a transformer's insulation is no better than its weakest spot. This secondary consists of 20,000 turns of No. 32 single cotton-covered copper wire wound in eight coils of 2,500 turns each, which are connected in series, four coils on each side.

The coils are rectangular in shape 1¼ inches wide, four inches square inside and six inches square outside dimensions. They are wound on a form 1¼ inches wide and four inches square, the lateral edges being slightly rounded off to facilitate winding. This form is carefully centered and a metal rod about six inches long of any convenient size is passed through, with a small crank fastened on one end. To keep the coil from sliding out of shape make two disks seven inches in diameter, and when centered screw one on each side of the form.

Set this form between two supports and begin winding, first a layer of Empire paper and then a layer of wire alternately, until the 2,500 turns are on. It will be found very easy to wind this fine wire in layers if it is allowed to slide over a rod a foot or so away and guided with one hand while winding with the other. Leave a margin of ¼ inch in each layer.

All coils should be tested to see if there are any bare places or if the wire is in one continuous piece. If not, do not attempt to use it as it will surely

burn out when run a short time. When all coils are completed they should be dried in an oven, not too hot, and then laid flat in hot petroleum and boiled for several hours, and then left to cool in the mixture until set, which will take quite a long time.

When thoroughly cold, take carefully out of the mixture and after taking the surplus off the coils, assemble on the core over the primary, four on each side. To keep the coils insulated from each other, cut 36 squares of Empire cloth 7 by 7 inches and cut out of their centers a hole that will fit snugly over the Empire cloth on the primary. Use six thicknesses between adjacent coils, there being only six places to use these separators.

The coils should all be connetced in series as though it were one continuous wire beginning at the top of one section and ending at the top of the other. (See Fig. 1).

Connect all coils so that they have the same relation to one another as the turns in the primary. Keep the coils one inch from the bottom of the core by inserting narrow strips of birch wood across the binding boards and cover with several thicknesses of Empire cloth.

When all the coils are assembled and connected properly, the top part of the core may be completed. A sheet of micante 9 by 4 by 0.1 inch should be used to separate the vertical sets of coils. Make a box of close-grained hardwood 7 inches wide by 15 inches high by 14 inches long inside measurements and coat thoroughly with hot paraffine to make it perfectly tight.

When the transformer is set in the box it may be fastened by screws to the bottom binding boards.

Bring the ends of the primary wires to one side of the box and the secondary to the other side where they can be connected to proper binding posts. The secondary wire should be kept clear from the core and be led out through hard rubber rod binding posts. The four primary wires should be arranged so that they can be easily connected either in series or parallel.

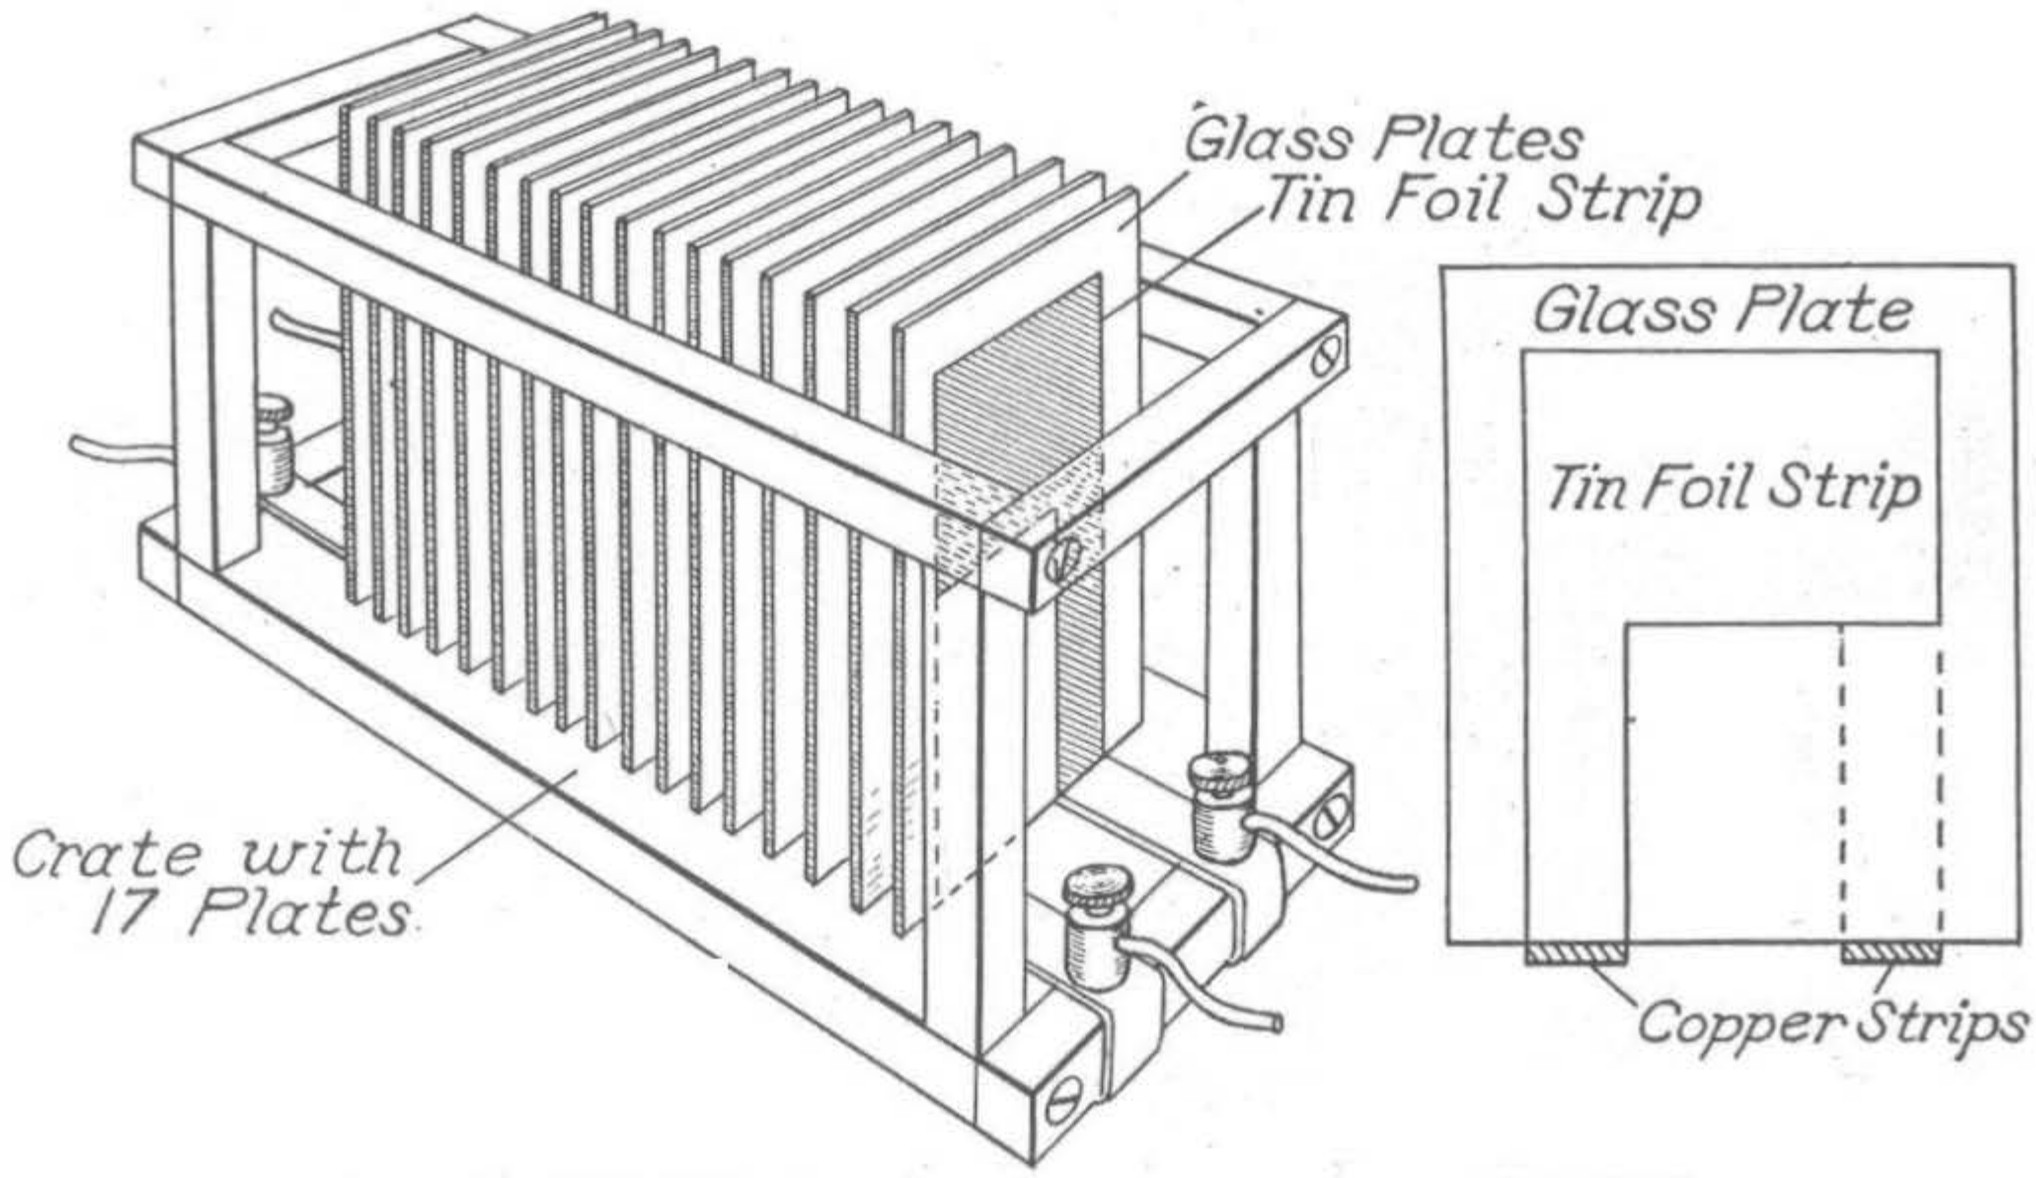


FIG. 2. CONDENSER FOR HIGH FREQUENCY APPARATUS.

Boil 40 pounds of extra amber petroleum and fill the box to the top and screw fast the cover and the transformer is complete.

Next we construct an adjustable condenser of 17 plates of double thickness window glass 10 by 12 inches. Coat all the plates with tin foil 5 by 6 inches on both sides. Leave a margin of two inches on top and sides and five inches on the bottom. On eight of these plates paste a strip of tin foil on the lower right hand corner to reach the bottom and on

the other nine paste them on the lower left hand corner of the foil. These are the connectors which rest on two copper strips laid parallel four inches apart on the bottom of the crate with binding posts on each end. The strips are fastened on and insulated from the bottom of the wooden crate, with slots in the sides to receive the plates. (See Fig. 2.)

The Tesla coil consists of a primary of seven turns of No. 6 bare copper wire and a secondary of 180 turns of No. 22 bare copper wire wound in a single layer on a drum 6 inches in diameter and

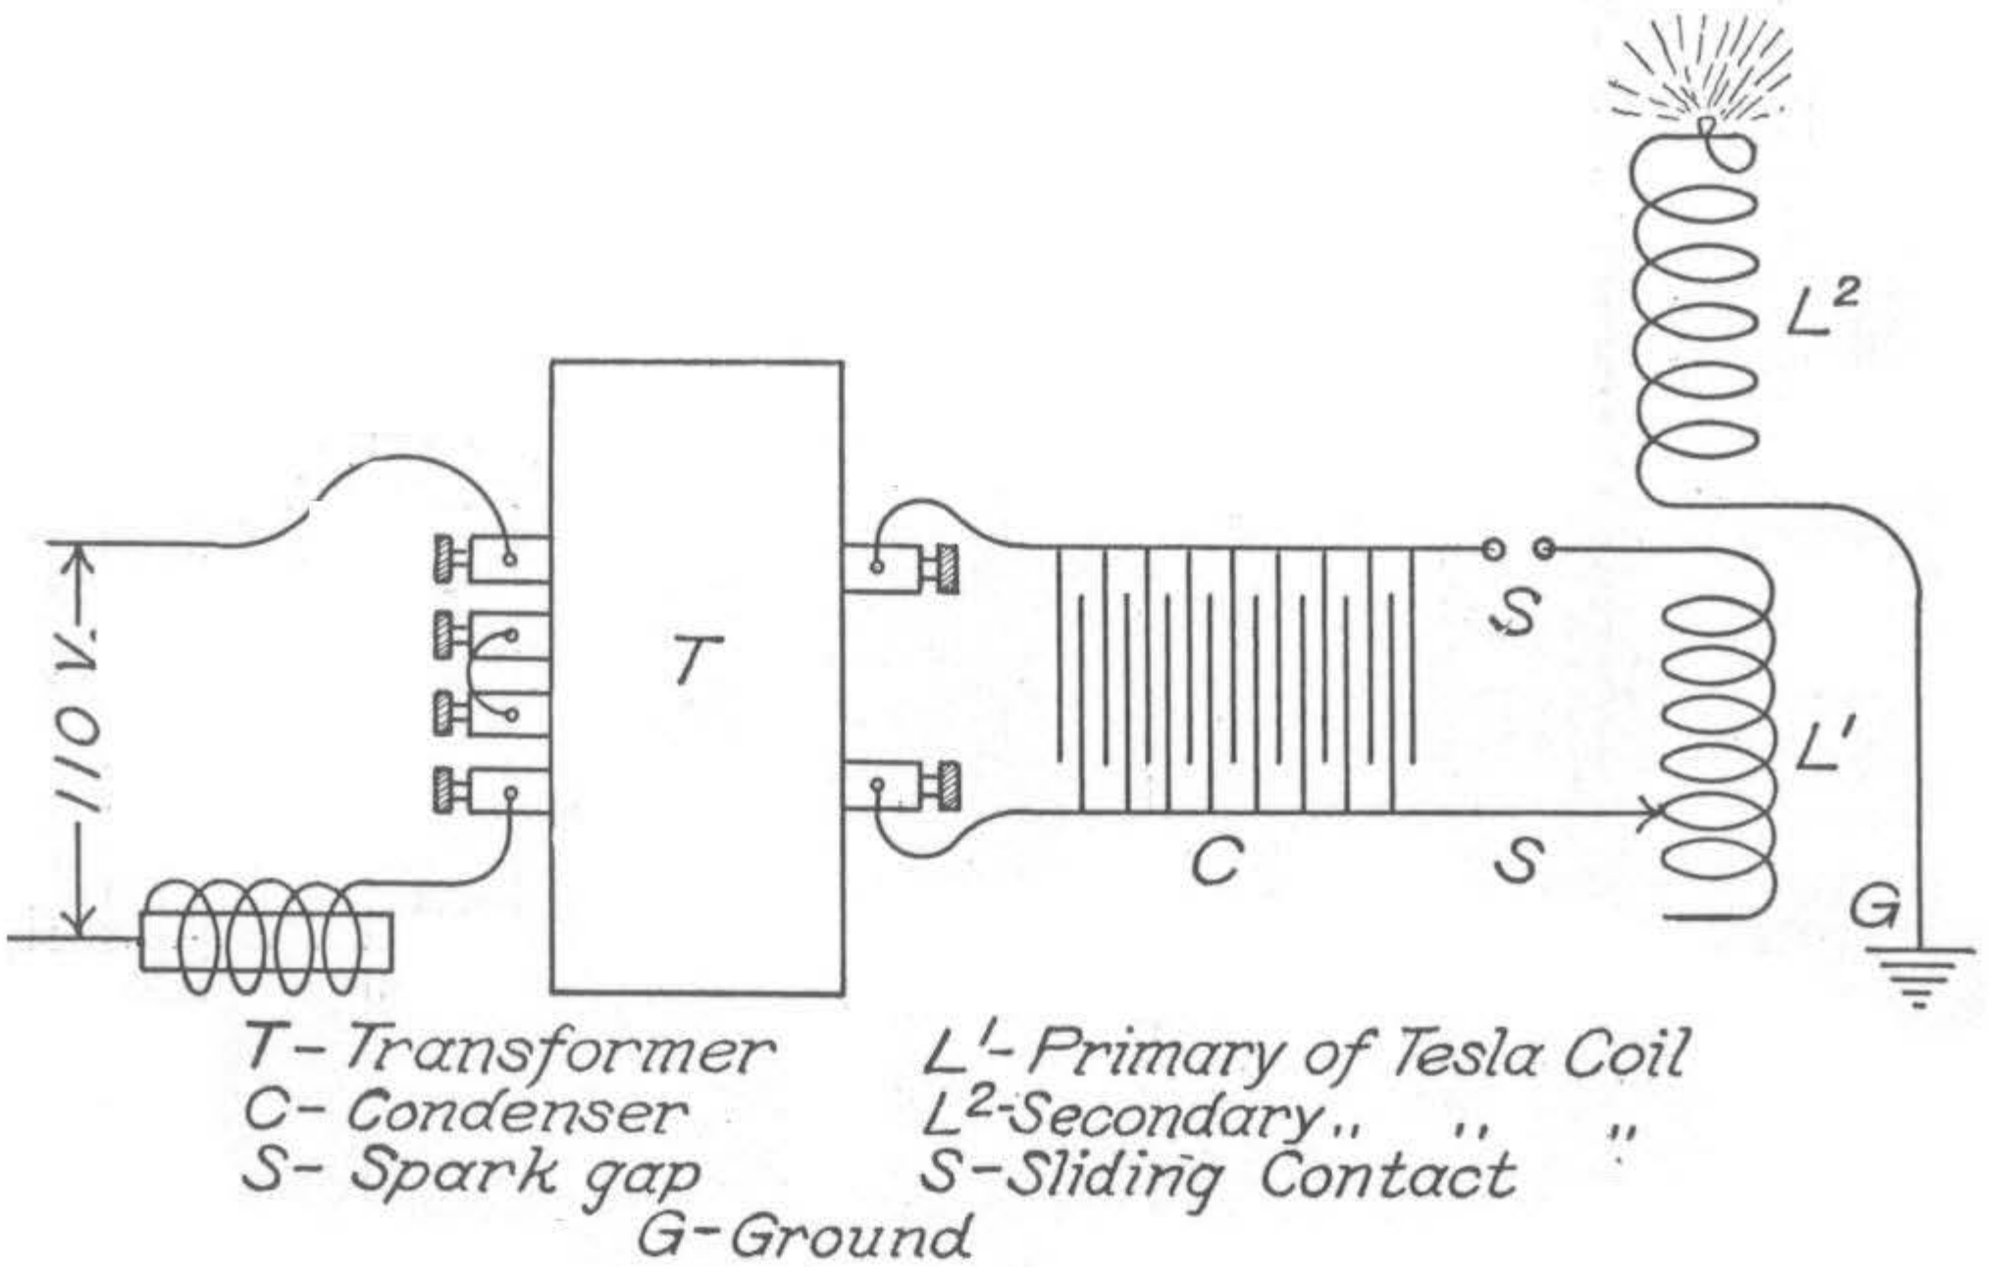

FIG. 3. CONNECTIONS FOR HIGH FREQUENCY APPARATUS.

14 inches long made of dry birch boards glued together in a circle and then turned off in a lathe. The turns of wire are carefully spaced apart 1-16 inch when winding, and leave a margin of ½ inch on the ends. The primary is wound on a wooden drum 8 inches in diameter and 4½ inches long, the turns being carefully spaced apart and fastened. The secondary coil is set on top of the primary coil and the base fastened to the bottom drum.

Give the secondary winding a coat of orange shellac, being careful not to disturb the turns while doing so. A nice turned top can be added for appearance, and a brass rod 4 inches long and ⅜-inch thick driven tightly in the center of the top and well rounded off, will be the discharge rod, being connected to the top end of the secondary wire.

The lower end of the secondary terminates in another binding post.

On the primary a binding post is fitted at only the upper end, while the other connection is a sliding contact.

For a spark gap take a glass jar about 6 inches in diameter and 8 or 10 inches in height and make a hole in the bottom ¼-inch in diameter. To do this take clay or putty and lay a thick layer over the center of the bottom of the jar. Make a ¼-inch hole in the clay down to the glass and fill with hot solder. The glass will fall out the shape of the hole in the putty or clay.

Make a cover from some nice hardwood to fit tightly in the top of the jar, and bore a hole in the center, in which fasten securely a threaded ¼-inch nut which is connected by a wire to a binding post on one edge of the cover.

A ¼-inch rod threaded the whole length is fitted with a hard rubber handle ¾ by 3 inches long. This is screwed in the threaded nut. The length of rod depends on the height of jar used. Another rod is fitted with a metal ball ¾-

inch in diameter and inserted in the hole in the bottom and then through a base of hardwood on which a binding post is placed.

Now to operate the completed apparatus connect as per diagram, Fig. 3.

Connect the lower terminal of the secondary of the Tesla coil to a good ground with stranded wire as a stranded wire is a better conductor for high frequency currents than is solid wire.

Although I obtained the results shown in the August issue by using the primary in parallel on 110 volts 60 cycles, consequently 20,000 volts secondary voltage, yet I have obtained as good results with better control by using the primary sections in series and an adjustable choke coil in series with them. The choke coil can be made from a mass of sheet iron 2½ by 2½ by 8 inches, which is inserted in a hollow coil of No. 10 copper wire of 110 turns.

By inserting the core in the coil the current can be varied according to the depth inserted. This outfit is for the unipolar or single pole method of generating high frequency currents. If all connections are correctly made the spark gap should be turned until the spark will just jump easily, then on the primary of the Tesla coil move the sliding contact on the second turn from the top. If the coil does not do as shown in the picture in the August issue move the contact on the next turn and so on until it does.

To light a lamp use the fourth or fifth turn and slide the lamp along the side until the brightest light is obtained.

Always disconnect the primary of the transformer before attempting to adjust the different parts.

By adding condenser plates or taking them out of the crate, one by one, the coils will be brought in tune under certain conditions.

---

tion belongs to the United States, there being a line at Camp Bird, Colorado, which is 13,000 feet above the sea level.

[317.]—TESLA COIL.—It is quite possible that the No. 20 wire is too large for the output of your coil, or, perhaps, you have leakage. Before making alterations, try if the effect is improved by inserting the new large coil in a basin of paraffin or linseed oil. If this does not improve matters, add more wire. Insulation is an important factor. Arthur E. R. Bottone.

[500.]—TESLA APPARATUS.—To Mr. Bottone.—This is practically a transformer, which can be used either as a "step up" or step down," according to whether you connect the primary or secondary to the terminals of your spark coil. It is necessary, however, to insulate the winding much more carefully, and, having wound the primary on the iron core, insert it bodily in an ebonite tube, over which wind the secondary; then immerse the whole in a non-conducting vessel of boiled linseed oil. The iron core should be of soft iron wire, making a bundle of about ¾in. diameter and 8in. long, and wound with two layers of No. 14 guttapercha-covered wire. The secondary may consist of about thirty layers of No. 26 silk-covered wire. Full particulars and illustrations are given in S. R. Bottone's book, "Electrical Instrument Making."

Arthur E. R. Bottone.

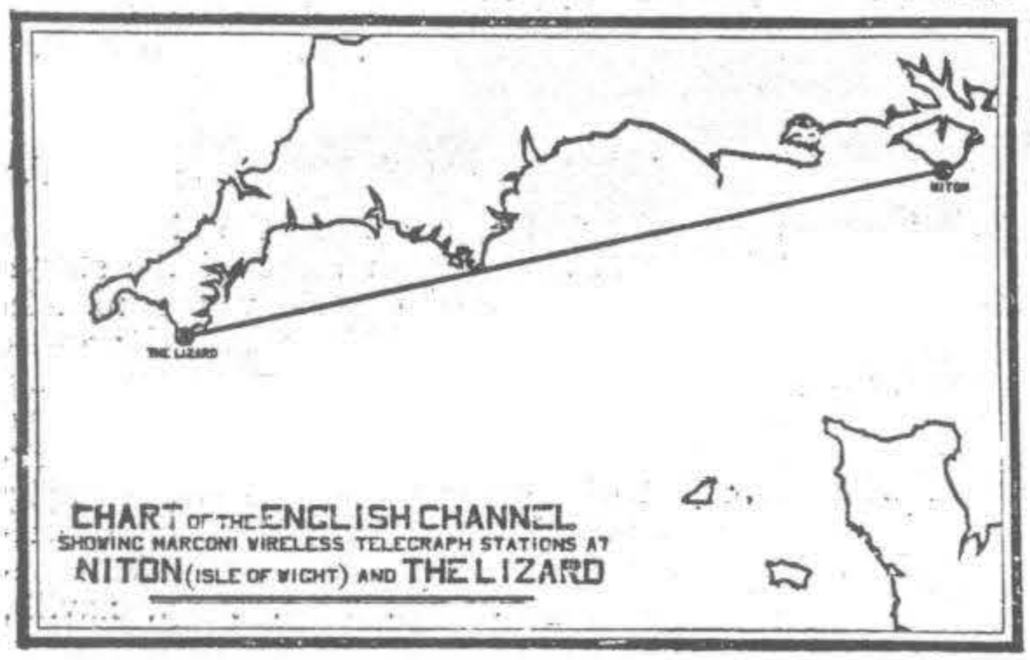
TRANSATLANTIC WIRELESS TELEGRAPHY.[1]

ON previous occasions I have had the honour of describing before this institution some of the stages through which the application of electric waves to telegraphy through space has passed. This evening I propose to confine myself chiefly to describing the results and observations recorded during the numerous tests and experiments which my collaborators and I have been carrying out with the object of proving that wireless telegraphy across the Atlantic was possible, not merely as an experimental feat, but as a new and practical means for commercial communication (Journ. Inst. Elec. Eng., xxviii., 1899, p. 291).

In March, 1899, communication was established by means of my system of wireless telegraphy across the Channel between England and France (see Fig. 1), and the *Times*

of March 29 of that year published the first Press telegram ever transmitted to England from abroad by means of electric-wave telegraphy.

At that time a considerable discussion took place in the Press as to whether or not wireless telegraphy would be practicable for much longer distances than those then covered, and a general opinion prevailed that the curvature of the earth would be an insurmountable obstacle to long-distance transmissions, in the same way as it was, and is, an obstacle to signalling over considerable distances by means of optical signals such as flashlights, the heliograph, or the semaphore.



Other difficulties were anticipated as to the possibility of being able practically to employ and control a transmitter capable of radiating an amount of electrical energy large enough to actuate a receiver at really great distances, and,

[1] From a discourse delivered at the Royal Institution on Friday, March 13, 1908, by Commendatore G. Marconi.

granting the possibility of this, whether such a powerful radiator would not interfere with the working of all other wireless stations which might be established on shore or ships within the sphere of influence of the long-distance sender.

What so often occurs in most pioneer work has repeated itself in the case of long-distance wireless telegraphy—the anticipated obstacles and difficulties were either imaginary or else easily surmountable; but in their place unexpected barriers manifested themselves, and my efforts and those of

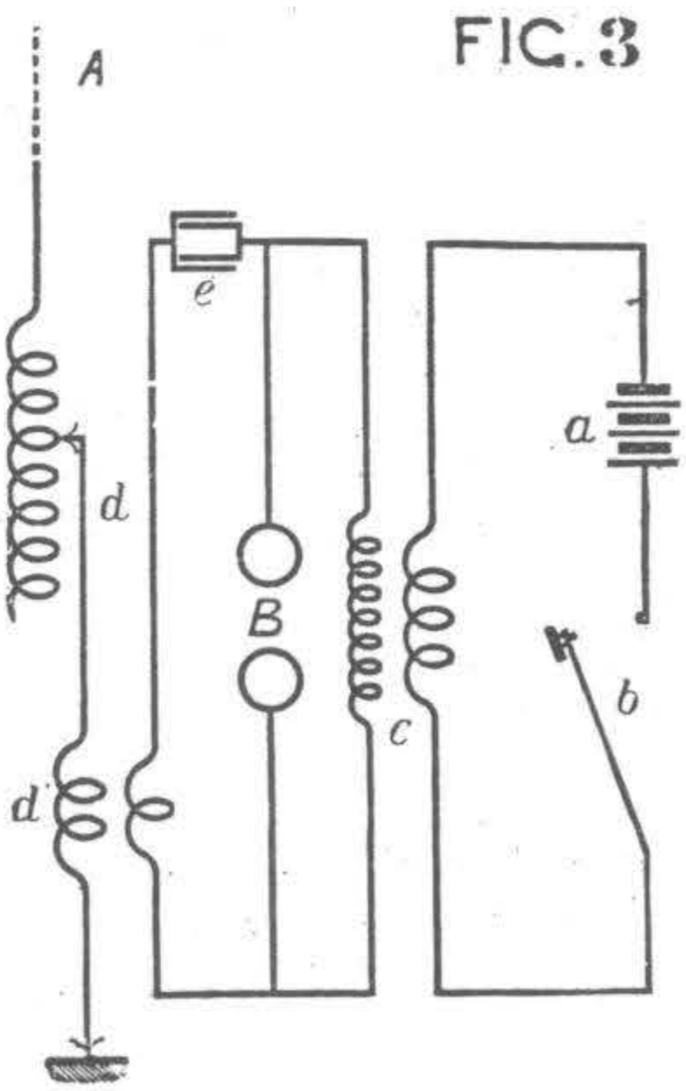
FIG. 2

my collaborators have been mainly directed to the solution of problems presented by difficulties which were not anticipated when the tests over long distances were first initiated.

In January, 1901, wireless communication was established between St. Catherine's Point in the Isle of Wight and Lizard in Cornwall, over a distance of 186 miles. The height of these stations above the sea-level did not exceed 300 feet (100 metres); whereas to clear the curvature of the earth a height of more than a mile at each end would have been necessary.

The result of these tests went far to convince me that electric waves produced in the manner I had adopted were able to make their way round the curvature of the earth, and that therefore it was not likely that this factor would constitute a barrier to the transmission of waves over greater distances. At this time I had achieved a considerable measure of success, by means of syntonic or tuning devices, in preventing mutual interference between stations, and Prof. Fleming described, in a letter to the *Times*, dated October 4, 1900, the results obtained, and which he and others had witnessed (Journ. Soc. Arts, xlix., No. 2530, 1901). The principle on which the transmitters and receivers at St. Catherine's Point and the Lizard were worked is shown in Figs. 3 and 4.

FIG. 3



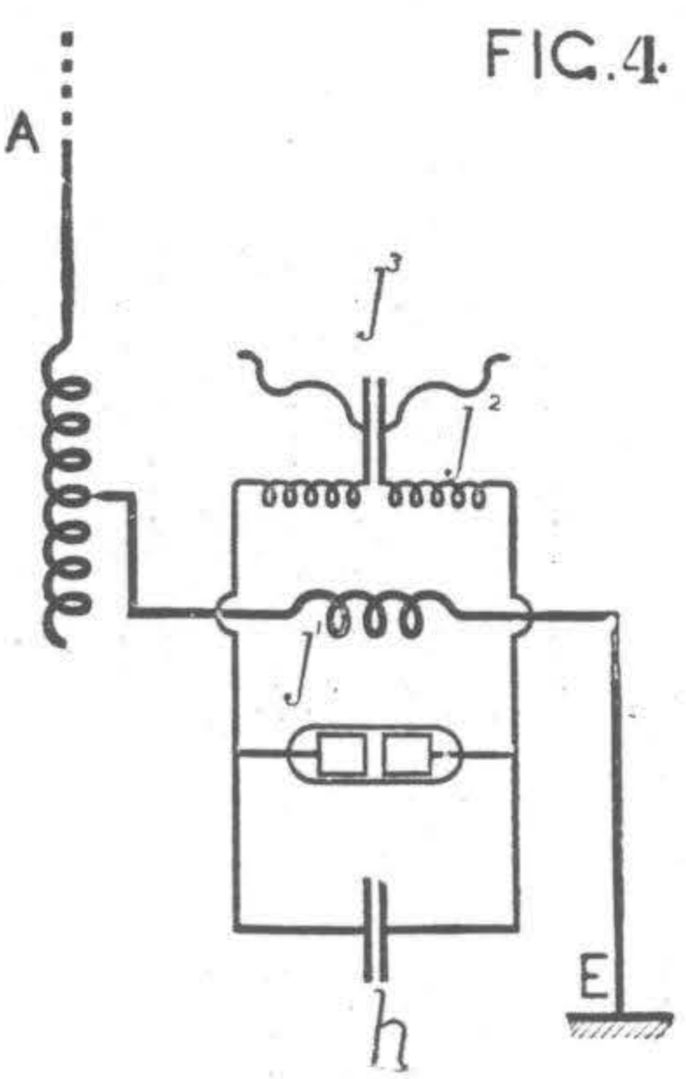


FIG. 4.

At the transmitting end a condenser, usually taking the form of a battery of Leyden jars, had one terminal connected to one spark-ball of an induction coil or transformer and the other to the primary circuit of an oscillation transformer. The opposite terminal of this transformer circuit was joined to the second spark-ball. The condenser was charged to the potential necessary to produce a suitable spark by means of an induction coil. The secondary circuit of the oscillation transformer was inserted between the vertical conductor, or aërial wire, and earth, and an adjustable inductance coil included in the circuit.

The circuits, consisting of the oscillating circuit and radiating circuit, were more or less closely "coupled" by varying the distance between the primary and secondary of the oscillation transformer. By the adjustment of the inductance inserted between the elevated conductor and earth, and by the variation of the capacity of the primary circuit of the oscillation transformer, the two circuits of the transmitter could be brought into resonance, a condition which I first found was absolutely necessary in order to obtain efficient radiation.

The receiver consisted also of a vertical conductor or aërial connected to earth through the primary of an oscillation transformer, the secondary of which included a condenser and a coherer, or other suitable detector, it being necessary that the circuit containing the aërial and the circuit containing the detector should be in resonance with each other, and also in tune with the periodicity of the oscillations transmitted from the sending station.

The energy employed to signal over a distance of 186 miles could be brought as low as 150 watts, and even less if a higher or larger aërial had been used.

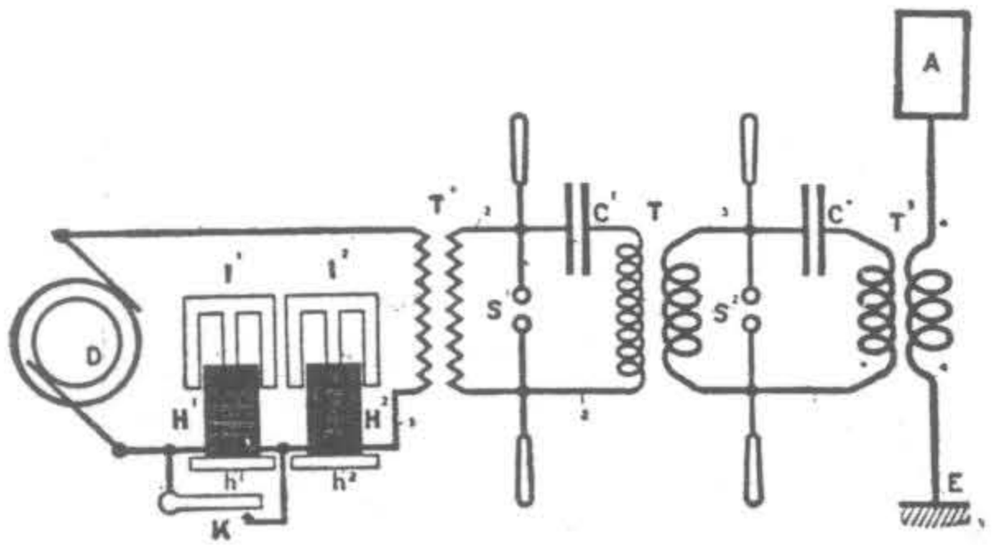
The facility with which distances of more than 100 miles could be covered prior to 1900, and the success of the methods for preventing mutual interferences (Journ. Soc. Arts, xlix., No. 2530, 1901), led me to advise that two large power stations be constructed, one in Cornwall and the other in North America, in order to test whether it was possible to transmit messages across the Atlantic Ocean.

I have often been asked why I did not first endeavour to establish commercial communication between places situated at a shorter distance. The answer is very simple. The cables which connect England to the Continent, and between most Continental nations, are Government-owned, and these Governments would not, and will not, allow the establishment of any system, wireless or otherwise, which might in any way tamper with the revenue derived from these cables.

As regards Transatlantic communication, however, the conditions were different. There was no law either here, in Canada, or in the United States to impede the working of wireless telegraphy across the Atlantic.

A further potent reason, moreover, an economical reason, prompted me to attempt communication with America. Notwithstanding the cost of high-power stations, I am convinced that it is more profitable to transmit messages at 6*d.* a word to America than at, say, ½*d.* a word across the Channel, and that the economical advantage of wireless over cables and land-lines increases instead of diminishing with the distance.

A site suitable for a long-distance station was chosen at Poldhu, in Cornwall, and here in 1900 work was commenced in earnest—work in which I was ably assisted by



Prof. J. A. Fleming, of the University of London. The transmitter at Poldhu was similar in principle to the one I have already described, but it is obvious that the considerable distance over which it was proposed to transmit signals necessitated the employment of more powerful electromagnetic waves than those ever previously used. These were obtained by means of a generating plant consisting of an alternator capable of an output of about 25 kilowatts, which, through suitable transformers, charged a condenser having a glass dielectric of great strength.

Time does not permit me to describe in detail all the engineering difficulties which were encountered in controlling electrical oscillations of a power which at that time was certainly unprecedented, and as the tests were made possible by commercial organisation, the objects of which do not consist solely in the advancement of science, you will understand that a detailed description of the plant used at the Transatlantic stations cannot, for the present at least, be made public.

My early tests on wireless transmission by means of the elevated capacity method had convinced me that when endeavouring to extend the distance of communication it was of little utility merely to increase the power of the electrical energy applied to the transmitting circuits, but that it was also necessary to increase the area or height of the transmitting and receiving elevated conductors.

As it was economically impracticable to use vertical wires of very great height, the only alternative was to increase their size or capacity, which, in view of the facts I had first noticed in 1895, seemed likely to make possible

FIG. 5

the efficient utilisation of large amounts of electrical energy (Journ. Inst. Elec. Eng., xxviii., 1899, pp. 278–9).

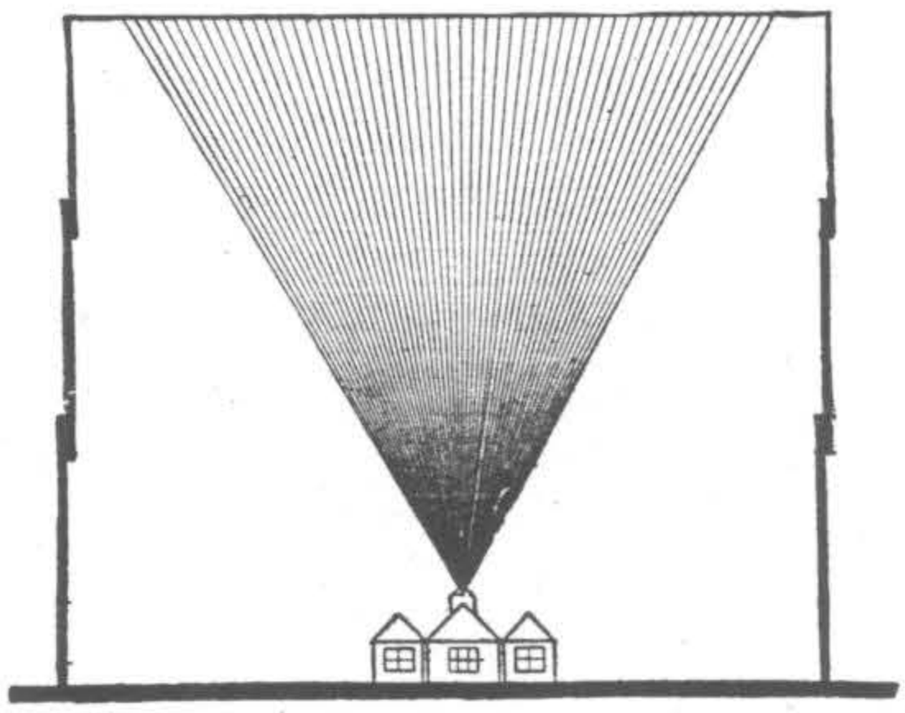
The form of aërial which I first proposed to employ consisted of a conical arrangement of wires insulated at the top and gathered together at a lower point in the form of a funnel. This aërial was supported by a ring of twenty masts each 200 feet high, arranged in a circle 200 feet in diameter.

During the first tests an arrangement of circuits (Fig. 5) proposed by Dr. Fleming, and consisting of a modification of the system shown in Fig. 3, was employed. In this arrangement, in place of one high-frequency oscillation circuit, two are employed, and the constants of the two circuits are so arranged that very high-tension discharges can be obtained from one of the condensers—the one which is inductively connected with the aërial—without danger of damage to the circuits of the generator ("The Principles of Electric Wave Telegraphy," 1906, p. 506).

Simultaneously with the construction of the station at Poldhu, the erection of another one on substantially the same plan was undertaken at Cape Cod, in the United States of America.

The completion of the arrangements was delayed owing to a storm, which wrecked the masts and aërial at Poldhu on September 18, 1901, but by the end of November the aërial was sufficiently restored to enable me to complete the preliminary tests which I considered necessary prior to making the first experiment across the Atlantic.

Another accident to the masts at Cape Cod seemed likely to postpone the tests for several months more. I therefore decided that in the meantime I would use a purely temporary receiving installation in Newfoundland for the purpose of testing how far the arrangements in Cornwall had been conducted on right lines.



The transmitting elevated conductor employed at Poldhu during the experiments with Newfoundland consisted of fifty almost vertical copper wires supported at the top by a horizontal wire stretched between two masts 48 metres high and 60 metres apart. These wires converged together at the lower end in the shape of a large fan, and were connected to the transmitting instruments situated in a building (Fig. 6).

The transmitting condenser used with this aërial had a capacity of one-fiftieth of a microfarad, and was charged to a potential sufficient to produce a suitable spark discharge between spheres 3 inches in diameter, 1½ inches apart, the wave-length being 1200 feet. The actual power employed for the production of the waves was about 15 kilowatts.

I left for Newfoundland on November 27, 1901, with two assistants. As it was impossible at that time of the year to set up a permanent installation with poles, I decided to carry out the experiments by means of receivers connected to elevated wires supported by balloons or kites—a system which I had previously used when conducting tests across the Bristol Channel for the Post Office in 1897.[1]

It will be understood, however, that when it came to flying a kite on the coast of Newfoundland in the month of December this method was neither an easy nor a comfortable one. When the kites were got up much difficulty was caused by the variations of the wind producing constant changes in the angle and altitude of the wire, thereby causing corresponding variations in its electrical capacity and period of electrical resonance. My assistants at Poldhu, in Cornwall, had received instructions to send on and after December 11, during certain hours every day, a succession of S's followed by a short message, the whole to be transmitted, at a certain pre-arranged speed, every ten minutes, alternating with five minutes' rest.

FIG. 6

Owing to the constant variations in the capacity of the aërial wire in Newfoundland, it was soon discovered that an ordinary syntonic receiver was not suitable, although, at one time, a number of doubtful signals were recorded. I therefore tried various microphonic self-restoring coherers placed either directly in the aërial or included in the secondary circuit of an oscillation transformer, the signals being read on a telephone.

On December 12 the signals transmitted from Cornwall were clearly received, at the pre-arranged times, in many cases a succession of S's being heard distinctly, although probably in consequence of the weakness of the signals and the constant variations in the height of the receiving aërial no actual message could be deciphered. The following day we were able to confirm the result. The signals were actually read by myself and by my assistant, Mr. G. S. Kemp.

1 "Signalling through Space without Wires," lecture by Sir William Preece, Royal Institution, June 4, 1897. Proc. R.I., xv., p. 467.

I have often been asked why I adhered to the practice of transmitting series of the letter S for these tests. The reason is that the switching arrangements at the sending station at Poldhu were not constructed at that time in such a manner as to withstand long periods of operation—especially if letters containing dashes were sent—without considerable wear and tear, and that if S's were sent an automatic sender could be employed. Moreover, the immediate object of these experiments was not to transmit actual messages across the ocean, but to ascertain the possibility of detecting the effects of electric waves at a distance of 2000 miles.

The result obtained, although achieved with imperfect apparatus, was sufficient to convince me and my co-workers that by means of permanent stations (that is, stations not dependent on kites or balloons for sustaining the elevated conductor) and by the employment of more power in the transmitters it would be possible to send messages across the Atlantic Ocean with the same facility with which they were being sent over much shorter distances.

About two months later, in February, 1902, further tests were carried out between Poldhu and a receiving station on board the American liner *Philadelphia*, *en route* from Southampton to New York. The sending apparatus at Poldhu was the same as that used for the Newfoundland experiments. The receiving aërial on the ship was fixed to the mainmast, the top of which was 60 metres above sea-level. As the elevated conductor was fixed, and not floating about with a kite, as in the case of the Newfoundland experiments, good results were obtained on a syntonic

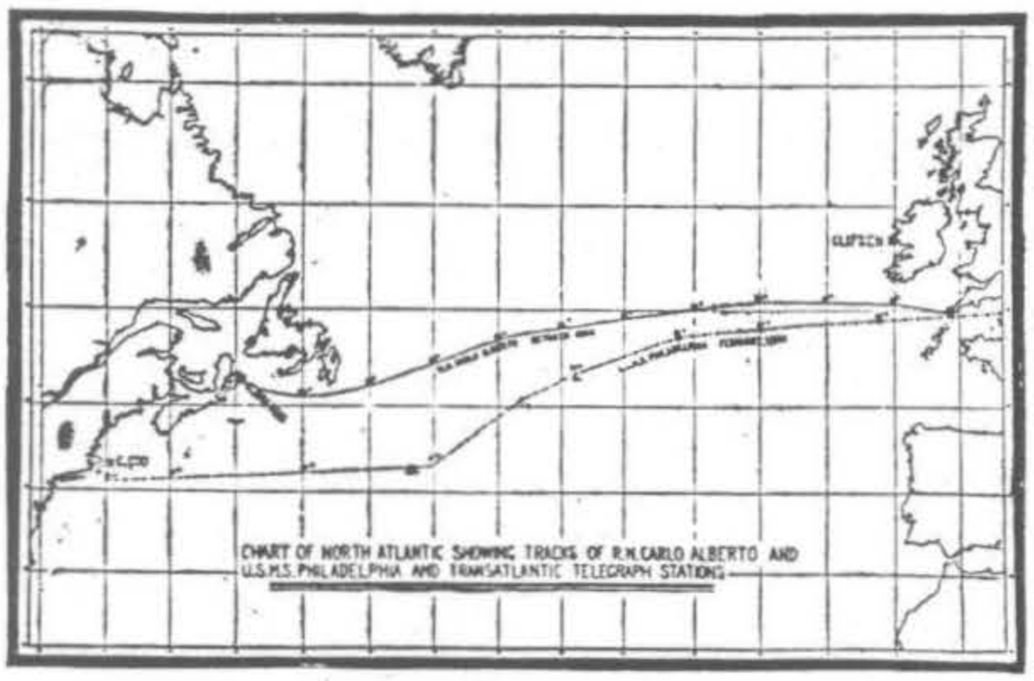


FIG. 7.

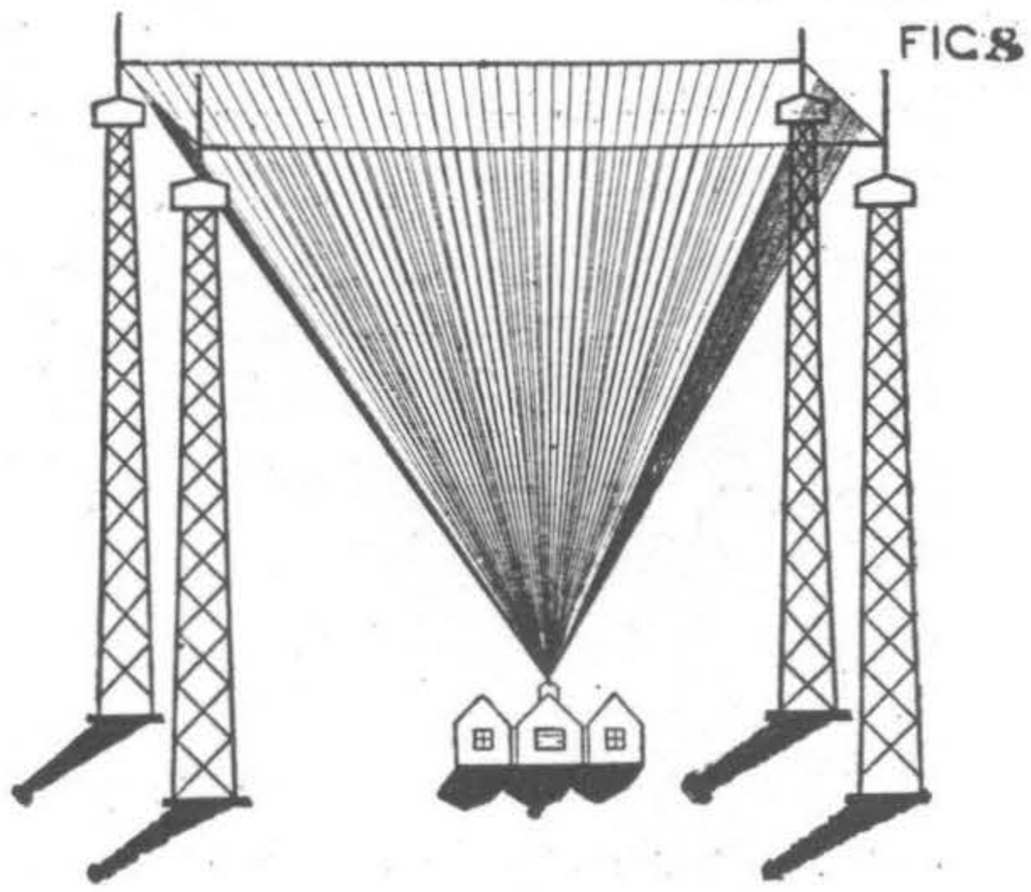
receiver, and the signals were all recorded on tape by the ordinary Morse recorder. On the *Philadelphia* readable messages were received from Poldhu up to a distance of 1551 miles, S's and other test letters as far as 2099 miles.

Although I never had the slightest doubt in my mind as to the genuineness of what was accomplished between Poldhu and Newfoundland, the results obtained on the *Philadelphia* amply prove that the station at Poldhu was capable at that time of transmitting signals to a distance of at least 2000 miles, which is the distance separating Cornwall from Newfoundland, and that if it was practicable to send a message over 2000 miles of sea from shore to ship, it should also be practicable to send it over the same space of ocean from shore to shore.



A result of some scientific interest which I first noticed during the tests on the s.s. *Philadelphia* was the very marked effect of sunlight on the propagation of electric waves over great distances.[1]

At the time of these tests I was of opinion that this effect might have been due to the loss of energy at the transmitter by daytime, caused by the dis-electrification of the highly charged transmitting elevated conductor operated by the influence of sunlight. I am now inclined to believe that the absorption of electric waves during daytime is due to the ionisation of the gaseous molecules of the air effected by ultra-violet light, and as the ultra-violet rays which emanate from the sun are largely absorbed in the upper atmosphere of the earth, it is probable that the portion of the earth's atmosphere which is facing the sun will contain more ions or electrons than that portion which is in darkness, and therefore, as Prof. J. J. Thomson (*Phil. Mag.*, August, 1902, Ser. 6, iv., p. 253) has shown, this illuminated and ionised air will absorb some of the energy of the electric waves.

The fact remains that clear sunlight and blue skies, though transparent to light, act as a kind of fog to powerful Hertzian waves. Hence the weather conditions prevailing in this country are usually suitable for long-distance wireless telegraphy.

Apparently the amplitude of the electrical oscillations and the lengths of waves radiated have much to do with the interesting phenomena, small amplitudes and long waves being subject to the effect of daylight to a less degree than large amplitudes and short waves. I never considered that this daylight effect would be an insuperable obstacle to Transatlantic telegraphy, as sufficient sending energy could be used during daytime to make up for the loss of range of the transmissions.

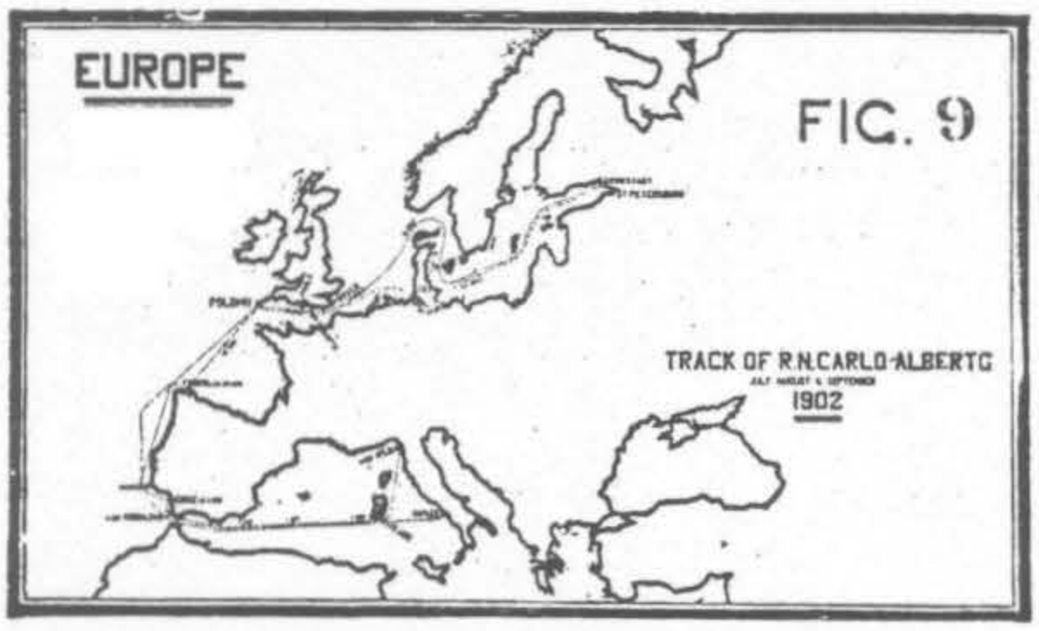
Turning again to Newfoundland, I ought to add that the experiments could not there be continued or extended in consequence of the hostile attitude of the Anglo-American Telegraph Company, which claimed all rights for telegraphy, whether wireless or otherwise, in Newfoundland.

However, as I had received an offer of assistance from the Canadian Government, it was decided to resume the tests between Great Britain and Canada, and these tests were very greatly facilitated by the subsidy of 16,000*l.* granted by the Canadian Government to support my experiments. The construction of another long-distance station was, therefore, commenced at Glace Bay, in Nova Scotia, and very extensive tests and experiments were carried on with Poldhu during the latter part of 1902.

Contemporaneously with the construction of the station at Glace Bay, alterations and modifications were executed at Poldhu. Four wooden lattice towers, each 210 feet high, were erected at the corners of a square of 200-feet side. The towers carried insulated triatic stays, from which was suspended a conical arrangement of four hundred copper wires forming the aërial, put up in sections, so that more or less could be employed (Fig. 8). The buildings for the generating plant were placed in the middle of the space between the towers. Additional machinery was obtained, and alterations carried out in accordance with the experience obtained from previous tests.

Identical towers and aërial arrangements were at that time adopted at the stations at Glace Bay, and at the similar installation in course of erection at Cape Cod, Mass.

In most of the experiments carried on from Poldhu the capacity of the sending condenser was one-thirtieth of a microfarad, the spark-length 1⅜ inches, and the wave-length 3600 feet. In these and subsequent tests the double con-



[1] Proc. Roy. Soc., lxx., p. 344, "A Note on the Effect of Daylight upon the Propagation of Electro-magnetic Impulses over Long Distances." Paper read June 12, 1902.

denser arrangement of Dr. Fleming was replaced by a single condenser, the arrangement being similar to that shown in Fig. 3.

During the time that constructional work was in progress at Glace Bay, I carried out some tests with Poldhu over considerable distances, and these tests were greatly facilitated by the interest taken in them by the Italian Government, which placed the cruiser *Carlo Alberto* at my disposal.

During these experiments the interesting fact was observed that, when using waves of more than 1000 metres in length, intervening land or mountains do not bring about any considerable reduction in the distance over which it is possible to communicate. Thus messages and Press despatches were received from Poldhu at the positions marked on the map (Fig. 9), which map is a copy of the one accompanying the official report of the experiments (*Revista Marittima*, Rome, October, 1902).

In December, 1902, messages were for the first time exchanged at night between the stations at Poldhu and Glace Bay, but it was found that communication was exceedingly difficult and untrustworthy from England to Canada, whilst it was good in the opposite direction. The reason for this is that the Glace Bay station was equipped with more powerful and more expensive machinery—a condition rendered possible by the subsidy granted by the Canadian Government; whilst as regards Poldhu, owing to

the uncertainty of what might or might not be the attitude of the British Government at that time towards the working of the station, my company was unwilling to expend large sums of money for the purpose of increasing its range of transmission.

As, however, messages could be sent then for the first time by wireless telegraphy from Canada to England, inaugural messages were dispatched to the Sovereigns of England and Italy, both of whom had previously given me much assistance and encouragement in my work, and who, by their gracious replies, attested their appreciation of the results which had been achieved. Other messages were also sent to England by the Government of Canada.

Further tests were shortly afterwards carried out with the long-distance station at Cape Cod, in the United States of America, and a message from President Roosevelt was transmitted from that station to His Majesty the King in London.

It is curious to note, in regard to the transmission of this message, that the energy employed at Cape Cod was barely 10 kilowatts, and it was not anticipated that this amount of energy would be sufficient to carry direct to Poldhu. The message was therefore transmitted from Cape Cod, instructions having been given to the operators at Glace Bay to be on the look-out, and to repeat wirelessly on to Poldhu any message received from Cape Cod, and my assistant, Mr. P. J. Woodward, at Poldhu, took in the message on one of my magnetic detectors.[1] The electromagnetic waves conveying this message travelled, therefore, 3000 miles through space over the Atlantic, which distance included about 500 miles of land, following an arc of 45 degrees on a great circle.

(*To be continued.*)

TRANSATLANTIC WIRELESS TELEGRAPHY.[1]

II.

IN the spring of 1903 the transmission of news messages from America to the London *Times* was attempted, in order to demonstrate that messages could be sent from America by means of the new method, and for a time these messages were correctly received and published in that newspaper.

By reference to the files of the *Times* I find that 267 words of news, transmitted across the Atlantic by wireless, were published in the London *Times* during the latter part of March and the early part of April of that year. A breakdown in the insulation of the apparatus at Glace Bay made it necessary, however, to suspend the service, and, unfortunately, further accidents made the transmission of messages uncertain and untrustworthy. In consequence of this it was decided not to attempt, for the time being, the transmission of any more public messages until such time as a trustworthy service could be maintained in both directions under all ordinary conditions.

As I found that many improvements evolved during the course of the numerous tests and experiments could not be readily applied to the plants at Poldhu and Cape Breton, it was decided to erect a completely new long-distance station in Ireland, and to transport the one at Glace Bay to a different site in the vicinity, where sufficient land was available for experimenting with aërials of much larger dimensions than had been hitherto employed.

Experiments were, however, continued with Poldhu, and in October, 1903, it became possible to supply the Cunard steamship *Lucania*, during her entire crossing from New York to Liverpool, with news transmitted direct from the shore.

In November of the same year tests similar to those carried out with the Italian cruiser took place on behalf of the British Admiralty between Poldhu and H.M.S. *Duncan*.

Communication with Poldhu was maintained during the entire cruise of this battleship from Portsmouth to Gibraltar, and further communication was established between Poldhu and the Admiralty station situated on the Rock of Gibraltar. It should be noted that the distance between Cornwall and Gibraltar is 1000 miles—500 over land and 500 over water.

[1] From a discourse delivered at the Royal Institution on Friday, March 13, 1908, by Commendatore G. Marconi. Continued from p. 237.

The aërial at Poldhu was shortly afterwards extended by the addition of wires sloping downwards, umbrella-fashion, as shown in Fig. 10. This increased the capacity of the aërial, and some further tests were carried out with a station at Fraserburgh, in the north of Scotland. From these tests considerable advantage appeared to be derived, at least for communication over land, by the adoption of much longer waves than had been hitherto employed, and with a wave-length of 14,000 feet it was found possible to telegraph over a distance of 550 miles with an expenditure of energy of about 1 kilowatt.

The operation of the long-distance stations in England and America made it possible to transmit messages to ships, whatever their position, between Europe and North

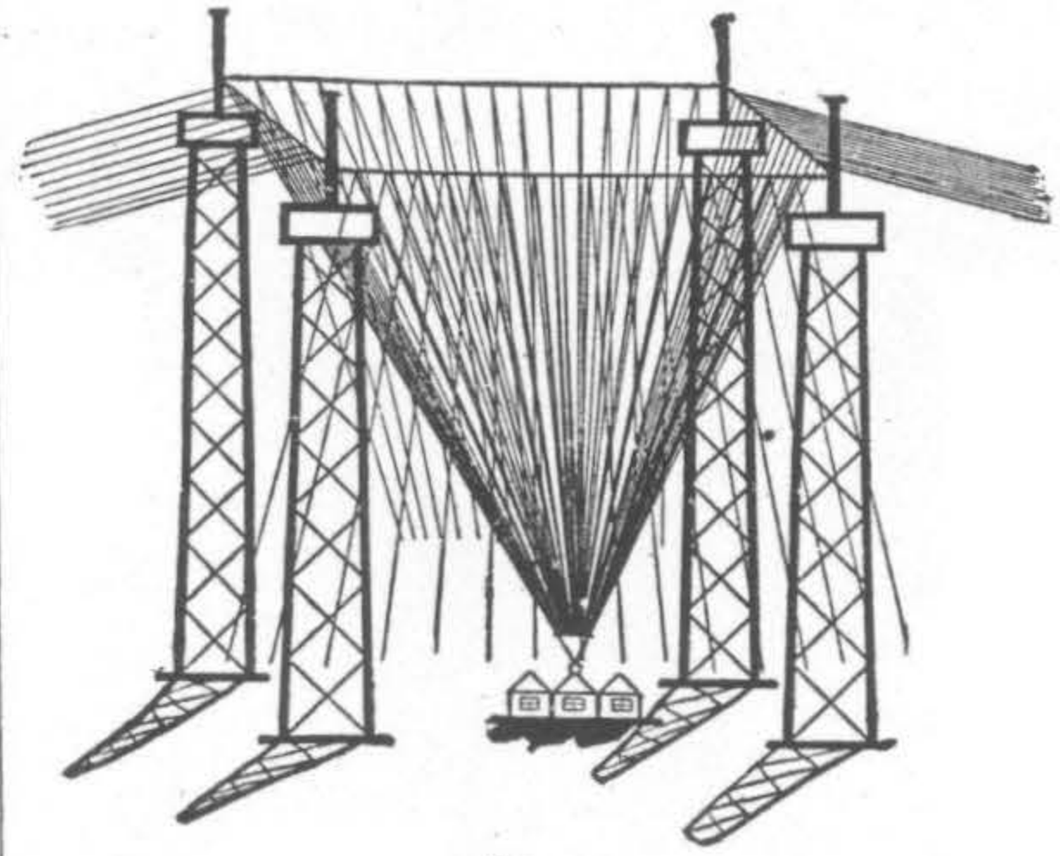

FIG. 10.

America; and to the Cunard Company belongs the credit of having greatly encouraged the long-distance tests, a circumstance which enabled them to commence, in June, 1904, the regular publication on their principal vessels of a daily newspaper, containing telegraphic messages of the latest news from Europe and America.

This daily newspaper has now been adopted by nearly all the large liners plying to New York and the Mediterranean, and it obviously owes its entire existence to long-distance wireless telegraphy. Therefore the tranquility and isolation from the outside world, which it is still possible to enjoy on board of some ships, is rapidly becoming a thing of the past; but, however much travellers may sigh over the innovations which have lately been brought about,

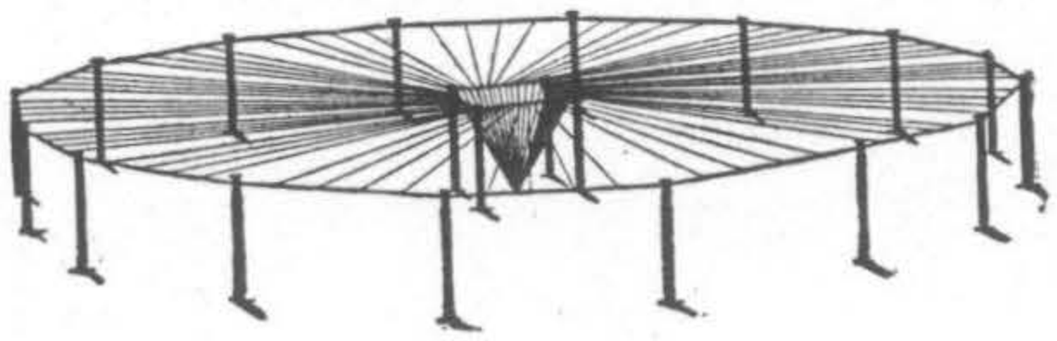

FIG. 11.

they seem anxious enough to avail themselves of the new method of communication on all possible occasions.

Early in 1905 the construction of the new station at Glace Bay was sufficiently advanced to allow of preliminary tests being carried out. The aërial was very large, and consisted of a vertical portion in the middle 220 feet long supported by four towers and attached to horizontal wires, 200 in number, each 1000 feet long, extending radially all round, and supported at a height of 180 feet from the ground by an inner circle of eight and an outer circle of sixteen masts (Fig. 11). The natural period of oscillation of this aërial gave a wave-length of 12,000 feet. The capacity employed was 1·8 microfarads, and the spark-length $\frac{3}{4}$-inch.

Signals and messages from this station were received at

Poldhu by day as well as by night, but no commercial use of the station was made at that time, in consequence of the fact that, although the signals came through by day as well as by night, they were exceedingly weak and faint, and also because the corresponding station on the same plan had not yet been erected in Ireland.

A further step in advance was the adoption at the Transatlantic stations of the directional aërial shown in Fig. 12.[1] The ordinary wireless telegraph aërials, which I have already described, send out electric radiation equally in all directions. This is, however, in many cases a disadvantage. Many suggestions respecting methods for limiting the direction of radiation have been made by various workers, notably by Messrs. Artom, Braun, and Bellini Tosi.

In some of my earliest experiments, in 1896, I used copper mirrors, by the aid of which it was possible to project a beam of electric radiation in a certain direction, but I soon found that this method would only work over short distances.

About three years ago I again took up the subject, and was able to determine that by means of horizontal aërials, disposed in a particular manner, it was possible to confine the effects of electric waves mainly to certain directions as desired. True, the limitation of transmission to one direction is not very sharply defined, but it is nevertheless very useful. The practical result of this method has been, so far, that messages can be sent over considerable distances in the desired directions, while they travel only over a comparatively short distance in other directions, and that, with aërials of moderate height, greater efficiency in a given direction can be obtained than can be obtained all round by means of the ordinary aërials.

When this type of aërial was adopted at Glace Bay a considerable strengthening of the received signals at Poldhu

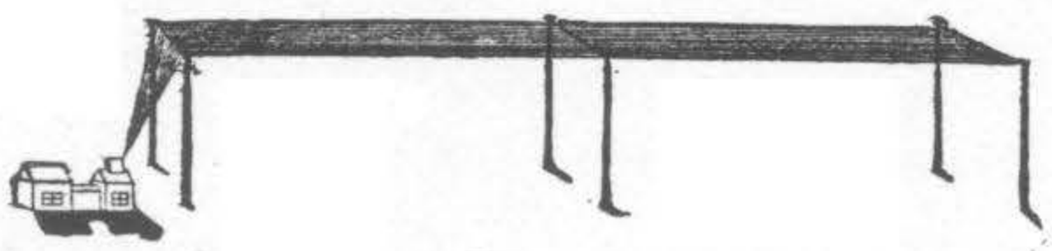

FIG. 12.

was noticed. It was therefore decided to adopt the directional aërial at all long-distance stations.

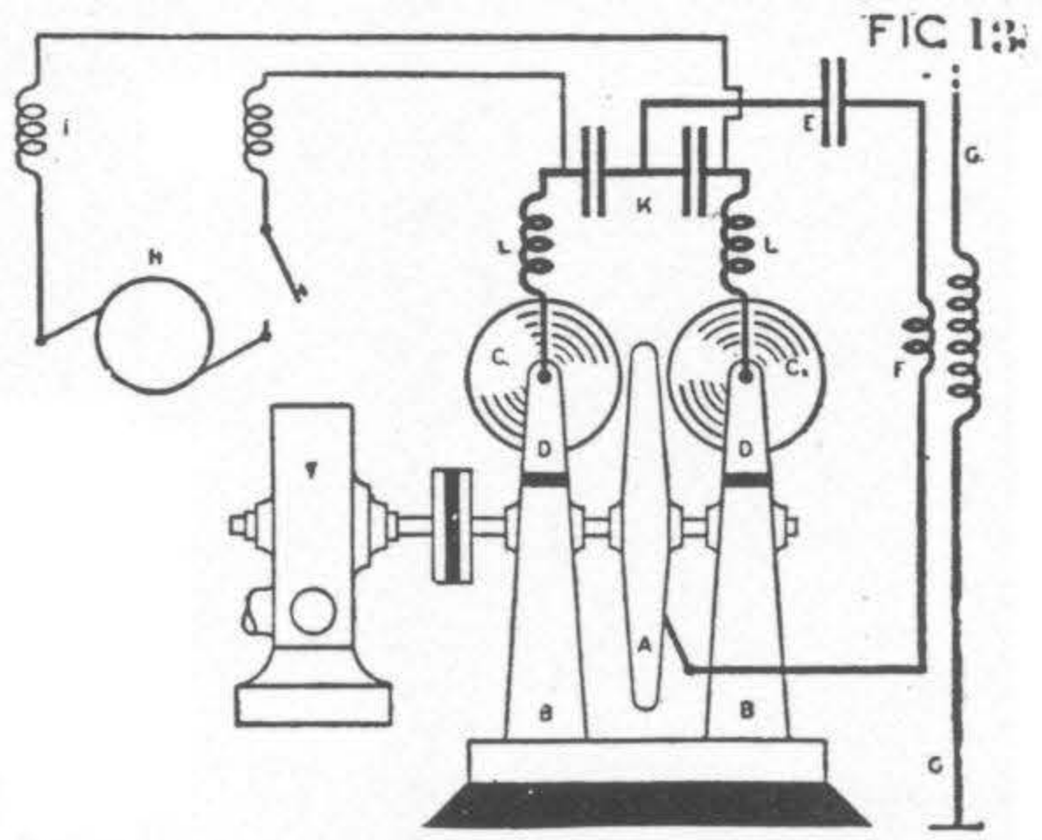
A further improvement introduced at Clifden and Glace Bay consisted in the adoption of air condensers, composed of insulated metallic plates suspended in air at ordinary pressure. In this manner it is possible to prevent the dissipation of energy due to losses caused by the dielectric hysteresis in the glass dielectric of the condensers previously employed, and a very appreciable economy in working, resulting from the absence of breakages of the dielectric, is effected. These air condensers, which have been in use since May, 1907, have been entirely satisfactory. After very considerable delay and expense, the new station at Clifden was got ready for tests by the end of May, 1907, and experiments were then commenced with Glace Bay.

The wave-length used during these tests was 12,000 feet, the capacity employed 1·6 microfarads, and the potential to which the condenser was charged 80,000 volts.

Good signals were obtained at Cape Breton from the very commencement of the tests, but some difficulty was encountered in consequence of the effects of atmospheric electricity due to the prevalence of thunderstorms in the eastern part of Canada during the first few days of the tests.

Simultaneously with these tests others were carried out from Poldhu to Glace Bay with a new system of transmitting apparatus, by means of which continuous or semi-continuous oscillations could be produced.

Proportionately to the energy employed the signals from Poldhu were so much better than those from Clifden that I decided at once to adopt this new method of transmission at Glace Bay and Clifden. The apparatus which I have been using for producing continuous or closely adjacent trains of electric oscillations is as follows[2]:—A metal disc A (Fig. 13), insulated from the earth, is caused to rotate at a very high speed by means of a high-speed electric motor or steam turbine. Adjacent to this disc, which I shall call the middle disc, are placed two other discs, C_1, C_2, which may be called polar discs, and which also can be rotated at a high rate of speed. These polar discs should have their peripheries very close to the surface or edges of the middle disc.



If a small amount of energy is used, stationary knobs or points may be used in place of the side discs.

The two polar discs are connected respectively through suitable brushes to the outer ends or terminals of two condensers K, joined in series, and these condensers are also connected through suitable inductive resistances to the terminals of a generator, which should be a high-tension continuous-current dynamo.

On the high-speed or middle disc a suitable brush or rubbing contact is provided, and connected between this contact and the middle point of the two condensers is inserted an oscillating circuit consisting of a condenser E in series with the inductance, which last is connected inductively or conductively to the aërial.

If the necessary conditions are fulfilled, and a sufficient E.M.F. is employed, a discharge will pass between the outer discs and the middle disc, which discharge is neither an oscillatory spark nor an ordinary arc, and powerful

FIG 13.

oscillations will be created in the signalling condenser E and oscillatory circuit F.

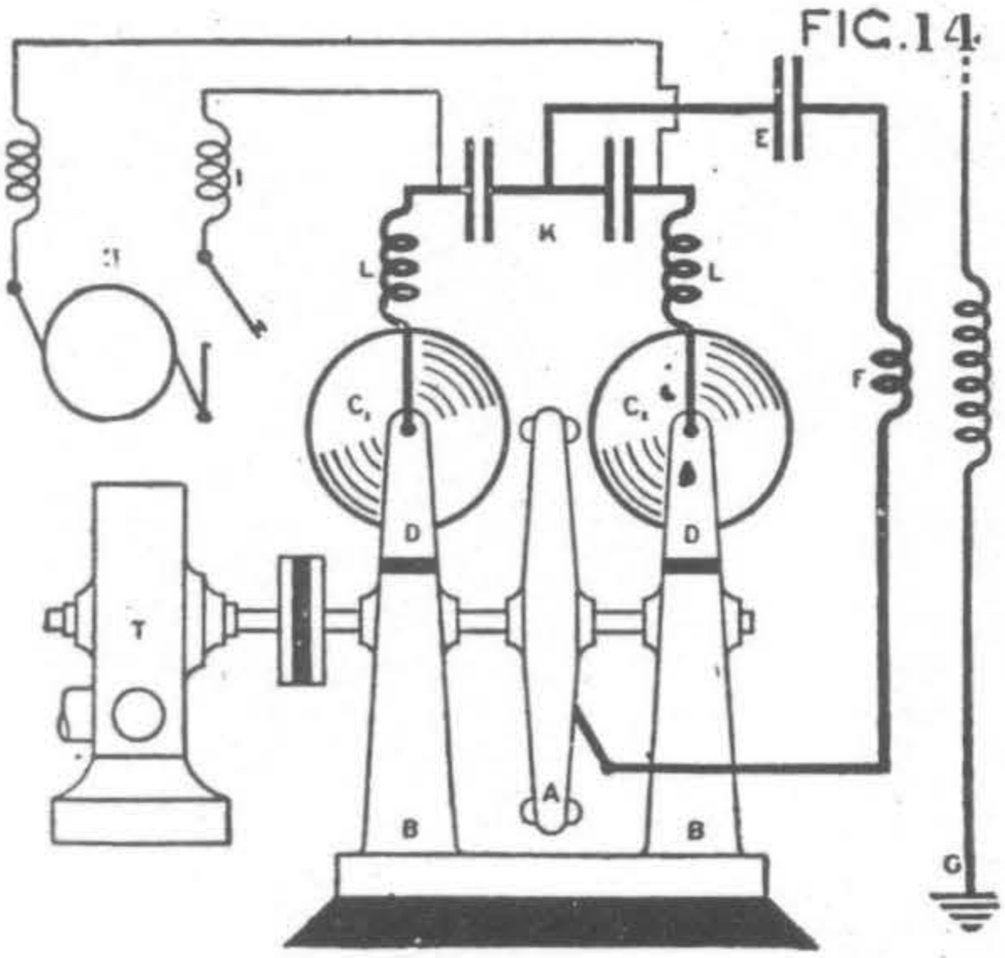
I have found that in order to obtain good effects a peripheral speed of more than 100 metres per second is desirable; therefore particular precautions have to be taken in the construction of the discs. Electrical oscillations of a frequency as high as 200,000 per second can be obtained.

The apparatus works probably in the following manner:—Let us imagine that the source of electricity is gradually charging the double condenser and increasing the potential at the discs, say C_1 positively and C_2 negatively; at a certain instant the potential will cause the charge to jump across one of the gaps, say between C_2 and A. This will charge the condenser E, which will then commence to oscillate, and the charge in swinging back will jump from A to C_1, which is charged to the opposite potential. The charge of E will again reverse, picking up energy at each reversal from the condensers K. The same process will go on indefinitely, the losses which occur in the oscillating circuit EF being made good by the energy supplied from the generator H. If the disc is not rotated, or rotated slowly, an ordinary arc is at once established across the small gaps, and no oscillations take place. The efficient cooling of the discharge by the rapidly revolving disc seems to be one of the conditions necessary for the production of the phenomena.

By means of this apparatus tests were carried out, but it was found, as was to be expected, that the oscillations were too continuous and of too high a frequency to affect a receiver, such as the magnetic detector, unless an interrupter was inserted in one of the circuits of the receiver.

[1] "On Methods whereby the Radiation of Electric Waves may be mainly Confined," &c. Proc. Roy. Soc., G. Marconi, A. lxxii., 1906.

[2] Patent Application No. 20,119, September 9, 1907.



A syntonic coherer receiver would, however, work, in consequence, no doubt, of the considerable rise of potential which occurred at its terminals through the cumulative effect of resonance.

The best results over long distances have, however, been obtained by a disc as shown in Fig. 14, in which the active surface is not smooth, but consists of a number of knobs or pegs, at the end of which the discharges take place at regular intervals. In this case, of course, the oscillations are not continuous, but consist of a regular succession of trains of undamped or slightly damped waves.

In that manner it is possible to cause the groups of oscillations radiated to reproduce a musical note in the receiver, distinguishable in a telephone, and thereby it is easier to differentiate between the signals emanating from the transmitting station and noises caused by atmospheric electrical disturbances. By this method very efficient resonance can, moreover, be obtained in appropriately designed receivers.

A few tests with apparatus based on the principle described were carried out between Glace Bay and Clifden, and on October 17 of the year 1907 a limited service for Press messages was commenced between Great Britain and America. Difficulties were experienced, however, over the question of rates with the telegraph companies working the land-lines between Glace Bay and the principal towns of Canada and the United States, and at present the strange

FIG. 14.

anomaly exists that the rates for Press messages on the American land-lines are much cheaper for messages going from England to New York than in the reverse direction. On February 3, 1908, this service was extended to ordinary messages between London and Montreal.

The stations at Clifden and Glace Bay are not complete, and the necessary duplication of the running machinery has not yet been executed, but nevertheless communication across the Atlantic has never been interrupted for more than a few hours since the commencement of commercial working on October 17, 1907.

There have, however, been several serious interruptions at Clifden, due to the untrustworthiness of the land-lines connecting Clifden to the ordinary telegraph system. On one occasion one of these interruptions lasted from 5.20 p.m. to 10.30 a.m., a duration of seventeen hours, and on another occasion the land telegraph wires were struck by lightning and disabled for twelve hours. There have also been recorded numerous other interruptions of shorter duration, which resulted in delays to private and Press messages. Further delays have also been caused through interruptions on the land-lines connected with the Canadian station.

During the first months, on account of imperfections in the auxiliary apparatus connected principally with the operating keys and switches, only a fraction of the available transmitting power was used. In consequence of this the speed of transmission was slow, and short interruptions somewhat frequent. Many of these difficulties have now been overcome, and in a few more months, when it should be possible to utilise the full power available, a very much greater speed and efficiency is likely to be attained.

Messages can now be transmitted across the Atlantic by day as well as by night, but there still exist certain periods, fortunately of short duration, when transmission across the Atlantic is difficult and at times ineffective, unless an amount of energy greater than that used during what I might call normal conditions is employed.

Thus, in the morning and evening when, due to the difference in longitude, daylight or darkness extends only part of the way across the Atlantic, the received signals are weak and sometimes cease altogether.

It would almost appear as if illuminated space possessed for electric waves a different refractive index from dark space, and that in consequence the electric waves may be refracted and reflected in passing from one medium to the other. It is therefore probable that these difficulties would not be experienced in telegraphing over equal distances from north to south, or *vice versâ*, as in this case the passage from daylight to darkness would occur almost simultaneously in the whole of the medium between the two points.

In the same manner a storm area in the path of the signals often brings about a considerable weakening of the received waves, whilst if stormy conditions prevail all the way across the Atlantic no interference is noticeable. Electric-wave shadows, like sound shadows, may be formed by the interference of reflected waves with the direct waves, whereby signals may be much less effective or imperceptible in the area of such electric-wave shadow.

In the same manner as there exist periods when signals across the Atlantic are unusually weak, there exist other conditions, especially at night, which make the signals abnormally strong. Thus on many occasions ships, and stations equipped with apparatus of a normal range of 200 miles, have been able to communicate over distances of more than 1000 miles. This occurred recently when a ship in the English Channel was able to correspond with another in the Mediterranean. But the important factor about wireless telegraphy is that a service established for a certain distance shall be able to maintain trustworthy communication over that distance.

Long-distance stations are now in course of erection in many parts of the world, the most powerful of all being that of the Italian Government at Coltano, and I have not the slighest doubt but that telegraphy through space will soon be in the position of affording communication between distant countries at cheaper rates than can be obtained by any other means.

As to the practicability of wireless telegraphy working over long distances, such as that separating England from America, there is no longer need for any doubt. Although the stations have been worked for only a few hours daily, 119,945 words of Press and commercial messages had been transmitted across the ocean by this means up to the end of February, 1908, since the service was opened.

The best judges of a service are those who have made use of it, and amongst newspapers, the chief users have been the *New York Times* and the London *Times*, which have already publicly expressed their opinion of this new method of communication.

Whether the new telegraphy will or will not injure or displace the cables is still a matter of conjecture, but in my opinion it rests a good deal on what the cables can do in the way of cheaper rates. It is not, as some appear to imagine, either the business or the wish of those concerned in the development of wireless telegraphy to injure the cable industry. They are endeavouring at present to demonstrate that the new method is not only valuable for shipping, but that it should be also regarded as a new and cheaper method of communicating with far distant countries. Whatever may be the view as to its shortcomings and defects, there can be no doubt but that wireless telegraphy across the Atlantic has come to stay, and will not only stay, but continue to advance.

In seven years the useful range of wireless telegraphy has increased from 200 miles to 2500 miles. In view of

that fact, he will be a bold prophet who will venture to affirm what may not be done in seven years more.

I shall not presume to say that at the present moment the wireless telegraph service between London and New York is as efficient and as rapid as that supplied by the cables. For nearly fifty years the Transatlantic cable organisation has been in existence, and there are now sixteen cables working across the North Atlantic, so that in the case of a breakdown of one cable the traffic is sent by one of the others. Moreover, long experience has served to bring their land-line connections to a high state of perfection. Nevertheless, I am convinced that if there were only one cable and the present wireless service, interruptions would be more frequent and much more serious in the case of the cable than in that of the wireless service.

We have only to look towards those parts of the globe such as India, South Africa, and so forth, where trans-oceanic communication is dependent upon only one or two cables, and the force of my remarks will be more readily appreciated. The cases of delay in regard, not only to commercial messages, but also to Government despatches, are only too frequent, as no doubt you have observed from time to time in the daily Press.

Among many people there seems to be a rooted conviction that wireless telegraphy is not suitable for the handling of code or cipher messages. Whatever gave rise to this idea I do not know, but I wish to emphasise that it is purely fictitious. Code messages can be sent just as well by wireless as by ordinary methods of telegraphy.

I need hardly say that most of the wireless messages passing between warships are now expressed in code, as are likewise the majority of the commercial messages handled by the Clifden and Cape Breton stations.

I do not wish to claim that wireless telegraphy is infallible, and although errors do sometimes occur, it is absolutely certain that, having regard to the London and Montreal service, most of the mistakes can be traced to the land-line telegraph transmission between London and Clifden, and between Glace Bay and Montreal.

I find, however, that probably the greatest ignorance prevails in regard to what is termed "tapping," or intercepting wireless messages. No telegraph system is secret. The contents of every telegram are known to every operator who handles it. It is incorrect to suppose that anyone can at will pick up wireless messages. On the other hand, it is easy for anyone knowing the Morse code to step into many telegraph offices and read off the messages by the click of the instruments.

Further, it is practicable, but illegal in this country, to make arrangements so that messages which pass over a telegraph line can be read by persons who are not operating the line at all. It is also expensive to erect a tall pole or tower and fix up all the instruments which are necessary before wireless messages can be taken in, and, moreover, such proceeding is contrary to the law of the land.

It should be remembered, too, that any ordinary telegraph or telephone wire can be tapped, and the conversation going through it overheard, or its operation interfered with. Results published by Sir William Preece show that it is possible to pick up at a distance, on another circuit, the conversation which may be passing through a telephone or telegraph wire.

At Poldhu, on a telephone connected to a long horizontal wire, the messages passing through a Government telegraph line a quarter of a mile away can be distinctly read. In a paper on his method of magnetic space telegraphy, Sir Oliver Lodge mentions an occasion on which he was able to interfere, from a distance, with the working of the ordinary telephones in the city of Liverpool.

Many instances can be enumerated showing that electric light and tramway power-stations have interfered with cables and land-lines. Nevertheless, there are penalties attached to the tapping of a telegraph wire, and it ought to be as well known that, since the passing of the Wireless Telegraphy Act, there are penalties involved if any wireless stations are erected or worked without the consent of the Postmaster-General. In conclusion, I may say that I am very confident that it is only a question of time, and that not a very long time, before wireless telegraphy over great distances, possibly round the world, will become an indispensable aid to commerce and civilisation.

SIGNALING TO MARS.

Not since those historic flashes from Mars were received, some years ago, which were probably caused by the reflection of sunlight falling on snow-covered surfaces, and which were promptly interpreted by Tesla and some exuberantly imaginative astronomers as attempts on the part of a hypothetical race of Martians to communicate with this earth of ours, has so much excitement been created as Prof. Pickering's proposal to build a system of mirrors, by means of which light can be rhythmically flashed to Mars. According to Prof. Pickering, a system of reflecting surfaces of adequate area could be constructed at a cost of $10,000,000. If Mars is inhabited by a race more highly developed than we, on the theory that their planet is older than ours, it is argued that they will have sufficient intelligence to devise a means of answering. Prof. R. W. Wood of Johns Hopkins University suggests the simpler and cheaper expedient of employing a huge strip of black cloth, which could be wound from one roller to another, and made to appear and disappear at regular intervals. He suggests the alkali deserts of the Southwest as a suitable place for the experiment. In all probability, neither Prof. Wood nor Prof. Pickering seriously believes that Mars is inhabited.

Would it be worth while to carry out the idea? To us it seems that if the experiment proved a failure, and no answering signal were received from Mars in a reasonable time, the matter would not be conclusively settled. Knowing practically nothing of the conditions on Mars, it would naturally be unsafe to conclude from a failure that the planet is uninhabited, for which reason the habitability of Mars would still engross Flammarion, Lowell, and the host of newspapers that accept their utterances as astronomical gospel. On the other hand, if an answering signal should be received, it would be safe to say that the event would transcend in human interest and importance the most stirring occurrence in the history of the earth, and would inaugurate a new era in the progress of the human race.

Even in the face of this tremendously alluring but exceedingly remote possibility, it seems to us that the $10,000,000 stipulated by Prof. Pickering, and the smaller indeterminate sum required by Prof. Wood, could be more worthily expended, particularly so when we examine the evidence on which the theory of Martian habitability is based.

To the indefatigable studies of Prof. Lowell we owe whatever facts have been gathered that bear at all on the question. But Prof. Lowell's arguments have been riddled by the inexorable logic of geologists, astronomers, and physicists. He is wedded to the Laplacean theory of planetary evolution, although that theory is considered inadequate by many astronomers in the light of recent celestial observations. He assumes that the history of the earth is the history of Mars. He advances the theory that Mars is a planet which has shriveled up during the course of ages; that its surface is one vast parched desert, with the exception of the snow that gathers each winter about the poles; and that the chief concern of the inhabitants, if inhabitants there be, is to conserve this paltry supply of water, and to conduct it, as the snow melts in the spring, to those regions in the equatorial and temperate zones which would still blossom if they were watered. Evidence of this gigantic irrigation system, which dwarfs anything of the kind that we have ever attempted, Lowell finds in that network of lines which Schiaparelli first discovered, and which were called by him "canals" for want of a better name. As spring and summer approach, the lines slowly creep down from the poles toward the equator, and the dull red or orange of the supposed desert region changes to green. With the advent of autumn and winter, the green resumes its dull red or orange hue, and the lines or "canals" gradually disappear. In these chromatic changes Prof. Lowell sees the seasonal growth and decay of vegetation. His argument for the habitability of our planetary neighbor is based on the undeniably remarkable regularity of the "canals." It is pointed out that they are usually the shortest distance between the points that they connect, and that they meet in groups of three, five, seven, and more in well-defined spots, which he terms "oases," like so many spokes converging in a wheel-hub. In other words, there is nothing haphazard in the arrangement of these canals as Prof. Lowell sees them. They are to him so artificial that they are the symbols of an intelligent race, who have sunk all political and international disputes in the one vital problem of postponing the day when their orb must eventually dry up and they themselves perish.

To reinforce his argument, Prof. Lowell points to the earth. He argues that all terrestrial life emerged from the ocean, although no geologist will positively assert how life did originate on this planet; that the earth was once wrapped in a damp, cloudy envelope, although there is much evidence that moisture, even in geologic times, was of local prevalence only; that the earth is gradually drying up, although all geological evidence points to the fact that the proportion of land to sea has always been a fluctuating quantity, with no marked tendency in either direction; and that deserts on the earth are the harbingers of an ultimate dearth of water extending over the entire earth, although geologists maintain that deserts have always existed. Perhaps the most vigorous attack on Lowell's theories has been conducted by Prof. Andrew E. Douglass, who has studied the "canals" by the methods of experimental psychology, and has shown that there are fundamental defects in the human eye which produce faint canal illusions, and that these have worked serious injury to our observations in the past. It must be confessed, however, that Prof. Douglass has not explained away the seasonal appearance and disappearance of the "canals" and "oases."

Ingenious as Prof. Lowell's explanation of Martian phenomena undoubtedly is, so much of it is based on unsound geological reasoning, and so much on sheer conjecture, that it seems almost futile to make any attempt at signaling in the hope of obtaining something like experimental evidence that Mars is really a living world peopled by intelligent beings.

The Brooklyn Eagle May 19, 1909

TESLA'S $1,000,000 COMPANY.

Albany, May 19—The Tesla Propulsion Company of New York, organized to manufacture motive power, machinery for vessels, capital $1,000,000, was incorporated to-day. The directors include Nikola Tesla, Joseph Headley, Walter H. Knight of New York.

The New York Herald May 20, 1909

TESLA SAYS HE HAS NEW POWER SECRET

Inventor Declares He Has Discovered a Mechanical Principle of Greatest Economic Value.

Following the incorporation of the Tesla Propulsion Company, with $1,000,000 capital stock, at Albany yesterday, to exploit one of Nikola Tesla's inventions, Mr. Tesla announced the adoption of the device by the Alabama Consolidated Coal and Iron Company.

"I have discovered a mechanical principle, entirely new and of the greatest economic value," Mr. Tesla said, "but I shall not be in a position to make known the details and exhibit the principle in operation for perhaps six weeks. It is a principle which minimizes the size of the power producing plant and increases to a maximum the power produced. The apparatus we will build for the Alabama concern will not be one-third of the size of the ordinary air blast machinery equipment for such work and the air blast and other effective results will be far superior in volume and value to those at present generally used.

"In connection with this plant I will install a turbine of my own invention, and the air blast will be supplied under a turbine principle. This new mechanical principle I have discovered is applicable to air, steam, gas or water power, and may be used for locomotives, automobiles or any form of power production. With it a locomotive as powerful as any now used would need to be less than half the size."

The Tesla Propulsion Company's directors include Mr. Tesla, Joseph Hoadley and Walter H. Knight, of New York. Mr. Tesla stated that machines of several types had been built and that successful demonstrations had been given with them to his associates in the new company and to representatives of the Alabama company.

HOW TO SIGNAL TO MARS

Wireless the Only Way Now, Says Nicola Tesla—Mirror Plan Not Practicable.

To the Editor of The New York Times:

Of all the evidences of narrow mindedness and folly I know of no greater one than the stupid belief that this little planet is singled out to be the seat of life, and that all other heavenly bodies are fiery masses or lumps of ice. Most certainly, some planets are not inhabited, but others are, and among these there must exist life under all conditions and phases of development.

In the solar system Venus, the Earth, and Mars represent, respectively, youth, full growth, and old age. Venus, with its mountains rising dozens of miles into the atmosphere, is probably as yet unfitted for such existence as ours, but Mars must have passed through all terrestrial states and conditions.

Civilized existence rests on the development of the mechanical arts. The force of gravitation on Mars is only two-fifths of that on earth, hence all mechanical problems must have been much easier of solution. This is even more so of the electrical. The planet being much smaller, the contact between individuals and the mutual exchange of ideas must have been much quicker, and there are many other re sons why intellectual life should have been on that planet phenomenal in its evolution.

To be sure, we have no absolute proof that Mars is inhabited. The straightness of the canals, which has been held out as a convincing indication to this effect, is not at all such. We can conclude with mathematical certitude that as a planet grows older and the mountains are leveled down ultimately every river must flow in a geodetically straight line. Such straightening is already noticeable in some rivers of the earth.

Believes Mars Signaled Him.

But the whole arrangement of the so-called waterways, as pictured by Lowell, would seem to have been designed. Personally I base my faith on the feeble planetary electrical disturbances which I discovered in the Summer of 1899, and which, according to my investigations, could not have originated from the sun, the moon or Venus. Further study since has satisfied me that they must have emanated from Mars. All doubt in this regard will be soon dispelled.

To bring forth arguments in any attempt should be made to establish interplanetary communication would be a useless and ungrateful undertaking. If we had no other reason, it would be justified by the universal interest which it will command, and by the inspiring hopes and expectations to which it would give rise. I shall rather concentrate my efforts upon the examination of the plans proposed and the description of a method by which this seemingly impossible task can be readily accomplished.

The scheme of signaling by rays of light is old, and has been often discussed, perhaps, more by that eloquent and picturesque Frenchman, Camille Flammarion, than anybody else. Quite recently Prof. W. H. Pickering, as stated in several issues of The New York Times, has made a suggestion which deserves careful examination.

The total solar radiation falling on a terrestrial area perpendicular to the rays amounts to eighty-three foot pounds per square foot per second. This activity, measured by the adopted standard, is a little over fifteen one-thousandth of a horse power. But only about 10 per cent. of this whole is due to waves of light. These, however, are of widely different lengths, making it impossible to use all to the best advantage, and there are specific losses unavoidable in the use of mirrors, so that the power of sunlight reflected from them can scarcely exceed 5.5 foot pounds per square foot per second, or about one one-hundredth of a horse power.

A Giant Reflector Needed.

In view of this small activity, a reflecting surface of at least one-quarter million square feet should be provided for the experiment. This area, of course, should be circular to insure the greatest efficiency, and, with due regard to economy, it should be made up of mirrors rather small, such as to meet best the requirements of cheap manufacture.

The idea has been advanced by some experts that a small reflector would be as efficient as a large one. This is true to a degree but holds good only in heliographic transmission to small distances when the area covered by the reflected beam is not vastly in excess of that of the mirror. In signaling to Mars, the effect would be exactly proportionate to the aggregate surface of the reflectors. With an area of one-quarter million square feet the activity of the reflected sunlight, at the origin, would be about 2,500 horse power.

It scarcely need be stated that these mirrors would have to be ground and polished most carefully. To use ordinary commercial plates, as has been suggested, would be entirely out of the question, for at such an immense distance the imperfections of surface would fatally interfere with efficiency. Furthermore, expensive clock work would have to be employed to rotate the reflectors in the manner of heliostats, and provision would have to be made for protection against destructive atmospheric influence. It is extremely doubtful that so formidable an array of apparatus could be produced for $10,000,000, but this is a consideration of minor importance to this argument.

Light Unlimited in a Vacuum.

If the reflected rays were parallel and the heavenly bodies devoid of atmospheres, nothing would be simpler than signaling to Mars, for it is a truth accepted by physicists that a bundle of parallel rays, in vacuo, would illuminate an area with the same intensity, whether it be near or infinitely remote. In other words, there is no sensible loss in the transmission of radiant energy through interplanetary or vacuous space. This being the case, could we but penetrate the prison walls of the atmosphere, we could clearly perceive the smallest object on the most distant star; so inconceivably tenuous, frictionless, rigid, and elastic is the medium pervading the universe.

The suns rays are usually considered to be parallel, and are virtually so through a short trajectory, because of the immense distance of the luminary. But the radiations, coming from a distance of 93,000,000 miles, emanate from a sphere 865,000 miles in diameter, and, consequently, most of them will fall on the mirrors at an angle less than by degrees, with the result of causing a corresponding divergence of the reflected rays. Owing to the equality of the angles of incidence and reflection, it follows that if Mars were at half the sun's distance, the rays reaching the planet would cover an area of about one-quarter of that of the solar disk, or in round numbers, 147,000,000,000 square miles, which is nearly 16,400,000,000,000 times larger than that of the mirrors. This means that the intensity of the radiation received on Mars would be just that many times smaller.

To convey a definite idea, it may be stated that the light we get from the moon is 600,000 times feebler than that of the sun. Accordingly, even under these purely theoretical conditions the Pickering apparatus could do no more than produce an illumination 27,400,000 times feebler than that of our full moon, or 1,000 times weaker than that of Venus.

Atmosphere the Chief Obstacle.

The preceding is based on the assumption that there is nothing in the path of the reflected rays except the tenuous medium filling all space. But the planets have atmospheres which absorb and refract. We see remote objects less distinctly, we perceive stars long after they have fallen below the horizon. This is due to absorption and refraction of the rays passing through the air. While these effects cannot be exactly estimated, it is certain that the atmosphere is the chief impediment to the study of the heavens.

By locating our observatories one mile above sea level the quantity of matter which the rays have to transverse on their way to the planet is reduced to one-third. But, as the air becomes less dense, there is comparatively little gain to be derived from greater elevation. What chance would there be that the reflected rays, reduced to an intensity far below that estimated above, would produce a visible signal on Mars? Though I do not deny this possibility, all evidence points to the contrary.

Lowell, a trained and restless observer, who has made the study of Mars his specialty and is working under ideal conditions, has been so far unable to perceive a light effect of the magnitude such as the proposed signaling apparatus might produce there. Phobos, the smaller of the two satellites of Mars—from seven to ten miles in diameter—can only be seen at short intervals when the planet is in opposition. The satellite presents to us an area of approximately fifty square miles, reflecting sunlight at least as well as ordinary earth, which has little over one-twelfth of the power of a mirror.

Stated otherwise, an equivalent effect at that distance would be produced by mirrors covering four square miles, which means two square miles of the same reflectors if located on earth, as it receives sunlight of twice the intensity. Now this is an area 200 times larger than that of the ten-million-dollar reflector, and yet Phobos is hardly perceptible. It is true that the observation of the satellite is rendered difficult by the glare of its mother planet. But this is offset by the fact that it is in vacuum and that its rays suffer little diminution through absorption and refraction of the earth's atmosphere.

Mirror Signals Impossible Now.

What has been stated is thought sufficient to convince the reader that there is little to be expected from the plan under discussion. The idea naturally presents itself that mirrors might be manufactured which will reflect light in parallel beams. For the time being this is a task beyond human power but no one can set a limit to the future achievement of man.

Still more ineffective would be the attempt of signaling in the manner proposed by Dr. William R. Brooks and others, by artificial light, as the electric arc. In order to obtain a reflected light-activity of 2,500 horsepower it would be necessary to install a power plant of not less than 75,000 horsepower, which, with its turbines, dynamos, parabolic reflectors and other paraphernalia, would probably cost more than $10,000,000. While this method would permit operations at favorable times, when the earth is nearer to, and has its dark side turned toward Mars, it has the disadvantage of involving the use of reflected rays necessarily more divergent than those of the sun, it being impossible to construct mirrors of the required perfection, and, without their use, the rays would be scattered to such an extent that the effect would be much smaller.

Reflecting surfaces of great extent can be had readily. Prof. R. W. Wood makes the odd suggestion of using the white alkali desert of the southwest for the purpose. Prof. E. Doolittle advises the employment of large geometrical figures. In my opinion none of these suggestions is feasible. The trouble is that the earth itself is a reflector, not efficient, it is true, but what it lacks in this respect is more than made up by the immensity of its area. To convey a perceptible signal in this manner it might require as much as 100 square miles reflecting surface.

Wireless Offers the Best Plan.

But there is one method of putting ourselves in touch with other planets. Though not easy of execution, it is simple in principle. A circuit properly designed and arranged is connected with one of its ends to an insulated terminal at some height and with the other to earth. Inductively linked with it is another circuit in which electrical oscillations of great intensity are set up by means now familiar to electricians. This combination of apparatus is known as my wireless transmitter.

By careful attunement of the circuits the expert can produce a vibration of extraordinary power, but when certain artifices, which I have not yet described, are resorted to the oscillation reaches transcending intensity. By this means, as told in my published technical records, I have passed a powerful current around the globe and attained activities of many millions of horse power. Assuming only a rate of 15,000,000, readily obtainable, it is 6,000 times more than that producecable by the Pickering mirrors.

But, my method has other and still greater advantages. By its employment the electrician on Mars, instead of utilizing the energy received by a few thousand square feet of area, as in a parabolic reflector, is enabled to concentrate in his instrument the energy received by dozens of square miles, thus multiplying the effect many thousands of times. Nor is this all. By proper methods and devices he can magnify the receives effect as many times again.

It is evident, then, that in my experiments in 1899 and 1900, I have already produced disturbances on Mars incomparably more powerful than could be attained by any light reflectors, however large.

Electrical science is now so far advanced that our ability of flashing a signal to a planet is experimentally demonstrated. The question is, When will humanity witness that great triumph. This is easily answered. The moment we obtain absolute evidences that an intelligent effort is being made in some other world to this effect interplanetary transmission of intelligence can be considered as an accomplished fact. A primitive understanding can be reached quickly without difficulty. A complete exchange of ideas is a greater problem, but susceptible of solution. NIKOLA TESLA.

Tesla Propulsion Company.

The Tesla Propulsion Company, with $1,000,000 capital stock, has been incorporated at Albany, N. Y. The directors include Mr. Nikola Tesla, Mr. Jos. Hoadley and Mr. Walter H. Knight. Mr. Tesla said the company will manufacture apparatus constructed on a mechanical principle of his discovery, entirely new, and of the greatest economical value, the details of which he will make known in about six weeks. The principle, he says, minimizes the size of a power producing plant and increases to a maximum the power produced. A plant now being built for the Alabama Consolidated Coal & Iron Company will not be one-third of the size of the ordinary equipment for its work, while the air blast which it will include and other details will have a far superior value. In connection with this plant Mr. Tesla said he would install a turbine of his own invention, and that the air blast will be supplied under the turbine principle. The new mechanical principle involved is applicable to air, steam, gas and water-power, and may be used for locomotives, automobiles or any power application. With it a locomotive as powerful as any now used need not be half the present size.

Tesla to Furnish Motive-Power Machinery for Vessels.

Nikola Tesla has another workable invention and has incorporated the Tesla Propulsion Company, with the principal office in New York city and a capital of $1,000,000, to manufacture motive-power machinery for vessels. The other directors are Joseph Hoadley and Walter H. Knight of New York city.

The New York Times May 31, 1909

THE INHABITANTS OF MARS.

Prof GOLDWIN SMITH is concerned about the prospective attempts to converse by wireless telegraph with the inhabitants of Mars because he infers that the idea of interplanetary communication is founded on the assumption that inhabitants of the sister planet must be human beings like ourselves. Not at all. Let the Professor remain tranquil. Of course, as he says, we have long been slaves to the idea that man is the greatest, and probably the final, product of creation. We have been practically unable to conceive of a living being finer and more commendable than a quadruped mammal walk- to share their own overestimate of the opinions they express, the orders they give, and the suggestions they offer.

Such offensive fellows have always existed, and do now, but our own impression is that present conditions of service and employment create them less often than did those of other days, and tend more to restrain them after they have been created. Peremptory commands, such as masters used to issue to their bound apprentices, are no longer given, for the very good reason that they could not be enforced and would be promptly resented. Of course the office tyrant and the brutal boss survive, and both get a measure of servility from underlings who remain after those who will not endure discourtesy have been eliminated, but, on the whole, intercourse between employers and employés has made an easily measurable gain in suavity in the last twenty years.

With the gain there has been some loss, since now the employer often does not know more than a few of his employés by sight, and yet even in these cases there has been of late a marked strengthening of the sense of responsibility, and on the whole things are getting better and better. Let's talk about the good new days instead of about the good old days—which were pretty bad, as a matter of fact—and look for the Golden Age in the future, where there may be one, not in the past, where there certainly wasn't any.

CURRENT COMMENT

Tesla is to signal to Mars, according to a two-column letter to the New York Times. He believes that certain electrical disturbances which he observed in the summer of 1889 must have emanated from Mars, but that all doubt in this regard will soon be dispelled. He criticised unfavorably the various methods that have recently been proposed to convey signals to Mars, and offers one of his own which he states is simple in principle, although perhaps not easy of execution. This consists, first, of a circuit properly designed and arranged, with one of its ends connected to an insulated terminal at some height, and the other to earth. Inductibly linked with this is another circuit in which electrical oscillations of great intensity are set up, the above combination being known as the Tesla wireless transmitter. By a careful attunement of circuits, and by means of certain methods which he has not yet described, oscillations of transcending intensity can be obtained.

Adopts Tesla's Device.

The Alabama Consolidated Coal and Iron Company has adopted Nicola Tesla's new device for increasing power while minimizing the size of the power-producing plant. Mr. Tesla says that he will not be in a position to make known the details and exhibit the principle in operation for perhaps six weeks. He also states that the apparatus to be built for the Alabama concern will not be one-third of the size of the ordinary air-blast machinery equipment for such work, and the air blast and other effective results will be far superior in volume and value to those at present generally used.

Signaling to Mars.

Buffalo, May 25, 1909.

To the Editors:

I have noticed in the press recently an announcement that a suggestion had been made that, with an expenditure of ten million dollars, communication could be established with the people of Mars.

As a matter of fact, this subject is not a joking matter at all, but a question of scientific research, and I am of the opinion that it can be done by solicitation, without any great expenditure of money, and without any individual assuming any financial obligation in carrying out the work.

It occurred to me several years ago that if the people of Mars are as far advanced in civilization as some scientists have reason to believe, that they are already studying the growth of our cities by noting their illumination at night, and that the easiest, cheapest and best way for us to communicate with them is to light up certain cities after midnight.

In the United States, for instance, we could pick out all the towns that fell on a state line—from which they would get the idea that we were one nation divided into many states.

Another plan would be to pick out such towns as would spell "United States" across our country from New York to San Francisco, or just "America."

Then, if we were answered in some way, the different states could letter themselves, from which they would learn our whole alphabet.

In fact, a number of towns that are lighted by electricity could probably be found in one state in such number and proximity as to be chosen to form any capital letter of the alphabet.

An association of these lighting communities could thus elect to spell our alphabet, giving every letter five minutes and repeating the performance, say every Sunday night, from which they would learn that we observed the seventh day.

I think this idea should be studied and well considered, and that such an association of lighting communities working in conjunction with astronomers with powerful telescopes, could certainly give impetus to the idea and get something started in a practical way.

Samuel E. Hitt, M. E.

Buffalo, N. Y., June 1.

The Construction of High-Frequency Apparatus.

By George T. Hanchett.

THE average student who reads and understands the time-honored experiments of Tesla and Thomson in high-frequency work and who realizes the simplicity of the apparatus by which such startling results were reached, very often desires to reproduce the experiments on a small scale. When high-frequency phenomena were first discovered they were of academic interest only and had little practical value, except that they afforded a beautiful exemplification of the principles of inductance and capacity. The high-frequency discharge is now of commercial importance, being used in wireless telegraphy,

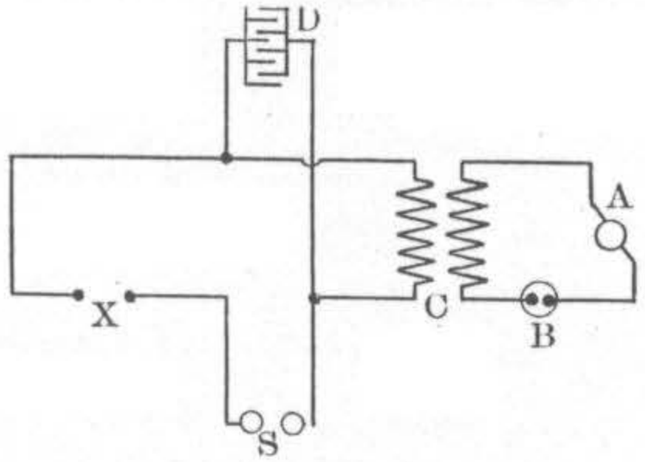


FIG. I.—DIAGRAM OF CONNECTIONS.

and in investigating the behavior of lightning arresters of various types, which are designed to deal with high-frequency condenser discharge.

The writer has had occasion to construct high-frequency apparatus and has encountered various details in construction which, if neglected, seriously impair results and may even render the efforts of the constructor futile. Some of the features are to be recommended by reason of their convenience and low cost, and although the subject is old it is believed that these considerations make a description of more or less interest.

Alternating currents of any of the commercial frequencies are best for producing the Tesla discharges. Very good results are obtained with 60-cycle current at 110 volts, using about 40 amp. It is necessary to step this potential up by a transformer of some sort from 10,000 volts to 20,000 volts. High-voltage, low-frequency current is passed directly to a condenser of the proper capacity, which is permitted to discharge across a short spark-gap, made preferably with screw adjustment and of moderately massive ball-shaped terminals. The discharge circuit of the condenser carries the high-frequency currents which it is desired to study, and the many beautiful and now familiar phenomena are obtained by connecting the different pieces of apparatus in series with this discharge circuit. An elementary diagram is shown in Fig. 1, where *A* répresents the alternating-current source of supply, suitably controlled by a rheostat or adjustable inductance *B*. C represents the step-up transformer, *D* the condenser, *S* the spark-gap, and at *X* in the condenser discharge circuit is connected the apparatus on which it is desired to impress high-frequency currents.

The most expensive and troublesome part of the apparatus is the step-up transformer. Several ordinary transformers

may be used to obtain the high-tension currents, but it will be found better, if time and means afford, to construct a special transformer of the open magnetic-circuit, oil-insulated type, of the transformer consists of a fiber tube of the dimensions given filled with fine, straight iron wire. This tube is fastened tightly to a thick cover, which may be of wood turned up in a

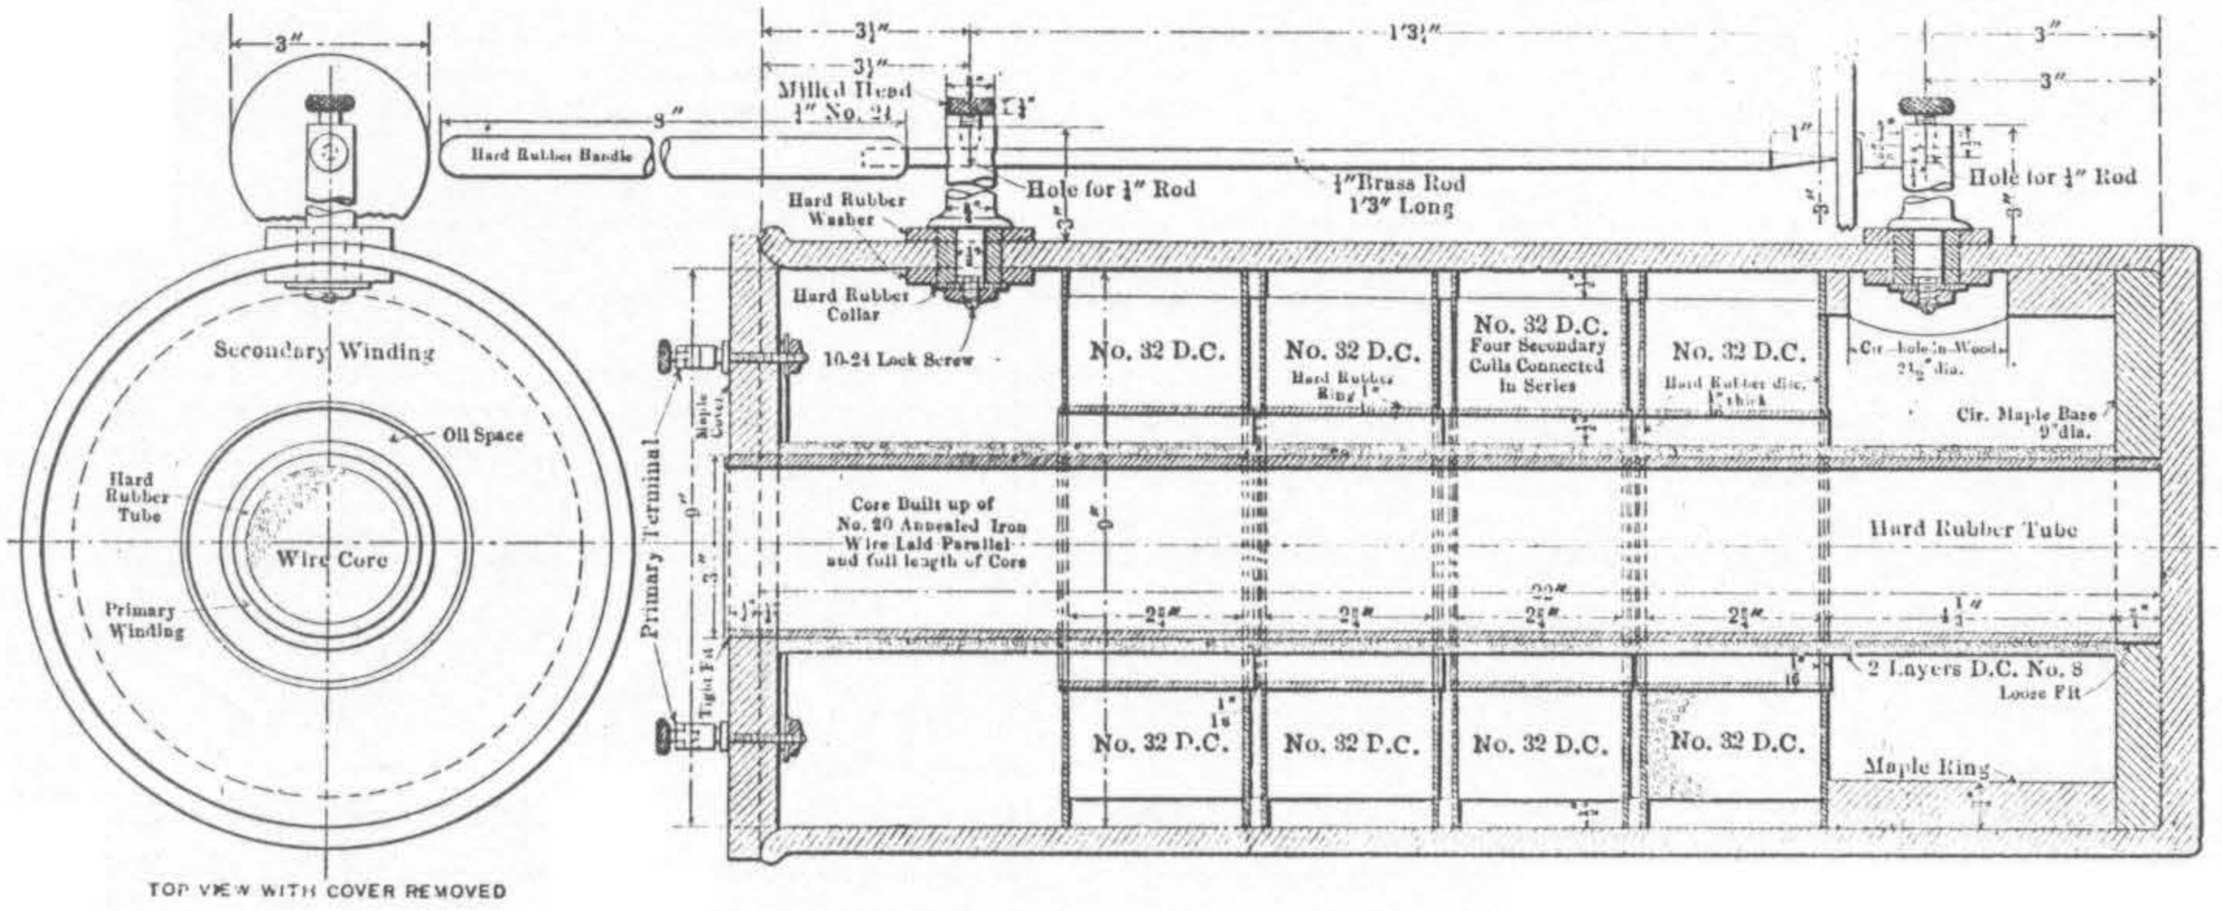

FIG. 2.—DETAILS OF STEP-UP TRANSFORMER.

for the surges that obtain in such a circuit are apt to puncture the insulation of the ordinary commercial apparatus. The writer has found a very successful arrangement in Fig. 2, which is a

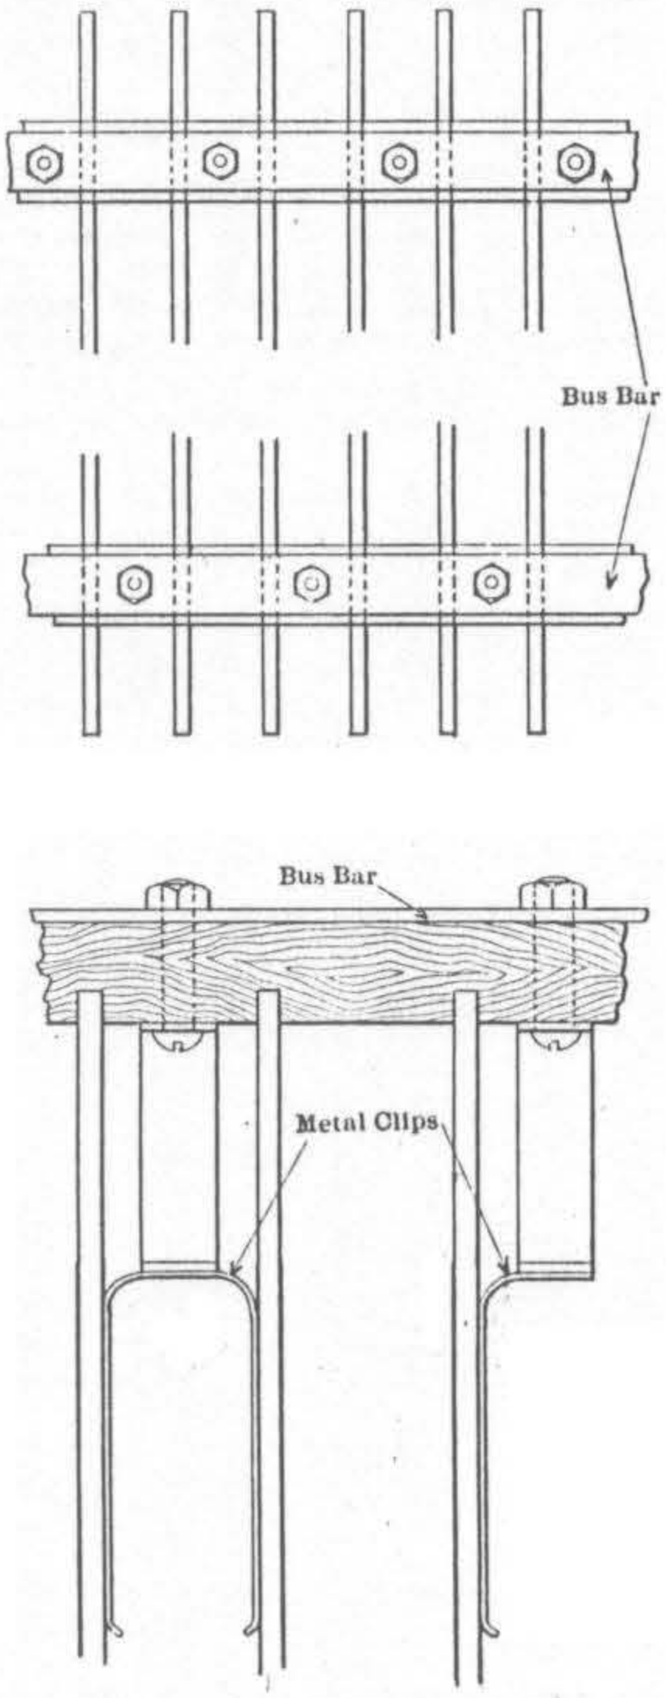

FIG. 3.—TOP AND SIDE VIEW OF CONDENSER RACK.

dimensional drawing of a transformer suitable for this purpose. The containing jar of this transformer is made of indurated fiber, which is oil tight and an excellent insulator. The primary lathe and impregnated with asphaltic compound. The two terminals of the primary may be brought to binding posts mounted on the wood. The advantage of this arrangement is found in the fact that removing the cover removes the primary coil also for inspection and also leaves the secondaries open so that they can be examined. The primary is wound with two layers of No. 8 double-cotton covered copper wire. Considerable care is necessary in insulating the layers from one another, particularly at the top where the primary coil is supported by the wood, for this top is likely to protrude out of the oil and between the layers at this point the highest difference of potential obtains. It is well, therefore, to use several layers of oiled linen to separate the primary layers at this point. The bottom of the indurated fiber jar contains a round disk of wood with a hole in the center which loosely fits the ends of the primary and keeps it central.

The secondary coils are wound on hard-rubber spools, made of tubes and collars, and using No. 32, double cotton-covered wire. Between each layer of wire should be placed a layer of unsized white paper, and care should be taken not to wind

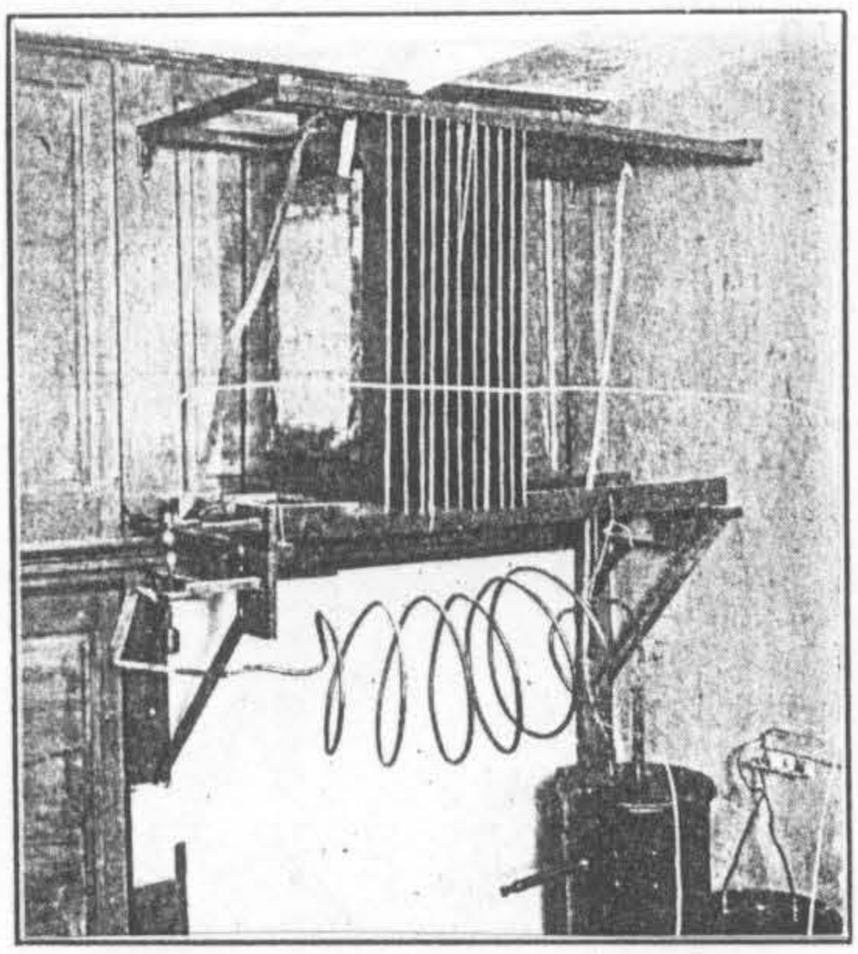

FIG. 4.—CONDENSER, SPARK GAP AND INDUCTANCE.

the layers clear across the full width of the spool. A space ¼ in. wide should be left at each end so that there will be no danger of the end turns dropping down between the spool col-

lars and the coil itself. The coils when completed should be boiled in paraffin, which should then be allowed to cool, and when the wax is of a mushy consistency the coil should be removed and pressed between two plates of glass with a weight. In this way much of the wax which would otherwise drain out between the interstices of the coil will remain there intact and afford valuable protection and insulation.

The finished coils may be assembled on the spools by slipping the latter through them, and the spools may then be placed in

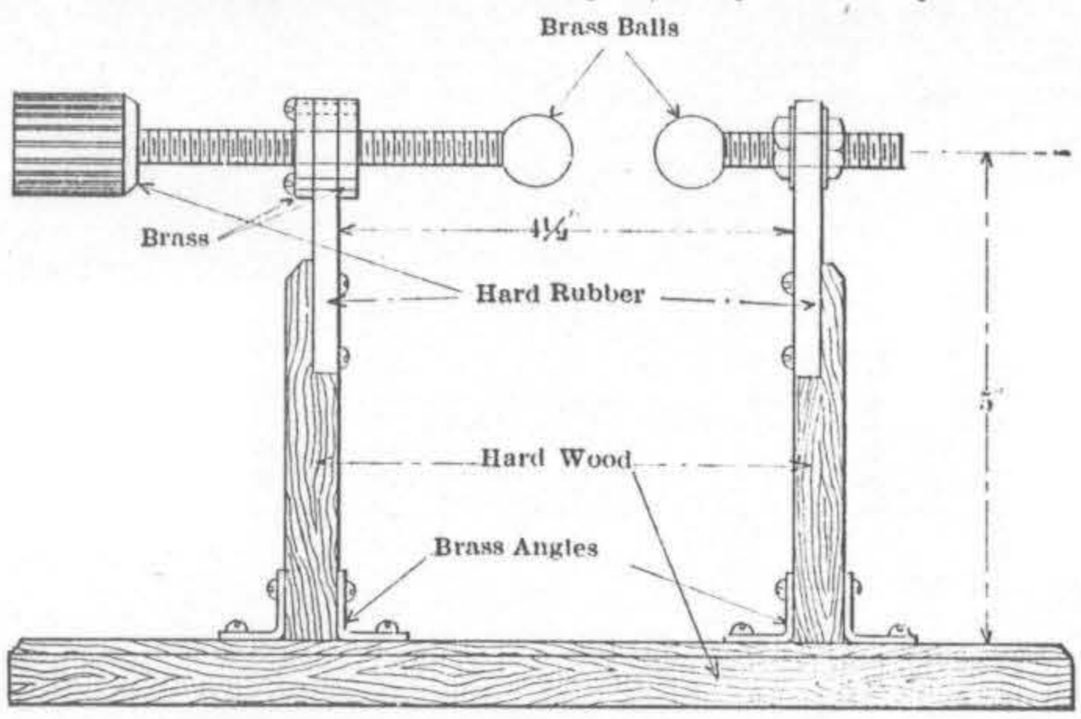

FIG. 5.—DISCHARGE CAP.

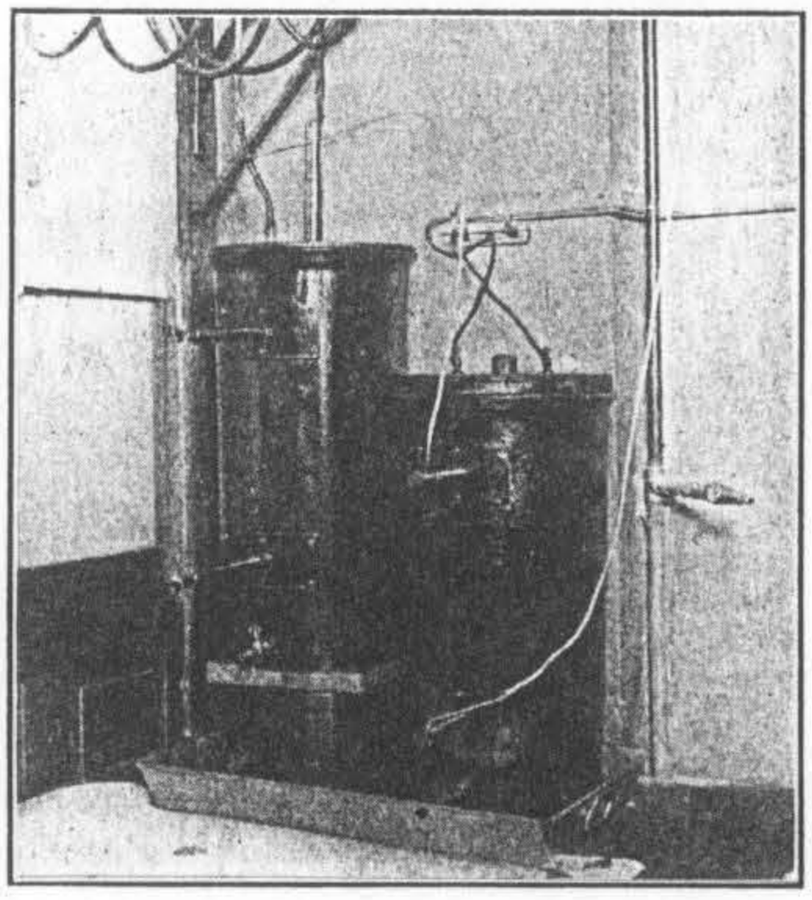
the jar, wooden rings being used as spreaders to separate them. Attention is called to the liberal spaces allowed between the primary and secondary, and when the jar is filled with a good grade of transformer oil the insulation between the primary and secondry is homogeneous and complete. An oil cock may be added at the bottom of the jar for the purpose of draining it and, as it is very hard to get the joints for the terminals tight, the jar may be placed in a metal pan which will catch all leakage.

The secondary terminals of the transformers are attached to hard-rubber tubes threaded into hard-rubber plates, which may be bent to fit the contour of the jar by placing them in hot water and securing them by bolts. The joints may be made tight with thick shellac. It may be well to bring the secondary terminals out from the ends of the coils, using a number of twisted wires for this purpose, instead of a single wire, which is likely to break and perhaps burn off.



A coil constructed in this way serves not only the purpose of a transformer, but, used in connection with the electrolytic interrupter with direct current, will provide discharges of low frequency and very high tension, 75,000 volts to 100,000 volts, and may be profitably used for breakdown testing of insulating materials.

For the Tesla experiments, however, this coil should be excited with alternating current, and the current from the secondaries should be led off to charge a condenser which may be made in the following manner: A dozen plates of glass (ordinary window glass of double thickness will answer) should be provided and a wooden rack made to contain them. The plates of glass are 18 in. x 24 in. and are covered with tin foil on each side, a space being left between the edge of the glass and the tin foil of at least 3 in. It will be well to shellac the plates and the edges of the tin foil, and the tin foil can be fastened to the plates with shellac very advantageously. The plates are assembled in the rack, which may be made of strips of wood having equally spaced saw cuts, and a set of busbars may be mounted upon strips of wood with similar saw cuts and carrying clips which extend down between the plates and make contact with the tin foil. Fig. 3 shows how this may be done, and Fig. 4 shows a photograph of the actual condenser constructed in this manner. The arrangement is to be recommended rather than the more economical one of placing the plates closely together and using alternate strips of tin foil between them, for the reason that if any plate should be overheated and crack through sparking, it can be removed without disturbing the others.

The discharge gap may be mounted on a wooden frame; the discharge points being carried on light pieces of hard rubber and equipped with balls ⅝ in. in diameter. One of the discharge points should be screw controlled through a nut so that the gap may be varied. A drawing of this discharge cap is shown in Fig. 5.

The apparatus upon which high-frequency currents are to be impressed is connected at *X* and the discharge gap shortened, so that when the switch is closed, the discharge jumps across the gap making a very noisy white spark, which is inclined to be calorific and not sharply broken off, but which can be corrected by opening the discharge gap a little, after the discharge is once started. In fact, it will be found to be best to do this to obtain the maximum results. If an inductance consisting of a coil of copper wire, say No. 2-0 trolley wire, be wound 8 in. in diameter and with 6 turns, and connected across the points *X*, the oscillatory current will experience considerable difficulty in traversing it. If a spark gap be shunted around this coil, it will be found that a potential of from 8,000 to 10,000 volts exists there. A vacuum tube of any type will be brilliantly illuminated if connected in shunt around this apparent short circuit. Still

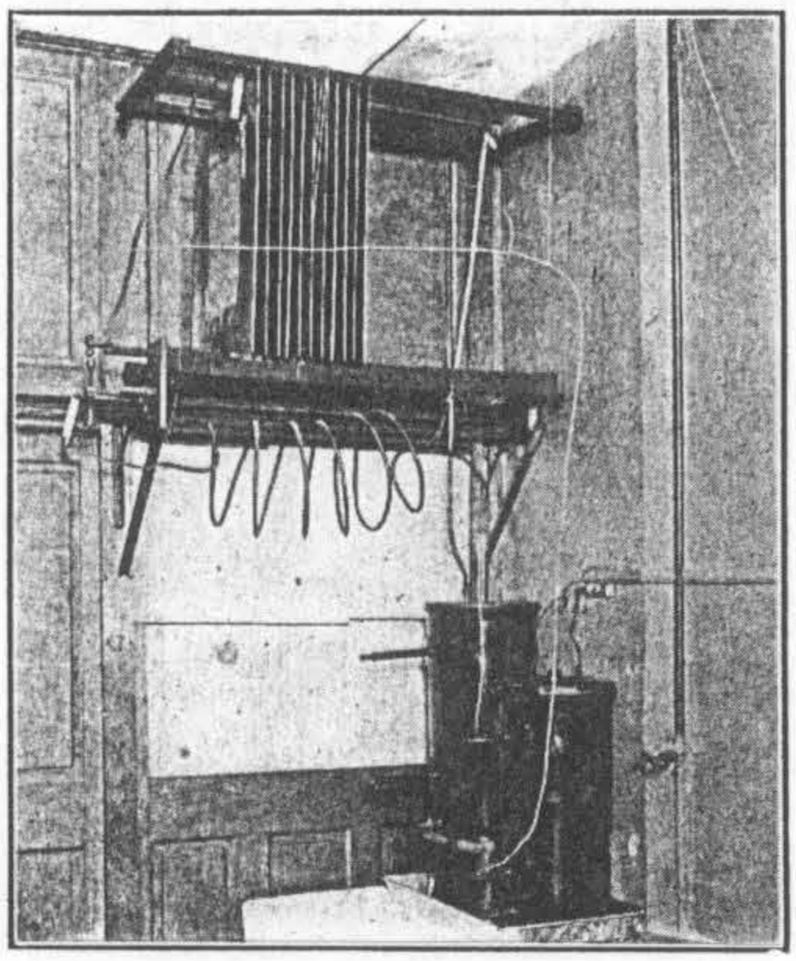


FIG. 6.—FRACTURED GLASS JAR OF TESLA COIL. FIG. 7.—TRANSFORMER AND TESLA COIL. FIG. 8.—GENERAL VIEW OF EQUIPMENT.

more puzzling is the fact that an incandescent lamp connected across the terminals of this coil, and apparently on dead short circuit, will light up brightly, but even under these conditions the experimenter will be presented with the curious phenomenon of the discharge striking across the terminals of the lamp within the bulb and also without, showing the existence of a high potential, and yet the filament will burn as it would under its normal 0.5 amp current.

A piece of No. 36 wire 3 or 4 ft. long, shunted across this coil will become red hot and burn out, and if the wire be coiled in approved magnet fashion on a glass tube with the insulated

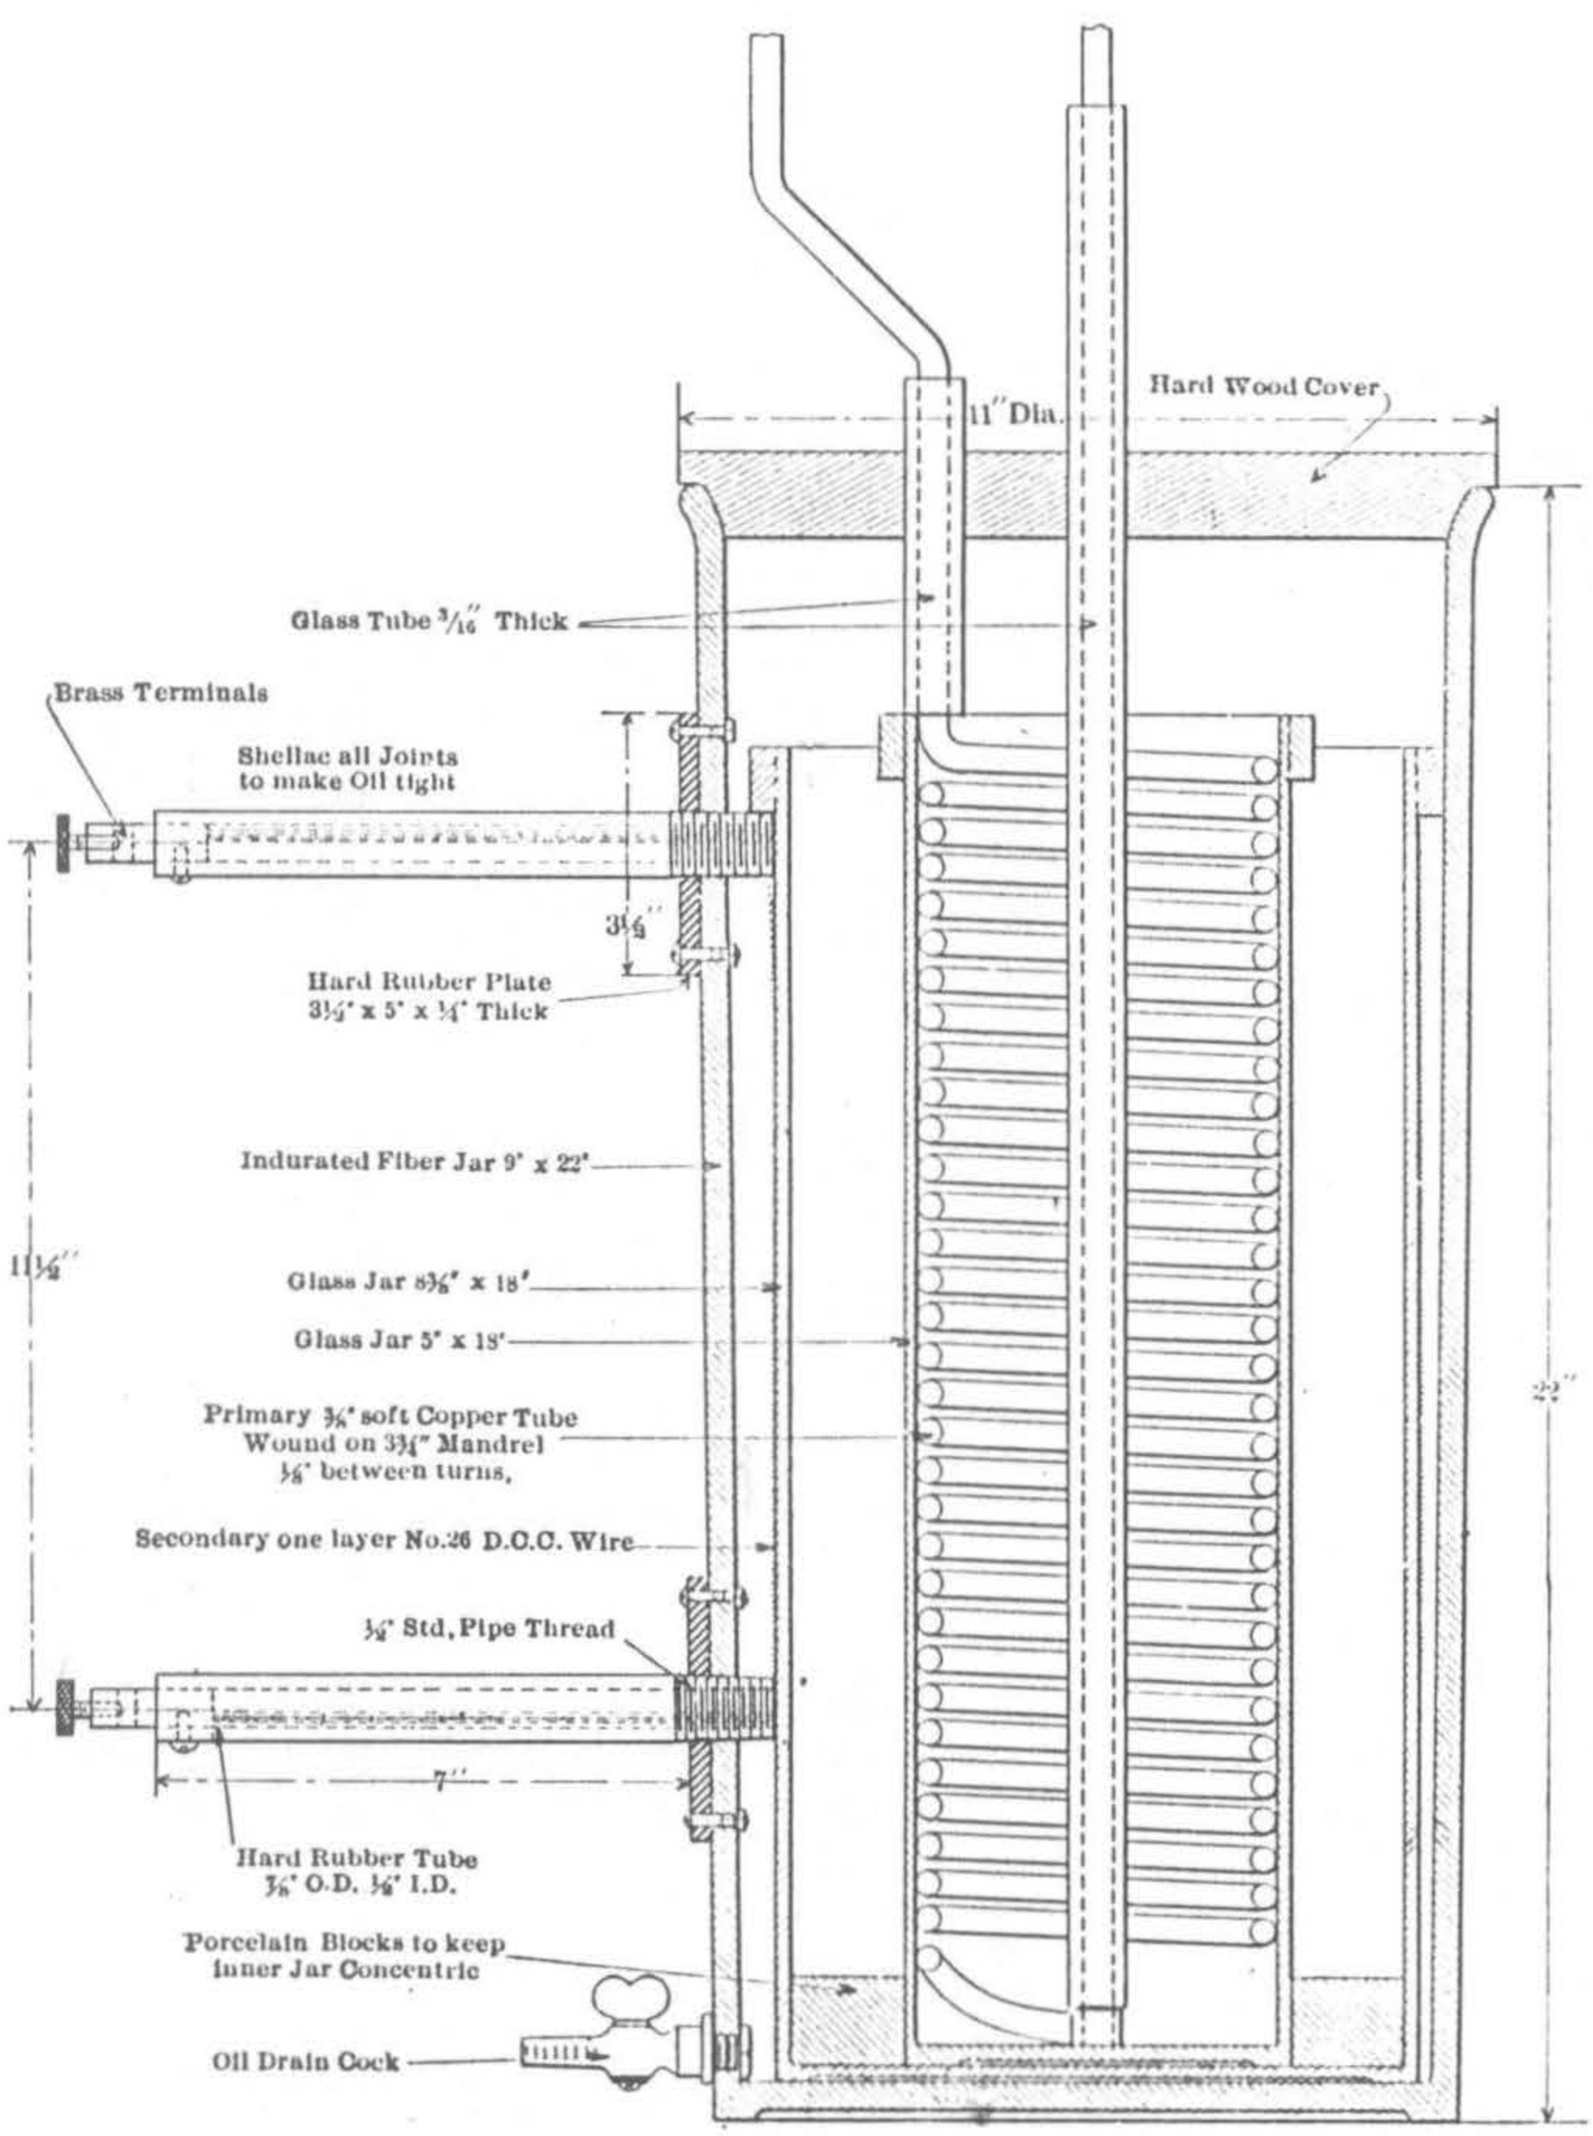

FIG. 9.—DETAILS OF TESLA COIL.

turns in close proximity and connected as above described, the current will jump from turn to turn on the coil rather than go through it. A very pretty experiment can be made by connecting at the point *X* a pair of busbars across which are shunted a spark gap, a vacuum tube, a 110-volt lamp, a 50-volt lamp, and at the extremities of the busbars a dead short circuit. With a little adjustment and manipulation, all of the lamps and tubes will light up simultaneously, while sparks will jump across the gap.

The Tesla experiments are not complete unless the step-up Tesla transformer is constructed. The coil described below is capable of producing voltages in the neighborhood of 150,000, and must, therefore, be insulated with a great deal of care. The primary coil consists of about 30 turns of No. 2-0 trolley wire, or a thin copper tube of the same diameter. This wire or tube is stiff enough to be wound in a single helix, having a return through the center, as shown in Fig. 6. The wire or tube should be coiled inside of a long glass jar, and one of those commonly employed in preserving specimens in alcohol will be found very suitable. The jar shown in the drawing is equipped with a heavy lip, the top of which is ground flat. The primary terminals are brought out through heavy glass tubes through the wooden cover, as shown in the drawing, and connected to the point *X*, Fig. 1.

The secondary coil consists of about 500 turns of No. 26 wire wound upon the outside surface of a second glass jar of considerably larger diameter than the first, but of about the same height. Care should be taken to wind these coils so that they do not pass beyond the high-tension terminals, for if this is not done, the turns beyond are likely to short-circuit against the lead brought up from the bottom of the jar or down from the top as the case may be. The coil should end at the terminals. The jar may be shellacked before winding the coil and allowed to dry, and after the coil is completed, a second coat of shellac should be given to prevent the wire from unwinding when manipulated. Double cotton-covered wire should be used.

The whole outfit may be immersed in oil in an umbrella jar of the same type as was used in the manufacture of the high-tension transformer, but it will be well to bring the terminals out farther in the case of the high-tension transformer, as the discharge is very unmanageable and will be found to strike into anything that may be within convenient reach. If the terminals are too short, the discharge will strike through the indurated fiber and oil back to the coil, and is likely to snap the wire of which the secondary is wound as neatly as if it were cut with a pair of shears. The terminals should be 12 in. apart. Like the case of the high-tension transformer, it is well to equip the jar with a drain cock.

The insulation of the Tesla coil may seem extravagant, but in the writer's opinion it is none too good, and perhaps may be improved upon. In the first experiments, the writer endeavored to construct a coil omitting the central jar, with the result that the jar was heavily punctured, the inside splintered and gnawed by the discharge, and the bottom of the jar was found to contain at least a heaping teaspoonful of powdered glass. This rupture is somewhat interesting for the reason that it was beyond all doubt the result of many successive punctures, and from the length of the rupture it was evident

that the discharge did not simply puncture one hole and enlarge it, but punctured again in another place rather than overcome the inductance of the slightly longer path through the original hole.

Owing to the fact that the high-tension terminals of the Tesla coil make everything in the vicinity of opposite polarity by electrostatic induction, this coil should be well insulated from the ground. This may be conveniently done by setting the whole jar on a heavy piece of marble or glass resting on a second indurated fiber jar. The photograph showing the high-tension coil and the Tesla coil in action illustrates a suitable arrangement. In this case both the high-tension transformer and the Tesla coil are contained in a shallow iron pan.

Vacuum tubes of any length can be illuminated by simple contact with one terminal. The current from these terminals is not dangerous, although the shock obtained by taking both terminals in the hands would probably be somewhat uncomfortable, and it is well to take the discharge, if it is to be taken into the body, through a metal rod so as to avoid burns at the point where the discharge enters. The experimenter may seat himself upon an ordinary wooden stool, keeping his feet clear from the floor, and need not fear to take from one of the terminals of the Tesla coil a fat, hot spark 6 in. long, using, of course, a metal rod to protect his fingers against burning. He may hold in his free hand a wire leading to an ordinary 8-cp incandescent lamp, another experimenter holding the second wire, but standing on the floor. Enough current will be transmitted through his body to light the lamp. Or seated upon the stool in this way, he may ignite the gas with his fingers, or may light vacuum tubes by touching them, or deliver sparks to an observer standing upon the floor; in fact, there is no end of variations of phenomena. In conclusion, the writer would earnestly caution the experimenter to confine these experiments to the discharge from the Tesla coil alone. The terminals of the high-tension transformer are highly dangerous, and any wires connected with them are, of course, equally so, and should be adequately supported and securely placed beyond the range of accidental contact.

[78.]—TESLA COIL.—I should use the larger and longer tubes, and wind the wires with air space between them if possible, to avoid "shorting." I have not found any appreciable difference between good linseed oil and others, and have often used ordinary petroleum with good results. Arthur E. R. Bottone.

Tesla Coil for X-Ray

Questions.—(A) In the high frequency apparatus in the March issue, (answer to E. H. B., Brooklyn) I wish to ask whether this coil can be used for X-ray purposes? (B) If this coil will perform the experiment on page 162 in July issue? (C) Can I use No. 35 wire in place of No. 31, and if so, what would be the effect? (D) How can I build a fluoroscope?—T. R. F., Pryor Creek, Okla.

Answers.—(A) Yes.

(B) No.

(C) Yes, but the Tesla coil would have to be varied to suit the change in the induction coil or transformer, as the coil voltage would be greater but the current less. Therefore a smaller condenser would have to be used, and the Tesla coil wound to suit the condenser. The induction coil described would require more careful insulation between secondary and primary if No. 35 wire were used as the voltage would be greater.

(D) To make a fluoroscope take a sheet of paper or other substance transparent to X-rays and cover it with a fluorescent substance such as tungstate of calcium or platino-barium-cyanide. Mount it in the large end of a stereoscope with the fluorescent surface turned toward the inside.

DECIDES AGAINST AMERICA'S CLAIM.

Tesla Dashes Polar Cup from Nation's Lips—Trip by Dirigible Balloon "Easy."

To the Editor of The Tribune.

Sir: According to a Washington dispatch in your issue of the 26th ultimo, the hydrographic office of the Navy Department is preparing a new map with the North Pole as American territory. Evidently, there is a Moltke in the hydrographic office. Nevertheless, much will have to be done before the claim is recognized by other nations. Permit me to point out a few reasons why it is, for the time being, untenable:

First—"The conquest of the pole" is an act which partakes nothing of the nature of discovery conveying a moral if not legal right to national possession. For centuries the position of that imaginary point was accurately determined, hence its discovery is out of the question. To reach the pole is an achievement noteworthy only because of the hardships and perils involved. It is but a sportsman's exploit, an athletic feat, which entitles the performer to a trophy or price, and nothing more.

Second—The extent of the polar region is still to be defined. That itself may become a subject of unending dispute.

Third—The polar region is located in the centre of an ocean which, be it frozen or not, is international property.

Fourth—The claim is further weakened by the fact that there can be nothing but frozen sea in that region, for the accumulation of water there is an unavoidable consequence of physical laws. This is strikingly illustrated by the old planet Mars, where for the greater part of the year virtually all the water is held in captivity at the poles.

Fifth—The measurements of the explorers were crude and uncertain, the sextant with an artificial horizon having been entirely depended upon to locate the pole. There are numerous obstacles to accurate observation in those regions, but the chief is that the air is filled with minute electrified crystals of ice which cause colorings, mirages and other effects of refraction. Under such conditions an error of as much as fifty miles is possible.

Sixth—There are no competent witnesses to verify the readings and observations. When a truth discovered is readily demonstrable witnesses are unnecessary, but in this particular instance, when immediate repetition of the experience is impossible and all traces are effaced, a corroboration is indispensable.

It is very likely that under the circumstances scientific institutions such as the Geographical Society or Geodetic Survey will accept the reports as nothing more than unconfirmed theories, especially since it must be plain to every member that these up-to-date polar explorations have little in common with the unselfish efforts of the early pioneers, being rather undertakings of daring men attracted by adventure hazard spirited enough to take all sorts of desperate risks for achieving fame and popularity.

In view of the great popular interest, which has been intensified to a degree of national feeling, it is necessary, if this country desires to retain the claim, that another expedition be immediately organized, either by popular subscription or appropriation through Congress. The dirigible balloon has been so far perfected that the exploration of the polar regions by its means is a simple and easy task. In Germany preparations, strongly supported by the Emperor, have already been undertaken, but it is very probable that if this country would signify at once the intention to organize such an expedition its wishes would be respected, for it is an undeniable fact that, however imperfect these recent attempts have been, they go toward laying the foundation to a just national claim, and certainly are a testimony to the wonderful energy and pluck of Americans.

New York, Oct. 1, 1909. NIKOLA TESLA.

VOL. XXIII.—WHOLE NO. 8,042 NEW YORK, TUE

TESLA SAYS HE CAN HARNESS ALL THE WIRELESS CURRENTS

Make Them Operate Airships and Give You Wireless 'Phone to the Ends of the Earth—As Easy to Talk to Australia as to Hoboken.

BY AND BY YOU CAN TALK TO MEN IN AEROPLANES

Won't Need High Towers to Send or Receive the Electric Waves—Ambitious Programme of the Noted Inventor Soon to Be Completed, He Says.

Nikola Tesla, electrical scientist and inventor, is planning to build a great electric power plant which will enable him to operate all the telephone, telegraph, lighting, traction and industrial systems of the earth by wireless currents. His plan also is so far-reaching that it takes in the operation of all aeroplanes and dirigibles and the keeping of them in telegraphic and telephonic touch with the earth at all times by the same method, no matter over what part of the earth they may be sailing or with what part of it they may desire to communicate. By this system, he says, all the wires which now are used to connect telegraph and telephone instruments and electric lights will be eliminated without changing in any degree the other features of the installations, and it will be easier then for a man in New York to step to a telephone and converse by wireless with a man in Melbourne, Australia, than it now is for him to talk by wire across a room.

Tesla was interviewed yesterday in his office at No. 165 Broadway. He said that probably his utterances would be regarded by many persons as those of a visionary, but that time would vindicate them fully.

"Mr. Tesla, I understand you have perfected a system whereby it will be possible to telephone, say, from New York city to Melbourne, Australia, by wireless process without any change in the present installations made by the telegraph and telephone companies.

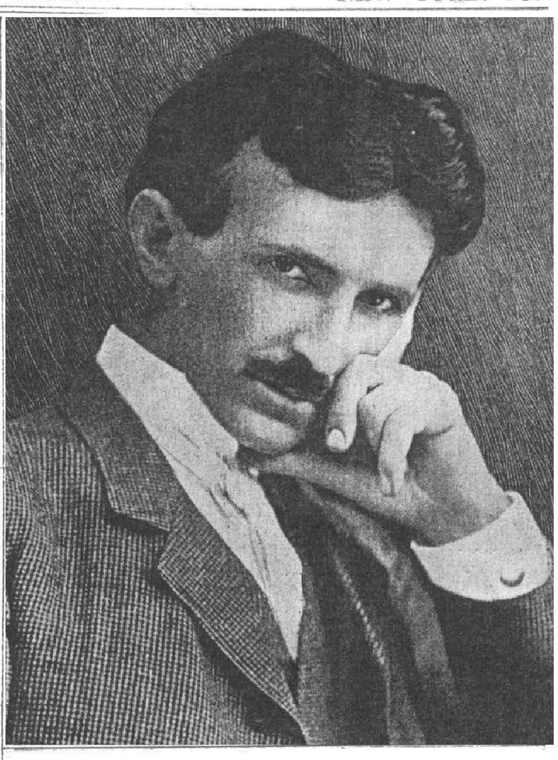
"I am glad to say that such is the case," Tesla replied. "I have worked persistently on the wireless transmission of energy since 1893, when I presented my paper on that subject before the National Electric Light Association in St. Louis and the Franklin Institute in Philadelphia. The popular idea is that the wireless system of transmission is just one invention, but the fact is that it involves in its present state of perfection six fundamental discoveries, or inventions, in combination. They are as follows:

"First—The method and apparatus for transforming ordinary currents into electrical oscillations of great intensity.

"Second—The apparatus for intensifying those vibrations sensibly, so they penetrate into the distance.

"Third—A receiving apparatus which collects and focuses energy which a transmitter supplies to a large territory. For instance, if such receiver, properly constructed be placed in Ireland it will collect practically the entire energy conveyed to that country from the transmitter.

"Fourth—The method and apparatus for making the electrical impulses secret and non-interferable. That is to say, making it impossible to prevent their passage or to read them. The energy of the transmitter, which is collected by the receiver, only can be released by a sort of safety lock or combination.



"Fifth—The production of stationary waves. That is, waves which excite the entire earth and pass through it under a vibration much the same as though you were to draw a string tight and then strike it. With these waves the distance is absolutely eliminated, as the effects are the same whether the receiver is thousands of miles away or close to the transmitter.

"Sixth—A number of inventions which cannot very well be described in a short interview, but which go together to make the system practically operative.

"With a plant constructed under the observance of these principles it will be just as easy to telephone from here to Melbourne, Australia, as across a room, and there will be absolutely no distortion of the voice, such as is observable now in communication by wire. This is not a theory, but a fact absolutely demonstrated by my experiments, which have shown that the current passes without loss over the entire extent of the globe and through the globe. I already have carried the construction of such an installation very far and hope that I shall be able to complete it during the coming summer. From that moment every telegraphic, telephonic as well as every wireless station will be ever so much more valuable, as they will be able to receive messages from any part of the world. All this will be done without the slightest change in the existing equipment."

"Will it be necessary under your plan, Mr. Tesla, to build high towers, on the shores of the countries using it, and also in interior points?" the inventor was asked.

"Not at all," Tesla replied. "In fact, large towers are comparatively ineffective. The tower I have built near Port Jefferson, L. I., is only 187 feet high, but the plant will produce an effect which can be pushed up to a rate of 1,000,000,000 horsepower, which is more than all the wireless plants that have been put up so far altogether. This enormous activity I secured by the use of certain artifices on which I have also based my confidence that it will be possible to flash signals

TESLA SAYS HE CAN HARNESS ALL THE WIRELESS CURRENTS

(Continued from First Page.)

through interplanetary space. To a majority of people such a statement would appear visionary, but I have the utmost confidence that I shall be able to do so."

"How much capital, Mr. Tesla, is invested already on the strength of your inventions bearing on the production of electrical power?"

"In the first place, I do not call these inventions altogether mine," Tesla said. "I have merely laid the foundation. Great work has been done in perfecting my inventions by the staff of engineers of the Westinghouse and General Electric companies, so that at present there are hundreds of millions invested in enterprises in which my alternating system forms the underlying foundation. We have harnessed 6,000,000 horsepower water falls. There are probably enterprises, aggregating 20,000,000 more under consideration. The enormous importance of this water power, or the so-called 'white coal,' a name given to water power, can be understood readily when it is borne in mind that one horsepower for twenty-four hours is equivalent to the average performance of twenty-four men. Therefore, the 6,000,000 horsepower which has been harnessed have virtually added to the world's population from the point of view of labor, 144,000,000 of workingmen, who consume no food and need no clothes."

"But what about the power other than that derived from the waterfalls?"

"I am happy to say that in this direction also I have been successful, having perfected a new reversible gas turbine of ideal simplicity and beauty, which will permit the harnessing of the waste of the steel and iron furnaces, in which we now are losing in the United States not less than 50,000,000 horsepower. I am just about to introduce that invention commercially."

"Will this wireless system of yours permit of the transmission of electric power for purposes of operation?"

"Certainly," the inventor said. "In fact, had it not been for unfortunate circumstances long ago a plant of this kind would have been in operation. Just one single plant, of say 10,000-horsepower, would be sufficient to drive several thousand flying machines, aeroplanes and dirigibles anywhere in the world. While supplying them with wireless power it also would keep them in constant touch with the earth by wireless telephone and telegraph."

"What encourages you, Mr. Tesla, to think that by the application of your principle you will be able to flash interplanetary signals?"

"In my experiments in Colorado, where I discovered certain planetary disturbances, I attained with my transmitter activities which surpassed in power in many ways those of lightning. In my present plant I shall be able to reach a rate of energy delivery of about 1,000,000,000-horsepower. A simple calculation will convince any expert that with such an intensity and energy reaching a certain area of the planet Mars, it is ample to produce a perceptible effect in a delicate instrument there."

"How will they flash back a signal?"

"I think they are flashing already, and waiting for us to answer their signals," Tesla replied, with a seriousness which showed that he believed confidently what he said about the inhabitants of Mars.

Tesla on Wireless Electric Power.

Mr. Nikola Tesla in an interview published Dec. 7 in the New York *Press* discussed the subject of wireless transmission of electric power. He said that he has worked persistently on the wireless transmission of energy since 1893, when he presented a paper on that subject before the National Electric Light Association in St. Louis and the Franklin Institute in Philadelphia. The popular idea, he said, is that the wireless system of transmission is just one invention, but the fact is that it involves in its present state of perfection six fundamental discoveries, or inventions, in combination. They are as follows:

First.—The method and apparatus for transforming ordinary currents into electrical oscillations of great intensity.

Second.—The apparatus for intensifying those vibrations immensely, so that they penetrate into the distance.

Third.—A receiving apparatus which collects and focuses energy which a transmitter supplies to a large territory. For instance, if such receiver, properly constructed, be placed in Ireland it will collect practically the entire energy conveyed to that country from the transmitter.

Fourth.—The method and apparatus for making the electrical impulses secret and non-interferable. That is to say, making it impossible to prevent their passage or to read them. The energy of the transmitter, which is collected by the receiver, only can be released by a sort of safety lock or combination.

Fifth.—The production of stationary waves. That is, waves which excite the entire earth and pass through it under a vibration much the same as though you were to draw a string tight and then strike it. With these waves the distance is absolutely eliminated, as the effects are the same whether the receiver is thousands of miles away or close to the transmitter.

Sixth.—A number of inventions which cannot very well be described in a short interview, but which go together to make the system practically operative.

With a plant constructed under the observance of these principles it will, he said, be just as easy to telephone from here to Melbourne, Australia, as across a room, and there will be absolutely no distortion of the voice, such as is observable now in communication by wire. This, he added, is not a theory, but a fact absolutely demonstrated by his experiments, which have shown that the current passes without loss over the entire extent of the globe and through the globe. He has carried the construction of such an installation very far and hopes to be able to complete its construction during the coming summer.

From that moment every telegraphic, telephonic as well as every wireless station will, he said, be ever so much more valuable, as they will be able to receive messages from any part of the world. All this will be done without the slightest change in the existing equipment.

"Will it be necessary under your plan, Mr. Tesla, to build high towers on the shores of the countries using it, and also in interior points?" the inventor was asked.

As to large towers these, he said, are comparatively ineffective. The tower he has built near Port Jefferson, L. I., is only 187 ft. high, but the plant will produce an effect which can be pushed up to a rate of 1,000,000,000 hp, which is more than all the wireless plants that have been put up so far altogether. This enormous activity is secured by the use of certain artifices on which he also bases a confidence that it will be possible to flash signals through interplanetary space.

Mr. Tesla added that his electric power inventions are not altogether his own, and that he has merely laid the foundation. Great work has been done in perfecting the devices by the staff of engineers of the Westinghouse and General Electric companies, so that at present there are hundreds of millions invested in enterprises in which his alternating system forms the underlying foundation. This has harnessed 6,000,000 hp waterfalls.

There are probably enterprises aggregating 20,000,000 more under consideration. The enormous importance of this water power, or the so-called "white coal," can be understood readily when it is borne in mind that 1 hp for 24 hours is equivalent to the average performance of 24 men. Therefore, the 6,000,000 hp which has been harnessed have virtually added to the world's population from the point of view of labor 144,000,000 of workingmen, who consume no food and need no clothes.

As to power other than that derived from waterfalls, he was happy to say that in this direction also he has been successful, having perfected a new reversible gas turbine of ideal simplicity and beauty, which will permit the harnessing of the waste of the steel and iron furnaces, in which we now are losing in the United States not less than 50,000,000 hp. Mr. Tesla added that he is just about to introduce that invention commercially.

As to his wireless system for the transmission of electric power, he said that if it had not been for unfortunate circumstances a plant of this kind would long ago have been in operation. Just one single plant, of, say, 10,000 hp, would be sufficient to drive several thousand flying machines, aeroplanes and dirigibles anywhere in the world. While supplying them with wireless power it also would keep them in constant touch with the earth by wireless telephone and telegraph.

Referring to interplanetary signals, he said he had in his experiments in Colorado discovered certain planetary disturbances, and attained with his transmitter activities which surpassed in power in many ways those of lightning. In his present plant he will be able to reach a rate of energy-delivery of about 1,000,000,000 hp. A simple calculation will, he said, convince any expert that with such an intensity and energy reaching a certain area of the planet Mars, it is ample to produce a perceptible effect in a delicate instrument there.

In answer to a question as to return signals, he said he believed that these signals are being flashed now and waiting for us to answer.

Nikola Tesla's New Wireless.

Mr. Nikola Tesla has announced that as the result of experiments conducted at Shoreham, Long Island, he has perfected a new system of wireless telegraphy and telephony in which the principles of transmission are the direct opposite of Hertzian wave transmission. In the latter, he says, the transmission is effected by rays akin to light, which pass through the air and cannot be transmitted through the ground, while in the former the Hertz waves are practically suppressed and the entire energy of the current is transmitted through the ground exactly as though a big wire. Mr. Tesla adds that in his experiments in Colorado it was shown that a very powerful current developed by the transmitter traversed the entire globe and returned to its origin in an interval of 84 one-thousandths of a second, this journey of 24,000 miles being effected almost without any loss of energy.

The New York World December 30, 1909

HIS WIRELESS LIGHT A FACT SAYS TESLA.

Cheap to Produce, He Explains, and Lamps Will Last Forever.

Nikola Tesla, who has been at work on a "wireless electric light" for twenty years, announced yesterday that he has practically brought it to a state of perfection. He says a plant for its production is now nearing completion at his laboratory on Long Island.

"It would be possible by my wireless transmitter of great power," said Mr. Tesla, "to light the entire United States. The current would pass into the air and, spreading in all directions, produce the effect of a strong aurora borealis. It would be a soft light, but sufficient to distinguish objects. Some day soon my idea will be carried out. I would like nothing better than to undertake to illuminate first the harbor of New York for a distance of, say, 100 miles around.

Lamps Last Forever.

"My present plan is to distribute this light from a central station, which is the most economical and also the best method of obtaining light of highest quality. My lamps will last forever, there being nothing in them to burn out. They are simply tubes or bulbs of glass hermetically sealed and containing nothing but rarefied gas.

"One advantage is the economy of production, which is greater than in any other light so far obtained. Still another is the wonderful quality of the light, which resembles sunlight so closely that it cannot be distinguished from it. It is very soothing to the eye, being diffused. A great saving will be effected by wireless distribution. I am intending chiefly to supply isolated dwellings which cannot be conveniently reached by wires or lighted in any of the ways heretofore used.

"In this system of distribution there is absolutely no difference where the dwelling is located. The force of the current is the same. The house might be 12,000 miles from the plant or 12 feet, it would be the same. The plant consists of only a little transformer which could easily be carried in the pocket, and will be sufficient to light the whole house. The current may be conveyed to the individual lamps either by wires, or all wires might be dispensed with and the lights rendered portable."

The scientist then explained that the current thus created was a "vibrating" one and was convertible for other purposes.

Other Uses of the System.

"Among other things," said he, "the same current can be used to carry the human voice or the telegraphic code. One plant will do all this without interference of one action with the other. This is done by the use of an invention which I have called the 'Art of Individualization.' This is a method and an apparatus for making signals or messages non-interfering and non-interferable, and it is based on the use of a number of vibrations in combination."

When asked how soon he expects to demonstrate his discovery in a completed form the inventor gave hint of another invention already completed.

"It will not take long to complete my plant," said he, "but I am now compelled to concentrate all my efforts on the introduction of my new steam and gas turbine, which my friends consider the most valuable result that I have accomplished. It has to do entirely with the great question of waste, and I believe, will be a tremendous money saver. Just as soon as I get it started on its way I shall devote all of my time to the wireless."

Those of our readers who have perused the long and thoroughly "documented" lecture of Mr. Marconi will turn with added interest to the words of that other happy worker in the same field. Mr. Nikola Tesla, in an interview with a representative of the New York *Press*, discussed the subject of wireless transmission of electric power. He said that he has worked persistently on the wireless transmission of energy since 1893, when he presented a paper on that subject before the National Electric Light Association in St. Louis and the Franklin Institute in Philadelphia. The popular idea, he said, is that the wireless system of transmission is just one invention, but the fact is that it involves in its present state of perfection six fundamental discoveries, or inventions, in combination. They are as follows :—

First.—The method and apparatus for transforming ordinary currents into electrical oscillations of great intensity.

Second.—The apparatus for intensifying those vibrations immensely, so that they penetrate into the distance.

Third.—A receiving apparatus which collects and focuses energy which a transmitter supplies to a large territory. For instance, if such receiver, properly constructed, be placed in Ireland it will collect practically the entire energy conveyed to that country from the transmitter.

Fourth.—The method and apparatus for making the electrical impulses secret and non-interferable. That is to say, making it impossible to prevent their passage or to read them. The energy of the transmitter, which is collected by the receiver, only can be released by a sort of safety lock or combination.

Fifth.—The production of stationary waves. That is, waves which excite the entire earth and pass through it under a vibration much the same as though you were to draw a string tight and then strike it. With these waves the distance is absolutely eliminated, as the effects are the same whether the receiver is thousands of miles away or close to the transmitter.

Sixth.—A number of inventions which cannot very well be described in a short interview, but which go together to make the system practically operative.

With a plant constructed under the observance of these principles it will, he said, be just as easy to telephone from here to Melbourne, Australia, as across a room, and there will be absolutely no distortion of the voice, such as is observable now in communication by wire. This, he added, is not a theory, but a fact absolutely demonstrated by his experiments, which have shown that the current passes without loss over the entire extent of the globe and through the globe. He has carried the construction of such an installation very far and hopes to be able to complete its construction during the coming summer.

From that moment every telegraphic, telephonic as well as every wireless station will, he said, be ever so much more valuable, as they will be able to receive messages from any part of the world. As this will be done without the slightest change in the existing equipment.

"Will it be necessary, under your plan, Mr. Tesla, to build high towers on the shores of the countries using it, and also in interior points ?" the inventor was asked.

As to large towers these, he said, are comparatively ineffective. The tower he has built near Port Jefferson, L.I., is only 187 ft. high, but the plant will produce an effect which can be pushed up to a rate of 1,000,000,000 h.p., which is more than all the wireless plants that have been put up so far altogether. This enormous activity is secured by the use of certain artifices on which he also bases a confidence that it will be possible to flash signals through interplanetary space.

Mr. Tesla added that his electric power inventions are not altogether his own, and that he has merely laid the foundation. Great work has been done in perfecting the devices by the staff of engineers of the Westinghouse and General Electric Companies, so that at present there are hundreds of millions invested in enterprises in which his alternating system forms the underlying foundation. This has harnessed 6,000,000 h.p. waterfalls.

There are probably enterprises aggregating 20,000,000 more under consideration. The enormous importance of this water power, or the so-called "white coal," can be understood readily when it is borne in mind that 1 h.p. for 24 hours is equivalent to the average performance of 24 men. Therefore, the 6,000,000 h.p. which has been harnessed have virtually added to the world's population from the point of view of labour 144,000,000 of working men, who consume no food and need no clothes.

As to power other than that derived from waterfalls, he was happy to say that in this direction also he has been successful, having perfected a new reversible gas turbine of ideal simplicity and beauty, which will permit the harnessing of the waste of the steel and iron furnaces, in which we now are losing in the United States not less than 50,000,000, h.p. Mr. Tesla added that he is just about to introduce that invention commercially.

As to his wireless system for the transmission of electric power, he said that if it had not been for unfortunate circumstances a plant of this kind would long ago have been in operation. Just one single plant of, say, 10,000 h.p., would be sufficient to drive several thousand flying machines, aeroplanes and dirigibles anywhere in the world. While supplying them with wireless power it also would keep them in constant touch with the earth by wireless telepone and telegraph.

Referring to interplanetary signals, he said he had in his experiments in Colorado discovered certain planetary disturbances, and attained with his transmitter activities which surpassed in power in many ways those of lightning. In his present plant he will be able to reach a rate of energy-delivery of about 1,000,000,000 h.p. A simple calculation will, he said, convince any expert that with such an intensity and energy reaching a certain area of the planet Mars, it is ample to produce a perceptible effect in a delicate instrument there.

In answer to a question as to return signals, he said he believed that these signals are being flashed now and waiting for us to answer.

Tesla's Plan for "Wireless" Electric Lighting.

In a recent newspaper interview Nicola Tesla is reported to have said that as the result of many years' effort his "wireless electric light" has practically been brought to a state of perfection, and a plant for its production is now nearing completion at his laboratory.

"It would be possible by my powerful wireless transmitter," said Mr. Tesla, according to this account, "to light the entire United States. The current would pass into the air and, spreading in all directions, produce the effect of a strong aurora borealis. It would be a soft light, but sufficient to distinguish objects.

"My present plan is to distribute this light from a central station, which is the most economical and also the best method of obtaining light of highest quality. My lamps will last forever, there being nothing in them to burn out. They are simple tubes or bulbs of glass hermetically sealed and containing nothing but rarified gas.

"One advantage is the economy of production which is greater than in any other light so far obtained. A great saving will be effected by wireless distribution. I am intending chiefly to supply isolated dwellings which cannot be conveniently reached by wires, and in this system of distribution there is absolutely no difference where the dwelling is located. The force of the current is the same whether the house is 12,000 miles from the plant or twelve feet."

New Mechanical Principles for the Conservation of Energy

By Nikola Tesla.

NIKOLA TESLA

THE spread of civilization may be likened to that of fire: First a feeble spark, next a flickering flame, then a mighty blaze, ever increasing in speed and power. We are now in this last phase of development.

Human activity has become so widespread and intense that years count as centuries of progress. There is no more groping in the dark or accidental stumbling upon discoveries. The results follow one another like the links of a chain. Such is the force of accumulated knowledge and the insight into natural laws and phenomena that future events are clearly projected before our vision. To foretell what is coming would be no more than to draw logical conclusions, were it not for the difficulty in accurately fixing the time of accomplishment.

The practical success of an idea, irrespective of its inherent merit, is dependent on the attitude of the contemporaries. If timely it is quickly adopted; if not, it is apt to fare like a sprout lured out of the ground by warm sunshine, only to be injured and retarded in its growth by the succeeding frost. Another determining factor is the amount of change involved in its introduction. To meet with instant success, an invention or discovery must come not only as a rational but a welcome solution. The year 1910 will mark the advent of such an idea. It is a new mechanical principle.

Since the time of Archimedes certain elementary devices were known, which were finally reduced to two, the lever and the inclined plane. Another element is to be added to these which will give rise to new conceptions and profoundly affect both the practical and theoretical science of mechanics.

This novel principle is capable of embodiment in all kinds and classes of machinery. It will revolutionize the propulsion apparatus on vessels, the locomotive passenger car and the automobile. It will give us a practical flying machine entirely different from those made heretofore in operation and control, a contrivance having nothing in common with the aeroplane or dirigible, swift, small and compact and so safe that a girl will be able to fly in it to school without the governess. But the greatest value of this improvement will be in its application in a field virtually unexplored and so vast that it will take decades before the ground is broken. It is the field of waste.

We build but to tear down. Most of our work and resource is squandered. Our onward march is marked by devastation. Everywhere there is an appalling loss of time, effort and life. A cheerless view, but true. A single example out of many will suffice for illustration.

The energy necessary to our comfort and safe existence is largely derived from coal. In this country alone nearly one million tons of this life-sustaining material are daily extracted from the bowels of the earth with pain and sacrifice. This is about seven hundred tons per minute, representing a theoretical activity of, say, four hundred and fifty million horse-power. But only a small percentage of this is usefully applied.

In heating, most of the precious energy escapes through the flue. The chimneys of New York City puff out into the air several million horse-power. In the use of coal for power purposes, we hardly capture more than 10 per cent. The exhaust of engines carries off more energy than obtained from live steam.

In many modern plants the power has been actually doubled by obviating this waste, but the machinery employed is cumbersome and expensive. The manufacture of light is in a barbarous state of imperfection and this may also be said of many industrial processes. Consider just one case, the manufacture of iron and steel.

America produces approximately 30,000,000 tons of pig iron per year. Each ton of iron requires about one and a half tons of coke and each ton of coke one and a half tons of coal, hence, in providing the iron market, 70,000,000 tons of coal per annum, or 133 tons per minute, are consumed. In the manufacture of coke a ton of coal yields, roughly, 10,000 cubic feet of gas of a mean heating value of 600 heat units per cubic foot.

Bearing in mind that 133 tons are used per minute, the total heat units developed in that time would be 798,000,000, the mechanical equivalent of which is about 19,000,000 horse-power. By the use of the new principle 7,000,000 horse-power might be rendered available. A similar condition exists in the blast furnaces, which are but gas retorts. A furnace of 200 tons produces approximately 17,000 cubic feet of gas per minute of a heat value of 100 units, corresponding to a theoretical performance of 40,000 horse-power, of which not less than 13,000 might be utilized in the improved apparatus referred to. The power derived by this method from all blast furnaces in the United States would be considerably above 5,000,000 horse-power.

The preceding figures, which are conservative, show that it would be possible to obtain 12,000,000 horse-power merely from the waste gases in the iron and steel manufacture. The value of this power, fairly estimated, is $180,000,000 per annum, and it must be made worth much more by systematic exploitation.

A part of the power could be advantageously employed for operating the blowers, rollers and other indispensable machinery and supplying electricity for smelting, steel making and other purposes. The bulk might be used in the manufacture of nitrates, aluminium, carbides and ice. The production of nitrates would be particularly valuable from the point of view of national economy. Assuming that 5,000,000 horse-power were apportioned for that purpose, the annual yield would be not less than 10,000,000 tons of concentrated nitric compound adequate to fertilizing 40,000,000 acres of land. A great encouragement would be given to agriculture and the condition of the steel and iron workers ameliorated by offering to them fertilizer at a reduced rate, thus enabling them to cultivate their farms with exceptional profit. Other conveniences and necessities, as light, power, ice and ozonized water, could be similarly offered and numerous other improvements, both to the advantage of capital and labor, carried out.

To appreciate the above it should be borne in mind that the iron and steel industry is one of the best regulated in the world. In many other fields the waste is even greater. For example, in the operation of steam railroads not less than 98 per cent. of the total energy of coal burned is lost. An enormous saving could be effected by replacing the present apparatus with new gas turbines and other improved devices for transmitting and storing mechanical energy. A study of this subject will convince that for the time being, at least, there is more opportunity for invention in the utilization of waste than in the opening up of new resources.

NOTES.

"LIGHT OF THE WORLD."

Under the above alluring title, the daily Press of New York and London have been discussing Signor Tesla's latest pronouncement on his achievements in the development of lighting by electricity. Having regard to the great amount of work that has been done in the way of testing various gases stored in air-tight glass globes for the production of some phenomena equivalent to incandescence (as in the case of mercury vapour lamps), and also the not altogether unsuccessful experiments of transmitting electricity by means of air-borne waves to filament lamps placed at a distance, one must hesitate to declare the clever Italian to be a visionary. We must, however, await an official statement from the inventor before attaching great importance to the subject in its present phase. All that Signor Tesla requires are hermetically sealed glass bulbs enclosing a rarified gas, and a central station where electricity would be generated, and then sent by means of his special "wireless" transmitter through the air, in order to energise the imprisoned gas into emitting light. His light would be diffused light, as soft and generalised as the sun rays.

TESLA'S METHODS.

If he has been correctly reported, Tesla is on the eve of creating a revolution in electric lighting that will cause the metallic filament lamps to pale their ineffectual fires, and give rise to more trouble among central station men than they have ever known before. He would not hesitate to undertake the lighting of the whole of the United States by means of his wireless transmitters, and rather longs to have a shot at illuminating New York harbour, for a hundred miles or so from one station, by means of lamps that will burn for ever.

ISOLATED HOUSE LIGHTING.

Meanwhile, Tesla proposes to come to the rescue of those who live isolated, far from city conveniences. To use his, or the reporter's, words: "I am intending chiefly to supply isolated dwellings which cannot be conveniently reached by wires or lighted in any of the ways heretofore used. In this system of distribution there is absolutely no difference where the dwelling is located. The force of the current is the same. The house might be 12,000 miles away from the plant or 12 ft., it would be the same. The plant consists of only a little transformer, which could be easily carried in the pocket, and will be sufficient to light the whole house. The current may be conveyed to the individual lamps either by wires, or all wires might be dispensed with and the lights rendered portable. The current used is a 'vibrating' one, and can be used for other purposes. Among other things, the current can be utilised for carrying the human voice or the telegraphic code. One plant will do all this without interference of one action with the other. This is done by the use of an invention which I have called the 'art of individualisation.' This is a method and an apparatus for making signals or messages non-interferable, and it is based on the use of a number of vibrations in combination."

[904.]—TESLA COIL.—Make an affair similar to a three- or four-legged stool; only, choose good, dry wood, and boil it in paraffin-wax, so that you have two discs, separated by the legs. Inside the legs wind the primary spiral, and on the outside wind on the secondary wire. Connect the terminals of your coil through spark-gaps to the primary wire, and take off your high-frequency current from the secondary winding. Arthur E. R. Bottone.

What Science May Achieve this Year.

New Mechanical Principles for the Conservation of Energy

By Nikola Tesla.

NIKOLA TESLA

THE spread of civilization may be likened to that of fire: First, a feeble spark, next a flickering flame, then a mighty blaze, ever increasing in speed and power. We are now in this last phase of development.

Human activity has become so widespread and intense that years count as centuries of progress. There is no more groping in the dark or accidentally stumbling upon discoveries. The results follow one another like the links of a chain. Such is the force of the accumulated knowledge and the insight into natural laws and phenomena that future events are clearly projected before our vision. To foretell what is coming would be no more than to draw logical conclusions, were it not for the difficulty in accurately fixing the time of accomplishment.

The practical success of an idea, irrespective of its inherent merit, is dependent on the attitude of the contemporaries. If timely it is quickly adopted; if not, it is apt to fare like a sprout lured out of the ground by warm sunshine, only to be injured and retarded in its growth by the succeeding frost. Another determining factor is the amount of change involved in its introduction. To meet with instant success an invention or discovery must come not only as a rational, but a welcome solution. The year 1910 will mark the advent of such an idea. It is a new mechanical principle.

\+ \+ \+

SINCE the time of Archimedes certain elementary devices were known, which were finally reduced to two, the lever and the inclined plane. Another element is to be added to these, which will give rise to new conceptions and profoundly affect both the practical and theoretical science of mechanics.

This novel principle is capable of embodiment in all kinds of machinery. It will revolutionize the propulsion apparatus on vessels, the locomotive, passenger car and the automobile. It will give us a practical flying machine entirely different from those made heretofore in operation and control, swift, small and compact and so safe that a girl will be able to fly in it to school without the governess. But the greatest value of this improvement will be in its application in a field virtually unexplored and so vast that it will take decades before the ground is broken. It is the field of waste.

\+ \+ \+

WE build but to tear down. Most of our work and resource is squandered. Our onward march is marked by devastation. Everywhere there is an appalling loss of time, effort and life. A cheerless view, but true. A single example out of many will suffice for illustration.

The energy necessary to our comfort and safe existence is largely derived from coal. In this country alone nearly one million tons of this life-sustaining material are daily extracted from the bowels of the earth with pain and sacrifice. This is about seven hundred tons per minute, representing a theoretical activity of, say, four hundred and fifty-million horsepower. But only a small percentage of this is usefully applied.

In heating, most of the precious energy escapes through the flue. The chimneys of New York city puff out into the air several million horsepower. In the use of coal for power purposes, we hardly capture more than 10 per cent. The exhaust of engines carries off more energy than obtained from live steam.

In many modern plants the power has been actually doubled by obviating this waste, but the machinery employed is cumbersome and expensive. The manufacture of light is in a barbarous state of imperfection, and this may also be said of many industrial processes. Consider just one case, the manufacture of iron and steel.

\+ \+ \+

AMERICA produces approximately 30,000,000 tons of pig iron per year. Each ton of iron requires about one and a half tons of coke, and each ton of coke one and a half tons of coal, hence, in providing the iron market, 70,000,000 tons of coal per annum, or 133 tons per minute, are consumed. In the manufacture of coke a ton of coal yields, roughly, 10,000 cubic feet of gas of a mean heating capacity of 600 heat units per cubic foot.

Bearing in mind that 133 tons are used per minute, the total heat units developed in that time would be 798,000,000, the mechanical equivalent of which is about 19,000,000 horsepower. By the use of the new principle 7,000,000 horsepower might be rendered available. A furnace of 200 tons produces approximately 17,000 cubic feet of gas per minute, of a heat value of 100 units, corresponding to a theoretical performance of 40,000 horsepower, of which not less than 13,000 might be utilized in the improved apparatus referred to. The power derived by this method from all blast furnaces in the United States would be considerably above 5,000,000 horsepower.

The preceding figures, which are conservative, show that it would be possible to obtain 12,000,000 horsepower merely from the waste gasses in the iron and steel manufacture. The value of this power, fairly estimated, is $180,000,000 per annum, and it must be made worth much more by systematic exploitation.

\+ \+ \+

A PART of the power could be advantageously employed for operating the blowers, rollers and other indispensable machinery and supplying electricity for smelting, steel making and other purposes. The bulk might be used in the manufacture of nitrates, aluminum, carbides and ice. The production of nitrates would be particularly valuable from the point of view of national economy. Assuming that 5,000,000 horsepower were apportioned for that purpose, the annual yield would be not less than 10,000,000 tons of concentrated nitric compound, adequate to fertilizing 40,000,000 acres of land. A great encouragement would be given to agriculture and the condition of the steel and iron workers ameliorated by offering to them a fertilizer at a reduced rate, thus enabling them to cultivate their farms with exceptional profit. Other conveniences and necessities, as light, power, ice and ozonized water, could be similarly offered and numerous other improvements, both to the advantage of capital and labor, carried out.

To appreciate the above it should be borne in mind that the iron and steel industry is one of the best regulated in the world. In many other fields the waste is even greater. For example, in the operation of steam railroads, not less than 98 per cent of the total energy of coal burned is lost. An enormous saving could be effected by replacing the present apparatus with new gas turbines and other improved devices for transmitting and storing mechanical energy. A study of this subject will convince that for the time being, at least, there is more opportunity for invention in the utilization of waste than in the opening up of new resources.

QUESTIONS AND ANSWERS

Use of this department is free to readers of Popular Electricity, but attention will not be given to questions which do not comply with the following rules: All questions must be written in the form of a letter addressed to the Questions and Answers Department and containing nothing for the other departments of the magazine; two-cent stamp must be enclosed for answer by mail, for space will not permit of printing all answers; the full name and address of the writer must be given.

Definitions; Pupin and Tesla Coils; Mercury Vapor Lamps

Questions.—(A) What is the difference between a spark coil and an open core transformer? (B) (1) What is inductance? (2) Impedance? (3) Reluctance? (4) Admittance? (C) What is a Tesla coil? (D) What is a Pupin coil? (E) Are mercury vapor lamps made to work on both 110 volts alternating and direct current? How many watts per candle-power do they consume?—M. S., Fort Worth, Texas.

Answers.—(A) A spark coil is built along the same lines as an open core transformer, and is a transformer. The ratio of transformation is usually much lower in the ordinary transformer than in the spark coil. In the latter a make-and-break contact with a condenser connected across this contact greatly increases the length, thickness, and brilliancy of the spark which is intermittent, while in the transformer a steady flow of current from the secondary is usual.

(B) (1) In general by inductance we mean that inexplicable formation of lines about a wire or coil of wire which a magnetic needle tells us are there when a current flows in the wire or coil. These lines represent energy and exercise an inductive effect on adjacent wires. (2) Circuits always have resistance as well as inductance. The combined effect of the two is called impedance and is expressed by the formula:

Impedance in ohms =

$$\sqrt{R^2 + (2x3.1416xfxL)^2}$$

in which

R = resistance of the circuit
f = frequency
L = inductance.

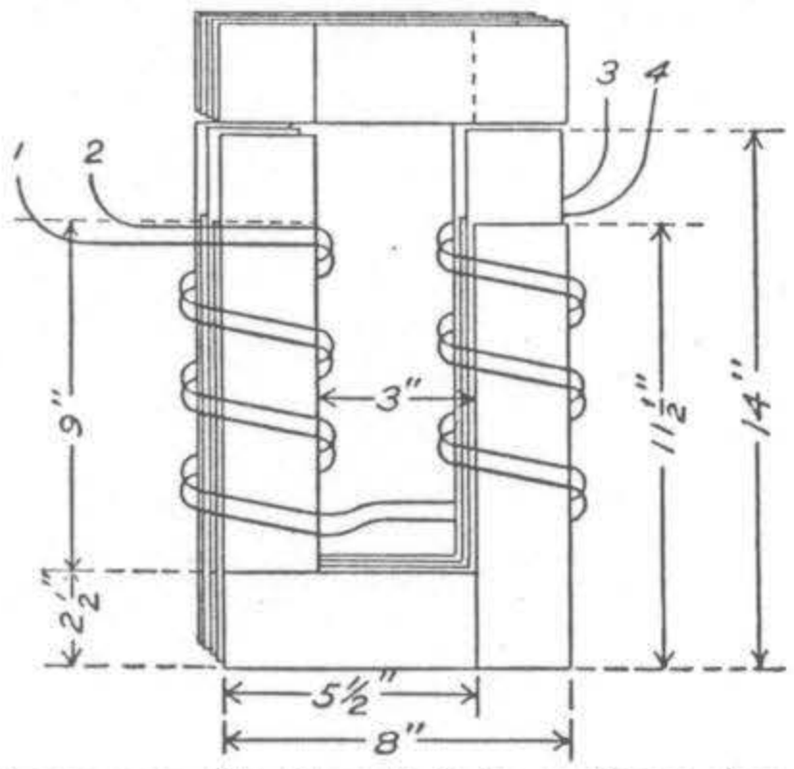
(3) The term reluctance applies to the resistance offered by a magnetic path to the flow of lines of force. For example, the reluctance of wrought iron is less than that of cast iron, the former requiring less ampere-turns to produce a given flux. (4) If I represents the impedance of a circuit in ohms, $\frac{1}{I}$ is its admittance. Used in figuring problems regarding A. C. circuits in parallel, into which calculations resistance, inductance and capacity enter.

(C) A form of induction coil built to give high potentials and high frequencies. This coil and the method of operation is described fully in the January, 1909, issue.

(D) In a long telephone cable the speaking current is distorted, due to the static capacity of the conductor, and is also blurred if the frequency is high. To balance this capacity and get rid of the blurred sound effect, Professor Pupin places an ordinary coil of wire containing a laminated iron core in each circuit at intervals one-eighth of a mile apart. By the introduction of this inductance the talking current is modified so that the proper sounds are registered at the receiving end.

(E) Mercury vapor lamps are made for either direct or alternating current, but the same lamp can be used only upon the kind of current for which it is designed. Lamps requiring 110 volts take 3.5 amperes or 385 watts, the candle-power ranging according to type from 300 to 800.

[407.]—TESLA TRANSFORMER.—I don't know enough about Tesla transformers to answer the first part of the question; but alternating current can be transformed with very slight loss, either up or down, by suitable transformers. With regard to the second part of the question, I don't think any two stations use exactly the same construction of aërial. Mostly phosphor-bronze stranded wire of ⅛in. diameter is used. A large number of stations use the umbrella antenna, some the fan, some inverted L, and others T-shape. In some cases, where multiple wires are used, they are arranged in the same plane, separated by bamboo spreaders; in other stations the spreaders are arranged as a ×, and the wires, therefore, form a sort of long box. The Admiralty seem to favour the latter type. I use the former, as fewer spreaders are necessary, which makes for less windage and weight.



Twickenham. W. J. Shaw.

Popular Electricty December 1910

Construction of a Tesla High-Frequency Apparatus

Many requests are received for information on the construction of a Tesla coil and transformer to go with it. As this requires specific directions of some length we believe it advisable to reprint the article by Mr. H. L. Transtrom which appeared in the January, 1909, issue of Popular Electricity. This article contains all the information necessary to construct a coil and transformer with which to perform the usual high frequency experiments such as lighting a sixteen candle-power lamp one terminal of which is held in the hand and the other connected to one terminal of the Tesla coil, the production of fantastic brush discharges, the melting of fine wire by high frequency current passed through the body, lighting of a vacuum tube, etc. The outfit may also be used for medical work and wireless telegraphy. Following is a description of the apparatus:

A transformer is needed, giving 10,000 to 20,000 volts to charge the condenser. To

Connect No.2 and 4 together for series connection and for parralell No.1 & 2, And also 3 and 4.

FIGURE I. TRANSFORMER FOR HIGH FREQUENCY WORK

construct one it is necessary to make a core from soft sheet iron strips, with a cross-section 2½ inches square, built in the shape of a rectangle eight by fourteen inches outside dimensions and three by nine inches inside (see Fig. 1).

Cut from the sheet iron, strips 2½ by 5½ inches and 2½ by 11½ inches, a sufficient number to make a mass five inches thick of each size when compressed in a vise.

Then take three strips at a time and build a core of the dimensions given in Fig. 1, leaving the top section unfinished until the secondary coils are placed in position.

To hold the core in shape after it is assembled, take two pieces of dry wood twelve by three by 1½ inches and bore a hole in the ends of each, nine inches apart. Put one board on each side of the bottom section and place in a vise, when the six-inch bolts can be drawn tight and then the core will be rigid.

On the vertical sections wrap tightly two or three layers of friction tape to within 2½ inches from the top. Over this wrap a couple of layers of Empire cloth.

The primary consists of 110 double turns wound in a single layer over the Empire cloth, the conductors being two No. 12 cotton-covered copper wires placed side by side, 55 double turns on each vertical section (see Fig. 1).

Over the primary winding next wind tightly 15 layers of No. 7 Empire cloth nine inches wide and we are ready for the secondary winding.

In winding the secondary much care must be exercised, as a transformer's insulation is no better than its weakest spot. This secondary consists of 20,000 turns of No. 32 single cotton-covered copper wire wound in eight coils of 2,500 turns each, which are connected in series, four coils on each side.

The coils are rectangular in shape 1¼ inches wide, four inches square inside and six inches square outside dimensions. They are wound on a form 1¼ inches wide and four inches square, the lateral edges being slightly rounded off to facilitate winding. This form is carefully centered and a metal rod about six inches long of any convenient size is passed through, with a small crank fastened on one end. To keep the coil from sliding out of shape make two disks seven inches in diameter, and when centered screw one on each side of the form.

Set this form between two supports and begin winding, first a layer of Empire paper

and then a layer of wire alternately, until the 2,500 turns are on. It will be found very easy to wind this fine wire in layers if it is allowed to slide over a rod a foot or so away and guided with one hand while winding with the other. Leave a margin of ¼ inch in each layer.

All coils should be tested to see if there are any bare places or if the wire is in one continuous piece. If not, do not attempt to use it as it will surely burn out when run a short time. When all coils are completed they should be dried in an oven, not too hot, and then laid flat in hot petroleum and boiled for several hours, and then left to cool in the mixture until set, which will take quite a long time.

When thoroughly cold, take carefully out of the mixture and after taking the surplus off the coils, assemble on the core over the primary, four on each side. To keep the coils insulated from each other, cut 36 squares of Empire cloth seven by seven inches and cut out of their centres a hole that will fit snugly over the Empire cloth on the primary. Use six thicknesses between adjacent coils, there being only six places to use these separators.

The coils should all be connected in series as though it were one continuous wire beginning at the top of one section and ending at the top of the other. (See Fig. 1.)

Connect all coils so that they have the same relation to one another as the turns in the primary. Keep the coils one inch from the bottom of the core by inserting narrow strips of birch wood across the binding boards and cover with several thicknesses of Empire cloth.

When all the coils are assembled and connected properly, the top part of the core may be completed. A sheet of micanite nine by four by 0.1 inches should be used to separate the vertical sets of coils. Make a box of close-grained hardwood seven by

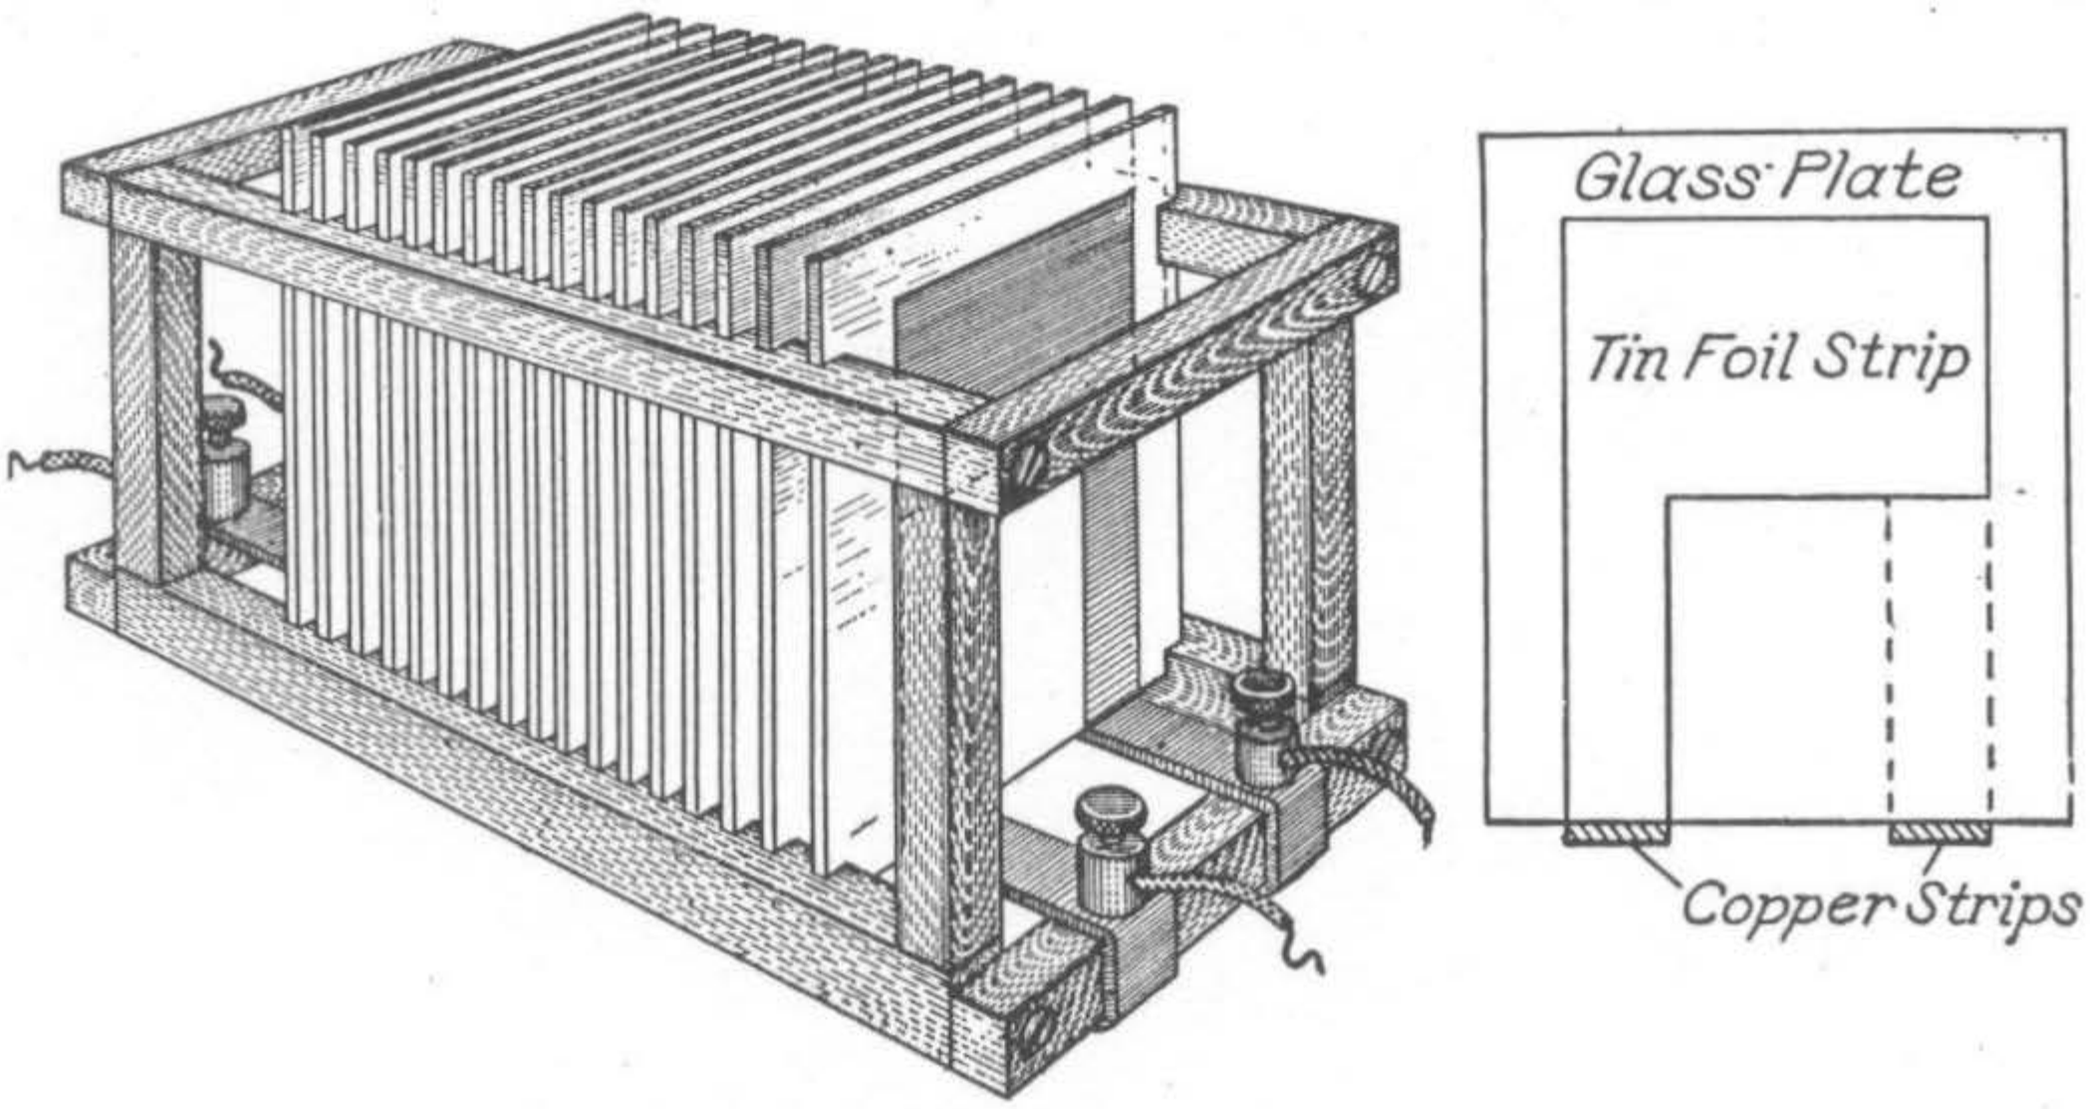


FIG. 2—CONDENSER FOR HIGH FREQUENCY APPARATUS

fifteen by fourteen inches inside measurements and coat thoroughly with hot paraffine to make it perfectly tight.

When the transformer is set in the box it may be fastened by screws to the bottom binding boards.

Bring the ends of the primary wires to one side of the box and the secondary to the other side where they can be connected to proper binding posts. The secondary wire should be kept clear from the core and be led out through hard rubber rod binding posts. The four primary wires should be arranged so that they can be easily connected either in series or parallel.

Boil 40 pounds of extra amber petroleum and fill the box to the top and screw fast the cover and the transformer is complete.

Next we construct an adjustable condenser of seventeen plates of double thickness window glass ten by twelve inches. Coat all the plates with tin foil five by six inches on both sides. Leave a margin of two inches on top and sides and five inches on the bottom. On eight of these plates

paste a strip of tin foil on the lower right hand corner to reach the bottom and on the other nine paste them on the lower left hand corner of the foil. These are the connectors which rest on two copper strips laid parallel four inches apart on the bottom of the crate with binding posts on each end. The strips are fastened on and insulated from the bottom of the wooden crate, with slots in the sides to receive the plates. (See Fig. 2.)

The Tesla coil consists of a primary of seven turns of No. 6 bare copper wire and a secondary of 180 turns of No. 22 bare copper wire wound in a single layer on a drum six inches in diameter and fourteen inches long made of dry birch boards glued together in a circle and then turned off in a lathe. The turns of wire are carefully spaced apart 1-16 inch when winding, leaving a margin of ½ inch on the ends. The primary is wound on a wooden drum eight inches in diameter and 4½ inches long, the turns being carefully spaced apart and fastened. The secondary coil is set on top of the primary coil and the base fastened to the bottom drum.

Give the secondary winding a coat of orange shellac, being careful not to disturb the turns while doing so. A nice turned top can be added for appearance, and a brass rod four inches long and ⅜ inch thick driven tightly in the centre of the top and well rounded off, will be the discharge rod, being connected to the top end of the secondary wire.

The lower end of the secondary terminates in another binding post.

On the primary a binding post is fitted at only the upper end, while the other connection is a sliding contact.

For a spark gap take a glass jar about six inches in diameter and eight or ten inches in height and make a hole in the bottom ¼ inch in diameter. To do this take clay or putty and lay a thick layer over the centre of the bottom of the jar. Make a ¼-inch hole in the clay down to the glass and fill with hot solder. The glass will fall out the shape of the hole in the putty or clay.

Make a cover from some nice hardwood to fit tightly in the top of the jar, and bore a hole in the centre, in which fasten securely a threaded ¼-inch nut which is connected by a wire to a binding post on one edge of the cover.

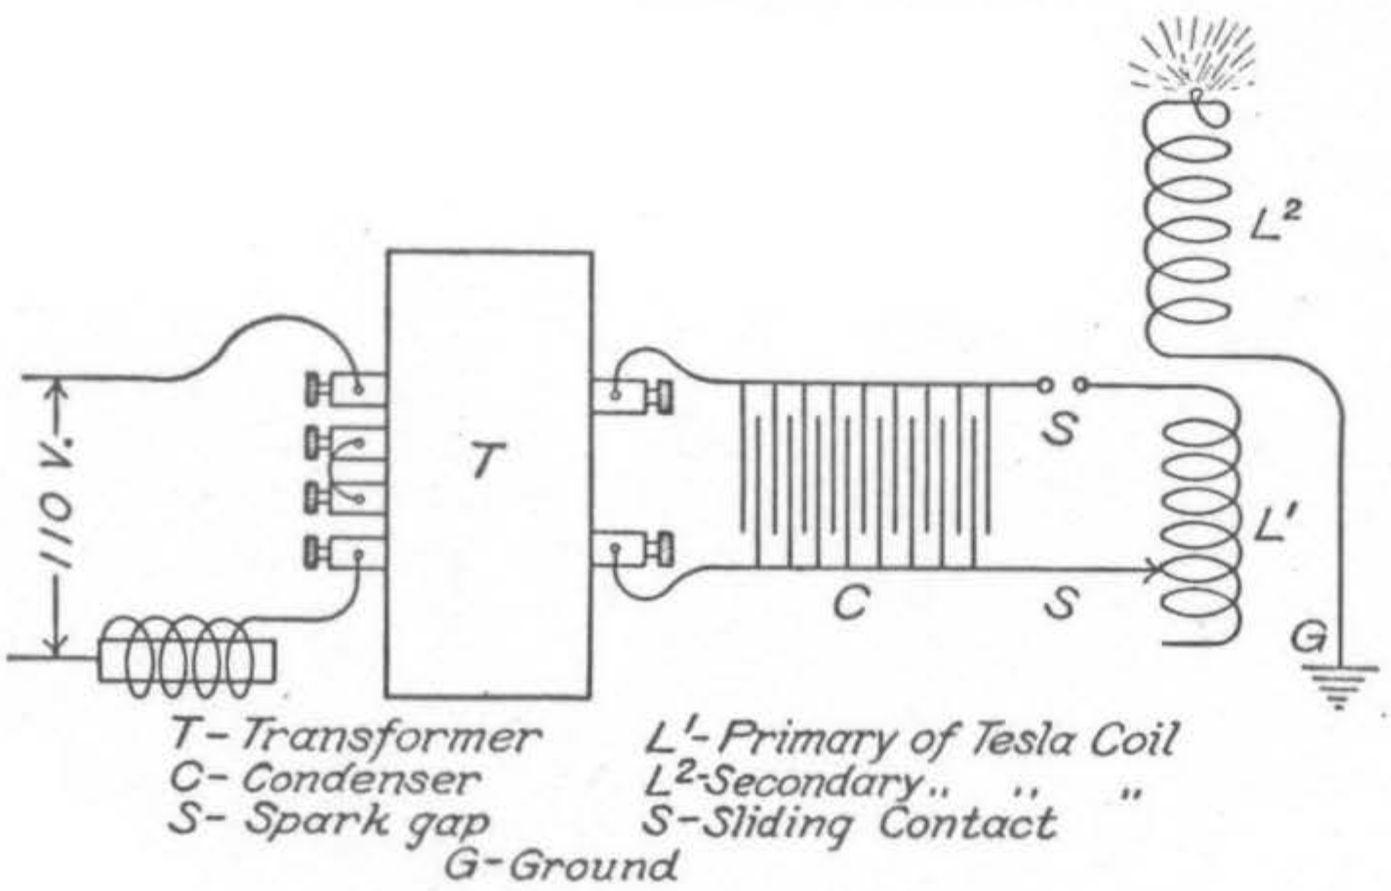

FIG. 3. CONNECTIONS OF TESLA OUTFIT

A ¼-inch rod threaded the whole length is fitted with a hard rubber handle ¾ by three inches long. This is screwed in the threaded nut. The length of rod depends on the height of jar used. Another rod is fitted with a metal ball ¾ inch in diameter and inserted in the hole in the bottom and then through a base of hardwood on which a binding post is placed.

Now to operate the completed apparatus connect as per diagram, Fig. 3.

Connect the lower terminal of the secondary of the Tesla coil to a good ground with stranded wire, as a stranded wire is a better conductor for high frequency currents than is solid wire.

Although good results can be obtained by using the primary in parallel on 110 volts, 60 cycles, consequently 20,000 volts secondary voltage, yet as good results with better control may be had by using the primary sections in series and an adjustable choke coil in series with them. The choke coil can be made from a mass of sheet iron 2½ by 2½ by eight inches, which is inserted in a hollow coil of No. 10 copper wire of 110 turns.

By inserting the core in the coil the current can be varied according to the depth inserted. This outfit is for the uni-polar or single pole method of generating high

frequency currents. If all connections are correctly made the spark gap should be turned until the spark will just jump easily, then on the primary of the Tesla coil move the sliding contact on the second turn from the top, then onto the next turn and so on until the desired results are obtained.

To light a lamp use the fourth or fifth turn and slide the lamp along the side until the brightest light is obtained.

Always disconnect the primary of the transformer before attempting to adjust the different parts.

By adding condenser plates or taking them out of the crate, one by one, the coils will be brought in tune under certain conditions.

Funnelless Ships, Engineless Aeroplanes, Rainfalls in the Deserts, Annihilation of Armies All to Be Controlled by the Man at the Button, Say the Scientists—A Dream of Wireless Energy Soon May Be Realized.

By W. S. Couch.

THE problem of energy solved!

That is the latest promise of Nikola Tesla to the world.

Within a year this wizard of the wires promises to demonstrate that he can deliver electrical energy without the help of wires from any point to any point in the world for domestic and commercial use. The Boer in Pretoria will be able to buy his house light and heat from Denver.

Tesla promises the perfection of the airship by his system.

"It will abolish war," he declares.

A recent London cable told of an address by Prof. Ferranti before the Institution of Royal Engineers, in which the scientist predicted remarkable and undreamed of developments in electricity. Prof. Ferranti talked of a universal supply at a minimum of the present cost, and he spoke of controlling weather with the cheap current thus generated.

Nikola Tesla smiled when this despatch was shown to him.

"Yes," he said, "I know Prof. Ferranti, and I know to what he refers. It is the general problem of electricity, the basic problem of wireless electricity, on which we have all been working. I am satisfied that I have solved it, and I hope to demonstrate my success within a year. The possible regulation of the weather is a comparatively easy feature. We'll harness Nature with the electric flash.

"Even a schoolboy can see how the directed use of a practically unlimited electrical current can affect the weather. Rain could be produced, for instance, without difficulty. What appeals to the imagination more is the possibility that an electrical current could be sent to any point, at any distance, without wires. You need put no limit on your imagination when you let it turn on that idea."

A talk with Nikola Tesla is like an interview with a Jules Verne, who has the scientific equipment to make his remarkable fiction come true in real life. In that connection it is worth noting again that modern science has reduced a good deal of the Verne fiction to hard, sound fact. Tesla has undertaken to supply both the fairy story and the magic touch which makes all real in the final transformation scene.

Prof. Ferranti said in his London address that "all things now achieved by coal could better be done with electricity. Consequently all coal should be converted into electricity at a few big centres and retailed from them. This would save annually 90,000,000 tons of coal."

"What Prof. Ferranti says about coal is fundamental," commented the New York scientist. "But you must not forget the water power, more important than coal, of which the professor does not speak. England has not water powers, but they are to be a most important factor in future American development. The harnessing of these water powers and the delivery of their energy is the great industrial problem of to-day."

Official Washington devoted a large part of its attention to this same problem last winter. The Ballinger-Pinchot controversy was one of the big questions for Congress and the National Administration to settle. It hinged in part on the future value to the nation of coal in Alaska, but also and to a much greater extent on the water power possibilities there and on the public lands in the West. Gifford Pinchot promised the greatest dividends to the public from this property of theirs if they would hold title to it. The "riches" and the "bank account" and the "resources" of the nation, he called those Western waterfalls.

Should Nikola Tesla succeed in making good his prophecy no glowing words that Pinchot ever spoke would equal the result. The coal and water power of Alaska are out of the reach of the United States to-day, and it is difficult for the people of Alaska to get the benefit of them. As far as that is concerned, no man has yet shown the country a way to distribute the energy of water power to any extent. The many falls of the Western mountains already harnessed have their distribution limited by the heavy wire that must carry the current, the cost of the circuit, and, still more, by the loss of the current the further it is carried.

Water power companies, as a rule, have yet to pay dividends, or at least respectable ones. The harnessing of Niagara Falls, even, has failed to produce the gold mine which was confidently expected. This present limit on water power, and the general failure of water power companies to realize on anything like their expectations, was the chief argument offered by the opposition to Gifford Pinchot's attitude. Pinchot's answer has been to hold on and wait. Tesla promises to end the waiting within the year.

"There ought to be nothing to startle people in the proposal to transmit electrical energy as I promise to do it," smiled Nikola Tesla. "The history of electrical development has been a continued story of what the public thought impossibilities becoming practical methods. It is obvious that improvement now lies along the path of transmission of the current without waste. I have contributed my current carried in hydrogen gas underground. That system guards against all loss of energy. It is underground, however.

"The people have seen wireless telegraphy grow from a theory to the practical working of the wireless. In this system, however, the wave lengths are sent broadcast. They radiate in every direction.

"If transmission without loss or waste of energy is possible and practical; and if wireless transmission is possible and practical, is the transmission of electrical energy through the air and without loss of energy an impossible feat for the imagination? Such transmission, of course, would have to have direction, and an easily controlled direction. It would not do to turn your energy loose to radiate to any point as the wireless waves are turned loose. Obviously this would mean a dissipation of the energy which it is desired to conserve.

"I do not propose now, hastily and in a interview, to describe my discovery. During the coming year I expect to give my demonstration, and then there will be time enough for its discussion in detail and in scientific and accurate terms. Take my word for it, though, the problem is solved.

"Think what possibilities it offers," added the inventor, after a moment's reflection. "What will it mean to the development of aeroplanes and aerial flight? It takes off the limit for the flyers.

"I had been studying the problem of the air with an eye to just this thing for many years before the present aviators succeeded in floating themselves, rather to the surprise of students. I had believed they must wait for just this command of electrical energy of which I have been speaking. They must wait for it now to make any real conquest of the air. The improvement of the automobile, with its improvement of the gasoline engine, has given them a motive power. This gasoline engine, if you will stop and think, is the only new thing right now in airships. The wings, the frame, the shape, everything but the light, effective motor power, had been perfected for a long time. You can find books printed many years ago, years before the Wright brothers began to experiment, with pictures of all these curious, birdlike shapes and forms built in canvas and light framework with which we are now growing daily more familiar.

"The gasoline engine, adapted from the automobile, gave the experimenters of to-day their long-desired motive power. They applied it promptly to the construction of their predecessors, and they are flying. This flying of to-day, however, is elemental, like a child learning to walk. It is strictly limited by the faults of the engine, imperfect as it is and limited in its capabilities even at its most perfect point.

"Such possibilities in the use of electrical energy as I intend to demonstrate will instantly enlarge the field of aeroplane flight to an extent which I hesitate to predict."

"Will the airman have a lighter engine?" the inventor was asked.

Tesla laughed outright.

"No engine at all," he declared. "But you must not ask for details. I am not ready to explain my discovery.

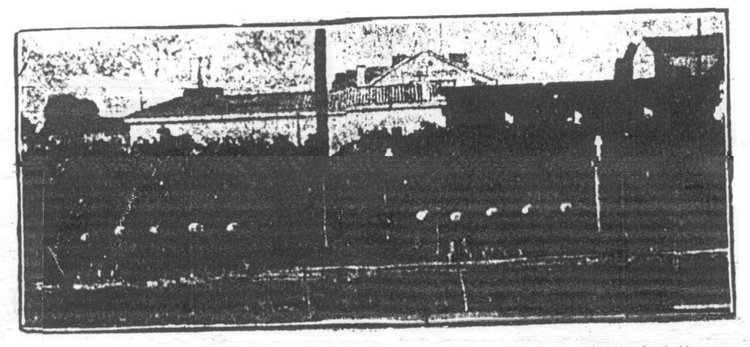
"The matter of war is easy," he replied to a question asking light on his statement that his discovery ought to end such conflicts. It does not require a diagram, does it, to see how impossible such control of electrical energy as I have described would make war, either on sea or land? I have told you that this energy can be sent from the Rocky Mountains to South Africa to light the home of some Boer. This without wires and without waste. Can you imagine the terrible result of such a power directed against an army or a battleship? It will never have to be so directed, I assure you."

It is necessary when you listen to Nikola Tesla talking electricity and the possibilities of its future use to remember that this man's hand is now in the machinerw of almost every motor in operation. That gives you an anchor for your mind in what is now an every-day something.

"But the motor was once looked upon as a visionary thing," laughs Tesla. He challenges the public to respectful attention for his prophecies on the evidence of past electrical miracles now come to be everyday realities. The new efforts at invention and application are no more impossible or bizarre, Tesla declares, than established achievements of to-day seemed to be in their inception.

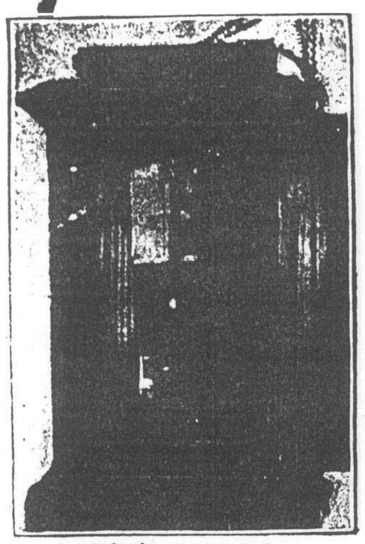
Tesla's proposition to handle electrical current without wires but under control over any distance is not put forward by him as a remarkable or extraordinary thing.

"If you follow the development of study and experiment with electricity or any world force," he says, "you will not be surprised when the work reaches its logical results."



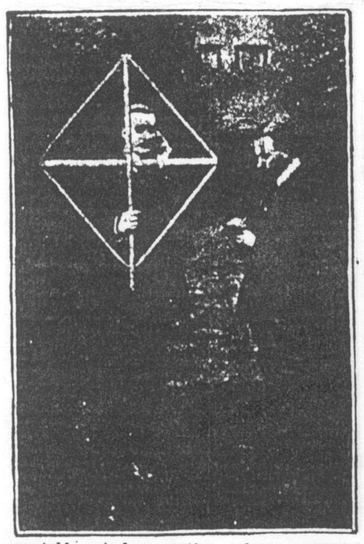
Tesla was early at the wireless. He soon proposed to transmit sight as well as sound. His proposition was not merely to send a photograph over the wires, which has been done, but actually to enable parties to a long distance telephone conversation to see each other as they talked. Perhaps his next proposal was a "cold storage" insulation of wires. By running them underground, through water, he undertook to eliminate the waste of electrical energy in transmission. Tesla was a pioneer in the study of X-rays, or Roentgen rays, as they have come to be known. He made recognized improvements here. He evolved a system of illumination without wires or globes. He devised an electrical oscillator, which he applied, or planned to apply, in connection with several of his other devices. He had a multiple motor intended to handle most economically the power of Niagara Falls.

Then broader motions attracted his attention. He argued for the use of electricity as a farm fertilizer. He discussed the use of a sea automaton for use in naval warfare. This motor boat was to be directed from the shore by a delicately sensitized plate and used with deadly and irresistible effect against the enemy. Tesla announced what he thought was a communication with Mars. At least his instruments registered what he believed he could demonstrate was a message from Mars. Tesla published a plan for the communication of sound without wires. He suggested that electricity could be used in disease for the destruction of all bacilli, that it could possibly cure consumption.



Now he proposes such a handling of electrical power as would revolutionize the world.

"Why not?" demands Tesla. "If the principle is the same, what difference does the size of the problem make?"



Tesla's idea, then, appealing as it is to the layman, will meet the instant challenge of many of his fellows in the world of volts and insulations.

Expiration of the Tesla Split-Phase Patents.

Two patents, generally known as the "Tesla split-phase patents," which have excited a great deal of attention and caused much litigation in the electrical industry will expire on Dec. 26, 1910. Both of these patents were issued to Nikola Tesla on Dec. 26, 1893. They were numbered 511,559 and 511,560 and related to the same invention, the former being a "process" patent and the latter a "system" patent. Patent No. 511,559 was entitled "Electrical Transmission of Power" and patent No. 511,560 bore the title "System of Electrical Power Transmission." Applications for both were filed on Dec. 8, 1888, and both were issued to Nikola Tesla, of New York, assignor to the Tesla Electric Company.

The first patent embraced two claims relating to the split-phase rotating field in the operation of alternating-current motors. In the second patent seven claims were allowed and the principal one of these covered a generator of alternating currents, a circuit therefrom, a motor having a field with two energizing circuits, means for rendering the magnetic effects of these two energizing circuits of different phase, and an armature in inductive relation thereto.

The Tesla Electric Company was composed of Mr. A. S. Brown and some other gentlemen who were interested in the inventions of Mr. Tesla. Tesla had previously invented the rotating-field principle for alternating-current generators and the patents covering this invention were issued in 1888 and expired in 1905. The two split-phase rotating-field patents were assigned to the Westinghouse Electric & Manufacturing Company before they were issued and about the year 1898 were included in the patent arrangement between the Westinghouse Electric & Manufacturing Company and the General Electric Company by which each of these companies agreed to extend to the other the use of its patents.

The split-phase patents were of great importance in the manufacture of alternating-current watt-hour meters and of small alternating-current motors. The Westinghouse Company began the manufacture of meters and small motors, utilizing the principle of the Tesla split-phase rotating-field patents. Suits for infringement under the patents were begun about 1896 or 1897 and for ten years or more thereafter the litigation was a familiar one in the patent law courts and in the electrical industry generally. Ultimately the United States courts of appeals upheld the patents in the First, Second, Sixth and Seventh Circuits. In all perhaps twenty suits were brought under these patents.

The defendants sued for infringement made a vigorous defense, asserting that Ferraris and others anticipated Tesla's invention of the split-phase rotating field, but the courts held that the patents were valid. The patents had their greatest effect on the meter industry and under the decisions of the

courts of last resort it was necessary that the maker of every alternating-current watt-hour meter should be licensed under these patents, as it was assumed to be necessary to employ the principle of Tesla's invention to make a practicable alternating-current watt-hour meter. Patents Nos. 511,559 and 511,560 will become public property on Dec. 26, 1910, and the invention therein described can be used freely by anyone after that date. Whether, however, supporting and "protective" patents will be brought forward to prevent such use remains to be seen.

Philosophical Society London - Proceedings
February 1911

XII. *Some Resonance Curves taken with Impact and Spark Ball-Dischargers.* *By* J. A. Fleming, *M.A., D.Sc., F.R.S.* *and* G. B. Dyke, *B.Sc., A.M.Inst.E.E.*

Read January 27, 1910.

In the course of the experiments on the energy losses in condensers traversed by high-frequency currents described in the previous Paper,* we had occasion to take many measurements with the cymometer of the frequency and inductance of the secondary circuit used in which oscillations were created by a primary circuit used both with the impact and with the ordinary spark-ball discharger. It then became an easy matter to take sufficient observations to delineate a complete resonance curve in each case. As these curves give a very interesting insight into the operations taking place in the secondary circuit and as they confirm the ordinary theory of the oscillation transformer, and, moreover, exhibit the striking difference between the action of an impact and of an ordinary spark-ball discharger, we have delineated for each such case a family of resonance curves taken over a certain range of frequency and with various degrees of coupling. The arrangements for experiments were just as described in the previous Paper, only the secondary circuit was moved to or from the primary to vary the coupling and the cymometer circuit was in all cases loosely coupled to the secondary circuit. The resistance of the secondary circuit was varied so as to give in one case a small decrement of about 0·01 per semi-period and in the other case a much larger decrement of 0·09 per semi-period. The spark-gap was 1 mm. in length and acted upon by a steady blast of air to produce uniform discharges.

The current in the cymometer circuit was measured by a hot-wire thermoelectric ammeter. In the diagrams given the vertical ordinates represent this cymometer current in milliamperes. The decrement of the cymometer itself was about 0·03. The impact discharger used was that described in the previous Paper on "Energy Losses in Condensers traversed by High-Frequency Currents" (*loc. cit.*).

The curves in Fig. 1 delineate the resonance curves taken with the ordinary spark-gap and with such resistance in the secondary circuit as to give a semi-period decrement of 0·01. The different curves correspond to different degrees of coupling k of the primary and secondary circuits, as shown in the diagram. When the coupling is about 33 per cent. the resonance curve 1 shows three well-marked maxima or humps. The frequency corresponding to the middle hump is the natural free period frequency of the secondary circuit. The frequencies of the other two maxima on either side correspond to the two oscillations which are created by the reaction between the primary and secondary circuits.

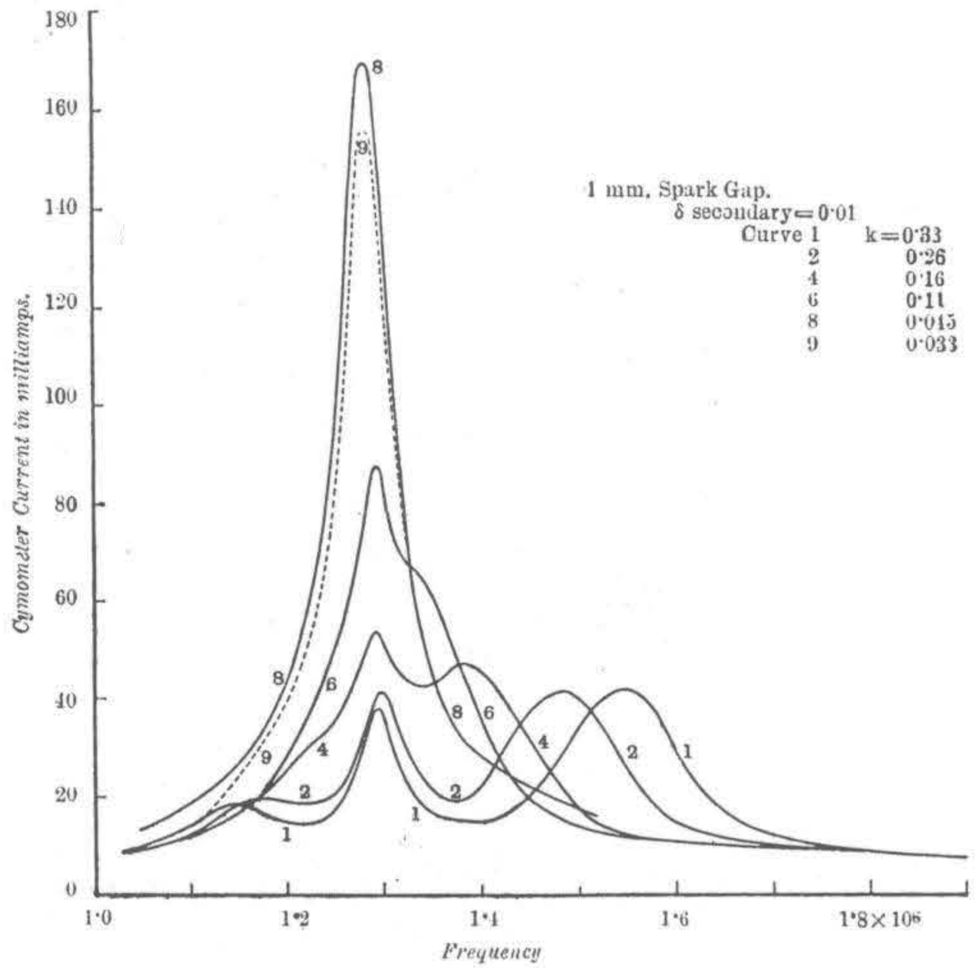

Fig. 1.

These three frequencies have such values that the square of the free frequency is the mean of the squares of the other two frequencies. This confirms and agrees with theory; also the calculated value of k agrees fairly well with that deduced from the two frequencies. As the coupling is reduced respectively to 26 per cent. and 16 per cent., we have the resonance curves 2 and

* "The Measurement of Energy Losses in Condensers traversed by High-Frequency Electric Oscillations." By J. A. Fleming and G. B. Dyke.

4 from which it is seen that the amplitudes of the two period oscillations are decreasing and the free oscillation survives. When the coupling is reduced to 11 per cent. there remains only a very slight indication of a forced oscillation. If the coupling is weakened still more we have only the free oscillation left and the secondary current comes to a maximum for a coupling of about 5 per cent. Beyond that weakening the coupling decreases the maximum current in the secondary circuit. If we take off the values of the maximum cymometer currents in each curve and plot these as ordinates of

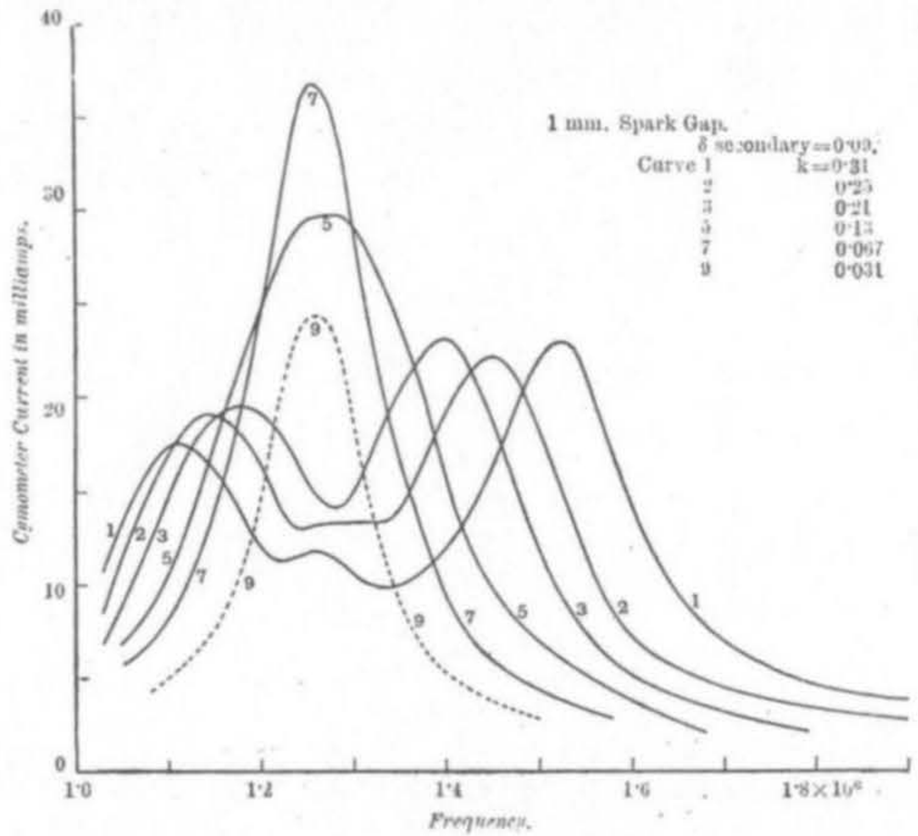

Fig. 2.

another curve to abscissæ representing the coupling, as done in Fig. 5, we have a curve (the upper dotted curve marked "spark") which shows us how the current in the secondary circuit varies with the coupling between the secondary and the primary. It has a well-marked maximum value for about 5 per cent. coupling.

The family of resonance curves in Fig. 2 is taken with the same spark-ball discharger in the primary circuit but with resistance added to the secondary circuit to increase its semi-

period decrement to 0·09. It will be seen that for a coupling of 31 per cent. there is a trace of a free vibration, but the predominant oscillations in the secondary are the two-period oscillations. As the coupling is weakened the free oscillation makes its appearance, but it is not until the coupling is weakened to 13 per cent. that the free oscillation alone survives.

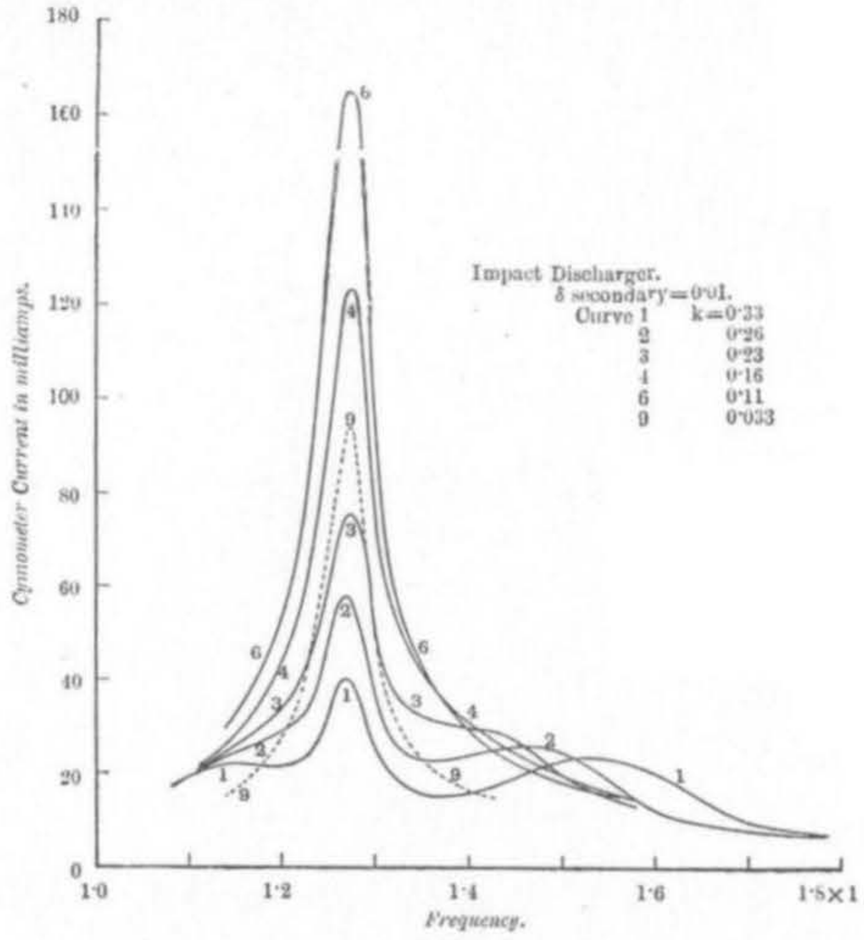

Fig. 3.

When the coupling is reduced to about 7 per cent. we have the maximum currents in the secondary circuit.

These observations were then repeated, using the impact discharger, and the same general phenomena are observed, as shown by the curves in Figs. 3 and 4, with the difference that for a secondary decrement of 0·01 the free secondary oscillation makes its appearance when the coupling is as strong as 25 per cent., and when the secondary decrement is 0·09 the free secondary oscillation alone appears even when the coupling is 20 per cent.

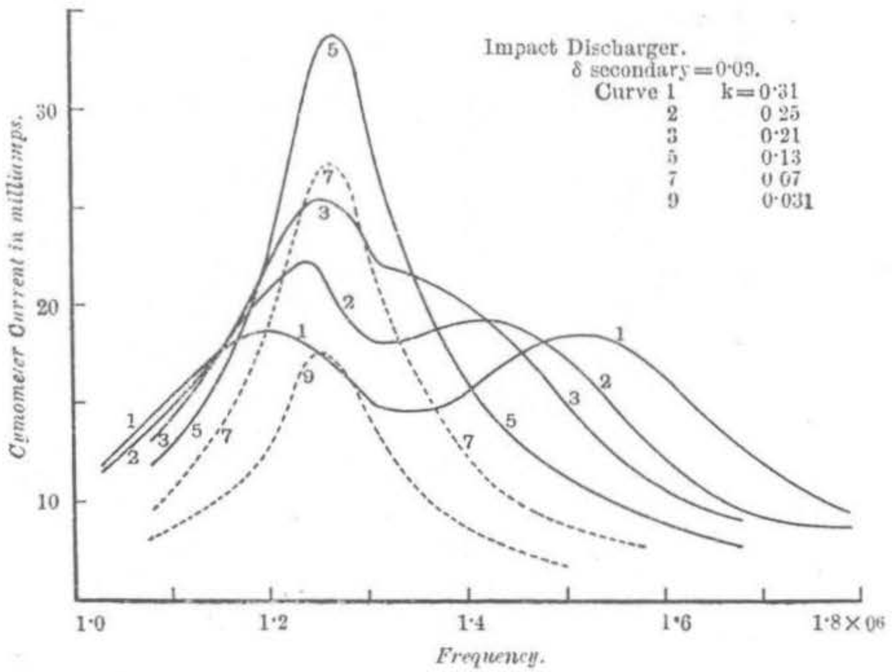

FIG. 4.

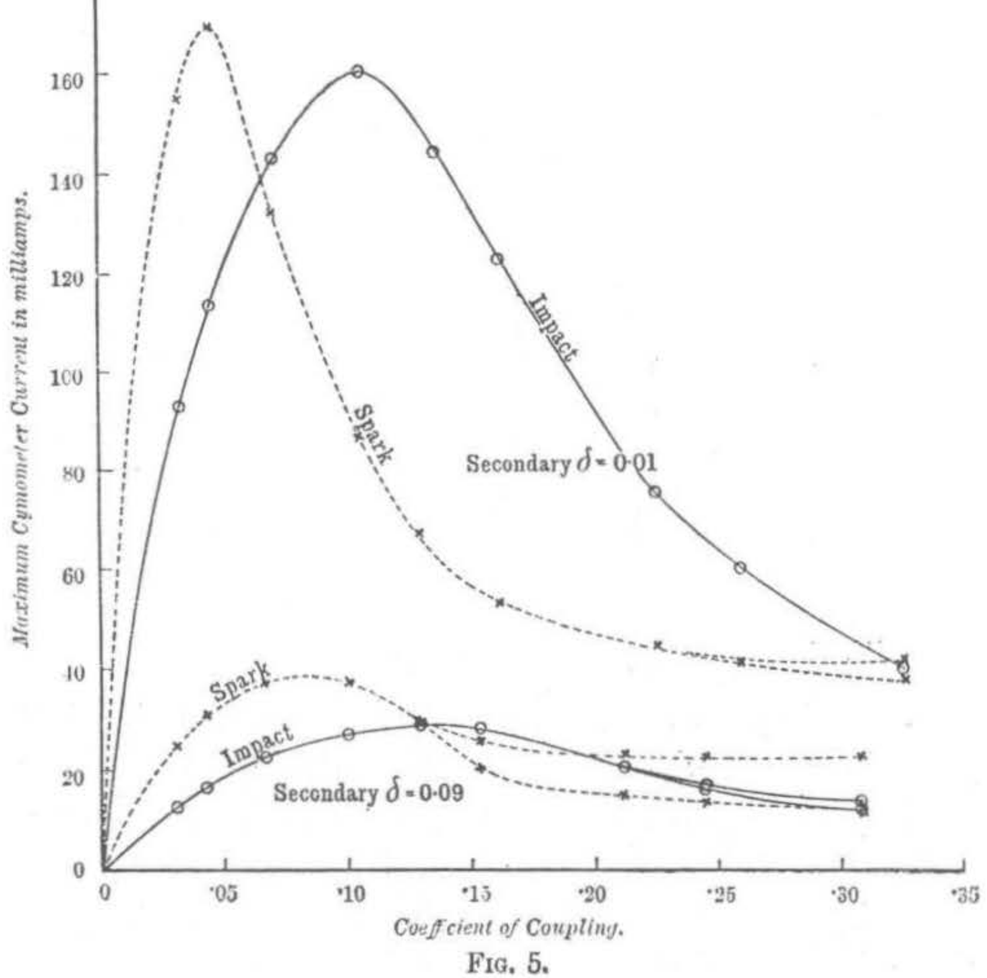

FIG. 5.

The firm line curves in Fig. 5 represent the variation of the secondary current as the coupling between primary and secondary varies. The advantages of the impact dischargers may therefore be summed up by saying that with it we can have closer coupling between the primary and secondary circuit and yet retain the advantage of having no other oscillations set up in the secondary circuit than its natural free oscillation. This, however, omits all consideration of the number of the discharges and of the efficiency of the transmitter as a whole. Closeness of coupling always is an advantage in increasing plant efficiency, provided we can secure it without setting up forced oscillations in the secondary which annihilate the sharp peak of the resonance curve and therefore render sharp tuning between a receiving station and that particular transmitter impossible.

ABSTRACT.

In the course of the experiments described in the previous Paper on the measurement of energy losses in condensers a large number of measurements had to be made with the cymometer of the frequency of oscillations in, and the inductance of, the secondary or condenser circuit. It was then an easy matter to draw complete resonance curves in each case, and this has accordingly been done with both the impac and spark ball dischargers in the primary circuit and for various resistances in the secondary circuit. The results are interesting as showing exactly what takes place in each case in the primary circuit. If we are using the spark ball discharger, and if the primary and secondary circuits are coupled with various degrees of coupling, then, for any close coupling, we find on the resonace curve three peaks which correspond, respectively, as regards frequency, with the free oscillation period of the secondary and with the two-period oscillations set up by the reaction of the secondary upon the primary circuit. As the coupling is weakened the double-period oscillations die out, and only the free oscillation of the secondary survives. There is always a certain coupling, not far from 10 per cent., which gives the maximum current in the secondary circuit in the form of a free oscillation. If the secondary circuit is more highly damped, then the two-period oscillations are more strongly marked, and the maximum free period oscillation has a lesser maximum value.

If we are using an impact discharger the double-period oscillations are only apparent when the coupling exceeds about 30 per cent., and die away with a very little reduction in the coupling, leaving the predominant free secondary oscillation as the survivor. These curves show how very quickly the primary spark is quenched when using the impact discharger. If the maximum secondary current is set up as ordinates in terms of the coupling as abscissa we obtain curves which rise up quickly to a maximum value and fall again, and which indicate that the maximum value of the secondary current is determined both by the coupling and the secondary decrements.

DISCUSSION.

Mr. A. CAMPBELL remarked that the want of constancy of the effective resistance as the current is changed seemed to be out of agreement with the results of other recent observers. Various condensers have been tested at the National Physical Laboratory at frequencies of 800 and 2,000 $\sim$ per second by Carey Foster's method. No divergence from the square law is found from 0·5 to 6 volts. It would be surprising if the square law did not hold at 500,000 to 1,000,000 $\sim$ per second. The formula employed by Dr. Fleming to give ρ can scarcely be expected to give accurate results, since so much depends upon the small difference $A_1 - A_2$. Monasch ("Electrician," June and July, 1907) has shown most conclusively that for frequencies about 80 $\sim$ per second the losses in glass and ebonite condensers (and also in cables) were exactly proportional to the square of the effective voltage between 1,000 and 8,000 volts. He has pointed out that the heating of the dielectric by the power spent in it very often appears to cause variation from the square law. Stöckly ("La Lumière Electrique," July, 1909) has recently found that the decrement of a Moscicki condenser rose from 0·0165 at 10°C. to 0·021 at 40°C.

Mr. W. DUDDELL expressed surprise that with low potential gradients the energy loss was not proportional to V^2. Increase of the losses in a rather peculiar way with the frequency—not necessarily proportional—was to be expected. He cited his experiments made with high frequencies on an aerial at Bushy. The easiest method of finding the losses was to put in a resistance to bring the current down to half value. This method was justified with an air condenser.

He remarked that he thought it was the *voltage* that was induced in the secondary that was fixed, and not the amount of *energy* that was transferred.

He pointed out that we were never certain as to how much energy was lost in each part of the secondary circuit, and drew attention to the importance of knowing just where all the energy losses took place, as then we could soon begin to make our apparatus efficient.

Mr. E. H. RAYNER suggested that a calculation of the power factors of the condensers would have given results which afforded considerably more information at a glance. If the losses varied as the square of the voltage, since they are small, the power factor would be constant at all voltages; if the losses increased faster than the square of the voltage the power factor would rise; if at a slower rate it would fall. The experimental results were not accurate enough to determine the constants of the formula employed by the authors. He had analysed the results given in the Paper, and found that some cases showed a diminishing power factor, giving an index less than 2, while the authors had given 2·15. He drew attention to some results which he had obtained on a gutta-percha cable showing a power factor practically constant from 10 volts to 4,000, demonstrating an exceedingly close approximation to the square law over a very great range of electric force.

Mr. F. JACOB remarked he had been for some time at Messrs. Siemens Bros. & Co.'s Cable Works, testing the leakance of gutta-percha cores and other dielectrics, or in other words the effective resistance of condensers, not certainly at the extra high periodicities of Prof. Fleming's most interesting and important results, but at such frequencies as obtained in telephonic transmission, say from 750 $\sim$ to 2,000 $\sim$. Their mode of testing was the bridge method, and the results obtained were correct within about 1 per cent. Two adjacent arms of the bridge are occupied by two equal resistances, the other two arms containing respectively the condenser K whose leakage resistance S is to be tested, and a variable condenser C, whose leakage is zero, in series with an adjustable resistance R. An alternating current and a telephone were employed. When balance is established

$$R - \frac{1}{ipC} = \frac{1}{S - ipK}.$$

Simplifying, and neglecting S^2 in comparison with p^2K^2 we find $K = C$ and $S/K = p^2RC$.

Hundreds of determinations on different materials show that for a given material and frequency S/K is a constant, and within ordinary electrical pressures independent of the same, and in some instances in direct proportion to the periodicity, but in others a little higher. His pressures corresponded very nearly to those given by Prof. Fleming's experiments.

S/K for air by his experiments was 0, and also for a mica condenser if of special construction.

In connection with Mr. Rayner's remarks, he stated that at 750 $\sim$ the value of S/K for the gutta-percha core of the loaded channel telephone cable was 114, and at 2,000 $\sim$, 0·320.

He hoped Prof. Fleming would apply his thermometric differential detector in a similar way, and thus obtain more directly the effective resistances of the condensers he had recently determined by comparison with an air condenser for which his experiments showed the effective resistance to be very small.

He had, on the assumption that the value S/K is proportional to the frequency, reduced Prof. Fleming's results to Messrs. Siemens standard form of S/K. He found no variation with electrical pressure. Below are excerpted values at the different frequencies comparing pairs which are at the same pressure.

EBONITE.

E.	C.	R.	$10^6 \sim$	S/K.	C 2,000 $\sim$
2·37	0·00084	1·37	2·0	182,500	182
2·39	0·00170	0·850	1·41	114,600	163
2·02	0·00170	0·704	1·41	94,900	135
1·96	0·00258	0·659	1·14	87,700	154
1·78	0·00170	0·657	1·41	88,600	126
1·82	0·00258	0·577	1·14	76,800	135

The last column of values reduced to 2,000 $\sim$ shows three values nearly identical and three differing, but no doubt further experiments will elucidate the cause.

At 2,000 $\sim$ for the best ebonite we get a value of 71, and at 800 of 29, which is practically proportional to those periodicities, but there are very different qualities of ebonite, and as there is oil also to take into account, and he did not know what part of the capacity is due to the two dielectrics in question.

The resistances found by Prof. Fleming are anyhow the effective values of these condensers, though we may not be able to separate the portion that is due to the dielectric alone. He found that the ordinary values of dielectric resistance measured after a minute, give no indication as to value of S/K.

Mr. G. L. ADDENBROOKE said his knowledge of high-frequency currents was not enough to enable him to speak authoritatively as to the accuracy of Dr. Fleming's method, but he had found that the form of the wave was of considerable importance, especially where the ammeter reading was relied on at all. Nevertheless he could support Dr. Fleming and Mr. Dyke in one point. He had himself found losses in air condensers after they had been in use for a time, and the loss increased until they might have a power factor of 1 per cent., that is in cases where the plates were about $\frac{1}{8}$ in. apart. He had intended calling attention to this before seeing Dr. Fleming's Paper.

Next as to the experiment in Dr. Fleming's formula where heating was not possible, he had always found the losses increased very nearly as the square of the current, but in a Paper sent into the Institution of Electrical Engineers some time since, the publication of which he had kept back, he had shown that excessive and long continued pressure might cause heating and greatly increase the losses, and more recently he had found the converse to

be the case, that the losses were considerably increased by heating the dielectric, though in different degrees in different dielectrics.

Dr. W. H. Eccles, referring to the Paper giving resonance curves got from a secondary circuit excited by a primary containing either an ordinary spark or a quenched spark, said there was an apparent conflict between the usual theory and the facts disclosed by these curves. A pair of coupled circuits of equal frequency form in general a system of two degrees of freedom, which therefore possesses two periods of oscillation lying one on each side of the natural period of either circuit. The fact that Dr. Fleming's curves show, for some degrees of coupling, three humps instead of two, indicates that the pair of circuits does not remain a double system throughout the oscillation. One circuit disappears at a more or less early stage of the process, that is to say, the primary spark dies out and virtually removes the primary circuit from the combination, so that thereafter the secondary circuit vibrates alone. Usually it is assumed in the case of ordinary sparks between two balls that the spark endures almost to the end of the train of oscillations, and in the case of quenched sparks it is assumed that the primary spark is stopped at the end of one or two half swings. Dr. Fleming's curves show that both of these assumptions would be wrong in the case of his apparatus: the ordinary spark dies out sooner and the quenched spark later than is usually thought. The former fact is perhaps accounted for by the spark being placed in a blast of air. The curves show that in both cases the closeness of coupling has a profound effect on the length of life of the spark; with loose coupling the spark dies out much earlier than with close coupling.

Prof. G. W. O. Howe said he would like to ask Dr. Fleming what he meant exactly by "a dead-beat spark." Dr. Fleming used this expression several times in speaking of the impact discharger. It was stated in the Paper that "it is a dead-beat discharge," and "the spark is damped out of existence instantly," and again, "the discharge is practically non-oscillatory." He did not believe that this was an accurate discription of what actually took place in the primary circuit of a so-called impact discharger.

The primary and secondary circuits having been tuned to exact resonance and coupled together, the energy set oscillating in the former circuit by the breaking down of the spark-gap is gradually transferred to the secondary. The rate of this transfer depends on the tightness of the coupling, but with the tightest coupling used by Prof. Fleming, viz. 0·33, it would take a cycle and a half to transfer all the energy to the secondary circuit. If the spark was quenched under these conditions one might perhaps be justified in speaking of the transfer of energy as an impact. The resonance curves in Fig. 3 show that the spark is not quenched at this point, but that the energy surges backwards and forwards several times just as it does in an ordinary spark-gap in air. On loosening the coupling the transfer of energy takes place less rapidly, and the interval during which the primary current has a small value may be so long that the spark is quenched sooner. To enable the spark to he quenched at the first opportunity, that is, at the moment when the energy has been transferred to the secondary circuit for the first time, it appears from Fig. 1 to be necessary to reduce the coupling to 0·11. With this weak coupling, however, about 5 complete cycles are required to transfer the energy from the primary to the secondary circuit. If the oil-gap be replaced by the 1 mm. air-blast gap, Fig. 1 shows that the coupling has to be still further reduced to 0·045 before the spark is quenched at the first opportunity. The air-gap spark is more persistent than the oil-gap spark, but the difference between the two is merely one of degree.

The train of waves that follows each spark may be divided into two parts; during the first part we have beats between two coupled circuits, giving the two outside humps on the wave-meter curves: during the second part we have a single oscillatory circuit, giving the middle hump in the curves.

In view of the nature of the phenomena involved, he did not think we could speak of a dead-beat spark or discharge, but, under the best conditions as regards coupling, we may have a dead-beat surge of energy from the primary to the secondary circuit. For this reason he thought that the term "quenched spark" was preferable to "impact" or "shock excitation."

Mr. W. C. S. Phillips remarked that he had found Prof. Fleming's Paper on "The Energy Losses in Condensers" of great interest, because it seemed to have some bearing on the results of some comparative tests of the capacities of condensers which he made some time ago.

Each condenser was in turn made part of an oscillating circuit by putting it in series with a known constant inductance, and the frequency of the oscillations was measured by means of a Fleming cymometer.

From a knowledge of the inductance of the oscillating circuit and its oscillation constant, the capacity of each condenser was obtained. When using a parallel plate condenser immersed in oil, a neon tube was quite satisfactory for the determination of the oscillation constant. Without in any way altering the adjustment of the two circuits the parallel plate condenser was replaced by a leyden-jar of equal capacity. The cymometer current was now so weak that it was impossible to detect the position of resonance by means of the neon tube. As care was taken not to alter the coupling of the circuits, nor to introduce any resistance by bad contact into the oscillating circuit, he could only explain the discrepancy by supposing that there was a considerable loss of energy in the condenser. The current supplied to the induction coil used for the production of the spark discharge was, of course, kept constant.

Dr. Fleming, in reply, said he noticed that surprise had been expressed by several speakers that the dielectric losses are not more nearly proportional to the square of the voltage or electric force. With one or two exceptions, their experiments show a loss varying as some power between 2 and 3. He did not think that we could infer from experiments at low frequency what was likely to take place at high frequency, because there are some special sources of loss in the latter case. Thus, for instance, losses due to brush discharges from points and edges of the metal coatings are by no means negligible. It was found necessary to remove a brass indicating pointer from the variable oil condenser and replace it by an ebonite one, because a very obvious electric brush formed on the metal tip. These ionization losses might vary as some power greater than 2.

It is certain that these brush discharge losses are always present in the case of high-frequency measurements. The slight departure from the square law in the case of many of the results such as 2·15 instead of 2·0, may well be due to unavoidable errors of experiment. The method employed required care in the calibration and use of the high-frequency ammeter used. The objection raised by Mr. Campbell to the fact that we have to take the difference of the squares of two nearly equal currents is not so serious as it seems. The thermoelectric ammeter used is associated with a Paul single pivot galvanometer, and the scale of this last instrument is equidivisional, and the readings proportional to the mean-square value of the alternating current passing through the wires. Hence the square value was read at once. He was glad to find Mr. Jacob's interesting results so nearly in accord with his own, for ebonite condensers.

The observations made by Mr. Phillips on the difference between the effects of a leyden-jar and an oil condenser of the same capacity, when used with a cymometer and neon tube, were quite in accord with his own experience. They are undoubtedly a proof that there is a larger dissipation of energy in the case of the leyden-jar.

Mr. Rayner's careful analysis of our Paper does much to show that there is a high degree of probability that the principal part of the dielectric loss is, at any rate, proportional to the square of the electric force. When dealing with high-frequency oscillations there is, of course, much more difficulty in getting very accurate results than with low frequency. The observations we have taken would be impossible altogether without the use of an impact discharger,

but it may be that the oscillations in the secondary circuit are not absolutely the free oscillations, and it is upon the assumption that they are free that our theory of the apparatus is based. As regards the last Paper on "Resonance Curves," Dr. Eccles puts the facts very concisely. There is undoubtedly a back effect produced, by the secondary oscillations, on the primary circuit, which results in a prolongation of the primary spark when close coupling is used, and this results in the appearance of the two-period oscillations superimposed on the free period oscillation in the secondary circuit.

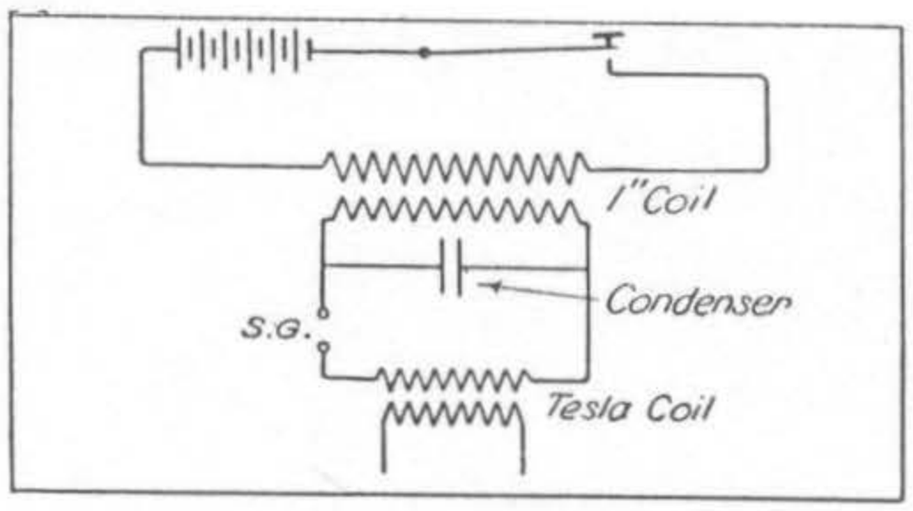
Replying to Prof. Howe as to the sense in which the phrase "dead-beat spark" is used, Dr. Fleming said that it was intended to imply a spark which is very quickly quenched. The resonance curves given in their Paper prove that the quenching of the spark is not absolutely instantaneous, but that even with the so-called "impact discharger" the primary spark does endure for a very short time. If, however, the coupling does exceed a certain value, the result is to set up in the secondary only the free oscillations, and the advantages of the impact discharger are that this condition pertains for a closer coupling than is the case with the ordinary spark ball discharger. He agreed that the term "impact discharger" is perhaps not the best that could be used, but it is well understood, and as they have used it, it communicates to the secondary circuit just one non-reverberatory wave of energy which is then dissipated in the secondary circuit as heat.

NEW BOOKS

THE TESLA HIGH FREQUENCY COIL. By George F. Haller and Elmer Tiling Cunningham. New York: D. Van Nostrand Co. 1910. 179 pages with 56 illustrations. Price $1.50

Describing the construction of a twelve-inch Tesla coil, with its transformer and all other accessories and introducing interesting information concerning the uses of the coil.

CONSTRUCTION OF INDUCTION COILS AND TRANSFORMERS. By H. Winfield Secor. New York: Modern Electrics Publication. 1910. 92 pages with 56 illustrations. Price, paper, 25 cents.



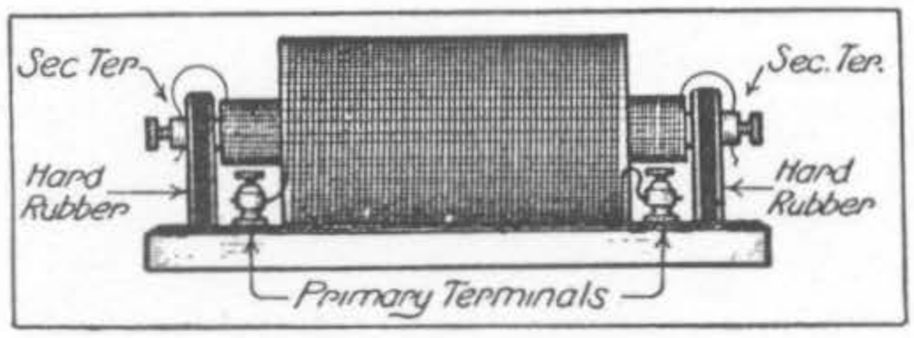
A book designed to place in ready form the latest data and tables desired by the average experimenter and builder of induction coils and transformers. A section is devoted to the Tesla coil. and instructions are given for building a large coil of this type for use on stage and lecture platforms. The construction of open and closed core transformers up to three kilowatts is given in detail.

An appendix contains practical tables covering coil and transformer dimensions, spark distances and wire values.

NEW BOOKS

THE TESLA HIGH FREQUENCY COIL, ITS CONSTRUCTION AND USES. By George F. Haller and Elmer T. Cunningham. New York: D. Van Nostrand Company. 1910. 119 pages, with 56 illustrations. Price, $1.25.

After a careful study of a twelve-inch spark coil the authors set forth in this book much information designed to save the builder of a Tesla coil time and trouble over details. One chapter of fourteen pages, is given up to the uses of the coil for lighting vacuum tubes, Roentgen ray work, etc.



CONNECTIONS OF TESLA COIL

The condenser cuts the spark down to about ⅛ inch but it is very white and "cracky." A zinc gap with an end area ⅛ inch square worked well. With needle points on the Tesla coil spaced three inches, a bright brush envelopes the points. With two wires placed ¾ inch apart and parallel the Tesla coil caused a ladder of brushes to be formed. Other interesting experiments will suggest themselves to the builder.—HAROLD KESSLER.

A Small Tesla Coil

The illustration shows a small Tesla coil which I built at very little expense and which I have used in performing many interesting experiments. For the secondary, wind No. 22 enameled wire on a mailing tube 1½ inches in diameter and eight inches long leaving a blank space of ⅜ inch at each end of the tube. Paint this winding with several good thick coats of shellac. For the primary provide a mailing tube 3¾ inches in diameter and six inches long.

SMALL TESLA COIL

Upon this wind 18 turns of fixture wire and shellac thoroughly. Use hard rubber supports on a dry wood base to support the secondary. The primary coil may be secured to the base by shellac. This may be operated in connection with a one-inch coil.

The condenser consists of 26 7 by 5 inch glass plates using 3 by 5 inch tinfoil sheets.

The New York Herald May 16, 1911

MR. TESLA PREDICTS WONDERS

He Says Wireless Telephone Soon Will Carry Messages Around the World.

Running street cars in Ireland by electric power supplied from a station on Long Island through underground wireless transmission will soon be simple, said Nikola Tesla last night in an illustrated lecture before the National Electric Light Association in the Engineering Societies' Building, in West Thirty-ninth street.

The wireless telephone, he said, was now an assured fact. Messages will be transmitted underground, he said, and any number of persons will be able to converse with one another around the world without having messages conflict.

The New York Times May 16, 1911

TESLA TELLS OF WONDERS.

Says He Will Soon Be Able to Transmit Wireless Power Across Seas.

Queen Isabella of Spain could not have been amazed more when Christopher Columbus told her about a new world than were the members of the New York Companies' Section of the National Electric Light Association in the Engineering Societies Building, 29 West Thirty-ninth Street, last night, when Nikola Tesla, the inventor, told them that within a short time he hoped to run street cars in Dublin, Ireland, by electrical energy generated in Long Island City.

"I have annihilated distance in my scheme," he said, "and when perfected it will not be one mite different than my present plans call for. The air will be my medium, and I will be able to transmit energy of any amount to any place in the world. I will also be able to send messages to all parts of the world, and I will send words out into the world which will come out of the ground in the Sahara Desert with such force that they can be heard for fifteen miles around.

"I also hope to set up a central wireless telephone station whereby there will be a force of 1,000,000-horse power behind each word uttered into my instrument, and in which distance will play no hindrances whatever. Many hundreds of people will be able to talk at the same time and without any interference with each other."

For the use of aeroplanes the inventor has a new steam engine perfected, he says, which will be of the turbine type, and a 10-horse power engine of this kind will weigh only one pound. On a larger scale, he said, this machine is now being tested, with good results, in the shops of the New York Edison plant. The machine, he says, will be the smallest thing ever seen on wheels and will be more powerful than any automobile engine ever manufactured.

The convention of the Electrical Association will be held in this city during the week beginning May 29.

THE NEW INVENTIONS OF TESLA.

The address made by Dr. Nikola Tesla before the New York Section of the National Electric Light Association this week, and reported upon other pages of this issue, is one which will attract great attention on account of the startling statements which were made by the speaker. Mr. Tesla has been working upon the inventions now announced for a number of years, and while it is impossible to estimate their importance until further details are made known, the claims made for transmitting energy and speech to great distances point to an epoch-making discovery.

The experiments made by Dr. Tesla upon high-frequency and high-potential currents about twenty years ago were most illuminating and opened a field of vast possibilities to both the scientist and the engineer—a field which is still being explored. His other discoveries have attracted considerable attention, and this latest announcement bids fair to prove the most important of all.

Aside from his work on electrical oscillations, Dr. Tesla has invented and constructed a prime mover for which remarkable results are claimed. This engine is said to deliver ten horsepower for each pound of weight, a ratio which will mean revolution in the fields of the automobile and the flying machine.

The scientific and technical world will eagerly await the further demonstration of all these possibilities, for their practical realization will mean a most important step forward in electrical and mechanical engineering.

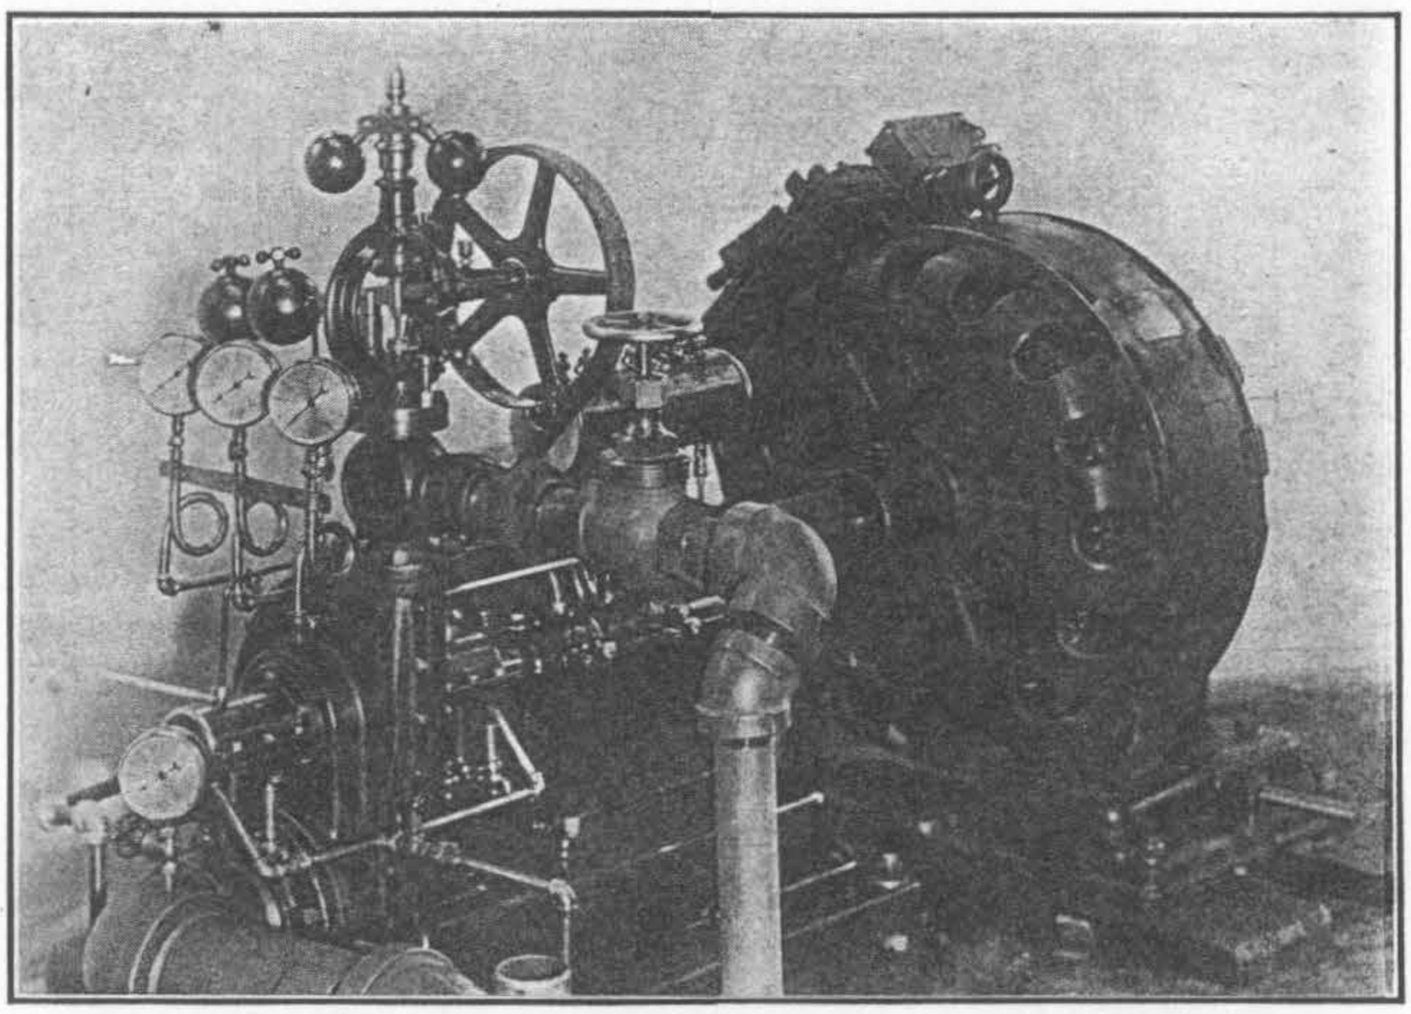
NEW INVENTIONS BY TESLA.

ADDRESS AT MEETING OF NEW YORK SECTION OF NATIONAL ELECTRIC LIGHT ASSOCIATION.

The meeting of the New York section of the National Electric Light Association was held at the Engineering Societies Building, New York City, on Monday evening, May 15, 1911. Chairman Williams presided. The report of Mr. Thomas, chairman of the Membership Committee, showed that the present membership of the section is approximately 1,300 and it is the aim of the committee to have the membership at least 1,500 by the time of the annual convention of the association, beginning May 29. Chairman Williams then outlined the entertainment to be tendered by the Greater New York lighting companies on the occasion of the convention.

T. C. Martin then introduced Nikola Tesla, preceding the introduction by a statement that the membership of the N. E. L. A. on May 15 was over 8,100, a growth of over 5,000 in eighteen months. Mr. Martin referred to the occasion when Mr. Tesla gave a demonstration of his earlier inventions at the time of the St. Louis Convention in 1893.

Mr. Tesla said that some time ago he experienced the necessity of testing an invention he had perfected under conditions existing in a modern plant and he approached the officers of the New York Edison Company for facilities and received most cordial co-operation, for which he was greatly indebted. He introduced the subject by saying that the gift of invention and discovery is a great one, and that there is no enjoyment that he could picture in his mind so exquisite as the triumph which follows an original invention or discovery. But the world is not always ready to accept the dictum of the inventor, and doubters are plentiful, so that discoverers have often to swallow bitter pills, and he had received an ample share of bitterness as well as pleasure.



He then referred to the fact that in 1887 or 1888 he had brought out the rotating magnetic field. It was at a time when the world was not yet prepared to receive the idea and he had to stand many attacks, and when his patents were fought he had a great deal of trouble. Some went so far as to assert that he had never invented anything.

Mr. Tesla alluded to the discoveries of Hertz which startled the world. He had tried to repeat the Hertz experiments, worked on them for two or three years and had to give them up. He called on Hertz and told him of his doubts. Since that time he has satisfied himself that Hertz had seen true.

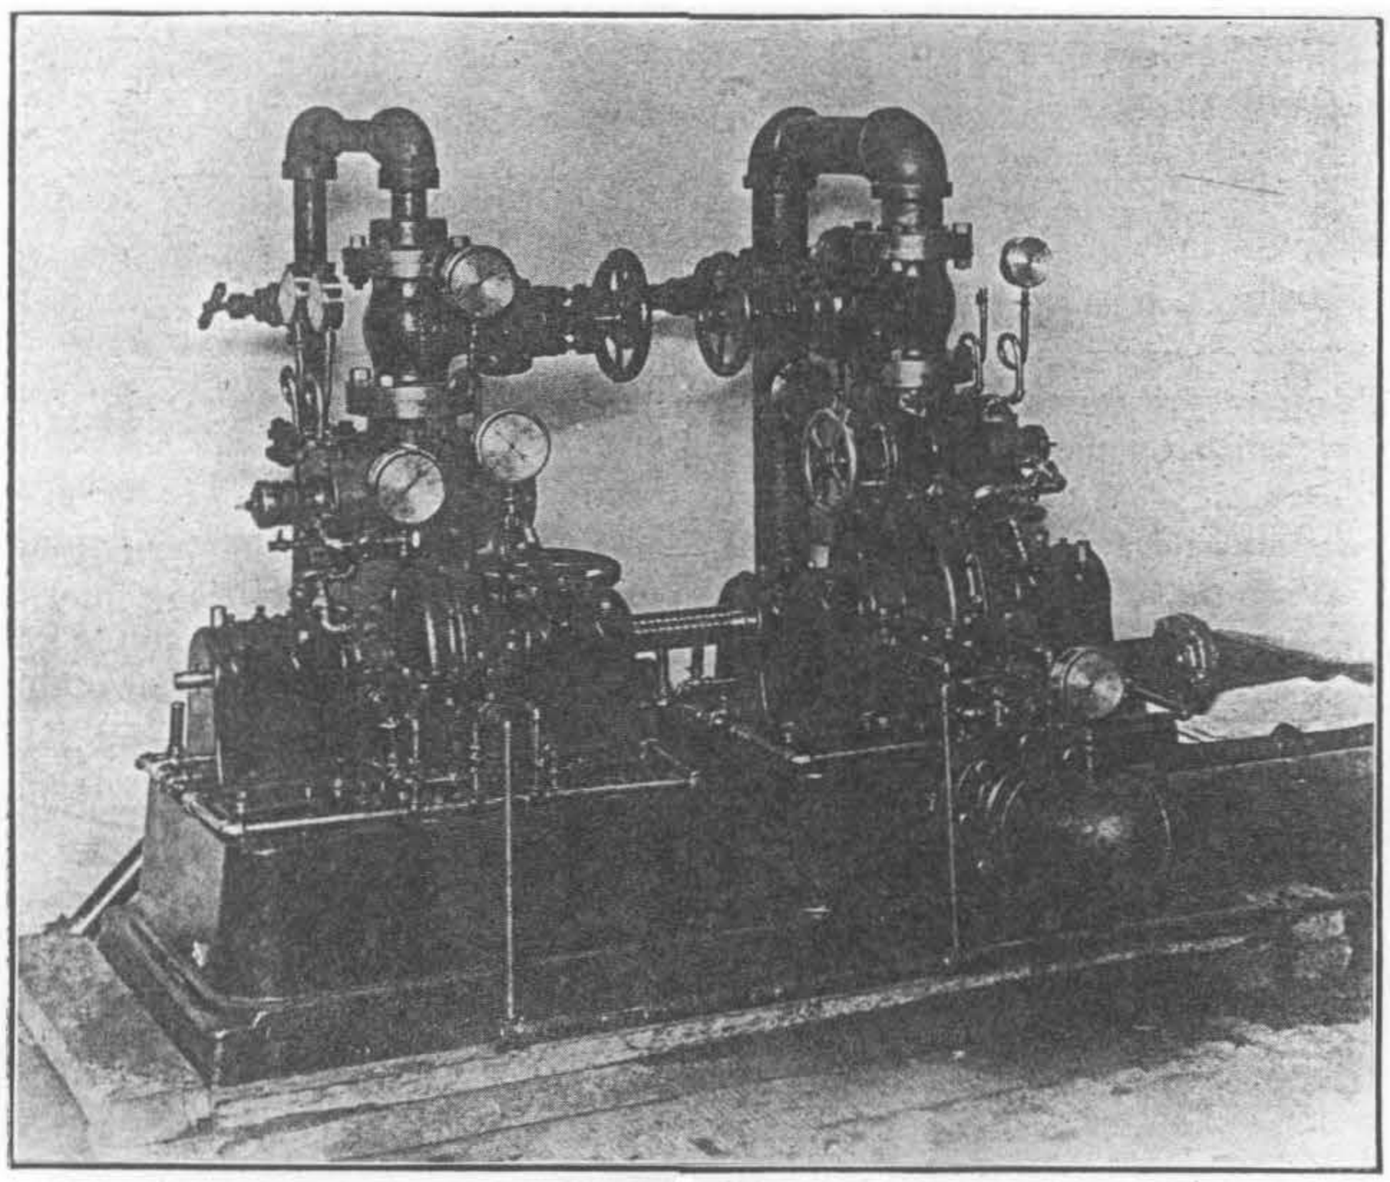
He mentioned the discovery by Roentgen in 1895. He had investigated the wonderful phenomenon which Roentgen investigated, and after long search finally ascertained the true nature of the rays and published the results in a series of papers in the ELECTRICAL REVIEW, declaring we had to deal with a new matter which was never before studied, showing that the particles projected were smaller than atoms, that they were of various sizes, that they carried electrical charges and moved with great velocities.

Mr. Tesla further said that in dealing with electrical matters, there is one branch to which he had devoted a large portion of his life, and it is proper he should speak on that subject. He referred to the wireless transmission of energy. The problem presented itself to him as follows: If we can transmit energy through a closed circuit, we should also be able to transmit it through a single wire, and return being effected through the medium.

He exhibited diagrams illustrating the electrical scheme, as well as a mechanical analog, and showed in slides experiments made in 1899 in which incandescent lamps were lighted in this manner. He then exhibited other diagrams of his wireless system and produced a slide showing a lamp lighted by wireless energy. The lamp he declared could have been lighted if it had been placed at the antipodes. Dwelling on his wireless system in detail he said that it comprised five distinct inventions. The first of these was his transformer. To convey an idea of the wonderful effects which can be produced with that instrument a slide was produced illustrating an experiment performed very frequently in the years of 1892-96. Behind a screen was placed the primary of such a transformer and before the screen a bulb of about fourteen inches in diameter and containing a drop of mercury. The experimenter holds the bulb in the air and the induction from the primary is so strong that it evaporates the mercury and produces an extremely powerful light.

TESLA TURBINE COUPLED TO FIFTY-KILOWATT WESTINGHOUSE GENERATOR.

He next described his "magnifying transmitter" and showed several striking experiments with the same on the screen. One slide showed the transmitter used by him in Colorado on an immensely large scale. Streamers were visible extending from the center of the coil and measuring fully forty feet, the width of the same being sixty-five feet. The discharge is so powerful that it goes through the open roof, being carried up by the heat produced.



He next showed another effect of such a magnifying transmitter with a large ball, thirty-nine inches in diameter, which was placed just a little above the building, the roof of which was removable. Several of these streamers could be followed a hundred feet into the air; from a distance it looked as if the building was on fire and the roar could be heard for ten miles. He remarked that this was one of the most difficult experiments because of the great force it takes to reach the required density.

Mr. Tesla then referred to his third invention called the "art of individualization in which the nervous system of the human body was imitated in a crude way" (indicating diagram).

"I will not bother you with theories and details," he said, "but can assure you that as long as the world exists, if all men were Faradays, they could never invent a scheme which would permit as accurate a transmission of messages or quantities of energy to a distance through a wire as has been found practicable without wire by this method; for in a wire transmission the secrecy is only the result of isolation in space, while in the wireless we get the benefit of combinations which are not practicable in a transmission through artificial channels. All the statements you read in the newspapers that wireless messages are interfered with, are because the workers in that field are laboring under delusions—they are transmitting messages by Hertz waves, and in this way no secrecy is possible."

He then showed a picture of a machine exhibited in 1898, to which he first applied this art of individualization.

After stating that his fourth invention pertaining to the system was a peculiar receiver condensing the energy, he dwelt on his discovery of the stationary waves which was the last and most important. Before he could transmit energy without wire economically he found it absolutely necessary to learn how this great body, the planet, behaved, how the current would pass through the same and what are its constants, capacity, self-induction and resistance. As he could not find opportunity in the city for investigating he went to Colorado Springs and erected a laboratory for the purpose. Several views of the same were projected on the screen. One showed in the center of the building a coil fifty-one feet in diameter and many smaller ones within, which had been attuned to respond to higher harmonics.

TWO TESLA TURBINES, OF 200-HORSEPOWER EACH, COUPLED TOGETHER BY TORSION SPRING.

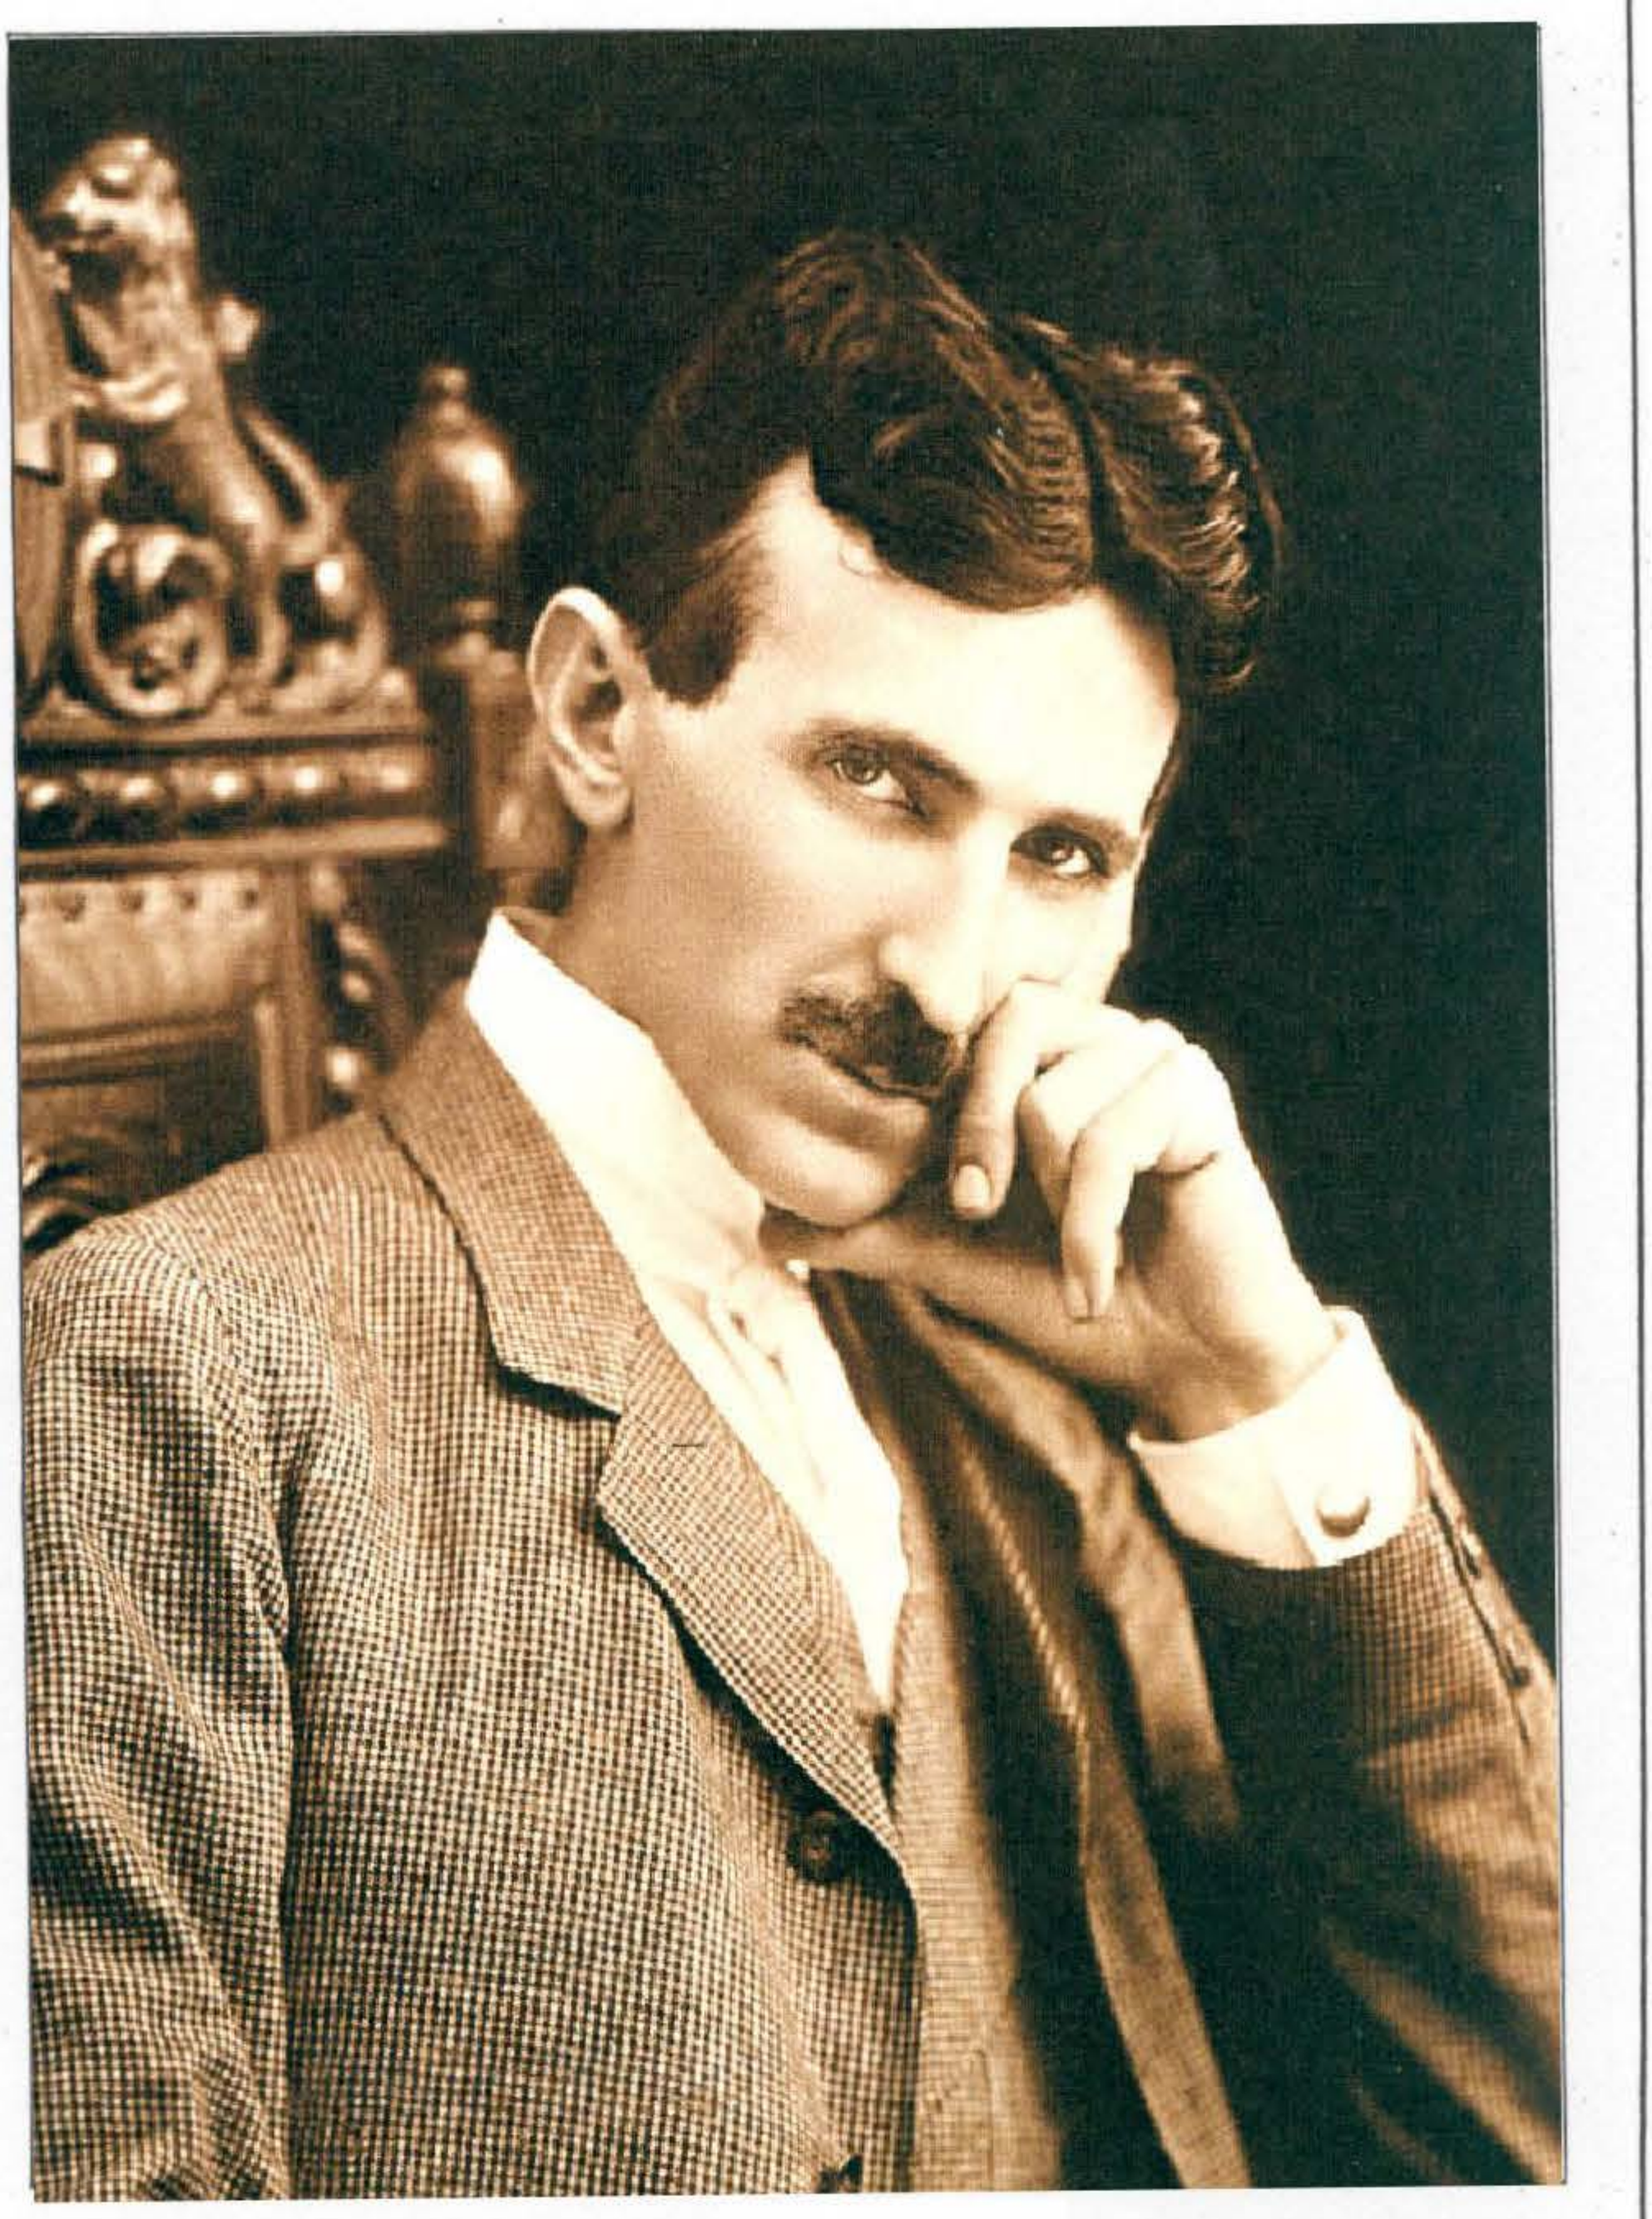
Another effect of the magnifying transmitter was next illustrated, showing a display with powerful streamers shooting out in all directions from a coil, as well as a ball of thirty-nine inches in diameter placed on the top.

Mr. Tesla then said: "I had not been in Colorado Springs but a few months when I made the most marvelous discovery I ever expect to make in my life. Before explaining it to you, let me say that I was not stirred at all by its practical value, though it was immense, but by its philosophical significance. You know that through ages past, man has always attempted to project in some way or other energy into space, but in all his attempts, no matter what agent he employed, he was hampered by the inexorable law of nature which says that every effect diminishes with the distance, generally as the square of the distance, and sometimes more rapidly. Now, the discovery I have made upset all that has gone before, for there was a means of projecting energy into space, absolutely without loss from any point of the globe to another, to the antipodes if desired. In fact, a force impressed at one point could be made to increase with the distance. I saw at once that distance was annihilated in all the three aspects; in the transmission of intelligence, in the transport of our bodies and materials, and in the transmission of the energies necessary for our existence. You can imagine how profoundly I was affected by this revelation. Technically, it meant that the earth, as a whole, had a certain period of vibration, and that by impressing electrical vibrations of the same period upon it, it could be thrown into oscillation of such nature that innumerable benefits could be derived from it. Let me tell you of but one application of the principle. Vessels could be equipped with simple devices enabling them to sail across the Pacific along the shortest routes and the captain of each vessel could tell the distance, from a point of reference, within a few feet. We do not today know the exact diameter of the globe. Astronomers have been unable to determine it within a thousand feet. By this discovery without any kind of surveying instrument or even without going out of the room, an electrician can determine the diameter of the globe within four feet. Thousands of such problems, which are of immense practical importance, can be solved and I have often thought that annihilation of distance is the only means of bringing about a quick understanding and universal peace between nations. It will remain for the

future to decide whether I have seen truly or not.

"On my return from Colorado I completed plans to demonstrate these principles on a larger and commercial scale, my laboraory in Colorado being only constructed for purposes of scientific demonstration. Here are some views of my plant on Long Island, erected in 1901. This plant is nothing but what I have called a magnified transmitter which, when completed, will enable you to pick up any telephone and, without the slightest change in the stations, talk as clearly as though sitting on the other side of the table to any subscriber in the world. It will make no difference where he is located, and if desired the voice may be made to come out of the ground with such force that it could be heard for miles. The plant was put up originally for the purpose of serving as such a telephone exchange, but was to serve also for other important uses. To give you an idea of the magnitude of the effects, when you speak into the telephone there will be electrical energy at the rate of one billion horsepower sending your voice across the globe, and not only this, but the plant will be so organized that hundreds of people can talk at the same time to any part of the world without the slightest interference. Of course, you will have to take my word for it now, but I hope that I shall live to realize what I have begun. I will carry out my plans exactly as they were first made.

"My project was evidently far in advance of the times. Its progress was retarded and I was compelled to devote myself for a time to other inventions which appealed more to practical men. After years of careful thinking, I found that what the world needed most, and would most readily accept, was an efficient prime mover, a converter of heat into mechanical energy. This all the more as a new world is about to be explored, the world of waste. When you consider that in the manufacture of steel and iron in this country, some thirty million horsepower could be harnessed and a proportionate income derived from that power, all of which is wasted today, you can see what value a good convertor of thermal energy into mechanical energy would have.



"But to conceive that a prime mover is valuable and to get up one, are two different things. After some thought I finally came to the following argument: suppose a number of plates are moved through a fluid medium, the medium will, of course, be dragged along with the plates, and a certain frictional loss will be incurred. Inside the casing are arranged on a shaft a number of disks with openings and spokes and there are orifices of entrance on the sides to produce a perfect balance, and the usual arrangement of outlets. This system of disks being rotated, the water or air is sucked into the channel, is taken hold of and moves in a logarithmic spiral with very nearly the velocity of the system. It was perfectly well known that a fluid would be dragged by rotating surfaces, but somehow nobody realized the conditions for economic working, nor has any one properly grasped the principles which could be applied to propulsion. So it happens again that it is my good fortune to come to the rescue, and I have produced a highly economical way of compressing or pumping fluids." Mr. Tesla then gave a practical demonstration of the working of the principle in a model pump.

"This is one of the early forms of blower which I constructed" (referring to diagram). "That was constructed three years ago. It is a two-stage blower. Far more important than the pump blower or compressor is the turbine. Here is a simple structure, a casing with two entrances, disks arranged on the shaft and outlets in the center for the escape. In this instance the power is applied to one of the openings and the fluid moves with decreasing velocity toward the center until its energy is exhausted and transferred to the shaft. If the theory is correct, I am able to take out the entire energy of steam in one single stage. In the present turbine, sixty-five per cent is the limit of efficiency; theoretically I should be able to get ninety-nine per cent of the total energy of the steam on the shaft in these turbines. These turbines are simple, they have a great torque, far better than other turbines, and a machine will develop ten horsepower for every pound of weight. This principle can also be applied to the gas turbine."

Several slides showing two turbines coupled together were then projected on the screen and a new method of power measurement described. Mr. Tesla then dwelt on the advantages of these machines and showed a number which were constructed and in operation. They have no ducts, nozzles or such complications which cause so much trouble, and besides the machines are perfectly reversible, working with the same efficiency back or forth, making a valuable machine for driving boats, locomotives, automobiles, etc. The accompanying illustrations show two of these turbines.

"In this new invention we have a beautiful solution of many mechanical problems. We have a prime mover which is reversible, ideally simple, of enormous torque, incomparably greater than the turbine possesses, so I am looking for a revolution in mechanics from the application of this principle."

Owing to the lateness of the hour, the other papers which were to have been presented at the meeting were laid over until the next meeting. The members of the Section and their guests were then entertained by an interesting vaudeville performance.

NIKOLA TESLA

Popular Electricity
In Plain English

VOL. IV JUNE 1911 No. 2

Tesla and His Wireless Age

By ARTHUR B. REEVE

"I have produced electrical oscillations which were of such intensity that when circulating through my arms and chest they have melted wires which have joined my hands, and still I have felt no inconvenience. I have energized with such oscillations a loop of heavy copper wire so powerfully that masses of metal placed within the loop were heated to a high temperature and melted, often with the violence of an explosion. And yet into this space in which this terribly destructive turmoil was going on I have repeatedly thrust my head without feeling anything or experiencing injurious after effects."

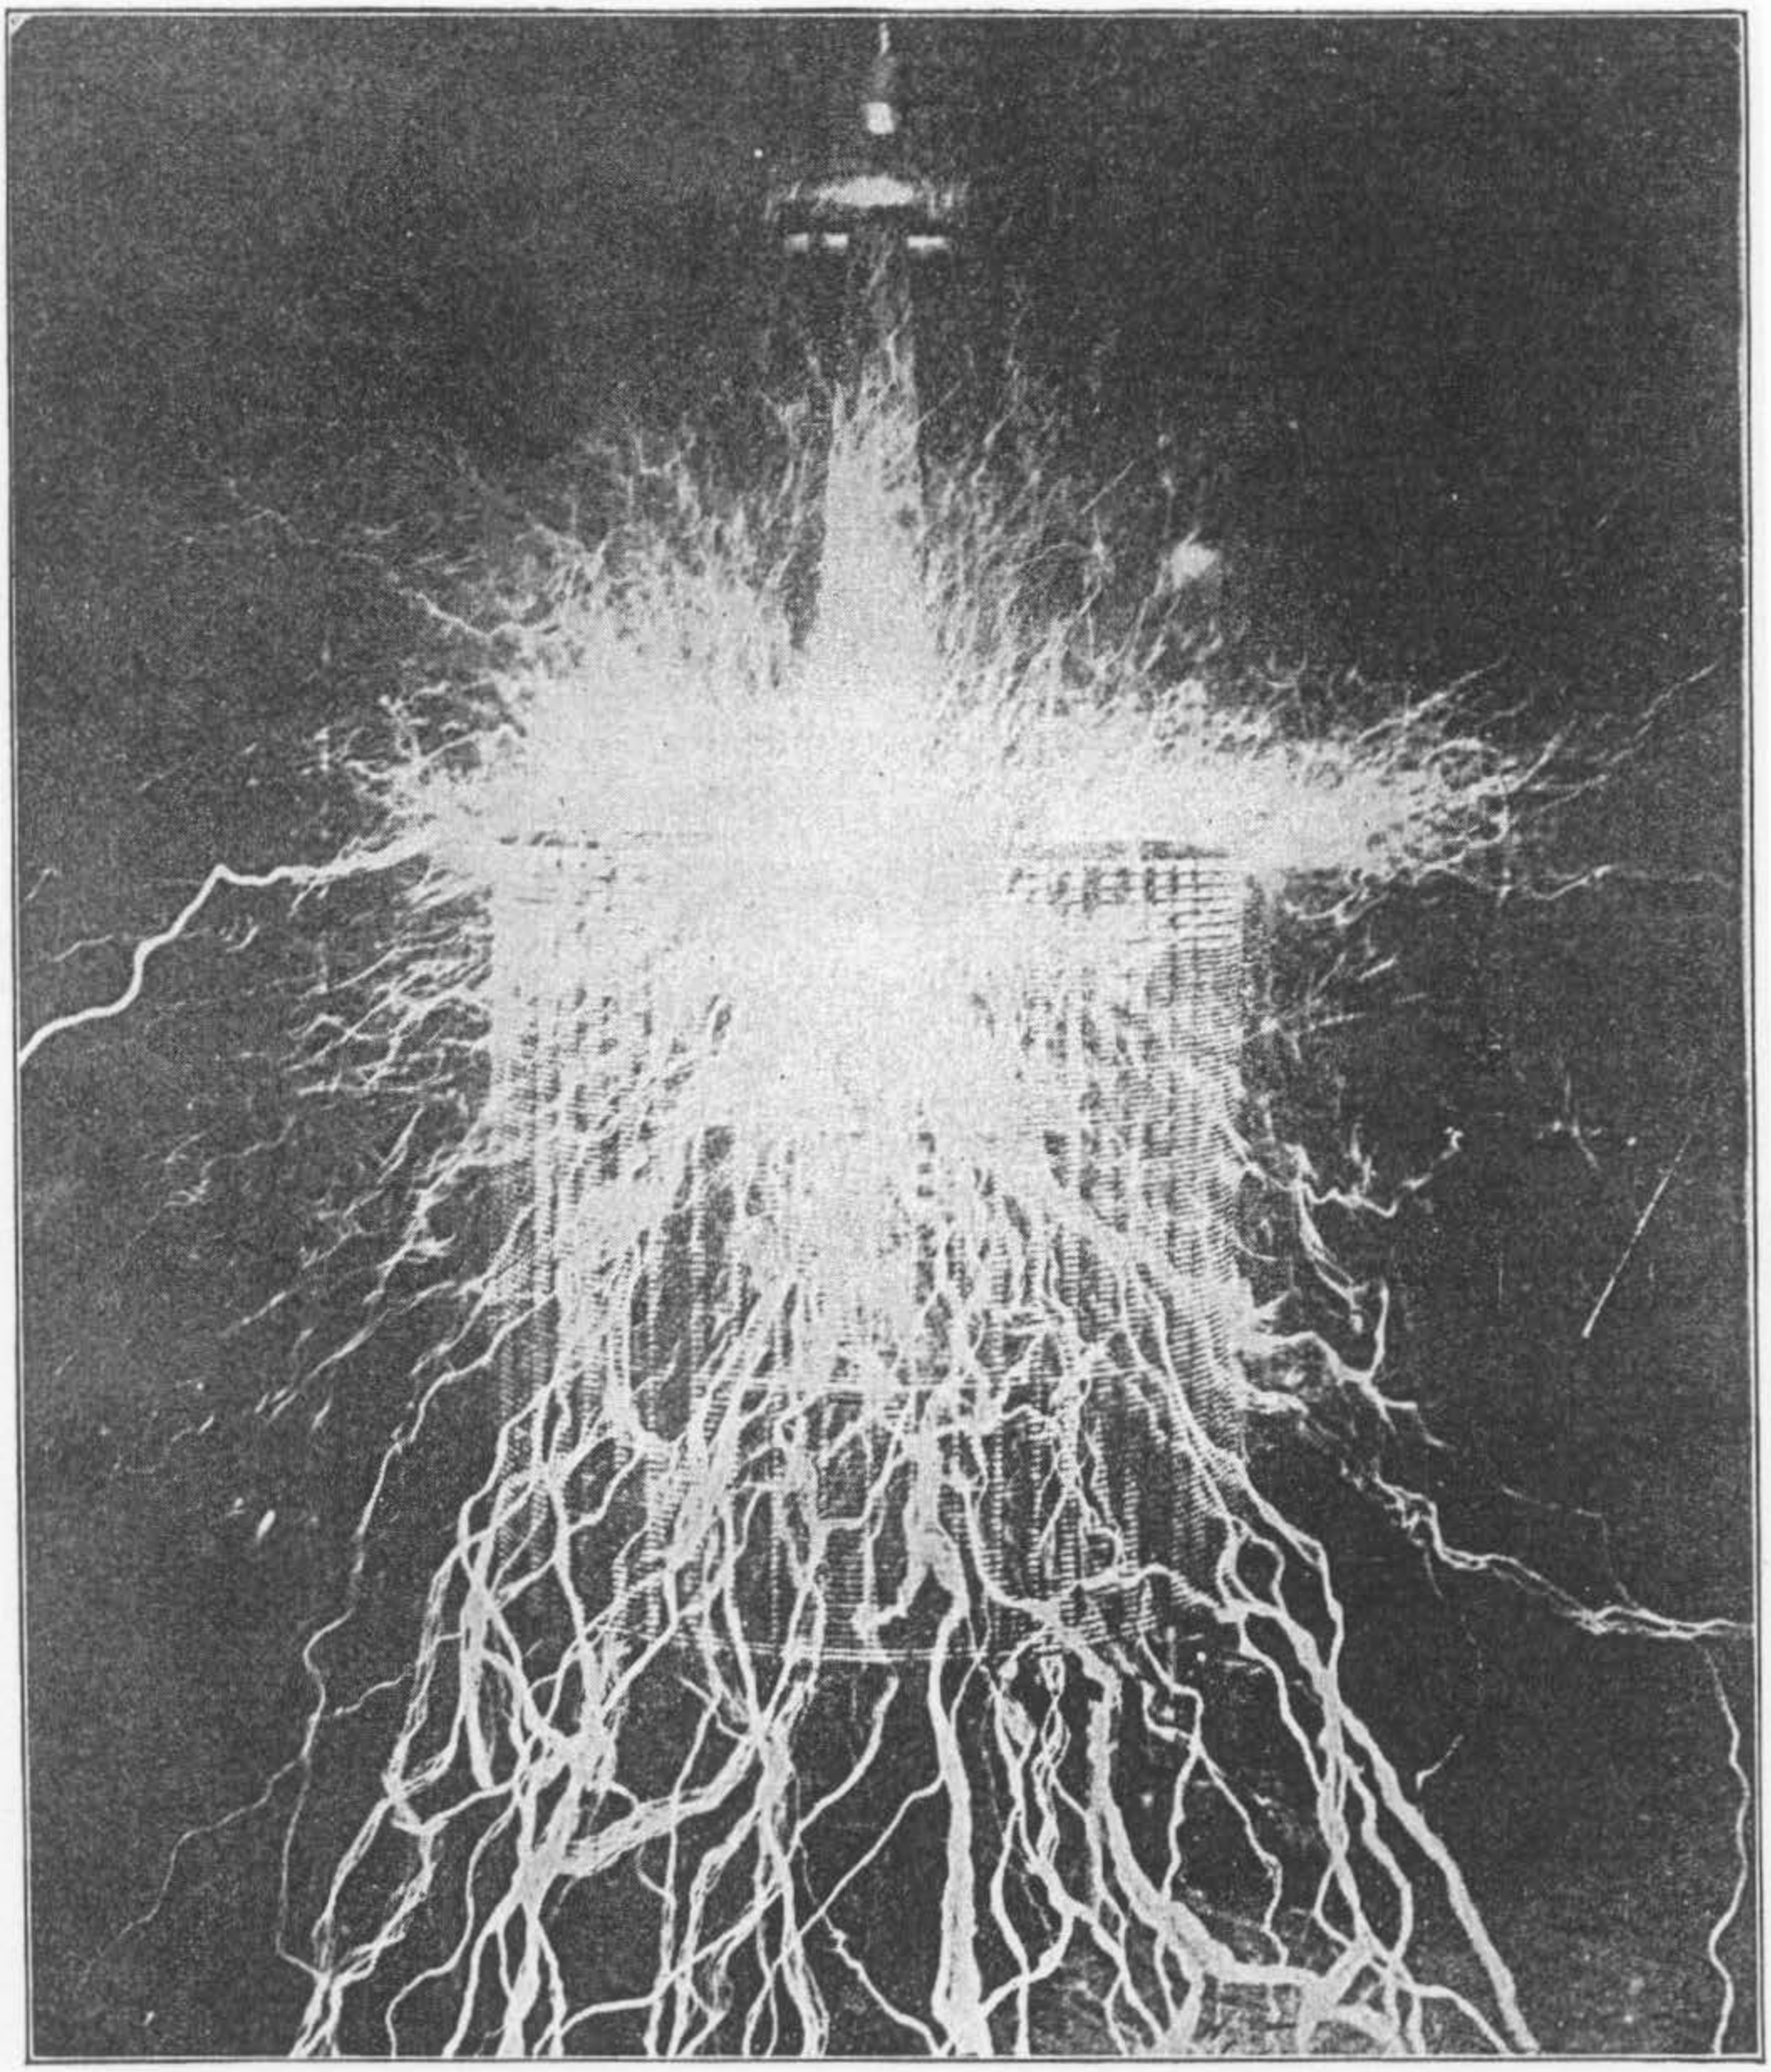
The speaker was a tall, spare man with a clean-cut, thin, refined face and eyes of exceptional keenness. He was sitting at a broad flat-top desk in his office on the twentieth floor of the Metropolitan Tower, and his eyes wandered restlessly in just pride from a photograph of his old friend Lord Kelvin on one wall to a large photograph of electrical streamers rivalling the lightning on the other. The speaker was Nikola Tesla.

But before describing his wonderful theories and experiments in the wireless transmission of energy, let me say something of the man and his life. And first of all, it

TESLA'S "WORLD SYSTEM" PLANT AT WARDENCLYFFE, LONG ISLAND

must not be forgotten that today over four million horsepower of water falls are harnessed by Tesla's alternating current system. That is like saying that forty million men—untiring, working without pay, consuming no food, shelter or raiment—are constantly laboring to provide for our wants. In these days of conservation, it is interesting to note that this vast electrical energy derived from waterpower saves a hundred millions of tons of coal every year. Our trolley roads, our subways, many of our electrified railroads, the incandescent lamps in our homes and offices, all use a system of power transmission of this man's invention.

Nikola Tesla was born at Smiljan, Lika, in the border country of Austria-Hungary in 1857. He was the son of a Greek clergyman and orator and Georgia Mandic, herself somewhat of an inventor like her father before her. The young Tesla attended the schools of Lika and Croatia, and later the Polytechnic at Gratz as well as the University of Prague, in Bohemia. At Gratz he saw and operated a Gramme machine for the first time, and was so struck with the objections to the use of commutators and brushes that he made up his mind to remedy that defect in dynamo-electric machines.



Tesla began his practical career in Buda Pesth in 1881. His first electrical invention was a telephone repeater. Later he was engaged in various branches of engineering and manufacture in Paris, and in 1884 he came to the United States. Here he found employment for a while with the Edison Company in Orange, New Jersey. After the prescribed period of residence he became a naturalized American citizen.

After numerous scientific addresses and papers and inventions like the third brush regulation he entered business for himself, the Tesla Electrical Company of New York being formed in 1887. Already he had conceived his great idea of the rotating magnetic field, which makes possible the transmission of power by alternating current, a system extensively used over long distances. His work with dynamos, transformers, induction coils, oscillators, arc and incandescent lamps, involving alternating currents of high frequency and high potential, at once brought him great fame. In fact, the immense stimulus of Tesla's work to the study of alternating current motors would alone stamp him a leader in the field of electricity if he had contributed nothing else. It has sometimes been asserted that Professor Ferraris anticipated Tesla in the rotating magnetic field, but as a matter of fact Ferraris was purely theoretical, halting and impractical in his work. The mere fact that he published a paper describing his work subsequently to Tesla's discoveries must rank only as one of those curious and frequent scientific coincidences. Ferraris himself stated some years ago that Tesla could not possibly have known of his (Ferraris's) work. These notable patents were acquired by Westinghouse, and were the subject of much litigation before being finally upheld.

A mere list of Tesla's inventions and discoveries is formidable. In 1886 he was the inventor and discoverer of a system of arc lighting, and in 1888 came the Tesla motor and system of alternating current power transmission, popularly known as the two phase and three phase multiphase, or polyphase systems. A system of electrical conversion and distribution by oscillatory discharges came in 1889, and a year later studies in the generation of high frequency currents and their effects. The transmission of energy through a single wire without return was announced in 1891, while from that year until 1893 he was engaged in investigation of high frequency effects and phenomena.

In 1893 he announced a system of wireless transmission of intelligence, and in 1894 and 1895 his work was on mechanical oscillators and generators of electrical oscillations. During the years 1896 to 1898 he was interested in research in radiation and the discovery of material streams and emanations. Finally in 1897 he first announced his "high potential magnifying transmitter" which, as he claims, makes possible a system of economical transmission of power without wires. From that date down to the present he has been constantly at work on this idea. No other human being knows anything like as much about this fascinating subject as Tesla.

Among his other inventions should be mentioned what he calls the art of telautomatics (1898-'99), a system for controlling the entire operation of, say, a boat by wireless impulses at a distance, even out of the range of vision. In 1899 and 1900 he was engaged in experiments in burning atmospheric nitrogen and the production of other

ONE OF TESLA'S "MAGNIFYING TRANSMITTERS" STRONGLY EXCITED

electrical effects of transcending intensity, while during the next two years he was working on methods and apparatus for magnifying feeble effects. From 1902 to 1903 he studied the problem and art of individualization, and since then his work has been in world telegraphy and telephony and in the designing and building of a large power plant for the transmission of power without wires, which I shall describe presently.

But as most people associate Tesla with high frequency, high potential electrical currents, rather than with such things as his electrolytic meter, his dynamo commutators and brushes without sparks, and the thousand and one other notable contributions he has made, I cannot leave the subject without another word. Prior to Tesla's inventions only direct current was used. Now we use alternating current. As one of the

justices who decided a case in his favor some years ago well put it:

"It remained to the genius of Tesla to capture the unruly, unrestrained and hitherto opposing elements in the field of nature and art and to harness them to draw the machines of man. It was he who first showed how to transform the toy of Arago into an engine of power. The Arago rotation taught the schoolboy fifty years ago how to make a plaything, and that plaything embodied the principle which Tesla discovered—that a rotating field could be used to rotate an armature. He first conceived the idea that the very impediments of reversal indirection, the contradiction of alternation, might be transformed into power, producing rotations, a whirling field of force. What others looked upon as invincible barriers, impassable currents, and contradictory forces he seized and, by harmonizing their directions, utilized in practical motors in distant cities the power of Niagara."

And now for Tesla's scheme of wireless transmission of energy. A few years ago it may be remembered he stood in the theater of the Royal Institution with oscillatory currents of unheard of voltage playing about his unharmed head. This taste for the sensational has always been one of Tesla's commanding characteristics. He prides himself on it. Others may criticise Tesla for this love of the sensational, but he himself will sit for hours talking about some of his seemingly impossible exploits, while the mention of one of the inventions which, as he says, "the world calls practical," will fail to elicit from him so much as a wink of an eyelash. As he himself told me, it is doubtful if anyone ever performed so many really dramatic, hair-raising experiments as he. He is as proud of them as a boy. The zest with which he tells of how, after showing Sarah Bernhardt his most dare-devil exploits, she hurried away almost in a state of nervous collapse, is equalled only by the offhand manner in which he mentions currents of 80,000,000 vibrations a second, and his descriptions of sparks and flames in his laboratory experiments which rival, if not equal, the lightning itself. I recall that, in referring to one of his experiments, somewhat like that in the opening paragraph of this article, he anticipated my inquiry by saying: "I don't do that any more; it is too dangerous."

But though there may be much of the pure love for the dramatic in Tesla's announcements, there is really more of what may be called truly scientific imagination. Such experiments with all their elaborate stage setting Tesla believes to be of far greater practical importance than even those of his inventions "which the world calls practical." For, as he tersely put it: "The economic transmission of power without wires is of all-surpassing importance to man."

It all began, as he will tell you, in his observations—"revelations" he calls them—during a great thunderstorm on July 3, 1899. Out of it came his "high potential magnifying transmitter," and such patents along this line of wireless transmission as Nos. 645,576 and 649,621, for transmission of electrical energy in any quantity to any distance with transmitting and receiving apparatus movable, as in ships and balloons.

"We are on a conducting body insulated in space, of definite and unchangeable dimensions and properties," he says. "It will never be possible to transmit electrical energy economically through the body and its environment except by essentially the same means and methods which I have discovered, and the system is so perfect now that it admits of but little improvement."

"Under certain conditions," says Tesla, "the atmosphere which is normally a high insulator assumes conducting properties and so becomes capable of conveying any amount of electrical energy. I would undertake to transmit through my body with such currents the energy of all the dynamos at Niagara."

To carry out his ideas he has devised a plant of which he says: "A popular error which I have often opportunity to correct is the belief that the energy of such a plant would dissipate itself in all directions. This is not so. Electricity is displaced by the transmitter in all directions equally through the earth and air, but energy is expended only at the place where it is collected and used to perform some work. A plant of 10,000 horsepower might be running full blast at Niagara, and one flying machine of 50 horsepower might be in another place. Only 50 horsepower would be furnished by the plant.

"Although the electrical oscillations would manifest themselves all over the

earth at the surface as well as high in the air, virtually no power would be consumed. My experiments have shown that the entire electrical movement which keeps the whole globe a-tremble can be maintained with but a few horsepower. Apart from the transmitting and receiving apparatus the only loss incurred is the energy radiated in the form of Hertzian or electro-magnetic waves which can be reduced to an entirely insignificant quantity."

Finally, as to the now famous Tesla Tower. This is a huge mushroom shaped tower at Wardenclyffe, Long Island, New York, a place some 60 or so miles out from the city along Long Island Sound. This tower is 185 feet high from the ground to the top of the cupola. The smallest dimension across the base of uprights is 97 feet. The height to the ledge of the cupola is 153 feet, while the cupola itself is 65 feet in diameter. The tower has eight sides, with a staircase and lift for reaching the cupola platform. It is from this cupola that wireless vibrations are to be shot out in any desired voltage to given points scattered over a very wide radius. Not only so, but Tesla dreams of making it a receiving station to which can be transmitted a ceaseless day and night service of millions upon millions of volts from such power plants as those of Niagara. Thence such a force could be transmitted to run the street cars, the elevateds, the subways, the factories, the electric lights, the railroads, the automobiles, the ferries, the trucks, the heaters in the cellars and the clocks in the parlors of the great city of New York.

Tesla's dream also includes the erection of towers similar to this at Wardenclyffe, at convenient places, everywhere, for the purpose of distributing wireless energy for all these purposes over their respective areas. Some towers would be supplied with power from such sources as Niagara Falls or Victoria Falls. Or plants will be erected alongside or between the main uprights, each distributing a huge horsepower under a tension of millions of volts. Mr. Tesla declares he can handle the most amazing voltage from such towers with absolute safety, and his dream is of an America dotted over with these towers, each supplying all the energy for, say, an area of 30 miles about and spaced from each other 60 miles in such a manner that practically every inch of ground is covered by his new wireless service.

Not only wireless power service but wireless telegraph and telephone service will be furnished by this network of towers, covering the entire earth and making it possible for a man in New York to talk directly with his friend in London. Tesla dreams of the day when a man may dictate his orders in San Francisco and they may be set up and printed directly in New York, of a day when not merely photographs will be transmitted by wireless, but when one can actually see over the wireless the friend to whom he is talking in some distant part of the earth, watch his facial movements, "see" him as plainly as if he were in the room. In fact the possibilities of the wireless age of the future as Tesla conceives it are boundless.

That is why he is more interested in schemes that are called "visionary" than in those of his inventions which "the world calls practical."

As he himself has put it in a recent statement: "A systematic research carried on for a number of years with the object of perfecting a method of transmission of electrical energy through the natural medium has led me to recognize three important necessities: First, to develop a transmitter of great power; second, to perfect means for individualizing and isolating the energy transmitted; and third, to ascertain the laws of propagation of currents through the earth and atmosphere."

All these things he now believes can be done. He believes that he has discovered a means of pouring electrical energy into the air, as it were, without loss except at the point where a properly tuned instrument will be able to draw it out, at the point where it is needed.

"When the great truth accidentally revealed and experimentally confirmed is fully recognized," he says in speaking of the inventions with which he believes he will make the wireless age a fact, "it will be seen that this planet, with all its appalling immensity, is to electric currents virtually no more than a small metal ball, and that by virtue of this fact many possibilities, each baffling imagination and of incalculable consequence, are rendered absolutely sure of accomplishment."

QUESTIONS AND ANSWERS

Rules:—Questions must be addressed to the "Question and Answer Department" and contain nothing for other departments. Full name and address of the writer must be given; only three questions may be sent at one time; 2-cent stamp must be enclosed for answer by mail. No attention will be paid to questions which do not comply with these rules.

Tesla Coil

Question.—Please explain what a Tesla coil is and what can be done with such a coil.—L. E. F., Madison, Maine.

Answer.—See "Construction of a Tesla High-Frequency Apparatus" on page 728 of the December, 1910, issue.

LXVIII. *The Induction-Coil.* *By* E. Taylor Jones, *D.Sc.*, *Professor of Physics in the University College of North Wales, Bangor, and* D. E. Roberts, *B.Sc., Fellow of the University of Wales* *

[Plates XII. & XIII.]

THE experiments described in the present paper were made with the object of determining the elements (periods, amplitudes, damping-factors, and phases) of the two electrical oscillations which are set up in the secondary of an induction-coil when the primary current is interrupted, and of calculating hence the maximum value of the secondary potential and the potential at any time during the oscillations.

The principal difficulties connected with the calculation of the secondary potential of an induction-coil are (1) the determination of the effective self- and mutual-inductances of the coils, (2) the determination of the capacity of the secondary coil; the first owing to the want of proportionality between magnetic induction and magnetizing force in the iron core, the second owing to the smallness of the capacity and to the fact that the capacity is distributed along the coil. Some attempt was made in the experiments described below to overcome these difficulties, but there are other circumstances, including condenser losses, hysteresis, and irregularities in the working of the interrupter, which will have to be taken into account, or avoided, before a complete solution of the induction-coil problem can be reached.

The papers of Oberbeck †, Walter ‡, and Lord Rayleigh §, on induction-coil potentials are well-known and are therefore only mentioned here.

§ Rayleigh, Phil. Mag., ii. p. 581 (1901).

General Description of the Method.

In a former communication one of us * arrived at the following expression for the difference of potential at the terminals of the secondary of an induction-coil at any time t seconds after a current i_0 is interrupted in the primary:—

$$2V_2 = \frac{Mi_0T}{(T^2-T'^2)\cos\delta}e^{-\frac{t}{T^2}\left(\frac{\theta_1+\theta_2}{2}-\beta\right)}\sin\left(\frac{t}{T}-\delta\right) - \frac{Mi_0T'}{(T^2-T'^2)\cos\delta'}e^{-\frac{t}{T^2}\left(\frac{\theta_1+\theta_2}{2}+\beta\right)}\sin\left(\frac{t}{T'}-\delta'\right), \quad . \quad . \quad (1)$$

where M is the mutual inductance of the primary and secondary coils,

$$\theta_1=\tfrac{1}{2}R_1C_1, \quad \theta_2=\tfrac{1}{2}R_2C_2,$$

$1/2\pi T$ and $1/2\pi T'$ are the frequencies of the two oscillations calculated from the well-known expression for coupled circuits

$$8\pi^2n^2=\frac{1}{1-k^2}\left[\frac{1}{L_1C_1}+\frac{1}{L_2C_2}\pm\sqrt{\left\{\left(\frac{1}{L_1C_1}-\frac{1}{L_2C_2}\right)^2+\frac{4k^2}{L_1C_1L_2C_2}\right\}}\right], \quad . \quad . \quad . \quad . \quad (2)$$

k being the coupling coefficient $M/\sqrt{L_1L_2}$.

The quantity β, and the phase-angles δ, δ', are to be calculated from the constants of the circuits as described in the former paper above referred to. R_1, R_2, C_1, C_2, L_1, L_2 are the primary and secondary resistances, capacities, and self-inductances.

In the paper referred to the above expression (1) was worked out for an *air-core* induction-coil with various condensers in the primary and secondary circuits, and the curve of secondary potential plotted from the results. The curve was also obtained photographically in each case by means of an electrostatic oscillograph, and was found to agree closely in its general form with the curve calculated from (1). The differences were mainly in the damping factors, and these discrepances probably arose from losses in the primary condensers.

Strictly speaking, the expression (1) is not applicable to a coil with an iron core, owing to the variable permeability of iron; all that can be expected is that suitable mean values

* E. T. Jones, Phil. Mag. January 1909, p. 28. This expression for the secondary potential was obtained by an application of Drude's 'Theory of the Oscillation Transformer,' *Ann. der Physik*, xiii. p. 512, 1904.

of the inductances may be found which will serve for the evaluation of the periods and amplitudes during at least a portion of the time of discharge. This was borne in mind in the experiments described below, and it was intended as far as possible to determine the mean inductances corresponding to the early portion of the discharge, since this portion includes the maximum secondary potential which is the quantity of greatest importance in an induction-coil.

The inductances of the primary and secondary coils were determined by electrical oscillation methods ; a condenser of known capacity being connected to the primary (or secondary) coil, and the curve of secondary potential being photographed and measured by methods which have been described in detail in former papers *.

It was thought that by measuring that portion of the damped oscillation-curve in which the current amplitude was approximately the same as in the early part of the double-period discharge, appropriate mean values of the inductances would be obtained, since the iron core passed through the same series of magnetic states in both cases. It was scarcely to be expected that this plan would lead to very accurate results, but it was hoped that it would suffice for the purposes of an approximate estimation of the secondary potential.

The coupling coefficient of the two coils was determined by finding the period of the oscillations of the secondary circuit, connected to a condenser, with the primary open and closed. The ratio of the squares of these periods is then $(1-k^2)$.

The value of the expression (1) was worked out for two induction-coils, a 12-inch spark coil by Max Kohl, and an 18-inch coil by the same maker. In the experiments with the smaller coil a condenser was connected to the terminals of the secondary coil ; otherwise the secondary capacity would have been so small that one of the oscillations would be too rapid to be accurately recorded by the oscillograph. In the case of the larger coil it was unnecessary to connect a condenser to the secondary, but the primary capacity was larger than is generally employed with induction-coils.

In these experiments the electrostatic oscillograph was provided with a steel strip under great tension in order to bring the amplitudes of the curves down to moderate dimensions. The metallic parts of the instrument were well sheathed in ebonite, and the terminals well separated, in order to prevent sparking.

* E. T. Jones, *loc. cit.* pp. 33-35; and Phil. Mag. August 1907.

The interrupter consisted of a copper rod making contact with the interior of an iron vessel containing petroleum. The rod was raised automatically, as the reflected rays of light were crossing the photographic plate, by a lever placed beneath the rotating mirror.

Experiments with a Condenser in the Secondary Circuit.

When a condenser is connected to the terminals of the secondary, the capacity of the secondary coil only comes in as a small correction, and it is unnecessary to know its value very accurately. It consists partly of the internal capacity, depending upon the capacity of one section of the coil on the next and upon the number of sections, and partly of the external capacity which depends upon the position of the coil with respect to other bodies and especially with respect to the primary coil. The methods by which these capacities were determined were described in a previous communication *.

Case I.—In the first experiment with the smaller induction-coil the primary was drawn out of the secondary until the curve of secondary potential, as shown by the oscillograph, had a simple and well-marked form, corresponding probably to some simple ratio between the two frequencies of oscillation. This case was intended as a preliminary test of the method.

The photograph is shown in Plate XII. fig. 8. The current broken in the primary circuit was 5·05 amperes, and the ordinate of the curve represents the square of the secondary potential at any subsequent time. The curve was photographed for four different values of the primary current i_0 ranging from 2·8 to 5·05 amperes, and the general form of the curve was the same in all, only the amplitude varying with the current. The amplitude of the first wave in each was measured on the negative with a travelling microscope and the values found were, within 4 per cent., proportional to the squares of the primary currents.

The lower curve in the photographs represents the oscillations of a 768 tuning-fork photographed simultaneously. Immediately after these curves were obtained another curve was photographed showing the secondary potential for an *air-core* induction-coil with known capacities and inductances in its circuits. This curve was similar to one of those discussed in the previous paper above referred to, and to which the expression (1) may be assumed to apply. By

* E. T. Jones, Phil. Mag., August 1907, p. 248.

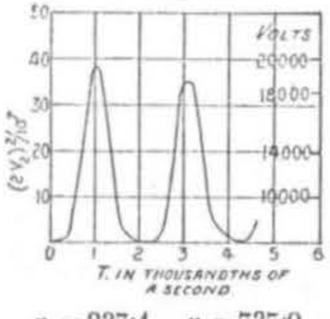
both measuring and calculating the maximum amplitude in this curve the electrometer may therefore be standardised.

The iron-cored induction coil was again connected to the oscillograph and photographs obtained for the purpose of measuring the primary and secondary inductances, the coupling coefficient, and the capacities if these were not already known. The values of these constants in the present case were as follows :—

$L_1 = \cdot 02342$ henries.
$L_2 = 258 \cdot 3$,,
$M = 1 \cdot 811$,,
$k^2 = 0 \cdot 5424$
$C_1 = 15 \cdot 95$ microfarads.
$C_2 = 0 \cdot 0004748$,,

This value of C_2 includes the capacity of the electrometer and of the secondary coil. The resistances of the primary and secondary coils were 0·32 and 14000 ohms.

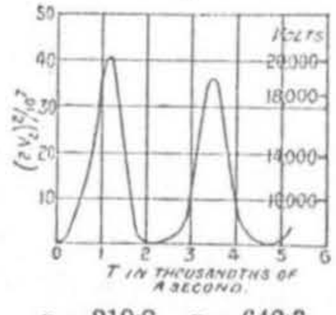
The two frequencies of oscillation, calculated by (2), were



$$n_1 = 237 \cdot 4, \qquad n_2 = 737 \cdot 0,$$

and the expression (1) for the secondary potential, taking the primary current i_0 as 5·05 amperes, becomes in volts

$$2V_2 = 15230\, e^{-6t} \sin (86453t - 0 \cdot 55) - 4910\, e^{-68 \cdot 15t} \sin (266334t - 1 \cdot 72),$$



in which t is the time in seconds after the interruption of the primary current, and the angles are given in degrees. This was worked out for a number of values of t, the results squared and plotted in a curve the early portion of which is shown in fig. 1.

Fig. 1.

$n_1 = 237 \cdot 4$, $n_2 = 737 \cdot 0$,
$i_0 = 5 \cdot 05$ amp.

Fig. 2.

$n_1 = 219 \cdot 8$, $n_2 = 642 \cdot 3$,
$i_0 = 4 \cdot 02$ amp.

The agreement between this curve and the photograph in

Plate XII. fig. 8, is evidently sufficiently close to justify the application of the method to the present case. The damping of the waves is much greater in the photograph than in the calculated curve. This is also the case in the other experiments described below, and is to be expected since the only cause of damping taken into account in the calculation is that which arises from the resistances of the circuits.

The calculated maximum value of the secondary potential is 19650 volts, and the amplitude of the first wave in the photograph is 0·9276 cm. Now the standardising curve obtained with the air-core coil showed that a deflexion of 0·3032 cm. in the photograph corresponds to 10200 volts. Hence taking the deflexion as proportional to the square of the potential, the amplitude of the first wave represents a maximum potential of 17850 volts.

When it is remembered that the damping due to hysteresis and condenser losses have been entirely neglected, the agreement between the calculated and observed values of the maximum secondary potential is perhaps as close as could be expected.

Case II.—This case is similar to the first except that the primary coil with its iron core was placed further inside the secondary in order to increase the secondary self-inductance and the coupling coefficient. The secondary capacity (a variable condenser with paraffin-oil dielectric) was adjusted so as to give a form of oscillograph curve slightly different from that of *Case I.* The constants of the circuits were :—

$L_1 = \cdot 02331$ henries.
$L_2 = 428 \cdot 1$,,
$M = 2 \cdot 436$,,
$k^2 = 0 \cdot 5949$
$C_1 = 15 \cdot 95$ microfarads.
$C_2 = 0 \cdot 000499$,,
R_1, R_2 as before.

The frequencies, calculated by (2), were

$$n_1 = 219 \cdot 8, \qquad n_2 = 642 \cdot 3,$$

and, with $i_0 = 4 \cdot 02$ amperes, the expression for the secondary potential in volts is

$$2V_2 = 15320\, e^{-5 \cdot 46t} \sin (79146t - 0 \cdot 51) - 5247\, e^{-51 \cdot 85t} \sin (231221t - 1 \cdot 49).$$

The curve representing the square of this expression is shown in fig. 2, the corresponding photograph in Plate XII. fig. 9, and again there is close agreement in the form of the curve.

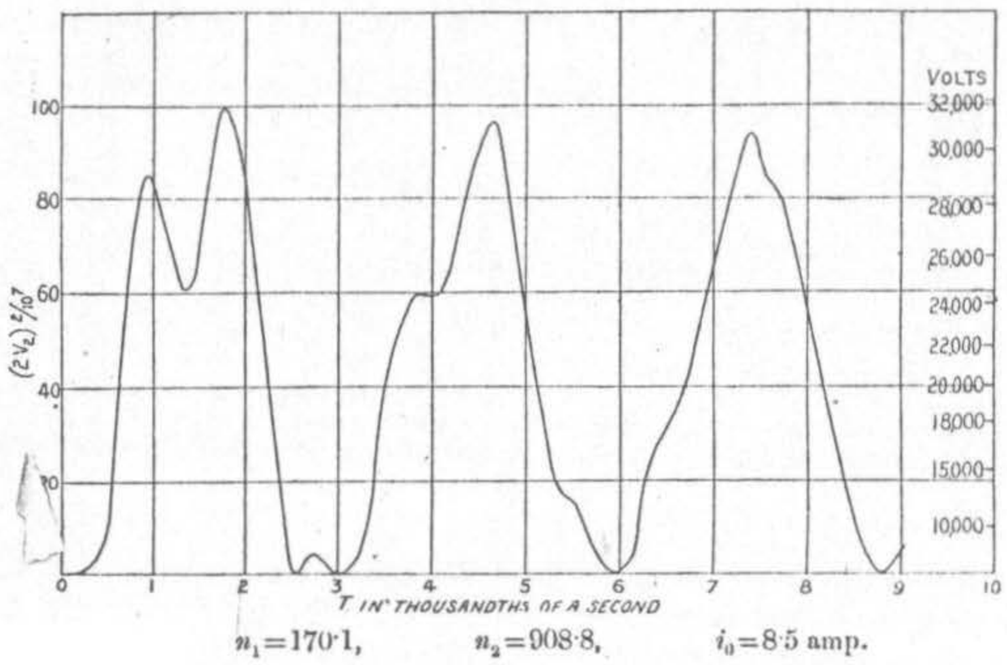
The maximum secondary potential (calculated) is 20085 volts, the observed value (by comparison with the curve given by the air-core coil) 17250 volts.

Case III.—The primary coil was placed fully inside the secondary so as to give the maximum values of the secondary self-inductance and the coupling coefficient. Owing to sparking between the plates of the oil condenser this was replaced by a leyden-jar. The constants for this case were:—

$L_1 = \cdot 02303$ henries.
$L_2 = 513$,,
$M = 3 \cdot 197$,,
$k^2 = 0 \cdot 8643$
$C_1 = 15 \cdot 95$ microfarads.
$C_2 = \cdot 001051$,,
R_1, R_2 as before.

The ratio of the frequencies was considerably greater than in the previous cases, their values being

$$n_1 = 170 \cdot 1, \qquad n_2 = 908 \cdot 8.$$



With a primary current of 8·5 amperes the expression for the secondary potential is

$$2V_2 = 30090\, e^{-6 \cdot 217t} \sin (61232t - 0 \cdot 55)$$
$$- 5640\, e^{-145 \cdot 6t} \sin (327157t - 2 \cdot 9).$$

The curve representing the square of this expression is given in fig. 3, and the corresponding photograph in Plate XII. fig. 10. Though there are differences in detail, in general form the resemblance between the two curves is close, and there is also good agreement, in this as well as in all the other cases, between the calculated and observed values of t at which the potential is zero. The calculated value of the maximum secondary potential is 31730, the observed value 26500 volts.

The greatest spark-length observed in this case between two brass spheres, each 2 centimetres in diameter, was 8·5 millimetres.

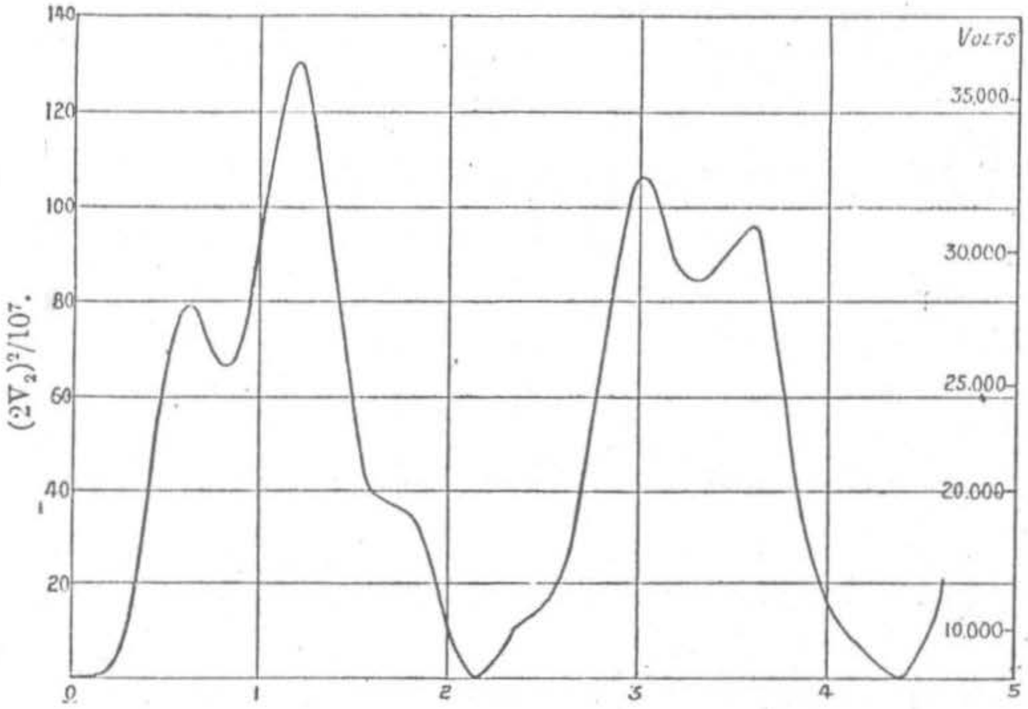
Fig. 3.

$n_1 = 170 \cdot 1$, $n_2 = 908 \cdot 8$, $i_0 = 8 \cdot 5$ amp.

Case IV.—This differs from the last only in the use of a smaller capacity in the secondary circuit, its value being ·0002213 microfarad. The frequencies were

$$n_1 = 230 \cdot 2, \qquad n_2 = 1444 \cdot 7,$$

and with $i_0 = 6 \cdot 75$ amperes the secondary potential is given by



$$2V_2 = 32411\, e^{-4 \cdot 884t} \sin (82888t - 0 \cdot 29)$$
$$- 5168\, e^{-145 \cdot 6t} \sin (520086t - 1 \cdot 82).$$

The maximum value of this expression, which occurs at the second peak of the curve, is 36060 volts. The curve is shown in fig. 4 (p. 714).

Several photographs were taken for this case, and though similar in their general features they differed considerably from one another in detail. Sometimes the first peak was equal to or higher than the second, sometimes the peak in the second principal wave was higher than both maxima in the first. These differences arise apparently from irregularities in the working of the interrupter, which seem to affect chiefly the amplitude and phase of the more rapid oscillation. The photograph in Plate XII. fig. 11 shows the type which occurred most frequently. By comparison with the air-core coil the highest point of the curve was found to correspond to a secondary (observed) potential of 27560 volts.

The greatest sparking-distance between the two spheres under the circumstances of this experiment was found to be 1 centimetre.

Fig. 4.

$n_1=230{\cdot}2$, $n_2=1444{\cdot}7$, $i_0=6{\cdot}75$ amp.

It will be observed that in all the above cases the calculated value of the secondary potential is considerably greater than the observed value, and that the percentage difference increases with the potential.

Experiments with no Condenser in the Secondary Circuit.

If the condenser is removed from the secondary circuit of the smaller induction-coil, one of the oscillations becomes too rapid to be faithfully recorded by the oscillograph. The 18-inch spark coil was therefore used for the three following cases, its secondary having much greater self-inductance and capacity.

In order to work out the expression (1) for these cases it is necessary to know the value of the effective capacity of the secondary coil with greater accuracy than was required in the former cases. After several methods had been tried for the determination of this quantity, the following was finally

adopted. The condenser having been disconnected from the primary circuit, a current was passed through the primary coil and the curve of secondary potential, produced at its interruption, was photographed. Under these circumstances the oscillations of the system depend only on the constants of the secondary circuit, and should give the value of the product of the self-inductance and capacity of the secondary coil. The photograph showed, in fact, a single damped oscillation with period lengthening as the oscillations died away owing to the variation in the permeability of the core, The period was measured in the early part of the curve, where the amplitude is large, and was found to be ·001763 sec. Taking this as being equal to $2\pi\sqrt{L_2C_2}$, we have

$$L_2C_2=0{\cdot}787\,.\,10^{-7}.$$

A condenser, of small known capacity C_2', was then connected to the secondary coil and the period of this circuit, with the primary open, determined. This gives in the same way the value of $L_2(C_2+C_2')$. From these two results the values of L_2 and C_2 can be determined. The values so found were $L_2=2350$ henries, $C_2=\cdot0000335$ microfarad. These values were used in working out the expression (1) for the following three cases. It may be noticed, however, that it is not so important to know the values of L_2 and C_2 separately as it is to know their product; C_2 occurs separately only in the damping factors of the two oscillations represented by (1).

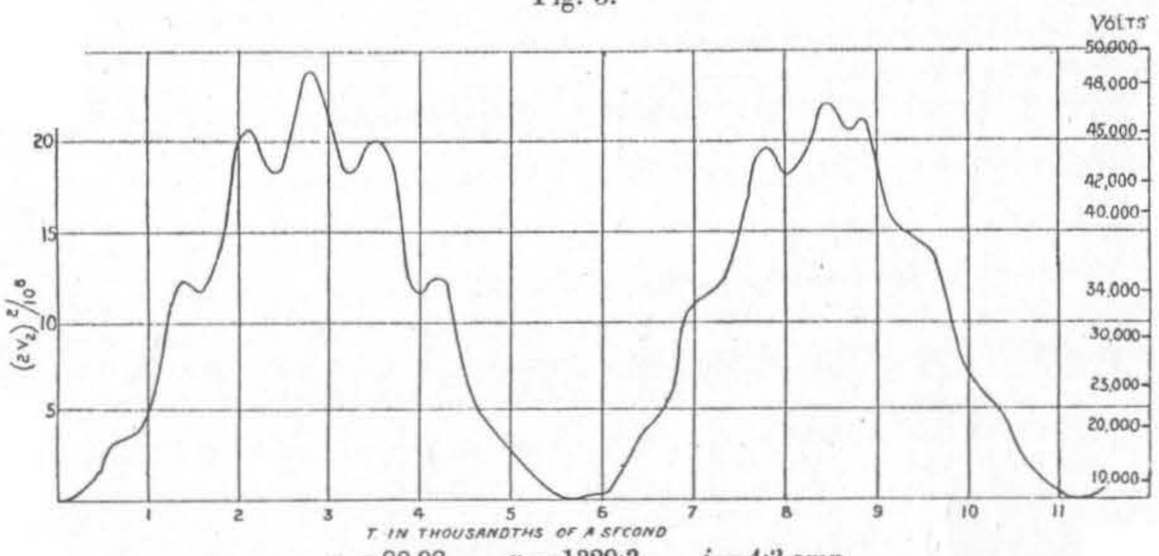
The self-inductance of the primary coil was determined by connecting to it the largest capacity available (20·73 microfarads), and photographing the curve of secondary potential produced at the interruption of a current in the primary. The curve obtained shows a double oscillation; but, since L_1C_1 is much greater than L_2C_2, one of the oscillations has a much longer period than the other, and it is not difficult to determine the frequency of the slower oscillation from the photograph. On substituting in the expression (2) we obtain the value of L_1.

As the potentials obtained in the following experiments were higher than those in the former cases, the oscillograph was made less sensitive by withdrawing the attracting plate to a greater distance from the steel strip. To prevent sparking inside the instrument the attracting plate was enclosed in a thicker sheath of ebonite. The distance of the edge of the plate from the strip was about 7 mm.

Case V.—The constants for this case were :

$L_1 = 0{\cdot}1974$ henries.
$L_2 = 2350$,,
$C_1 = 15{\cdot}95$ microfarad.
$C_2 = {\cdot}0000335$,,
$k^2 = 0{\cdot}8142$.
$M = 19{\cdot}44$ henries.
$R_1 = 1{\cdot}90$ ohms.
$R_2 = 38000$,,
$i_0 = 4{\cdot}3$ amperes.

The expression (2) gives for the frequencies



$$n_1 = 88{\cdot}98, \qquad n_2 = 1329{\cdot}3.$$

By (1) the secondary potential is

$$2V_2 = 46950\,e^{-4{\cdot}654t}\sin(32033t - 0{\cdot}05) - 3143\,e^{-62{\cdot}72t}\sin(478548t - 0{\cdot}8).$$

The curve representing the square of this expression is shown in fig. 5, and its maximum value is 48960 volts. The

Fig. 5.

$n_1 = 88{\cdot}98$, $n_2 = 1329{\cdot}3$, $i_0 = 4{\cdot}3$ amp.

photograph is given in Plate XIII. fig. 12, but it should be stated that the amplitude of the short wave varied considerably in different photographs, it being sometimes larger, sometimes smaller than is here shown. As in some other cases, these variations appear to arise from irregularities in the action of the interrupter.

The oscillograph was standardised in this and the two following cases, not directly with the air-core coil, but with the coil and condensers used in Case III., the greatest deflexion for a current of 8·5 amperes in that case being taken as representing 26500 volts. A comparison of the curves leads to 39480 volts as the greatest observed value of the secondary potential, which is again considerably below the calculated value.

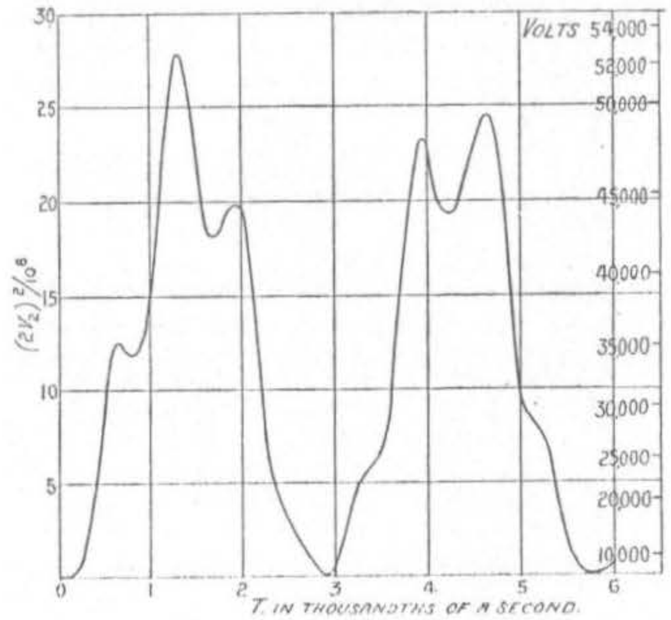
The sparking-distance between the two spheres with the same primary current was found to be 1·6 centimetres.

Case VI.—In order to approximate more closely to the ordinary working conditions of an induction-coil, the primary capacity was now considerably reduced in value. This has the effect of increasing the secondary potential, and at this stage it was noticed that at high potentials a brush discharge took place freely between the ebonite sheath enclosing the attracting plate of the oscillograph and other parts of the instrument. The attracting plate and its connecting rod were therefore provided with still thicker coverings of ebonite, and the terminals of the instrument were removed to a greater distance from each other, in order to diminish as far as possible the leakage due to this cause.

The primary capacity was in the present case 3·89 microfarads, which gives, by (2), using the values given under Case V. for the other constants of the circuits,

$$n_1 = 174{\cdot}4, \qquad n_2 = 1371.$$

The expression for the secondary potential in volts is



$$2V_2 = 21650\,i_0 e^{-4{\cdot}14t}\sin(62770t - 0{\cdot}1) - 2753\,i_0 e^{-65{\cdot}26t}\sin(493452t - 0{\cdot}83),$$

where i_0 is the primary current in amperes. The curve representing the square of this expression was drawn for $i_0 = 2{\cdot}25$ amperes, and is shown in fig. 6 (p. 718).

Photographs were taken at the interruption of various currents in the primary circuit. One of these is shown in Plate XIII. fig. 13. The curves obtained were all of the same type, only the amplitude varying with the primary current. The greatest ordinate in each photographic curve was measured and compared with that of the standardising curve. The results are contained in Table I., in which the first column contains the values of the current interrupted in

the primary circuit, the second the maximum potential calculated by (1), the third the maximum potential deduced by measurement of the plates.

Fig. 6.

$n_1=174{\cdot}4$, $n_2=1371$, $i_0=2{\cdot}25$ amp.

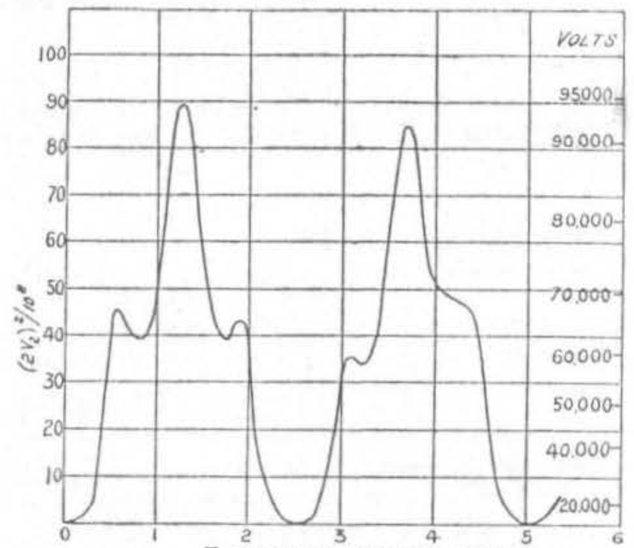
TABLE I.

i_0, amperes.	Maximum Potential in volts.	
	Calc.	Obs.
2·64	61910	72220
3·16	74110	84110
3·90	91460	101070
4·44	104120	118560
5·10	119600	132940

The greatest spark-length observed between the two spheres with the current of 5·1 amperes, was 7·3 centimetres.

The observed value of the secondary potential is in this case greater than the calculated value. Probably the calculated value is too small, owing to the fact that the expression (1) does not correctly represent the phase relation of the two oscillations, as we see by comparing the photograph Pl. XIII. fig. 13, with the calculated curve fig. 6.

Case VII. The primary capacity was further reduced, its value in this case being 2·933 microfarads. Taking the other constants as before, we have



$$n_1=198{\cdot}2, \qquad n_2=1388,$$

and the expression for the secondary voltage is

$$2V_2=24730\,i_0e^{-3{\cdot}975t}\sin(71359\,t-0{\cdot}12)$$
$$-3530\,i_0e^{-65{\cdot}42t}\sin(499860\,t-0{\cdot}83).$$

The curve, calculated for $i_0=3{\cdot}4$ amperes, is shown in fig. 7.

Fig. 7.

$n_1=198{\cdot}2$, $n_2=1388$, $i_0=3{\cdot}4$ amp.

The photograph shown in Plate XIII. fig. 14 is typical of the oscillograph curves obtained in this case. It again differs from the calculated curve in the relative phases of the two oscillations, and this probably accounts in part for the differences between the observed and calculated maximum voltages given in Table II.

TABLE II.

i_0, amperes.	Maximum Potential in volts.	
	Calc.	Obs.
2·74	75630	70440
3·24	89430	76950
4·00	110400	101100
4·42	122000	112100
5·10	140800	142400

With the current 5·1 amperes the greatest sparking-distance between the two spheres was found to be 11·2 centimetres.

To sum up, the results given above show that the expression (1) represents in its main features the wave of potential at the terminals of the secondary coil when a current is interrupted in the primary, and that it also gives the order of magnitude of the maximum secondary potential. In each of the cases described above some uncertainty with regard to the maximum potential arises from the fact that the amplitude of the oscillograph curve is not always the same with the same primary current; and although each curve was photographed a number of times and the curve of greatest amplitude selected for measurement, we could never be quite certain that the greatest possible amplitude was actually obtained.

Similar differences are observed with other kinds of interrupter. In Plate XIII. fig. 15, are shown the curves of secondary potential at two successive interruptions of the primary current produced by a motor mercury-interrupter of the centrifugal type. The coils and condenser in action at the time were the same as in Case VII.

Bangor, July 1911.

"In What Was Left of the Cities Starvation Stalked Like a Gigantic Death. The Aeroplanes, Searching Like Enormous Birds for Food, Were One by One Washed Away."

How Nature with a Second Deluge Washed Earth Clean of Mankind.

EACH year some new idea concerning the way Man and his Works will be conquered finally by Nature appears. Only once in a decade, however, will be evolved some theory sufficiently striking to grip the reader.

The unusual heat of this Summer, which affected not only America, but all of Europe, the consequent drought, the destruction of immense crops, and finally on August 16, the juxtaposition of the planets Mars and Saturn

and the moon, could be depended upon to stimulate some writer to predict what these phenomena meant.

In France, where scientific men do not hesitate to place their ideas in the form of fiction, M. Marcel Roland, a member of the French Institute of Science, has written a startling book upon the Second Deluge, which in the Fall of 1911 is supposed to follow these portents. The tale is told by a survivor of the deluge and is here abridged.

By M. Marcel Roland.

THERE had been a searing drought for many months. For five years the rain fall had steadily decreased. Throughout the Summer the heat had been killing. All over the world crops had been ruined; the wheat was burned on its stalks. Many people died. The sun burned with a lurid, reddish lustre that fretted the nerves. Suicides and murders kept steadily increasing.

November dawned. The Seine was so low that the talking rock, that carved stone whose appearance always means evil, had long grown commonplace. In New York the water riots had claimed their thousands of lives. The great tongue of the city stretching into the bay was only a mass of blackened skeletons of iron.

My uncle, a great meteorologist, had predicted that in this month would come the break in the great drought. He warned the people of the world to take precautions; that there would be great and disastrous floods. Paris and the world laughed at him, called him a Twentieth Century Noah, bade him build an ark, and went about their pleasures as undisturbed as might be in that time of stress.

The skies began gradually to thicken; the heat became more intense. Blacker and blacker grew the heavens. Down and down dropped the barometer. At last came the rain.

Although it was nearing Winter the weather did not grow cold. Reports from the far North did not grow cold. Reports from the far North and the far South showed that the warmth extended even there. The great ancient fields of snow and ice were melting under the deluge and were sending their immemorial fettered floods into the air as rain and into the seas as water to swell the rising oceans.

Every one moved upstairs, for the cellars were flooded. Business stopped. Many now began to build boats and to sail for the higher lands. Then began those series of awesome tempests which must have been like those mighty winds that moved over the face of earth when it was being created. No boats could live in these hurricanes.

The great liners, bought in the emergency by the money kings of America and stocked to the limit with food, went down one by one. The American Midases each in his separate Ark were wiped from the face of the earth, or the waters.

It was John Rockefeller who conceived the idea of propitiating Deity by imitating Noah and bringing into his ocean leviathan pairs of all the animals and creatures he could find. Behind his Ark he towed thousands of barges laden with oil, to calm the waves. He kept in touch with the world by his wireless for forty days, beseeching the people to repent and pray. Then Aetna blew up, dropping the island of Sicily under the waves. Mr. Rockefeller was not far away from the volcano and his Ark. The New Olympic must have been overwhelmed in that cataclysm.

By that time all the world was afloat. In what was left of the cities, starvation stalked like a gigantic death. The aeroplanes darting hither and thither through the torrents, searching like enormous birds for food, were one by one washed away to destruction. Only Antoni, the Italian inventor, in his Triton, that wonderful combination of submarine and flying machine, remained an active fighter against this gigantic upheaval of Nature. The world starved in its garrets and drowned in its streets. It fed on floating carrion and then in madness turned into a frery of cannibalism.

We had locked ourselves in our house, my uncle and I. He was an old man, and on the hundredth day of the rains he died. Then I was alone. The earth rocked with explosions, with lightnings and the tempest. I looked over Paris. It was a sea covered with floating dead. On the first of February my provisions were exhausted I determined to break through into the garret of the next house, still standing, where I believed that a store of groceries had been placed. As I drove my axe through the last partitions a sudden light shone in the sky, and there was a terrifying roar of thunder. The walls cracked. With a cry of terror I looked into the face of a woman. It was Eva Vanhoem, the daughter of my neighbors, who had tried to escape by yacht from the Deluge.

On the eighth day at 4 o'clock I was awakened by the water creeping toward us over the floor of the roof to which we had fled.

"To the ladder!" I cried. We climbed out on the roof. There we stood cowrapped in the awful night. The water crept up and up—over the roof. I held the girl above my head. I know not why, but I began to shout again and again for help. Suddenly a gigantic black form swept over my head. Two arms seized mine, lifted from them the form of the girl, lifted me, and I was swept away into the blackness.

When I awoke I found that it was Antoni who had saved us. We were in his flying submarine.

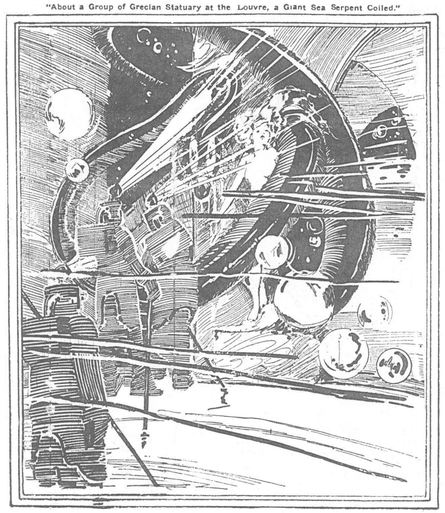
"We will go to the Louvre," said Antoni.

"There is a necklace there that once belonged to a great Egyptian queen that I have always coveted." The Triton was filled with the rarest treasures of vanished humanity, which the Italian had taken from earth's drowned museums. We swam between the dark masses that had once been the buildings of proud Paris. We passed the obelisk, now fallen; the library, the grand opera house. Everywhere were the bodies of men and women floating about.

The Triton stopped at the doors of what had been the Louvre. He brought out some new diving suits he had invented.

Antoni, Eve and I each put one on. We carried a light rope, which connected us with the Triton. We entered the Louvre. There were its priceless treasures waiting for the water to subside and to be rediscovered by a new race of men thousands of years from now. About a group of Grecian statuary a giant sea serpent coiled. We fought it off with our electrically charged iron rods and took what we wished from the treasure house of Paris.

On the two hundredth day Antoni said: "To-morrow the rain will cease." He was right, but when we called upon Benin we found him drunk in a corner. He refused to work any longer. "There's only us four in the world," he said. "I'm as good as any of you. Who gets the woman?"



Before I could grasp the import of this we heard peculiar sound, almost like prolonged whistling. Through the port holes we saw masses of brown bones flashing past. An enormous masked face looked in at us. It was gigantic walrus. We rose to the surface. The sea was covered with walrus herds driving down from the melted north.

"Go inside!" I cried to Eve Antonio joined me. "Inside all, and close the openings!" Easier said than done. We were fighting our way through the horde when Bonin leaped upon the back of one monster. He plunged his knife into its throat. Both sank. Antonio drove at the others. I snatched Eva and threw ourselves below. As I dropped I saw Antoni, spitted on tusks, go over the side.

We closed the openings and sank. We were the last people, we thought, on the world

Now day by day the waters subsided. A stench of death was in the air. We drove South. On the two hundred and fiftieth day we saw two islands. They were all that were left of the great peaks of Java. As we drove toward them a horde of ape-like men and women rushed to meet us. They greeted us as gods. And here we have taken up our home—a new Adam and Eve to lead these people into development. We are sure that we are the last of civilized humanity to remain on earth!

But once again man will rise and conquer!

"About a Group of Grecian Statuary at the Louvre, a Giant Sea Serpent Coiled."

To Turn Earth into One Gigantic Dynamo,

The Wireless Wonders That Tesla's "World System" May Perform.

1. Television, making it possible to see any object at any distance.
2. Universal twenty-four-hour daylight by wireless illumination.
3. Instantaneous transmission of typed or hand-written characters all over the world.
4. Operation of flying machines by wireless power.
5. Navigation of ships through fogs and channels by wireless "tuned" compasses.
6. Communication with Mars.
7. Operation of all manufacturing and transportation machinery.
8. Every clock and watch in the world set and regulated by wireless at certain time each day.
9. Universal telephony, making it possible to speak to any distance.
10. A perfect government secret signal service by exclusive wireless waves.
11. Simultaneous operation of all stock-tickers throughout the world.
12. Universal system of musical transmission on atmospheric currents.
13. Irrigation and fertilization of arid lands by wireless power.
14. The magnetizing of enemy's battleships to attract torpedoes.
15. Reproduction of drawings and photographs at any distance.
16. Absolutely exclusive telegraphy and telephony.

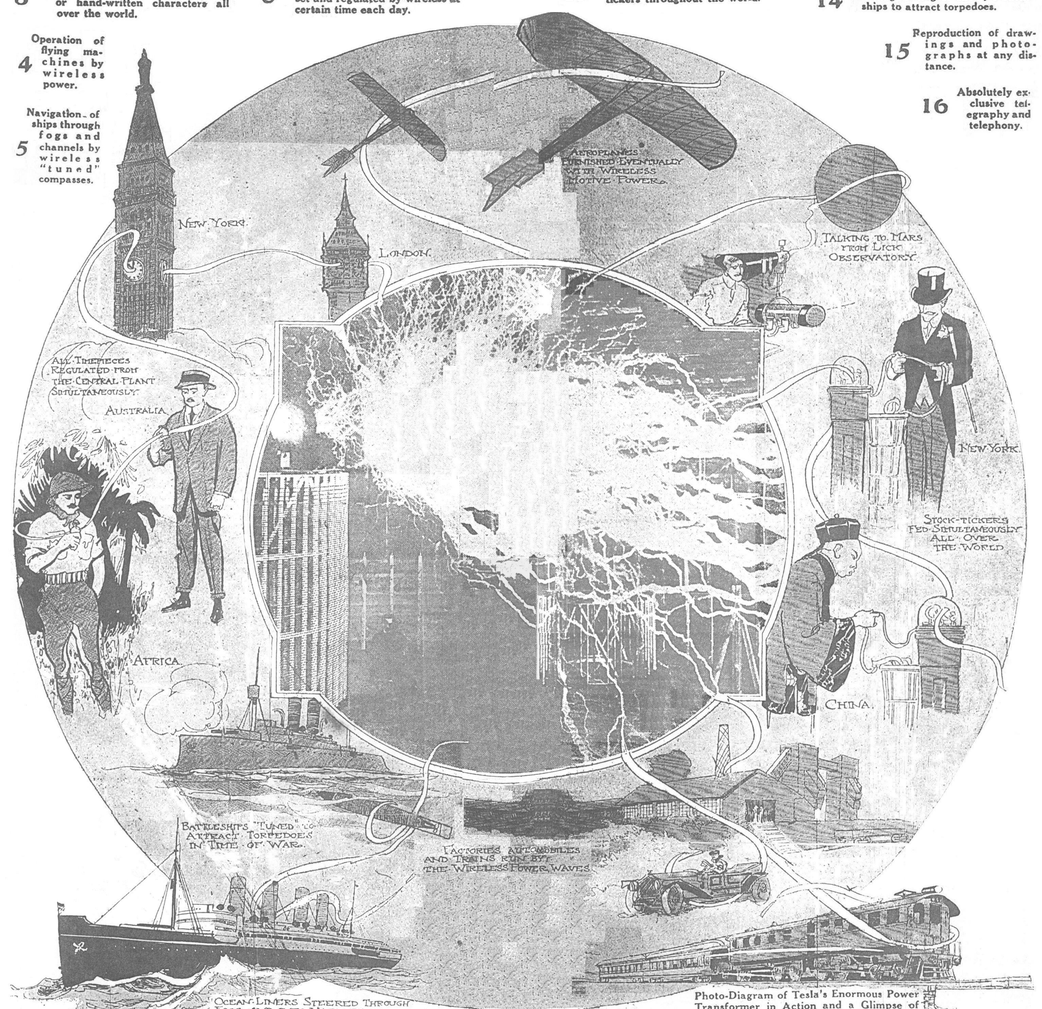


Photo-Diagram of Tesla's Enormous Power Transformer in Action and a Glimpse of What He Hopes to Accomplish With It.

How Man May Derive His Power in the Ages Still to Come.

A COUPLE of years ago James J. Hill, the railroad magnate, declared that before the end of the present century the available fuel supply of the country will be practically exhausted. This state of affairs will be brought about as a result of the destruction of our forests and the overproduction of coal.

How far this contingency might interfere with Nicola Tesla's remarkable plan to convert the earth into a huge dynamo to do the work of the universe depends entirely upon the available substitutes for coal and wood for the generation of heat. When our coal and wood are all gone, where will we get the energy to run the great earth dynamo?

In this connection, several plans which have been presented from time to time suggest themselves.

Perhaps the most remarkable is that of M. Camille Flammarion, the great French astronomer and physicist, who suggested boring a hole through the crust of the earth to sap the inexhaustible supply of heat believed to exist in its centre.

This plan is particularly interesting, because so little is known as to exact conditions to be found within the crust of the earth. The deepest shaft ever built penetrated but a mile and a quarter below the surface an insignificant distance compared with the four thousand miles between the surface and the centre.

It has been estimated that on an average the temperature increases one degree centigrade for every four yards in depth. On this basis a depth of two feet would bring us to the boiling point, while the temperature at the centre of the earth would be no less than two hundred thousand degrees! According to Flammarion. It would be necessary to bore not more than four miles before an inexhaustible supply of heat emitted might be applied to industrial purposes were real.

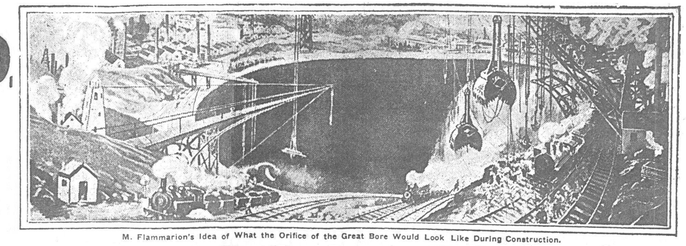
How would we proceed to dig this four-mile shaft? "Besides being very deep," says Flammarion, the shaft ought also to be of considerable diameter—say two hundred to three hundred yards, supported by a heavy thick, cast-iron lining.

"The excavated earth would most conveniently be disposed of by throwing it into the sea, to which it would be transported by railway.

"But, it will be asked, what of the insurmountable obstacles which will be encountered in the excavation of such a shaft? What of subterranean rivers? What of the landslips and the caving-in of the inside of the shaft?

"The reply is simple. These things can be forseen and provided against. The use of freezing mixtures, now so well understood, would here play a considerable part by freezing the moist and moving earth into rigidness and immobility."

Flammarion believes that his plan is practicable and possible, and, if so, it would, no doubt, provide the energy necessary for Tesla's great "world system."



Another project which would prove equally effective, if feasible, is that of harnessing the rays of the sun. The heat radiating from the great solar body is sufficient to run the world-dynamo for millions of years, but how can we avail ourselves of it?

Sun-machines of various descriptions have been announced from time to time by ambitious inventors, but have proved either absolute failures or capable of generating only an insignificant amount of energy.

The scientists of the world have been diligently working on this problem for years, however and there seems to be no reason to believe that success will not ultimately be attained.

The newly discovered properties of radium likewise hold out great promise in this connection. At the present time, of course, the available supply of this element is too small to be of much service, but there is no doubt that it exists in almost inexhaustible quantities and scientific research will eventually discover a method of obtaining it in any amount desired. Indeed, Flammarion has suggested that his plan of boring a hole through the earth, if it had no other result, would probably reveal the existence of enormous radium mines in the bowels of the earth.

With all these possible sources of energy the state of future man on this globe would seem to be assured.

M. Flammarion's Idea of What the Orifice of the Great Bore Would Look Like During Construction.

Nicola Tesla for the First Time Describes His New System for Supplying Wireless Power to Run All the Earth's Industries.

BY a series of discoveries and inventions just perfected, Nikola Tesla, the electrical scientist, has upset what has hitherto been regarded as one of the fixed laws of nature

"Every effect diminishes with the distance," is the way the text books have expressed it. Tesla now asserts that instead of decreasing, like other forces, electricity may be made to increase in intensity with the distance travelled.

The full significance of this discovery may not be at once apparent. It is obvious, however, that it annihilates space. There can be no limit to the power of an electric wave which increases in intensity the further it travels.

For nearly twenty years Tesla has been working on his plan. He calls it his wireless "World System." If it is put into successful execution it will convert the earth into a gigantic conduit, which will pass power for all earthly activities, and make possible communication with the other planets.

From time to time Tesla has made partial announcements as his work progressed. This, however, is the first comprehensive account of his system as a whole that the inventor has consented to give to the world.

"Through ages past," Mr. Tesla declared, "man has always attempted to project in some way or other energy into space. In all his attempts, no matter what agent he employed, he was hampered by the inexorable law of nature which says that every effect diminishes with distance, generally as the square of the same, and sometimes more rapidly.

"Now the discovery I made upset all that had gone before, for there was a means of projecting energy into space, absolutely without loss from any point of the globe to another, to the Antipodes if desired. In fact, a force impressed at one point could be made to increase with the distance.

"I saw at once that space was annihilated in all the three aspects; in the transmission of intelligence, in the transport of our bodies and materials and in the transmission of the energies necessary for our existence. You can imagine how profoundly I was affected by this revelation. Technically, it meant that the earth, as a whole, had certain periods of vibration, and that by impressing electrical vibrations of the same periods upon it, it could be thrown into oscillations of such nature that innumerable benefits could be derived."

"It is difficult to convey an idea of these inventions without resorting to technical terms," Tesla continued. "The first and best known of these is my transformer, which enables the production of electrical vibrations of transcending intensities. I have already attained activities of many millions of horse power; but this is nothing compared to those which I am expecting to get with my improved apparatus.

"The second is what I have termed my magnifying transmitter, which I look upon as my best electrical invention, and with which any distance can be bridged. I have already passed a powerful current around the globe by the use of this wonderful instrument, and am confident that a message can be flashed to such a distance as the planet Mars.

"Some technical men would be disposed to look upon such statements as those of a dreamer, but it is only because they have not had opportunities to see experiments which I have actually performed. The third invention I have designated as the art of individualization,' which enables the transmission of an unlimited number of messages through a wire or wireless, without the slightest interference. Not before this improvement is universally adopted will the world fully realize the benefits of telegraphy and telephony. The fourth invention is my receiver, which concentrates the energy transmitted over a wide area into the operating device."

"What would the voltage of your transmitter be?"

"In the transmission of telegraphic and telephonic messages I shall employ from five to ten million volts, but in transmitting power in great quantities, as much as one hundred million volts will be used.

"How will your 'World System' compare with those now in use as regards cost?"

"We could easily afford to offer a transmission of telegraphic and telephonic messages to any terrestrial distance for five cents a word. In a short while no one will think it anything out of the way to dictate or to write a long letter across the Pacific."

"How long does it take for the transmission of a message by your system, around the world?"

"The exact time is, according to my measurements, 42-1000 of a second, which is a speed about 50 per cent greater than that of light.

"The impulse starts from my magnifying transmitter with infinite speed, slows first rapidly and then at a lesser rate until, when it has penetrated to a distance of six thousand miles from the transmitter, it proceeds with approximately the speed of light. From there on it accelerates, first slowly and then more rapidly, and reaches the opposite point of the globe again with infinite speed only to rebound and pass through the same phases on its way back to the transmitter.

"This movement of electricity through the earth, which takes place strictly in accordance with a mathematical law, enables a great number of accurate measurements and determinations to be made, which are of immense practical and scientific value."

"Is your universal marine service based upon this principle?"

"Largely so. In setting up and maintaining stationary waves in the earth its entire surface is subdivided in perfectly definite zones of electric activity, so that any observer of all those data

The Drills at the Base of Flammarion's Gigantic Geothermic Pit Strike a Pocket of Living Radium From Such Pits Tesla Might Draw His Power for His "World System."

Tesla's Magnifying Transmitter in Action—A Medusa Head of Lightnings.

and other place he wishes without loss of time in the transmission. It will be exactly as though he had his stenographer close by. In the same manner it will be practicable to send a hand-written letter or even a check, and what is more important, it will not be possible to falsify the signature."

"Will the transmission of complex musical productions require complicated apparatus?"

"Not at all. The apparatus at any of the master plants, transmitting a great number of musical compositions, will be of necessity complicated, but the subscriber will need only a telephone receiver, and, if he desires exclusiveness, an individualizing device in connection, which, however, will be rarely required. He will be none the less able to listen to the most complex opera played in some remote part of the world. What is more, he can carry the entire outfit with him on his walks and travels, and wherever he desires to listen to the music he can do so.

"The wireless system which I have developed does not contemplate competition with established lighting systems in densely populated districts, but it offers an ideal solution for the illumination of isolated places. The light will be furnished by exhausted glass tubes, bent in all sorts of ornamental shapes, and is of surpassing beauty, resembling closely the daylight. The lamps will last forever. The entire apparatus for lighting the average country dwelling will contain no moving part whatever, and could be readily carried about in a small valise. It will be quite immaterial in which region of the earth the house to be lighted is located. Distance will not affect the charge."

"How far from the earth's surface can power be transmitted by this wireless system?"

"To any distance; in fact, the greater the elevation above ground the easier it is to supply the power to the vehicle, such as an airship crossing the ocean."

"What do you consider the most important application of your system?"

"The transmission of power, of course. The operation of aerial machines alone will be of a revolutionizing influence, inasmuch as it will afford a perfect solution of this important problem. Another great field will be the irrigation and fertilization of the soil by wireless power. The time is not distant when a farmer will have installed on his place apparatus for continuously manufacturing, from the gases of the atmosphere, nitric compounds which will be used to fertilize, while a motor will pump the water and perform other duties, all the energy being supplied from a plant perhaps thousands of miles away. This system can be extended so as to make productive vast tracts of now barren lands located in various countries. I believe that the export of wireless power will be one of the chief resources of the United States and other fortunately situated countries in times to come."

"A business man will be able to dictate in his office a letter which will appear in type at

Nikola Tesla Sued for $18,081.30.

Nikola Tesla, the electrical inventor, was today made the defendant in an action filed in the Supreme Court against him by the corporation of Westinghouse, Church, Kerr & Company, to recover the sum of $18,081.40 on a note. The complaint recites that on April 17 1907 the inventor executed the note to the order of the plaintiff, due in four months, and bearing six per cent. interest, "for value received."

The New York Press September 6, 1911

Sues Nicola Tesla for $18,081.30.

Nicola Tesla inventor, was yesterday made defendant in an action filed in the Supreme Court by the corporation of Westinghouse, Church, Kerr & Co. to recover the sum of $18,081.30 on a note for merchandise

FLUID PROPULSION.

On other pages of this issue we present Dr. Nikola Tesla's description of a new principle of fluid propulsion, which is the culmination of his labors of a number of years. As all generation of mechanical power involves the use of a fluid as the vehicle of energy, the underlying idea is a broad one and bears on all the branches of mechanics.

Dr. Tesla avails himself of the two fundamental properties of a fluid, adhesion and viscosity, in an effort to produce a highly efficient mechanism. The fluid, whether receiving or imparting energy, is made to pass along the surfaces of a system of rotating disks in free natural spirals—that is, along paths of least resistance. The efficacy of the machines he has constructed on this principle is evidenced by their remarkable performance, small turbines or rotary engines being run at a peripheral speed scarcely more than half of that of reaction turbines, and giving several times the output of the latter. For example, a small steam turbine exhibited at the Edison station in New York, having a rotor only nine and three-quarters inches in diameter and two inches wide, was capable of developing 110 horsepower with free exhaust. This machine had no blades, vanes, valves or sliding contacts of any kind.

On account of the great simplicity of this apparatus, reversibility and extraordinary output, it will undoubtedly find an immense variety of uses, and the commercial world can not fail to be deeply interested in this new development. The electrical industry, in particular, should be greatly benefited by this latest effort of Dr. Tesla.

TESLA'S NEW METHOD OF AND APPARATUS FOR FLUID PROPULSION.

INVENTION OF A TURBINE AND PUMP.

In an address before the New York section of the National Electric Light Association on May 15 of this year, Nikola Tesla devoted a few remarks to a new mechanical principle he had developed, and exhibited diagrams and working drawings in explanation of the same. He also alluded to the fact that several of his machines were to be seen in operation at the Waterside Station of the New York Edison Company, which had courteously extended to Dr. Tesla its facilities. The ELECTRICAL REVIEW AND WESTERN ELECTRICIAN of May 20 published an exclusive and full report of Dr. Telsa's address.

We present herewith the first authoritative description in the inventor's own words, which, on account of the great importance of the subject, cannot fail to excite interest in engineering circles the world over.

In the practical application of mechanical power based on the use of a fluid as vehicle of energy it has been demonstrated that, in order to attain the highest economy, the changes in velocity and direction of movement of the fluid should be as gradual as possible. In the present forms of such apparatus more or less sudden changes, shocks and vibrations are unavoidable. Besides, the employment of the usual devices for imparting to, or deriving energy from a fluid, as pistons, paddles, vanes and blades, necessarily introduces numerous defects and limitations and adds to the complication, cost of production and maintenance of the machine.

The purpose of the invention is to overcome these deficiencies and to effect the transmission and transformation of mechanical energy through the agency of fluids in a more perfect manner, and by means simpler and more economical than those heretofore employed.

This is accomplished by causing the propelled or propelling fluid to move in natural paths or stream lines of least resistance, free from constraint and disturbance such as occasioned by vanes or kindred devices, and to change its velocity and direction of movement by imperceptible degrees, thus avoiding the losses due to sudden variations while the fluid is receiving or imparting energy.

It is well known that a fluid possesses, among others, two salient properties; adhesion and viscosity. Owing to these a body propelled through such a medium encounters a peculiar impediment known as "lateral," or "skin resistance," which is twofold: one arising from the shock of the fluid against the asperities of the solid substance, the other from internal forces opposing molecular separation. As an inevitable consequence a certain amount of the fluid is dragged along by the moving body. Conversely, if the body be placed in a fluid in motion, for the same reasons, it is impelled in the direction of movement. The accompanying drawings illustrate operative and efficient embodiments of the idea.

Fig. 1 is a partial end view, and Fig. 2 a vertical cross-section of a pump or compressor, while Figs. 3 and 4 represent, respectively, in corresponding views, a rotary engine or turbine, both machines being constructed and adapted to be operated in accordance with the invention.

Figs. 1 and 2 show a runner composed of a plurality of flat rigid disks *1* of a suitable diameter, keyed to a shaft *2* and held in position by a threaded nut *3*, a shoulder *4* and washers *5* of the requisite thickness. Each disk has a number of central openings *6*, the solid portions between which form spokes *7* preferably curved, as shown, for the purpose of reducing the loss of energy due to the impact of the fluid.

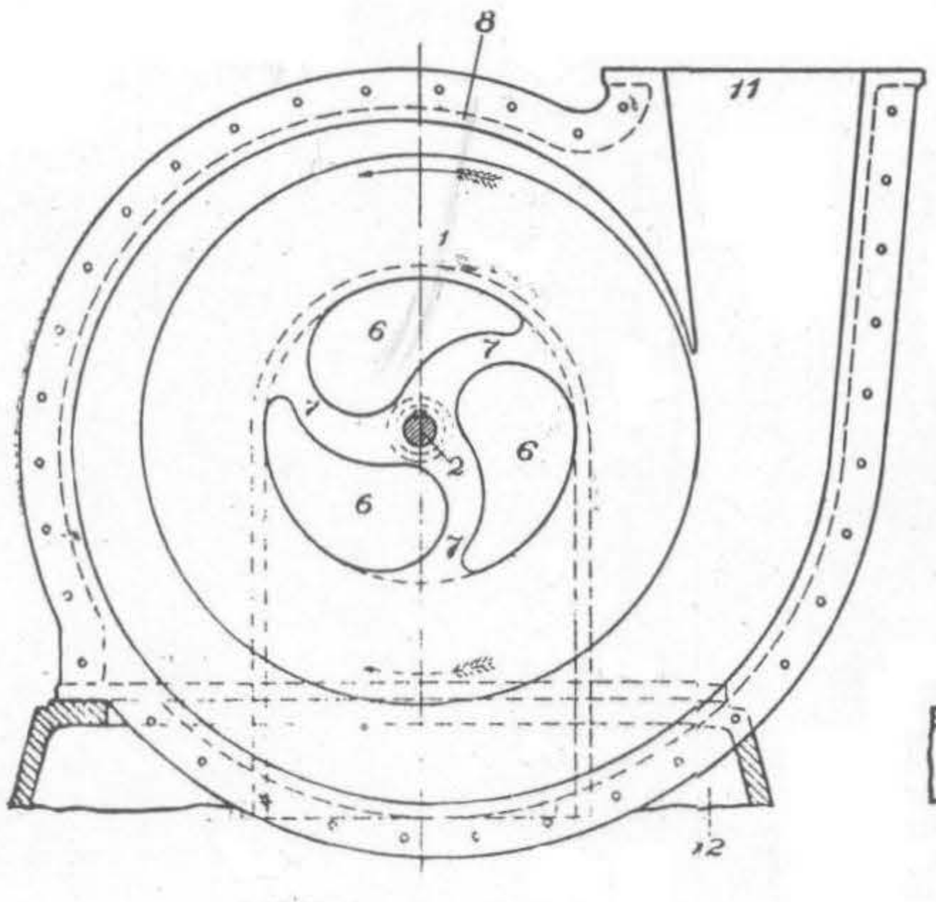

FIG. 1.

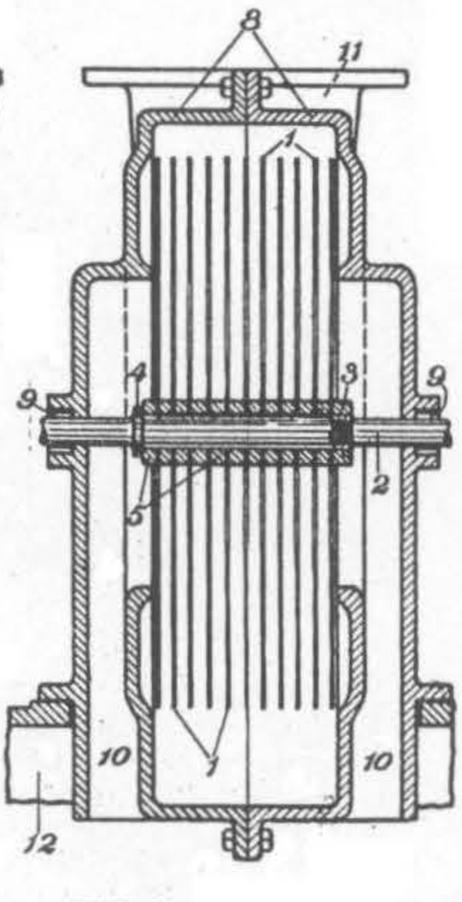

FIG. 2.

This runner is mounted in a two-part volute casing *8* having stuffing boxes *9* and inlets *10* leading to its central portion. In addition a gradually widening and rounding outlet *11* is provided formed with a flange for connection to a pipe as usual. The casing *8* rests upon a base *12* shown only in part and supporting the bearings for the shaft 2, which, being of ordinary construction, are omitted from the drawings.

An understanding of the principle embodied in this apparatus will be gained from the following description of its mode of operation.

Power being applied to the shaft and the runner set in rotation in the direction of the solid arrow, the fluid, by reason of its properties of adherence and viscosity, upon entering through the inlets *10* and coming in contact with the disks *1* is taken hold of by the same and subjected to two forces, one acting tangentially in the direction of rotation, and the other radially outward. The combined effect of these tangential and centrifugal forces is to propel the fluid with continuously increasing velocity in a spiral path until it reaches the outlet *11* from which it is ejected. This spiral movement, free and undisturbed and essentially dependent on these properties of the fluid, permitting it to adjust itself to natural paths or stream lines and to change its velocity and direction by insensible degrees, is characteristic of this method of propulsion and advantageous in its application.

While traversing the chamber inclosing the runner, the particles of the fluid may complete one or more turns, or but a part of one turn. In any given case their path can be closely calculated and graphically represented, but fairly accurate estimates of turns can be obtained simply by determining the number of revolutions required to renew the fluid passing through the chamber and multiplying it by the ratio between the mean speed of the fluid and that of the disks.

It has been found that the quantity of fluid propelled in this manner is, other conditions being equal, approximately proportionate to the active surface of the runner and to its effective speed. For this reason, the performance of such machines augments at an exceedingly high rate with the increase of their size and speed of revolution.

The dimensions of the apparatus as a whole, and the spacing of the disks in any given machine, will be determined by the conditions and requirements of special cases. It may be stated that the intervening distance should be the greater, the larger the diameter of the disks, the longer the spiral path of the fluid and the greater its viscosity. In general, the spacing should be such that the entire mass of the fluid, before leaving the runner, is accelerated to a nearly uniform velocity, not much below that of the periphery of the disks under normal working conditions and almost equal to it when the outlet is closed and the particles move in concentric circles.

It may also be pointed out that such a pump can be made without openings and spokes in the runner, as by using one or more solid disks, each in its own casing, in which form the machine will be eminently adapted for sewage, dredging and the like, when the water is charged with foreign bodies and spokes or vanes are especially objectionable.

Another application of this principle, thoroughly practicable and efficient, is the utilization of machines such as described for the compression or rarefaction of air, or gases in general. In such cases most of the general considerations obtaining in the case of liquids, properly interpreted, hold true.

When, irrespective of the character of the fluid, considerable pressures are desired, staging or compounding may be resorted to in the usual way, the individual runners being, preferably, mounted on the same shaft. It should be added that the same end may be attained with one single runner by suitable deflection of the fluid through rotative or stationary passages.

The principles underlying the invention are capable of embodiment also in that field of mechanical engineering which is concerned in the use of fluids as motive agents, for while in some respects the actions in the latter case are directly opposite to those met with in the propulsion of fluids, the fundamental laws applicable in the two cases are the same. In other words, the operation above described is reversible, for if water or air under pressure be admitted to the opening *11* the runner is set in rotation in

the direction of the dotted arrow by reason of the peculiar properties of the fluid which, traveling in a spiral path and with continuously diminishing velocity, reaches the orifices *6* and *10* through which it is discharged. If the runner be allowed to turn freely, in nearly frictionless bearings, its rim will attain a speed closely approximating the maximum of that of the fluid in the volute channel and the spiral path of the particles will be comparatively long, consisting of many almost circular turns. If the load is put on and the runner slowed down, the motion of the fluid is retarded, the turns are reduced, and the path is shortened.

Owing to a number of causes affecting the performance, it is difficult to frame a precise rule which would be generally applicable, but it may be stated that within certain limits, and other conditions being the same, the torque is directly proportional to the square of the velocity of the fluid relatively to the runner and to the effective area of the disks and, inversely, to the distance separating them. The machine will, generally, perform its maximum work when the effective speed of the runner is one-half of that of the fluid. But to attain the highest economy the relative speed or slip, for any given performance, should be as small as possible. This condition may be to any desired degree approximated by increasing the active area and reducing the space between the disks.

When apparatus of the kind described is employed for the transmission of power, certain departures from similarity between transmitter and receiver may be necessary for securing the best result. It is evident that, when transmitting power from one shaft to another by such machines, any desired ratio between the speeds of rotation may be obtained by proper selection of the diameters of the disks, or by suitably staging the transmitter, the receiver, or both. But it may be pointed out that in one respect, at least, the two machines are essentially different. In the pump, the radial or static pressure, due to centrifugal force, is added to the tangential or dynamic, thus increasing the effective head and assisting in the expulsion of the fluid. In the motor, on the contrary, the first named pressure, being opposed to that of supply, reduces the effective head and the velocity of radial flow towards the center. Again, in the propelled machine a great torque is always desirable, this calling for an increased number of disks and smaller distance of separation, while in the propelling machine, for numerous economic reasons, the rotary effort should be the smallest and the speed the greatest practicable. Many other considerations, which will naturally suggest themselves, may affect the design and construction, but the preceding is thought to contain all necessary information in this regard.

The greatest value of this invention will be found in its use for the thermodynamic conversion of energy. Reference is now made to Figs. 3 and 4, illustrative of the manner in which it is, or may be, so applied.

As in the previous figures, a runner is provided made up of disks *13* with openings *14* and spokes *15* which, in this case, may be straight. The disks are keyed to and held in position on a shaft *16*, mounted to turn freely in suitable bearings, not shown, and are separated by washers *17* conforming in shape with the spokes and firmly united thereto by rivets *18*. For the sake of clearness but a few disks, with comparatively wide intervening spaces, are indicated.

The runner is mounted in a casing comprising two end-castings *19* with outlets *20* and stuffing boxes *21*, and a central ring *22*, which is bored out to a circle of a diameter slightly larger than that of the disks, and has flanged extensions *23* and inlets *24* into which finished ports, or nozzles *25* are inserted. Circular grooves *26* and labyrinth packings *27* are provided on the sides of the runner. Supply pipes *28*, with valves *29*, are connected to the flanged extensions of the central ring, one of the valves being normally closed.

With the exception of certain particulars, which will be elucidated, the mode of operation will be understood from the preceding description. Steam or gas under pressure being allowed to pass through the valve at the side of the solid arrow, the runner is set in rotation in clockwise direction.

In order to bring out a distinctive feature assume, in the first place, that the motive medium is admitted to the disk chamber through a port, that is, a channel which it traverses with nearly uniform velocity. In this case, the machine will operate as a rotary engine, the fluid continuously expanding on its tortuous path to the central outlet. The expansion takes place chiefly along the spiral path, for the spread inward is opposed by the centrifugal force due to the velocity of whirl and by the great resistance to radial exhaust. It is to be observed that the resistance to the passage of the fluid between the plates is approximately proportional to the square of the relative speed, which is maximum in the direction towards the center and equal to the full tangential velocity of the fluid. The path of least resistance, necessarily taken in obedience to a universal law of motion, is virtually, also that of least relative velocity.

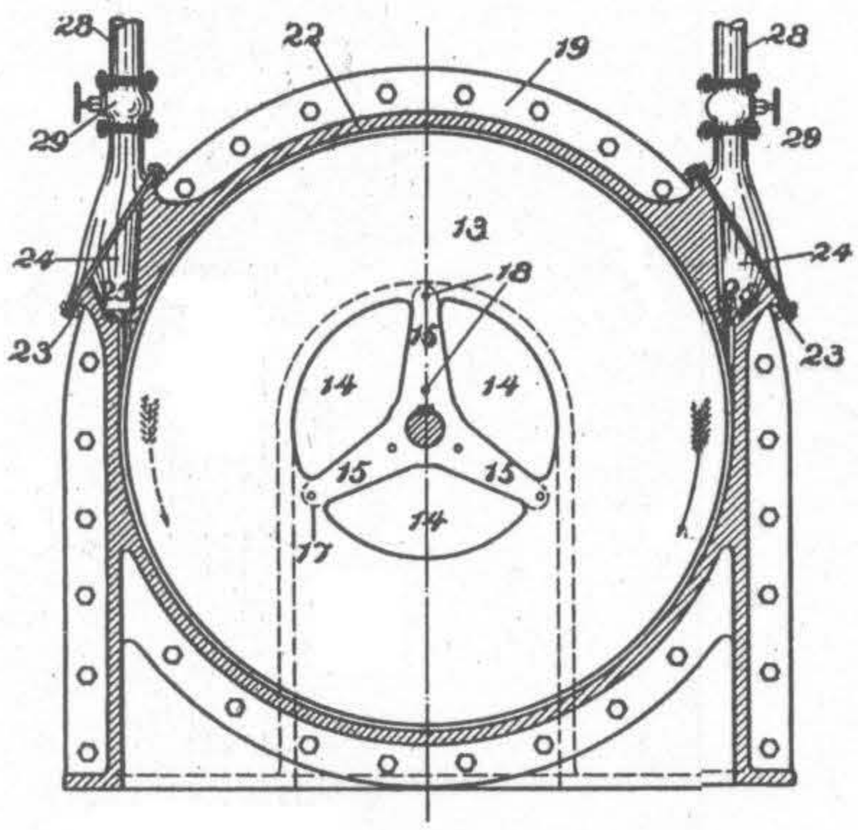

FIG. 3.

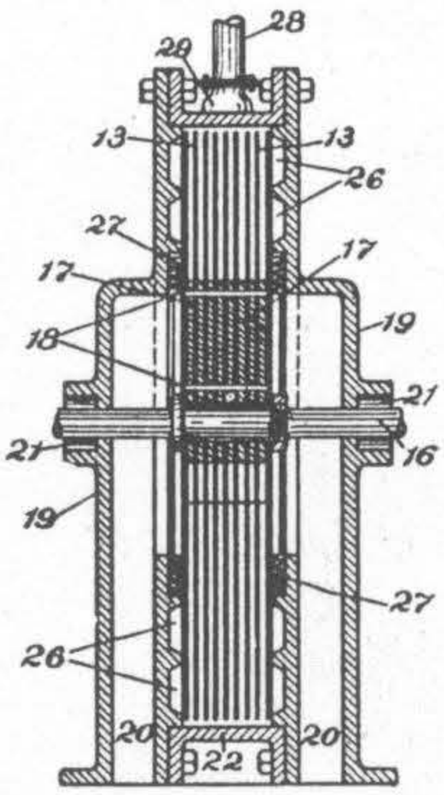

FIG. 4.

Next, assume that the fluid is admitted to the disk chamber not through a port, but a diverging nozzle, a device converting, wholly or in part, the expansive energy into velocity-energy. The machine will then work rather like a turbine, absorbing the energy of kinetic momentum of the particles as they whirl, with continuously decreasing speed, to the exhaust.

The above description of the operation is suggested by experience and observation and is advanced merely for the purpose of explanation. The undeniable fact is that the machine does operate, both expansively and impulsively. When the expansion in the nozzle is complete, or nearly so, the fluid pressure in the peripheral clearance space is small; as the nozzle is made less divergent and its section enlarged, the pressure rises, finally approximating that of the supply. But the transition from purely impulsive to expansive action may not be continuous throughout, on account of critical states and conditions, and comparatively great variations of pressure may be caused by small changes of nozzle velocity.

In the preceding it has been assumed that the pressure of supply is constant or continuous, but it will be understood that the operation will be, essentially, the same if the pressure be fluctuating or intermittent, as that due to explosions occurring in more or less rapid succession.

A very desirable feature, characteristic of machines constructed and operated in accordance with this invention, is their capability of reversal of rotation. Fig. 3, while illustrative of a special case, may be regarded as typical in this respect. If the right hand valve be shut off and the fluid supplied through the second pipe, the runner is rotated in the direction of the dotted arrow, the operation, and also the performance, remaining the same as before, the central ring being bored to a circle with this purpose in view. The same result may be obtained in many other ways by specially designed valves, ports or nozzles for reversing the flow, the description of which is omitted here in the interest of simplicity and clearness. For the same reasons but one operative port or nozzle is illustrated, which might be adapted to a volute but does not fit best a circular bore. It is evident that a number of suitable inlets may be provided around the periphery of the runner to improve the action and that the construction of the machine may be modified in many ways.

Still another valuable and probably unique quality of such motors or prime movers may be described. By proper construction and observance of working conditions the centrifugal pressure, opposing the passage of the fluid, may, as already indicated, be made nearly equal to the pressure of supply when the machine is running idle. If the inlet section be large, small changes in the speed of revolution will produce great differences of flow which are further enhanced by the concomitant variations in the length of the spiral path. A self-regulating machine is thus obtained bearing a striking resemblance to a direct-current electric motor in this respect, that, with great differences of impressed pressure in a wide open channel, the flow of the fluid through the same is prevented by virtue of rotation. Since the centrifugal head increases as the square of the revolutions, or even more rapidly, and with modern high-grade steel great peripheral velocities are practicable, it is possible to attain that condition in a single-stage machine, more readily if the runner be of large diameter. Obviously this problem is facilitated by compounding. Now irrespective of its bearing on economy, this tendency which is, to a degree, common to motors of the above description, is of special advantage in the operation of large units, as it affords a safeguard against running away and destruction.

Besides these, such a prime mover pos-

sesses other advantages, both constructive and operative. It is simple, light and compact, subject to but little wear, cheap and exceptionally easy to manufacture as small clearances and accurate milling work are not essential to good performance. In operation it is reliable, there being no valves, sliding contacts or troublesome vanes. It is almost free of windage, largely independent of nozzle efficiency and suitable for high as well as for low fluid velocities and speeds of revolution. The principles of construction and operation are capable of embodiment in machines of the most widely different forms, and adapted for the greatest variety of purposes.

TESLA POINTS WAY TO TURBINES

Famous Scientist Invents Radical Steam Engine With Gasolene Possibilities—New Principle in Fluid Propulsion.

Safe to say, no form of engine could be more attractive either to motorist or automobile manufacturer than that which Dr. Nikola Tesla has evolved in applying his new method of fluid propulsion. A simple form of casing, hardly more complicated than the housing over an emery wheel, a rotating shaft, a number of plain circular disks equally spaced apart and fastened to the shaft and suitable arrangements for the admission of the working fluid and release of the waste products—these few elements constitute the sole requisites of a complete and efficient engine, if the Servian-American scientist is correct in his reasoning. That there is nothing in the underlying principle to qualify the new form of engine more particularly for steam than for gas and that early tests have shown enormous power to be derivable from very small units lends strength to predictions that the Tesla system ultimately may exert a revolutionizing influence on the automobile industry.

So new is the invention that it is impossible to determine what are the limitations of the system nor in exactly what manner it will prove applicable. Tesla himself is authority for the statement that the action will be essentially the same whether the pressure of the working fluid be constant, fluctuating or intermittent; the latter condition being such as might obtain were the system applied to the internal combustion engine. One of the experimental steam engines, having disks, or blades, 9¾ inches in diameter and occupying a lateral space of two inches has developed 110 horsepower, as told by the Motor World last week. On the hypothesis that a practical form of gas engine ultimately may be developed it is apparent that space emonomy as well as high efficiency and low cost will be among its leading features.

In explaining the underlying method Tesla prefers to deal first with its application to pumping. The first authoritative description of the system, in which the Electrical Review quotes the inventor's own language, in part is as follows:

"In the practical application of mechanical power based on the use of a fluid as vehicle of energy it has been demonstrated that, in order to attain the highest economy, the changes in velocity and direction of movement of the fluid should be as gradual as possible. In the present form of such apparatus more or less sudden changes, shocks and vibrations are unavoidable. Besides, the employment of the usual devices for imparting to, or deriving energy from a fluid, as pistons, paddles, vanes and blades, necessarily introduces numerous defects and limitations and adds to the complication, cost of production and maintenance of the machine.

"The purpose of the invention is to overcome these deficiencies and to effect the transmission and transformation of mechanical energy through the agency of fluids in a more perfect manner, and by means simpler and more economical than those heretofore employed.

"This is accomplished by causing the propelled or propelling fluid to move in natural paths or stream lines of least resistance, free from constraint and disturbance such as is occasioned by vanes or kindred devices, and to change its velocity and direction of movement by imperceptible degrees, thus avoiding the losses due to sudden variations while the fluid is receiving or imparting energy.

"It is well known that a fluid possesses among others two salient properties: adhesion and viscosity. Owing to these a body propelled through such a medium encounters a peculiar impediment known as 'lateral,' or 'skin resistance,' which is twofold: one arising from the shock of the fluid against the asperities of the solid substance, the other from internal forces opposing molecular separation. As an inevitable consequence a certain amount of the fluid is dragged along by the moving body. Conversely, if the body be placed in a fluid in motion, for the same reasons, it is impelled in the direction of movement. The accompanying drawings illustrate operative and efficient embodiments of the idea.

"Fig. 1 is a partial end view, and Fig. 2 a vertical cross-section of a pump or compressor, while Figs. 3 and 4 represent, in corresponding views, a rotary engine or turbine, both machines being constructed and adapted to be operated in accordance with the invention.

"Figs. 1 and 2 show a runner composed of a plurality of flat rigid disks, 1, of a suitable diameter, keyed to a shaft, 2, and held in position by a threaded nut, 3, a shoulder, 4, and washers, 5, of the requisite thickness. Each disk has a number of central openings, 6, the solid portions between which form spokes, 7, preferably curved, as shown, for the purpose of reducing the loss of energy due to the impact of the fluid.

"This runner is mounted in a two-part volute casing, 8, having stuffing boxes, 9, and inlets, 10, leading to its central portion. In addition a gradually widening and rounding outlet, 11, is provided formed with a flange for connection to a pipe as usual. The casing, 8, rests upon a base, 12, shown only in part and supporting the bearings for the shaft, 2, which, being of ordinary construction, are omitted from the drawings.

"An understanding of the principle embodied in this apparatus will be gained from the following description of its mode of operation.

"Power being applied to the shaft and the runner set in rotation in the direction of the solid arrow, the fluid, by reason of its properties of adherence and viscosity, upon entering through the inlets, 10, and coming in contact with the disks, 1, is taken hold of by the same and subjected to two forces, one acting tangentially in the direction of rotation, and the other radially outward. The combined effect of these tangential and centrifugal forces is to propel the fluid with continuously increasing velocity in a spiral path until it reaches the outlet, 11, from which it is ejected. This spiral movement, free and undisturbed and essentially dependent on these properties of the fluid, permitting it to adjust itself to natural paths or stream lines and to change its velocity and direction by insensible degrees, is characteristic of this method of propulsion and advantageous in its application. . . .

"It may also be pointed out that such a

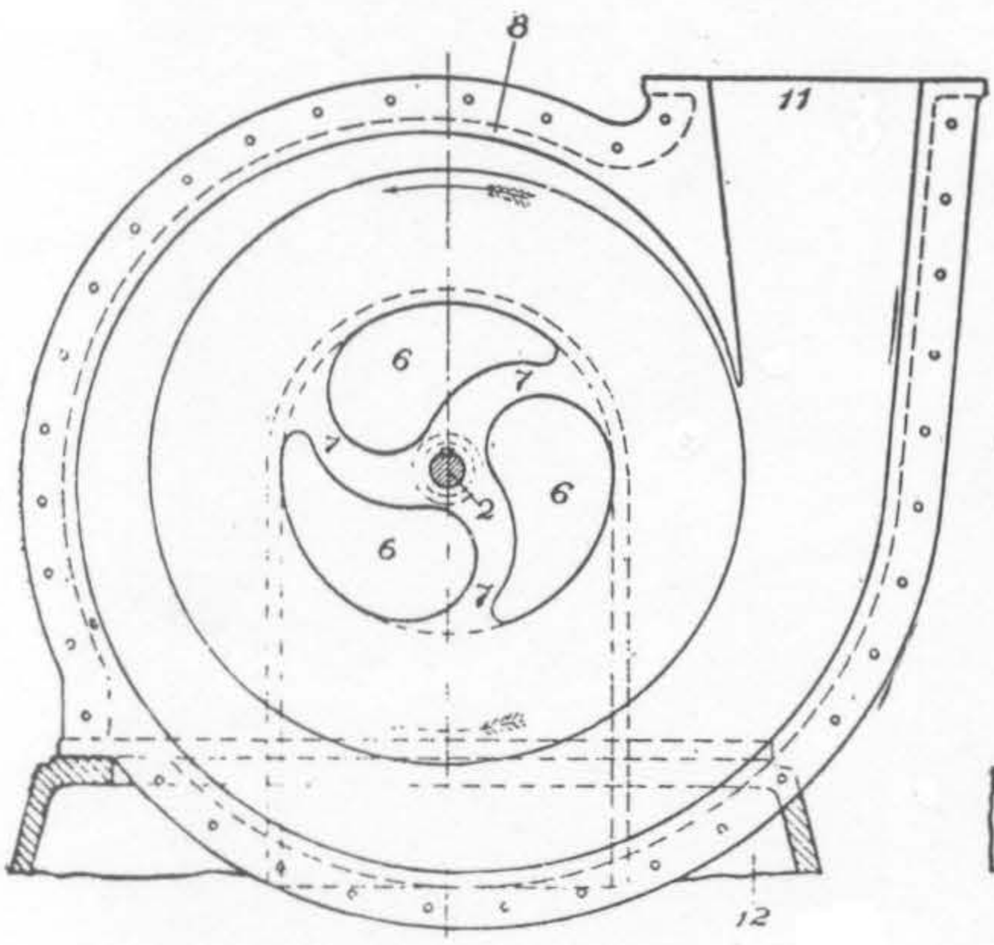

FIG. 1

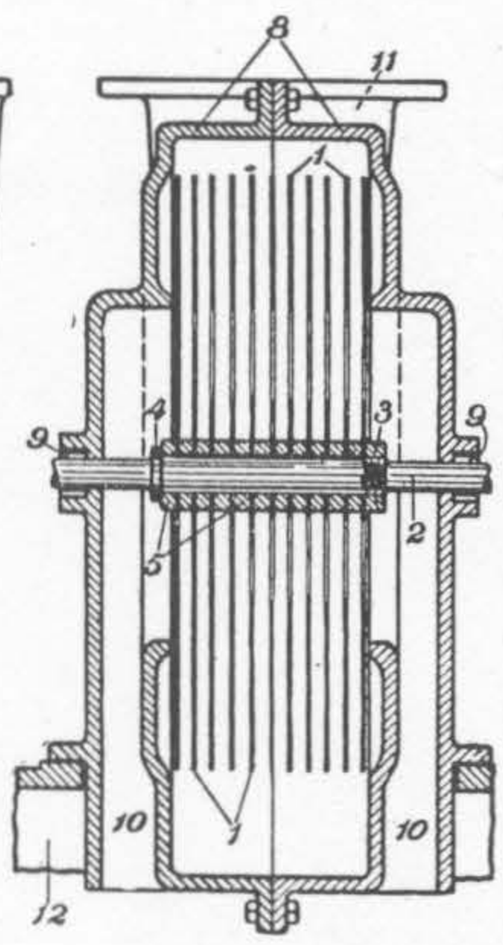

FIG. 2

pump can be made without openings and spokes in the runner, as by using one or more solid disks, each in its own casing, in which form the machine will be eminently adapted for sewage, dredging and the like, when the water is charged with foreign bodies and spokes or vanes are especially objectionable.

"Another application of this principle, thoroughly practicable and efficient, is the utilization of machines such as described for the compression or rarefication of air, or gases in general. In such cases most of the general considerations obtaining in the case of liquids, properly interpreted, hold true.

"When, irrespective of the character of the fluid, considerable pressures are desired, staging or compounding may be resorted to in the usual way, the individual runners being, preferably, mounted on the same shaft. It should be added that the same end may be attained with one single runner by suitable deflection of the fluid through rotative or stationary passages.

"The principles underlying the invention are capable of embodiment also in that field of mechanical engineering which is concerned in the use of fluids as motive agents, for while in some respects the actions in the latter case are directly opposite to those met with in the propulsion of fluids, the fundamental laws applicable in the two cases are the same. In other words, the operation above described is reversible, for if water or air under pressure be admitted to the opening, 11, the runner is set in rotation in the direction of the dotted arrow by reason of the peculiar properties of the fluid which, traveling in a spiral path and with continuously diminishing velocity, reaches the orifices 6 and 10 through which it is discharged. If the runner be allowed to turn freely, in nearly frictionless bearings, its rim will attain a speed closely approximating the maximum of that of the fluid in the volute channel and the spiral path of the particles will be comparatively long, consisting of many almost circular turns. If the load is put on and the runner slowed down, the motion of the fluid is retarded, the turns are reduced, and the path is shortened. . . .

"When apparatus of the kind described is employed for the transmission of power, certain departures from similarity between transmitter and receiver may be necessary for securing the best result. It is evident that, when transmitting power from one shaft to another by such machines, any desired ratio between the speeds of rotation may be obtained by proper selection of the diameters of the disks, or by suitably staging the transmitter, the receiver, or both. But it may be pointed out that in one respect, at least, the two machines are essentially different. In the pump, the radial or static pressure, due to centrifugal force, is added to the tangential or dynamic, thus increasing the effective head and assisting in the expulsion of the fluid. In the motor, on the contrary, the first named pressure, being opposed to that of supply, reduces the effective head and the velocity of radial flow towards the center. Again, in the propelled machine a great torque is always desirable, this calling for an increased number of disks and smaller distance of separation, while in the propelling machine, for numerous economic reasons, the rotary effort should be the smallest and the speed the greatest practicable. . . .

"The greatest value of this invention will be found in its use for the thermodynamic conversion of energy. Reference is now made to Figs. 3 and 4, illustrative of the manner in which it is, or may be, so applied.

"As in the previous figures, a runner is provided made up of disks, 13, with openings, 14, and spokes, 15. which, in this case, may be straight. The disks are keyed to and held in position on a shaft, 16. mounted to turn freely in suitable bearings not shown, and are separated by washers, 17, conforming in shape with the spokes and firmly united thereto by rivets, 18. For the sake of clearness but a few disks, with comparatively wide intervening spaces, are indicated.

"The runner is mounted in a casing comprising two end-castings, 19, with outlets, 20, and stuffing boxes, 21, and a central ring, 22, which is bored out to a circle of a diameter slightly larger than that of the disks, and has flanged extensions, 23, and inlets, 24, into which finished ports, or nozzles, 25, are inserted. Circular grooves, 26, and labyrinth packings, 27, are provided on the sides of the runner. Supply pipes, 28, with valves, 29, are connected to the flanged extensions of the central ring, one of the valves being normally closed.

"With the exception of certain particulars, which will be elucidated, the mode of operation will be understood from the preceding description. Steam or gas under pressure being allowed to pass through the valve at the side of the solid arrow, the runner is set in rotation clockwise direction.

"In order to bring out a distinctive feature assume, in the first place, that the motive medium is admitted to the disk chamber through a port, that is, a channel which it traverses with nearly uniform velocity. In this case, the machine will operate as a rotary engine, the fluid continuously expanding on its tortuous path to the central outlet. The expansion takes place chiefly along the spiral path, for the spread inward is opposed by the centrifugal force due to the velocity of the whirl and by the great resistance to radial exhaust. It is to be observed that the resistance to the passage of the fluid between the plates is approximately proportional to the square of the relative speed, which is maximum in the direction towards the center and equal to the full tangential velocity of the fluid. The path of least resistance, necessarily taken in obedience to a universal law of motion, is virtually also that of least relative velocity.

"Next assume that the fluid is admitted to the disk chamber not through a port, but a diverging nozzle, a device converting, wholly or in part, the expansive energy into velocity-energy. The machine will then work rather like a turbine, absorbing the energy of kinetic momentum of the particles as they whirl, with continuously decreasing speed, to the exhaust. . . .

"In the preceding it has been assumed that the pressure of supply is constant or continuous, but it will be understood that the operation will be, essentially, the same if the pressure be fluctuating or intermittent, as that due to explosions occurring in more or less rapid succession.

"A very desirable feature, characteristic of machines constructed and operated in accordance with this invention, is their capability of reversal of rotation. Fig. 3, while illustrative of a special case, may be

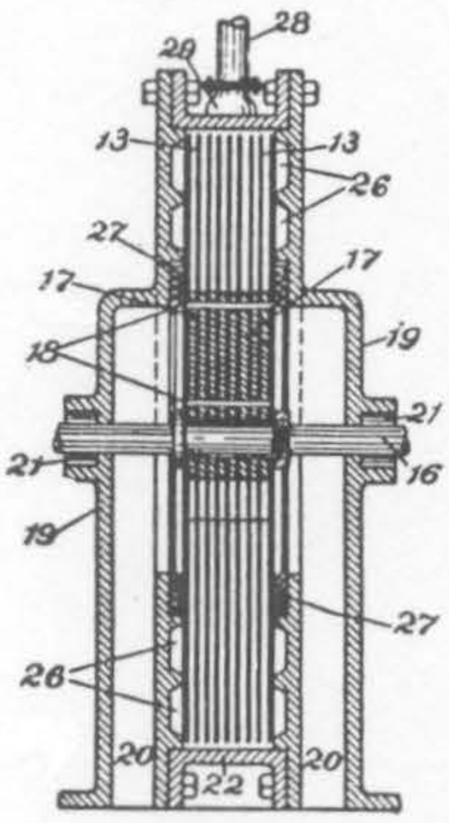

FIG. 3

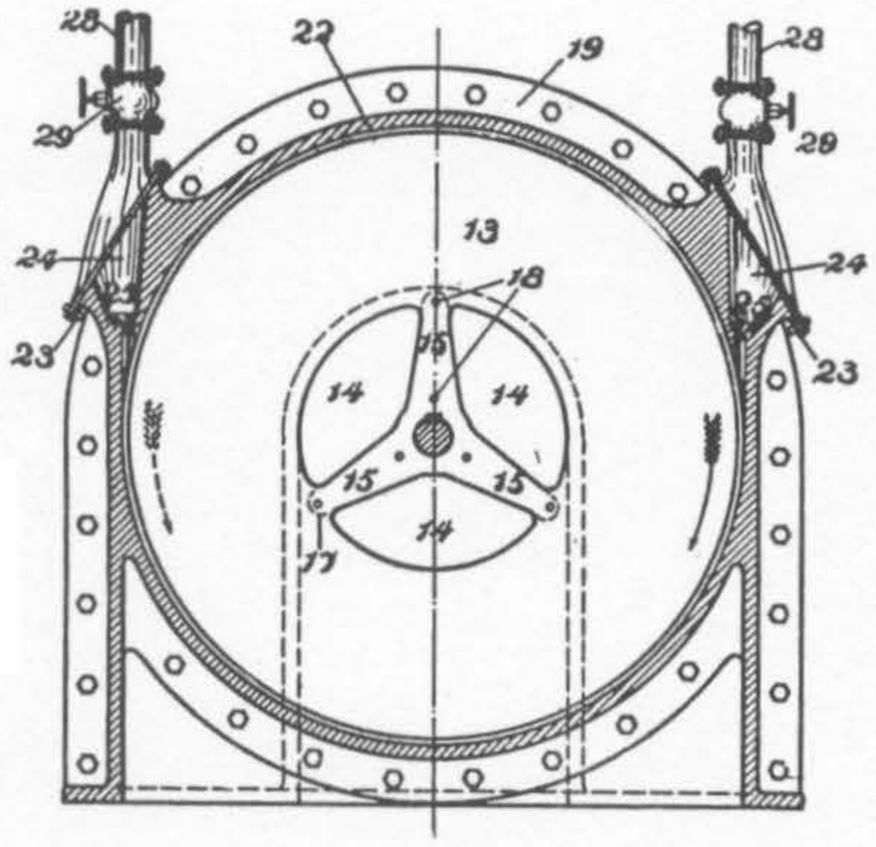

FIG. 4

regarded as typical in this respect. If the right hand valve be shut off and the fluid supplied through the second pipe, the runner is rotated in the direction of the dotted arrow, the operation, and also the performance, remaininfg the same as before, the central ring being bored to a circle with this purpose in view. The same result may be obtained in many other ways by specially designed valves, ports or nozzles for reversing the flow, the description of which is omitted here in the interest of simplicity and clearness. . . .

"Still another valuable and probably unique quality of such motors or prime movers may be described. By proper construction and observance of working condidtions the centrifugal pressure, opposing the passage of the fluid, may, as already indicated, be made nearly equal to the pressure of supply when the machine is running idle. If the inlet section be large, small changes in the speed of revolution will produce great differences of flow which are further enhanced by the concommitant variations in the length of the spiral path A self-regulating machine is thus obtained bearing a striking resemblance to a direct-current electric motor in this respect, that, with great differences of impressure pressure in a wide open channel, the flow of the fluid through the same is prevented by virtue of rotation. . . .

"Besides these, such a prime mover possesses other advantages, both constructive and operative. It is simple, light and compact, subject to but little wear, cheap and exceptionally easy to manufacture, as small clearances and accurate milling work are not essential to good performance. In operation it is reliable, there being no valves, sliding contacts or troublesome vanes. It is almost free of windage, largely independent of nozzle efficiency and suitable for high as well as for low fluid velocities and speeds of revolution. The principles of construction and operation are capable of embodiment in machines of the most widely different forms, and adapted for the greatest variety of purposes."

TESLA PROMISES BIG THINGS

PLANELESS, SCREWLESS AIRSHIP SAFE IN ANY STORM.

Says His Engine Could Convert Factory Gases Now Wasted Into Prodigious Power for Use on Land or Sea or in the Air—Believes He Proved It.

Dr. Nikola Tesla leaned back in his chair at the Waldorf last night and talked calmly of airships without planes, propellers or any of the other gear of the now familiar aeroplanes hurtling through space at tremendous speed or driving more slowly carrying great loads, and in either case always as safely as the most prosaic of wheeled vehicles.

He spoke of harnessing the energy of the gases given off by the great steel plants and producing therefrom 25,000,000 or 50,000,000 horse-power with a value of say $450,000,000 a year. He spoke of these things as of things already accomplished.

"They have called me a dreamer," he said, "but this is not a dream. It is not an experiment."

Then he went on to tell something about the new mechanical principle on the development of which he has been at work for several years and concerning which, he said, he felt free to talk since the publication yesterday of the *Electrical Review* in which Dr. Tesla's invention is described. He said:

"Virtually in all generation, transmission and transformation of mechanical power we must avail ourselves of a fluid, a liquid or a gas, either to impart or receive energy. In a steam engine, for instance, the fluid is a gas under pressure which transmits its potential energy to a mechanical system. In a pump just the reverse process takes place, the fluid, be it a liquid or a gas, having energy imparted to it by a moving material system. This invention of mine is a novel means of imparting to or deriving energy from a fluid, and therefore bears on all the branches of mechanics.

"It is rather difficult, he continued in reply to a question, "to give the average reader a correct idea of such a technical advance. But I assume that every one will understand that any fluid is possessed of two properties, one of which is to adhere to the surface of a solid and the other to hold on, as it were, to its own particles. It is a surprising fact that gases and vapors are possessed of this second property to a greater degree than are liquids such as water. Owing to these properties if a solid body is moved through a fluid more or less of the same is dragged along; conversely if a body is immersed in a fluid in motion it is impelled in the direction of movement. The new principle is based on these fundamental facts."

In reply to a question as to how the principle was applied to practical use in his new invention Dr. Tesla said:

"Let us suppose that it is desired to derive energy from steam under pressure. In this case a number of disks are mounted on a shaft and the whole is placed in a casing with an inlet for the steam tangential to the disks. The steam entering into this orifice by reason of the properties mentioned exercises a pull on the disks and sets them in rotation, circulating under the influence of the centrifugal and tangential forces in a spiral with gradually diminishing velocity, giving up its energy on the rotating system and finally escaping at a centre virtually devoid of dynamic energy.

"In this manner," continued Dr. Tesla, "an ideal rotary engine without any buckets, vanes or sliding contacts is obtained, and one which in performance surpasses by far any other mechanism yet invented. I have developed 110 horse-power with disks only 9¼ inches in diameter and making a thickness of about two inches. Under proper conditions the performance might have been as much as 1,000 horse-power. In fact there is almost no limit to the mechanical performance of such a machine."

Dr. Tesla said that his machine would work with gas, as in the usual type of explosion engine used in automobiles and aeroplanes, even better than it did with steam. "Tests which I have conducted have shown that the rotary effort with gas *is* greater than with steam," is the way he put it.

It is the utilization through his invention of energy now allowed to go to waste that seemed most to interest the inventor.

"The field of fuel waste," he said, "is the greatest of all, offering almost unlimited opportunities for exploitation. In the manufacture of steel and iron, according to data which I have carefully collected, in this country alone from 25,000,000 to 30,000,000 horse-power are wasted through the hot gases escaping into the atmosphere. These gases have a high heating value and by means of the new principle the energy could be readily and cheaply harnessed. If you place the value of one horse-power per annum at $15 this would mean an annual revenue from this source of $450,000,000 per annum.

The ability of his new engine to act in either direction—its "reversibility" the inventor calls it—and the wonderful energy that may be developed by a machine of little weight Dr. Tesa says makes the engine particularly well suited to propelling ships.

"Applied to a vessel," he said, "these engines will make the carrying of reverse turbines unnecessary and will greatly reduce the expense, weight and bulk of the others."

"How about aerial navigation?" Dr. Tesla was asked. He considered for a moment or two and then replied with great deliberation:

"The application of this principle will give the world a flying machine unlike anything that has ever been suggested before. It will have no planes, no screw propellers or devices of any kind hitherto used. It will be small and compact, excessively swift, and, above all, perfectly safe in the greatest storm. It can be built of any size and can carry any weight that may be desired."

Dr. Tesla in conclusion emphasized again his assertion that the engine that is to do all this is a fact, with its performances matters of record.

"I have built a great many machines, steam and gas turbines, pumps, compressors and other apparatus," he said, "and a number have been in practical use for some time past. Yes, it is a big thing, but it is for the big things only that I **care to work.**"

The New York Times September 13, 1911

TESLA'S NEW ENGINE.

Mr. CHARLES WILSON PRICE, editor of The Electrical Review, does not say that NIKOLA TESLA'S latest invention of a rotary engine operated by steam or gases will save most of the 30,000,000 horse power wasted annually by manufacturing plants in this country, power that is worth upward of half a billion dollars. He has not said, as Mr. TESLA is reported as saying, that the new engine will give the world a flying machine that, without planes or screw propellers, "excessively swift, and, above all, perfectly safe in the greatest storm," will be small and compact compared with present machines, but capable of being built to carry shiploads of passengers. What Mr. PRICE does say about the engine, however, arrests attention. A small turbine with a rotor two inches thick and hardly ten inches in diameter, without vanes, blades, valves, or sliding contacts, has been exhibited at the Edison station here, and has been found "capable of developing 110 horse power." In fact, several of TESLA'S engines have been tested. The Electrical Review publishes his description of them, declaring that his invention "cannot fail to excite interest in engineering circles the world over."

Sir WILLIAM RAMSAY said in his recent address before the British Association that "a good steam engine converts about one-eighth of the potential energy of the fuel into useful work; seven-eighths are lost as unused heat and useless friction." In a good gas engine two-thirds of the fuel energy is wasted. It is quite conceivable that inventions will be made to conserve the enormous energies now wasted. TESLA'S turbine, operating without the shocks or vibrations of engines that work with pistons, paddles, vanes, or blades, directs the propelling fluid along rotating disks in free spirals, and by its adhesive and viscous properties the fluid communicates its energy to the disks. By a reverse process the disks may be made to impart motion to fluids, thus acting as a pump which, if what is said about it is true, will effect great changes in mining operations. As a motor its inventor says the machine will presently be seen in automobiles, working by gas or steam, in locomotives and ocean liners, and in factories all over the world.

Mr. TESLA has acquired a reputation for revolutionary inventions that never quite arrived at the point of practical utility. But some of his inventions have proved to be practical and eminently useful. The new engine may be one of them.

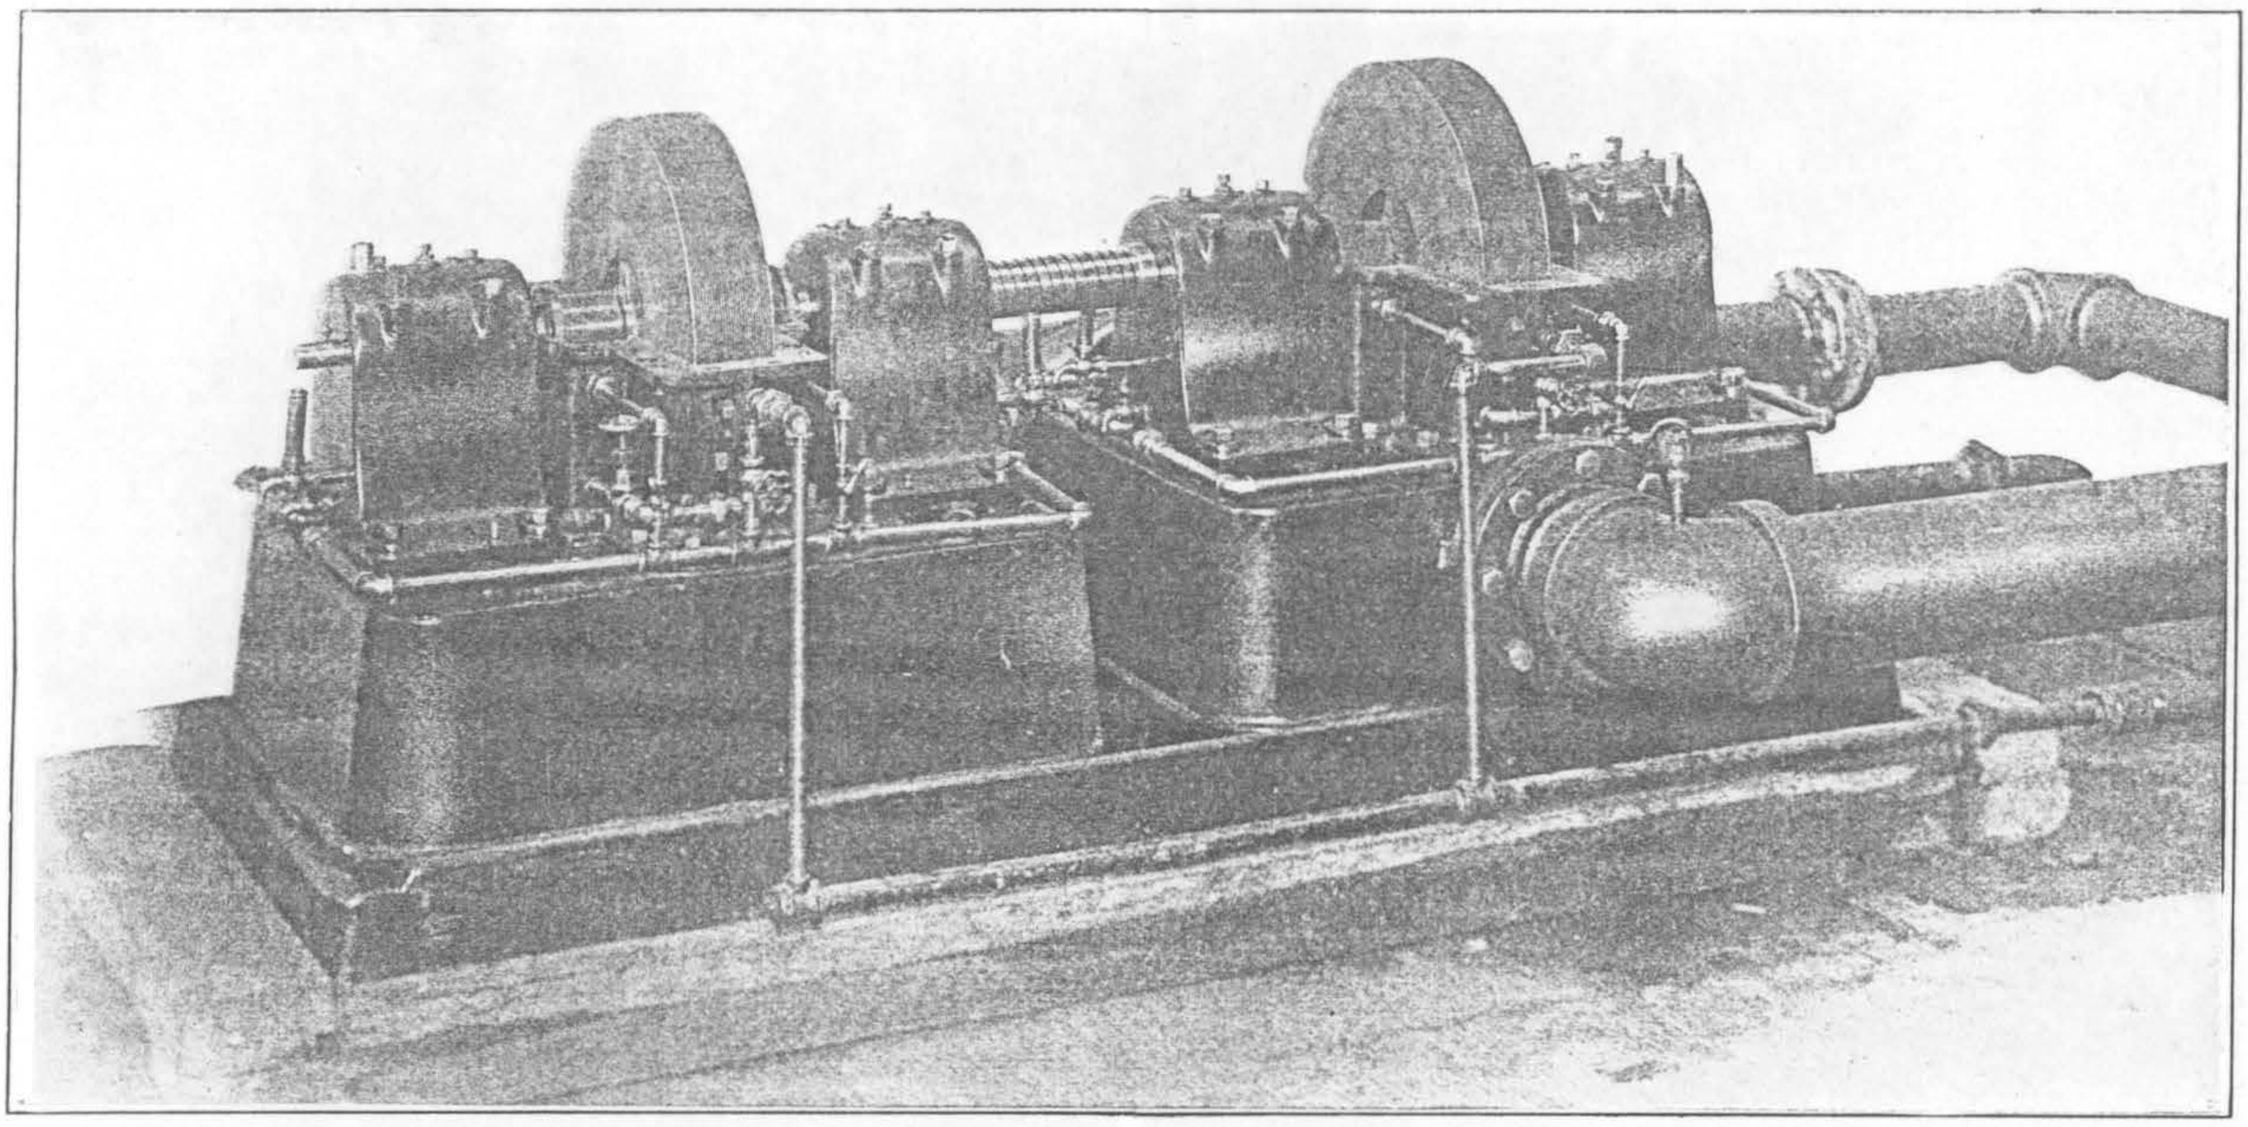
The Tesla Turbine.

The accompanying illustrations which were taken at the request of the editor of this journal, give a very good idea of one of the small Tesla turbines which have been built and operated with slight changes of the rotors and accessories as steam, gas, air and water turbines or rotary engines, and also as pumps and compressors. The characteristics and the mechanical principles involved in the construction and operation of the Tesla turbine were discussed comprehensively in the

THE TESLA 110-HORSEPOWER TURBINE, CONVEYING AN IDEA OF THE SIZE OF THIS MACHINE.

ELECTRICAL REVIEW AND WESTERN ELECTRICIAN of September 9. Through the courtesy of the New York Edison Company the machine illustrated was installed at its Waterside station where long-continued tests were carried on under greatly varying conditions.

Mr. Tesla, when seen on Tuesday of this week by a representative of the ELECTRICAL REVIEW AND WESTERN ELECTRICIAN, gave the following statements respecting the operation and economy of his turbine:



"The turbine has readily developed 110 horsepower with free exhaust, but this does not convey even an approximate idea of the possibilities offered in power production by the new principle of propulsion. It would not have been difficult to develop twice as much power were it not for the torsional stress to which the shaft was subjected. However, even with the result attained, bearing in mind that the rotor weighs only twenty pounds, and that the casing itself could have been pressed steel sheet, the weight of which together with the bearings would not exceed thirty pounds, a performance of more than two horsepower per pound of material was realized.

"As to steam economy, it is highly satisfactory, comparing well with the best turbines, the consumption being thirty-six pounds per horsepower-hour with free exhaust and back pressure of a few pounds, which would mean less than seventeen pounds for a two-stage machine of that size. This economy could still be greatly increased for the turbine was operated under conditions of maximum output and not maximum economy."

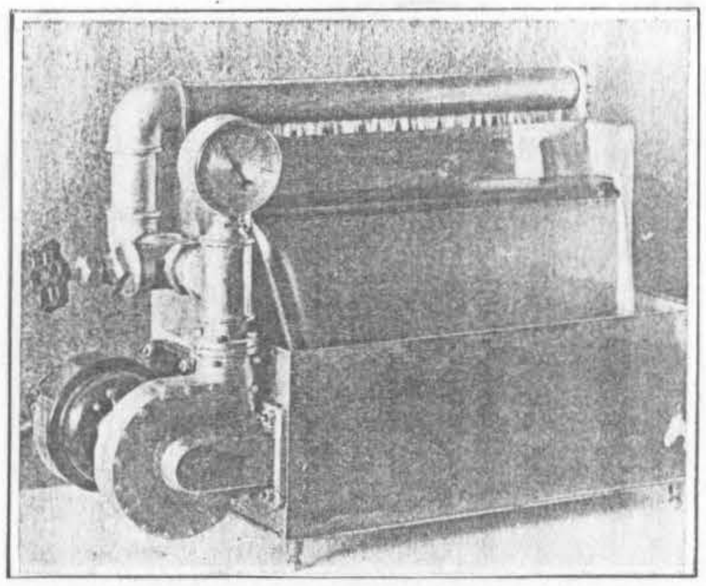
Mr. Tesla stated that there was no limit to the capacity for which this turbine could be built and said that the peculiar characteristics of this form of construction would make it possible to attain economy of operation with superheated steam not heretofore realized. When operated as a water turbine it greatly simplified the present methods of regulation and opened up a field of application which was stupendous.

THE ROTOR OF THE 110-HORSEPOWER TESLA TURBINE. WEIGHT, TWENTY POUNDS.

The top half of casings is removed, showing two rotors. Each rotor consists of 25 disks 3/16-inch thick by 18 inch diameter. The steam enters at the periphery, and flows in spiral paths to exhaust at the center of the disks. The driving turbine is to the left, the brake turbine to the right. Between them is a torsion spring. The steam inlets are on opposite sides on the two rotors; the driving rotor moving clockwise. The torsion of the spring is automatically shown by beams of light and mirrors and the horse-power is read off a scale. At 9,000 revolutions per minute, with 125 pounds at the throttle and free exhaust, this turbine develops 200 horse-power. It weighs two pounds per horse-power.

The Tesla turbine testing plant at the Edison Waterside Station, New York.

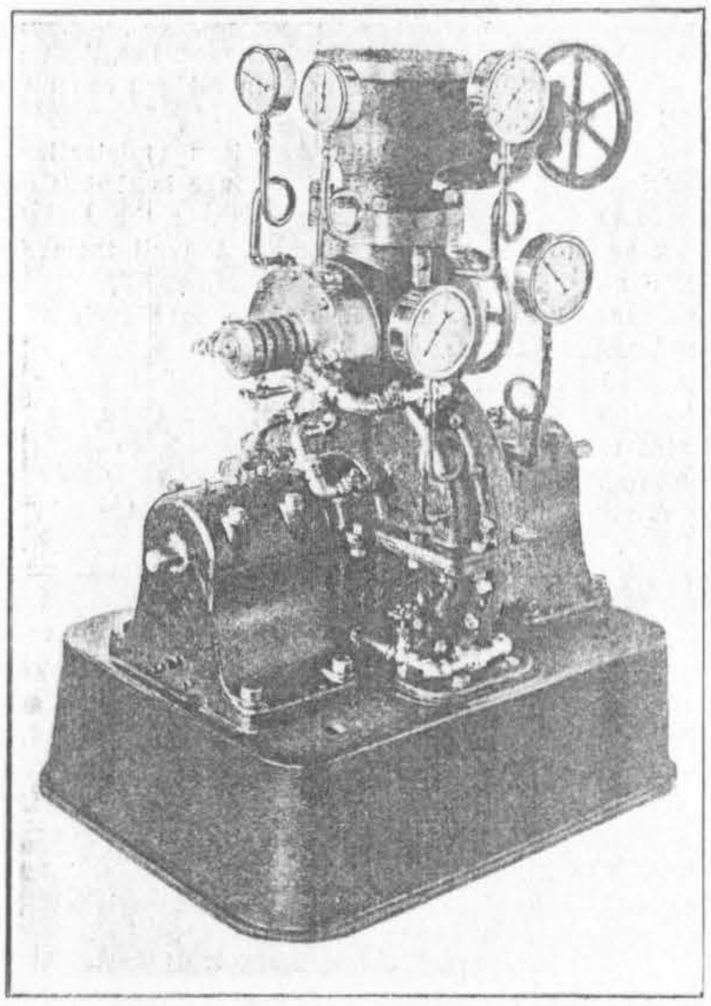
The Tesla Steam Turbine



The Rotary Heat Motor Reduced to Its Simplest Terms

IT will interest the readers of the SCIENTIFIC AMERICAN to know that Nikola Tesla, whose reputation must, naturally, stand upon the contributions he made to electrical engineering when the art was yet in its comparative infancy, is by training and choice a mechanical engineer, with a strong leaning to that branch of it which is covered by the term "steam engineering." For several years past he has devoted much of his attention to improvements in thermo-dynamic conversion, and the result of his theories and practical experiments is to be found in an entirely new form of prime movers shown in operation at the Waterside station of the New York Edison Company, who kindly placed the facilities of their great plant at his disposal for carrying on experimental work.

By the courtesy of the inventor, we are enabled to publish the accompanying views, representing the testing plant at the Waterside station, which are the first photographs of this interesting motor that have yet been made public.



The basic principle which determined Tesla's investigations was the well-known fact that when a fluid (steam, gas or water) is used as a vehicle of energy, the highest possible economy can be obtained only when the changes in velocity and direction of the movement of the fluid are made as gradual and easy as possible. In the present forms of turbines in which the energy is transmitted by pressure, reaction or impact, as in the De Laval, Parsons, and Curtiss types, more or less sudden changes both of speed and direction are involved, with consequent shocks, vibration and destructive eddies. Furthermore, the introduction of pistons, blades, buckets, and intercepting devices of this general class, into the path of the fluid involves much delicate and difficult mechanical construction which adds greatly to the cost both of production and maintenance.

The desiderata in an ideal turbine group themselves under the heads of the theoretical and the mechanical. The theoretically perfect turbine would be one in which the fluid was so controlled from the inlet to the exhaust that its energy was delivered to the driving shaft with the least possible losses due to the mechanical means employed. The mechanically perfect turbine would be one which combined simplicity and cheapness of construction, durability, ease and rapidity of repairs, and a small ratio of weight and space occupied to the power delivered on the shaft. Mr. Tesla maintains that in the turbine which forms the subject of this article, he has carried the steam and gas motor a long step forward toward the maximum attainable efficiency, both theoretical and mechanical. That these claims are well founded is shown by the fact that in the plant at the Edison station, he is securing an output of 200 horse-power from a single-stage steam turbine with atmospheric exhaust, weighing less than 2 pounds per horse-power, which is contained within a space measuring 2 feet by 3 feet, by 2 feet in height, and which accomplishes these results with a thermal fall of only 130 B.T.U., that is, about one-third of the total drop available. Furthermore, considered from the mechanical standpoint, the turbine is astonishingly simple and economical in construction, and by the very nature of its construction, should prove to possess such a durability and freedom from wear and breakdown as to place it, in these respects, far in advance of any type of steam or gas motor of the present day.

This little pump, driven by a motor of 1/3 horse-power, is here shown delivering 40 gallons of water per minute against a 9-foot head.

The turbine used as a pump.

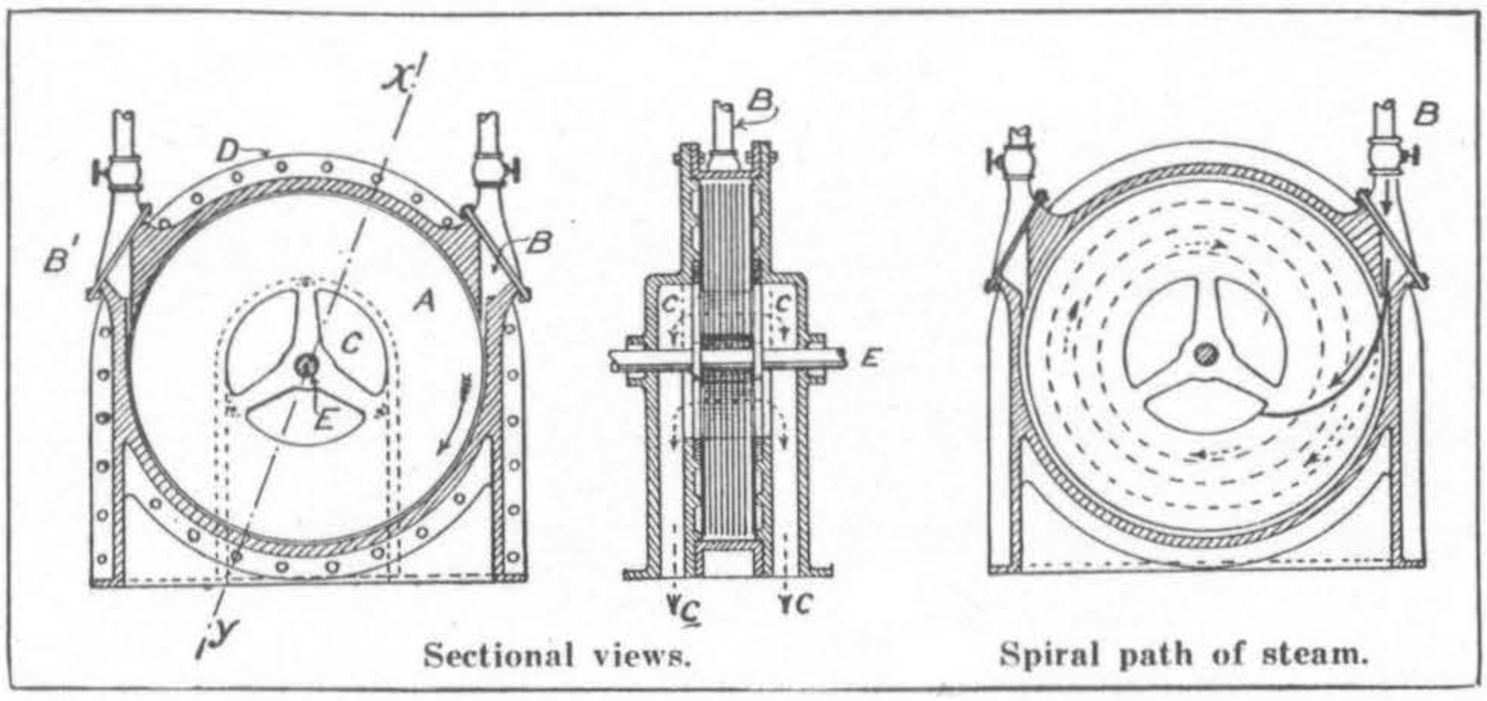
This view shows one complete high pressure unit, with the steam throttle above, and below it the reversing valve and the compact turbine. Note the many gages used in the tests.

A 200-horse-power high-pressure turbine.

Briefly stated, Tesla's steam motor consists of a set of flat steel disks mounted on a shaft and rotating within a casing, the steam entering with high velocity at the periphery of the disks, flowing between them in free spiral paths, and finally escaping through exhaust ports at their center. Instead of developing the energy of the steam by pressure, reaction, or impact, on a series of blades or vanes, Tesla depends upon the fluid properties of adhesion and viscosity—the attraction of the steam to the faces of the disks and the resistance of its particles to molecular separation combining in transmitting the velocity energy of the motive fluid to the plates and the shaft.

By reference to the accompanying photographs and line drawings, it will be seen that the turbine has a rotor *A* which in the present case consists of 25 flat steel disks, one thirty-second of an inch in thickness, of hardened and carefully tempered steel. The rotor as assembled is 3½ inches wide on the face, by 18 inches in diameter, and when the turbine is running at its maximum working velocity, the material is never under a tensile stress exceeding 50,000 pounds per square inch. The rotor is mounted in a casing *D*, which is provided with two inlet nozzles, *B* for use in running direct and *B'* for reversing. Openings *C* are cut out at the central portion of the disks and these communicate directly with exhaust ports formed in the side of the casing.

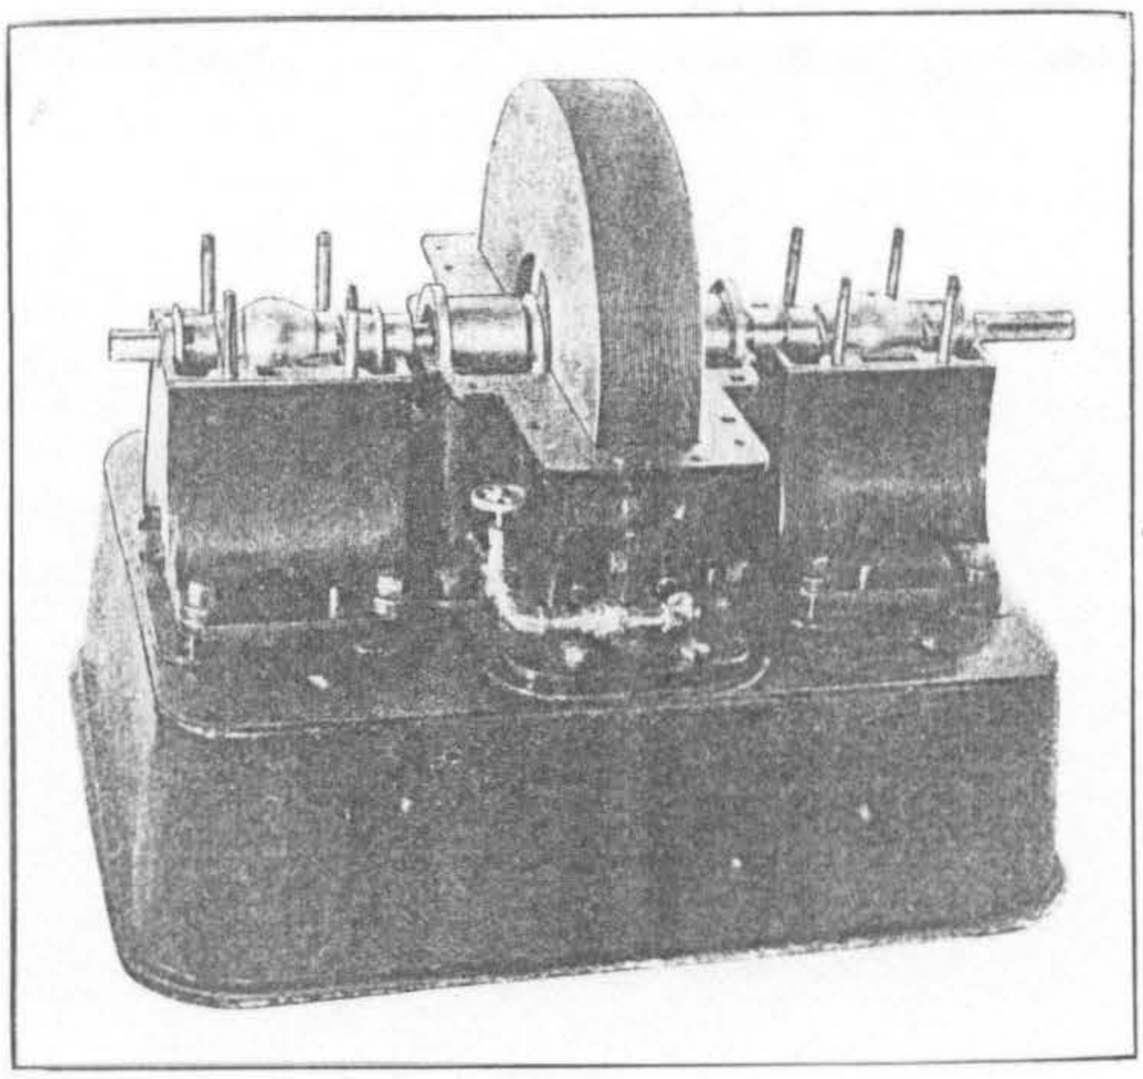
In operation, the steam, or gas, as the case may be, is directed on the periphery of the disks through the nozzle *B* (which may be diverging, straight or converging), where more or less of its expansive energy is converted into velocity energy. When the machine is at rest, the radial and tangential forces due to the pressure and velocity of the steam cause it to travel in a rather short curved path toward the central exhaust opening, as indicated by the full black line in the accompanying diagram; but as the disks commence to rotate and their speed increases, the steam travels in spiral paths the length of which increases until, as



in the case of the present turbine, the particles of the fluid complete a number of turns around the shaft before reaching the exhaust, covering in the meantime a lineal path some 12 to 16 feet in length. During its progress from inlet to exhaust, the velocity and pressure of the steam are reduced until it leaves the exhaust at 1 or 2 pounds gage pressure.

The resistance to the passage of the steam or gas between adjoining plates is approximately proportionate to the square of the relative speed, which is at a maximum toward the center of the disks and is equal to the tangential velocity of the steam. Hence the resistance to radial escape is very great, being furthermore enhanced by the centrifugal force acting outwardly. One of the most desirable elements in a perfected turbine is that of reversibility, and we are all familiar with the many and frequently cumbersome means which have been employed to secure this end. It will be seen that this turbine is admirably adapted for reversing, since this effect can be secured by merely closing the right-hand valve and opening that on the left.

It is evident that the principles of this turbine are equally applicable, by slight modifications of design, for its use as a pump, and we present a photograph of a demonstration model which is in operation in Mr. Tesla's office. This little pump, driven by an electric motor of 1/12 horse-power, delivers 40 gallons per minute against a head of 9 feet. The discharge pipe leads up to a horizontal tube provided with a wire mesh for screening the water and checking the eddies. The water falls through a slot in the bottom of this tube and after passing below a baffle plate flows in a steady stream about ¾ inch thick by 18 inches in width, to a trough from which it returns to the pump. Pumps of this character show an efficiency favorably comparing with that of centrifugal pumps and they have the advantage that great heads are obtainable economically in a single stage. The runner is mounted in a two-part volute casing and except for the fact that the place of the buckets, vanes, etc., of the ordinary centrifugal pump is taken by a set of disks, the construction is generally similar to that of pumps of the standard kind.



In conclusion, it should be noted that although the experimental plant at the Waterside station develops 200 horse-power with 125 pounds at the supply pipe and free exhaust, it could show an output of 300 horse-power with the full pressure of the Edison supply circuit. Furthermore, Mr. Tesla states that if it were compounded and the exhaust were led to a low pressure unit, carrying about three times the number of disks contained in the high pressure element, with connection to a condenser affording 28½ to 29 inches of vacuum, the results obtained in the present high-pressure machine indicate that the compound unit would give an output of 600 horse-power, without great increase of dimensions. This estimate is conservative.

The testing plant consists of two identical turbines connected by a carefully calibrated torsion spring, the machine to the left being the driving element, the other the brake. In the brake element, the steam is delivered to the blades in a direction opposite to that of the rotation of the disks. Fastened to the shaft of the brake turbine is a hollow pulley provided with two diametrically opposite narrow slots, and an incandescent lamp placed inside close to the rim. As the pulley rotates, two flashes of light pass out of the same, and by means of reflecting mirrors and lenses, they are carried around the plant and fall upon two rotating glass mirrors placed back to back on the shaft of the driving turbine so that the center line of the silver coatings coincides with the axis of the shaft. The mirrors are so set that when there is no torsion on the spring, the light beams produce a luminous spot stationary at the zero of the scale. But as soon as load is put on, the beam is deflected through an angle which indicates directly the torsion. The scale and spring are so proportioned and adjusted that the horse-power can be read directly from the deflections noted. The indications of this device are very accurate and have shown that when the turbine is running at 9,000 revolutions under an inlet pressure of 125 pounds to the square inch, and with free exhaust, 200 brake horse-power are developed. The consumption under these conditions of maximum output is 38 pounds of saturated steam per horse-power per hour—a very high efficiency when we consider that the heat-drop, measured by thermometers, is only 130 B.T.U., and that the energy transformation is effected in one stage. Since about three times this number of heat units are available in a modern plant with superheat and high vacuum, the above means a consumption of less than 12 pounds per horse-power hour in such turbines adapted to take up the full drop. Under certain conditions, however, very high thermal efficiencies have been obtained which demonstrate that in large machines based on this principle, in which a very small slip can be secured, the steam consumption will be much lower and should, Mr. Tesla states, approximate the theoretical minimum, thus resulting in nearly frictionless turbine transmitting almost the entire expansive energy of the steam to the shaft.

Sectional views. Spiral path of steam.

Details of turbine.

This turbine, whose rotor consists simply of a set of flat disks 18 inches in diameter, develops 200 brake horse-power on test.

Turbine with upper half of casing removed.

The Tesla Steam Turbine.

A novel design of steam turbine was mentioned before a local meeting of the National Electric Light Association in New York City, on May 15, 1911, by Mr. Nikola Tesla, whose name has become famous in connection with the rotating magnetic field and other alternating-current developments. Several different types of power apparatus, both driving and driven, embodying the underlying principle of this turbine design have now been built and tested in the Tesla laboratories, including a turbine which has been running at the Waterside Station of the New York Edison Company for several months. The general results of this early work have recently been made public by Mr. Tesla.

The following outline of the designs and the underlying principle running through them all has been made after a conversation with Mr. Tesla and a study of the apparatus. The fundamental principle underlying these several designs appears to be broadly applicable to apparatus wherein a fluid moves some device or the device causes the fluid to move. This includes hydraulic, steam and internal combustion motors, hydraulic and air pumps, etc.

The study of this most interesting line of designs may be approached through the case of either prime movers or driven devices. For the purposes of this article it is perhaps simpler to consider first a pump for a fluid like air, gas, vapor, or liquid. Fig. 1 shows, more or less diagrammatically, a rotary pump in which a series of smooth, flat disks revolves in a casing, with a volute delivery passage. The disks are fastened to a driving shaft but have central openings which serve as inlets for the fluid. On rotating the shaft and disks, the fluid film in contact with the disks is set in motion, even with perfectly smooth disks, on account of the molecular adhesion between disk and fluid. The fluid between disks is also dragged along by the molecular attraction between particles of the fluid (viscosity). The motion of each point of the disk being circular, it is evident that the particles of fluid receive impelling forces which are always tangential to the circular paths. The successive points on the disk that impel given particles of fluid are at increasing distances from the center. The fluid being mechanically unconstrained by walls or vanes except in an axial direction is free to travel in spiral paths from the axis to the periphery.

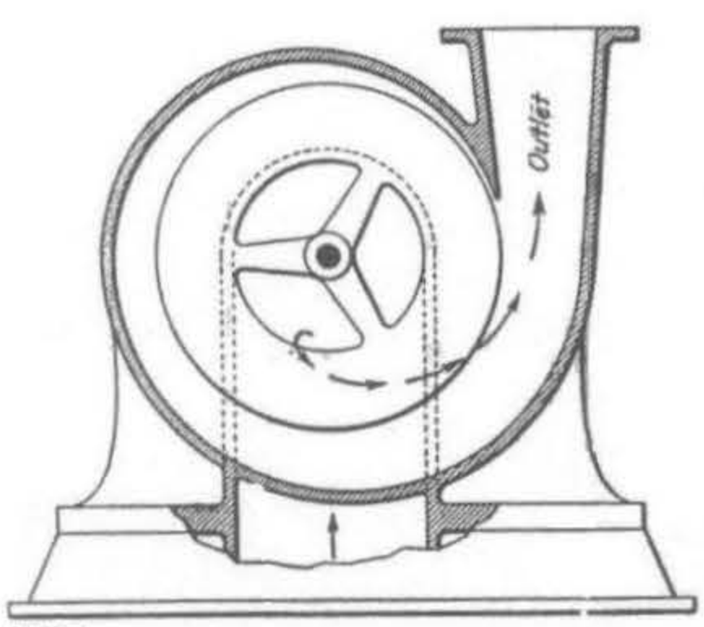
The fluid, in traversing the space from inlet to periphery, may follow a long spiral of several turns or a short one of part of a turn, depending on the quantity of fluid that is allowed to escape from the outlet. With unrestricted flow from the casing, there is little resistance to flow in a radial direction (that is from the backing up and development of pressure), and the tangential slip between disk and fluid is large. The pressure in the casing depends on the velocity with which the particles of fluid leave the periphery of the disk; the maximum pressure with the exit throttled is then proportional to the speed of the disks, the velocity head being converted to pressure head in the volute passage of the casing. The power absorbed is proportional to the square of the slip.

To one seeing such a piece of apparatus in action for the first time, the capacity of a small machine is surprising, especially in the absence of all vanes and projections of every sort which have heretofore been deemed necessary to force the fluid along. A moment's consideration, however, shows that the whole surface of each disk is effective in impelling the fluid along (solely by molecular drag), and the useful surfaces may be made very great in a machine of modest dimensions, in direct contrast with other analogous apparatus where only the relatively small area of buckets, blades, or other projections is effective.

Consideration also shows that any buckets or projecting parts that a disk might carry would constrain the fluid to travel in paths less natural or free, with the consequent development of impact and eddy friction which may be expected to decrease the efficiency over that of simple disks depending for their hold on the fluid only on natural molecular forces. In the case of the Tesla disks, the particles of fluid may be mentally pictured as rolling along on their spiral paths in orderly procession, held to the disks by some gravitation or force; whereas in the case of a disk with projections, the fluid would be pushed and crowded along by impact, with consequent disturbances.

It has been found, as theory would indicate, that the quantity of fluid discharged off the disks is proportional to the area of the disks; that is, the capacity of such machines increases nearly directly with their length along the shaft and about as the square of their diameter, the discrepancies arising naturally from the casing not having impelling surface but adding to the diameter and length of the machine.

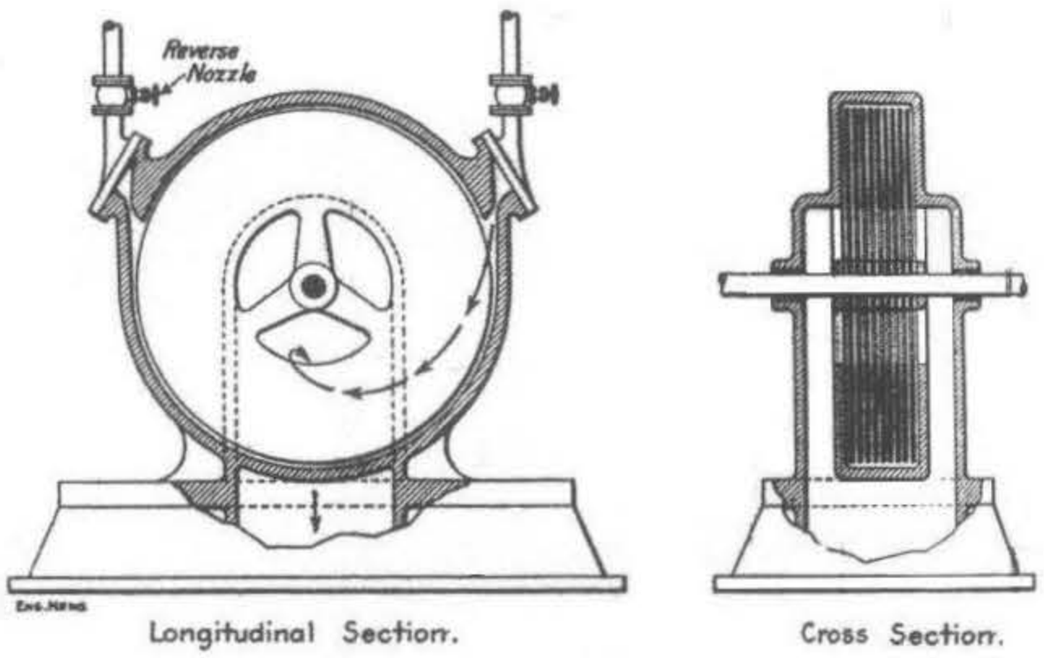
The spacing of the disks in such a machine would depend on the conditions under which it had to operate—increasing with the viscosity and diameter and decreasing with the allowable slip. The aim of the designer would be to deliver the fluid from the disks at not much below peripheral speed under normal load conditions. When limitations of practical design would prevent the securing of desired pressures with one simple set of disks, the multiplication of stages is easily accomplished. The fluid then would pass from the exit passages of one stage to the inlet of a second, and so on.



The operations of a pump, as above described, are in general reversible for the production of power from a fluid moving with considerable velocity or under pressure. If a fluid under pressure, but of low velocity, enters the casing of the device shown in Fig. 1 in order to flow along the volute of decreasing cross-section and through the inter-disk spaces to what is now the outlet, it must constantly accelerate, converting its pressure head to velocity head. This moving fluid will exert a pull on the disks on account of molecular adhesion and viscosity. If the shaft were blocked so that it could not rotate, the particles of fluid would take short spiral paths from the volute to the outlet.

If the disks are allowed to rotate, however, the particles of fluid in contact with the disks would be subjected to a force preventing travel along the shortest spirals to the outset. The resultant of the centrifugal force exerted by the disk and that coming from the velocity of the steam constrains the fluid then to follow a longer spiral path. This reminds one of the counter E. M. F. developed in the armature windings of an electric motor opposing the impressed voltage.

It is evident that the torque developed by the disk increases with the difference in peripherial velocity of the disk and of the fluid in contact As in the analogous case of the pump, the torque rises as the square of the slip. When the shaft runs free, without load, the speed rises and the centrifugal counter force on the fluid traveling in very long spirals (almost concentric circles) would cause the casing pressure to rise nearly to the supply pressure, the difference being only that required to do the work of supplying energy losses.



Such a prime mover would give its maximum output at about 50% average slip, but the maximum efficiency would come with a comparatively small slip, the actual figure depending upon the fluid employed, on the working conditions, and on the mechanical limitations of design.

The greatest interest in the Tesla design, as outlined above, probably centers in its application to a heat motor, such as the Tesla steam turbine. While a device like Fig. 1 would operate with steam, it probably would be advisable for obvious reasons to modify the mechanical features—for instance, to suppress the volute passage in the casing, coming down to the simple construction indicated in Fig. 2.

Longitudinal Section. Cross Section.

FIG. 1. THE TESLA DISK-IMPELLER PUMP.

Longitudinal Section. Cross Section.

FIG. 2. THE TESLA DISK WHEEL IN A STEAM TURBINE.

If the steam is expanded in a diverging nozzle it may be expanded over any of the usual ranges of pressure drop, the heat energy then being converted into kinetic energy The high velocity steam escaping from the nozzle is caused to impinge tangentially on the edges of the disks. In order to escape, it has to take a spiral path from the periphery of the disks to the center openings The velocity energy of the steam is utilized through the molecular drag on the surface of the disks. With such a nozzle it is seen that the machine is essentially of the so-called "impulse" type of turbine. The arrangement shown in Fig. 2 has a very simple and convenient means of reversing, it merely being necessary to provide a duplicate nozzle discharging against the opposite diameter of the disks and in the opposite direction. When the machine is at rest or running slowly, as in starting, steam takes a short path from the nozzle to the exhaust and develops a comparatively large torque, since this would be proportional to the square of the difference in velocity of steam and disk. As the machine speeds up, the difference in velocity between steam and disks decreases and the centrifugal forces tend to lengthen the spiral path, so that a given quantity of steam may make several revolutions before finally passing out the exhaust.

It is not necessary, however, to expand the steam before it reaches the disks, and in place

*For early statements of these developments see "Electrical Review and Western Electrician," Sept. 9 and 30, 1911; "The Scientific American," Sept. 30, 1911.

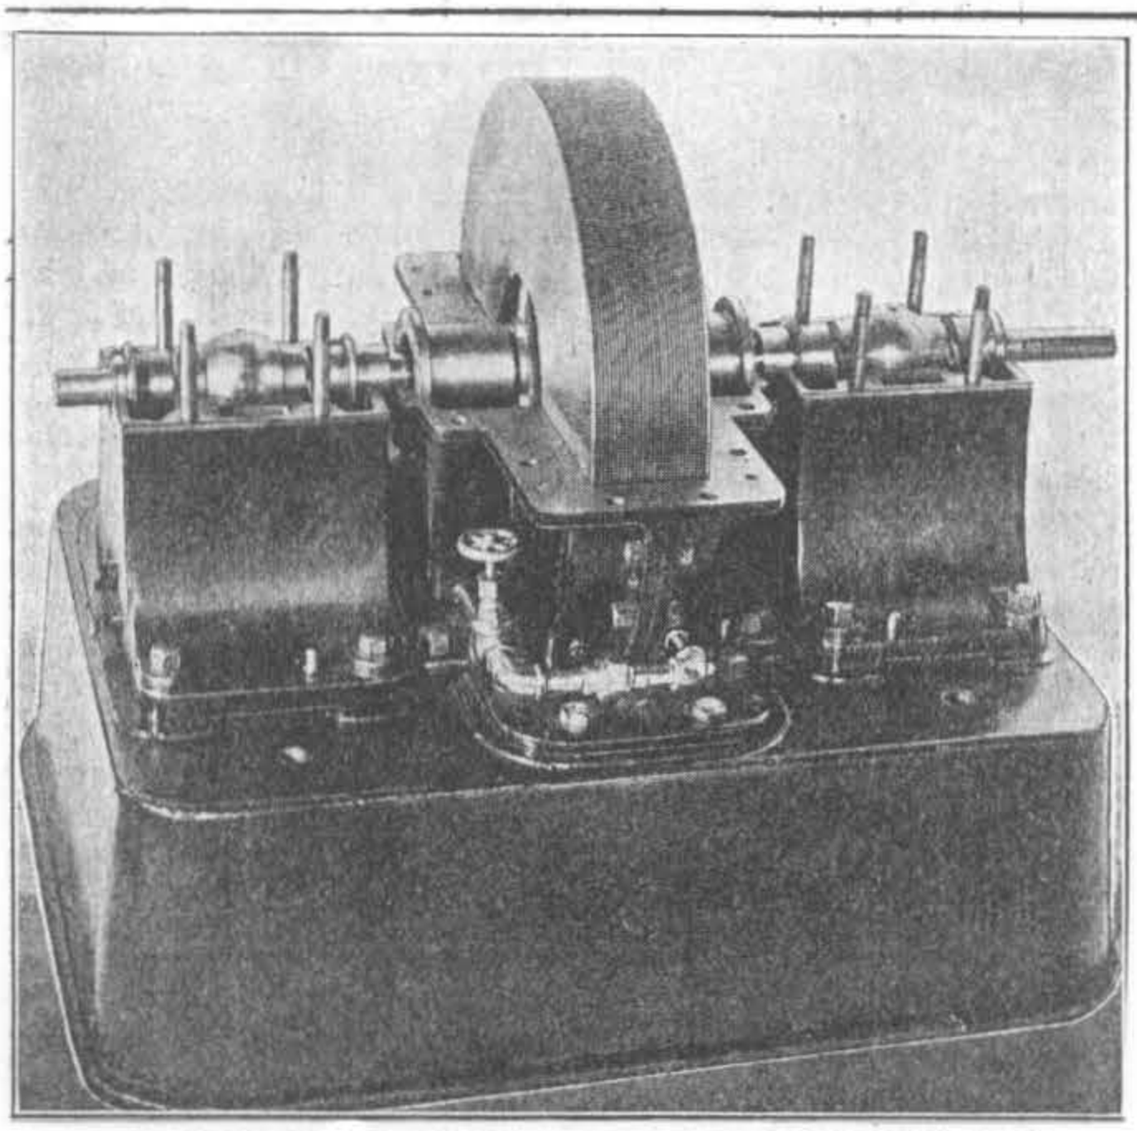


FIG. 3 A 200-HP TESLA TURBINE WITH THE UPPER CASING SECTION REMOVED.

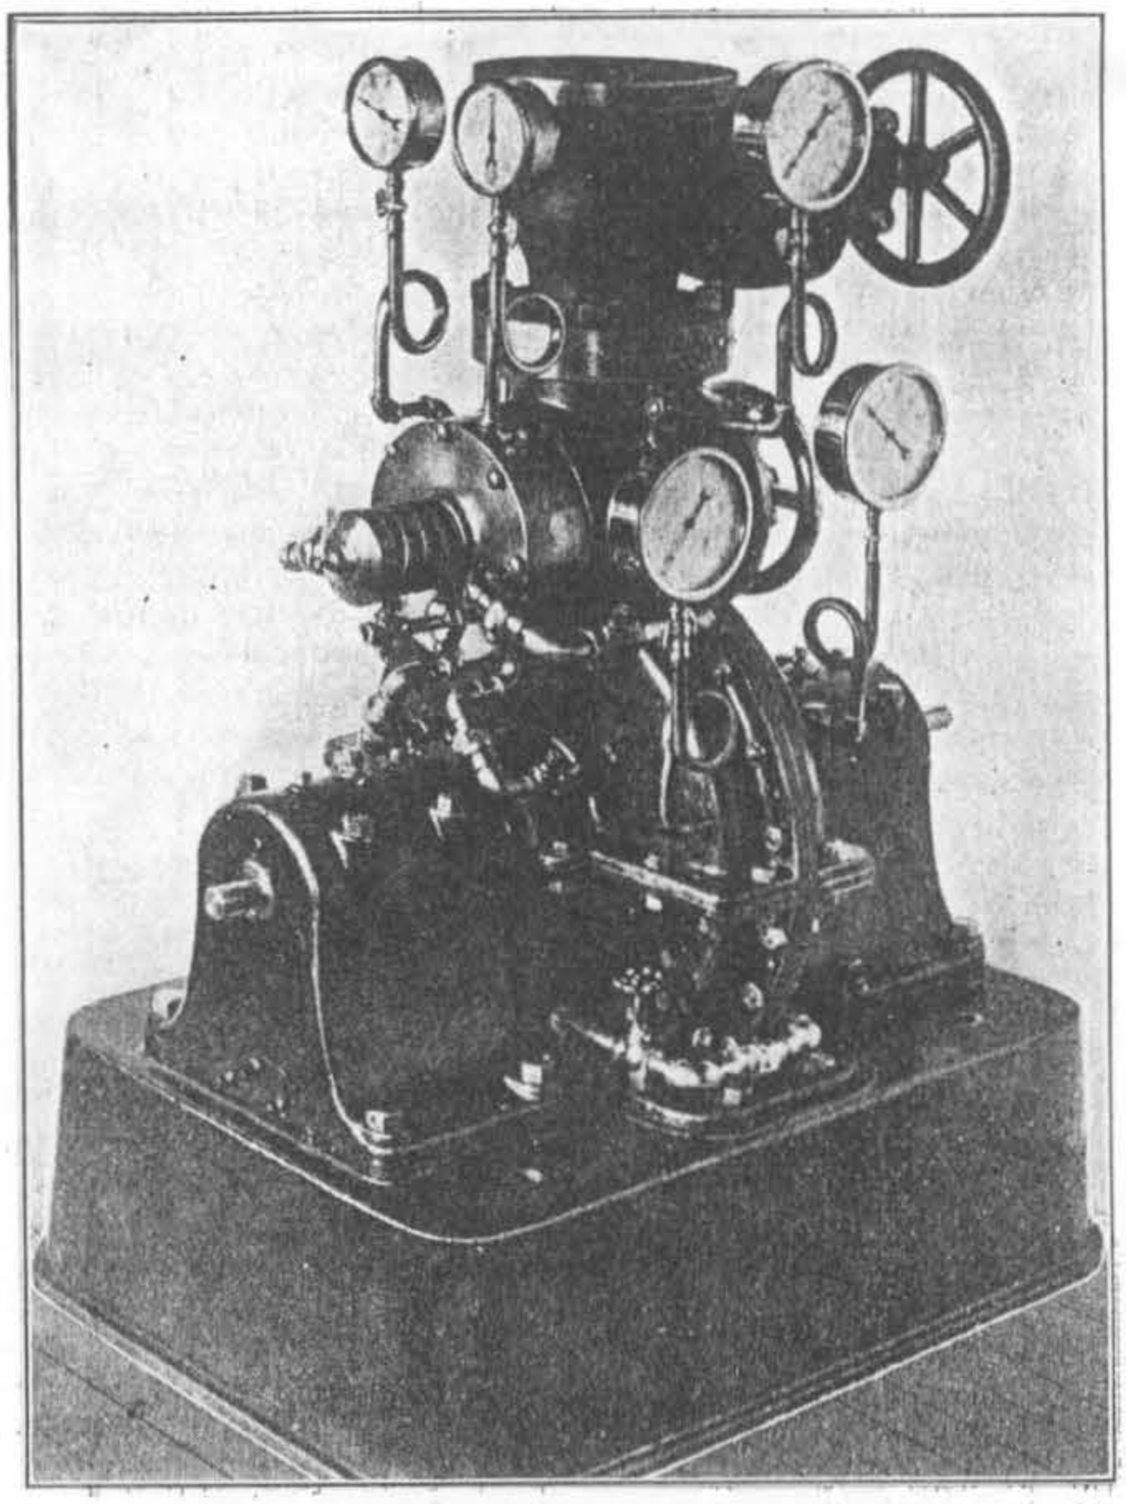

FIG. 4. A 200-HP TESLA STEAM TURBINE AS TESTED AT THE WATERSIDE STATION OF THE NEW YORK EDISON CO.

of he nozzles shown there may be simple ports. The machine then apparently will operate as a reaction type of turbine, the steam expanding as it flows in its path from port to exhaust. The expanding steam might develop a slight reactive thrust against the disk, but it would depend probably more for its influence on the peculiar action of increasing the velocity of the steam in small increments as it flows along; and absorbing the kinetic energy as fast as developed, in driving the disk.

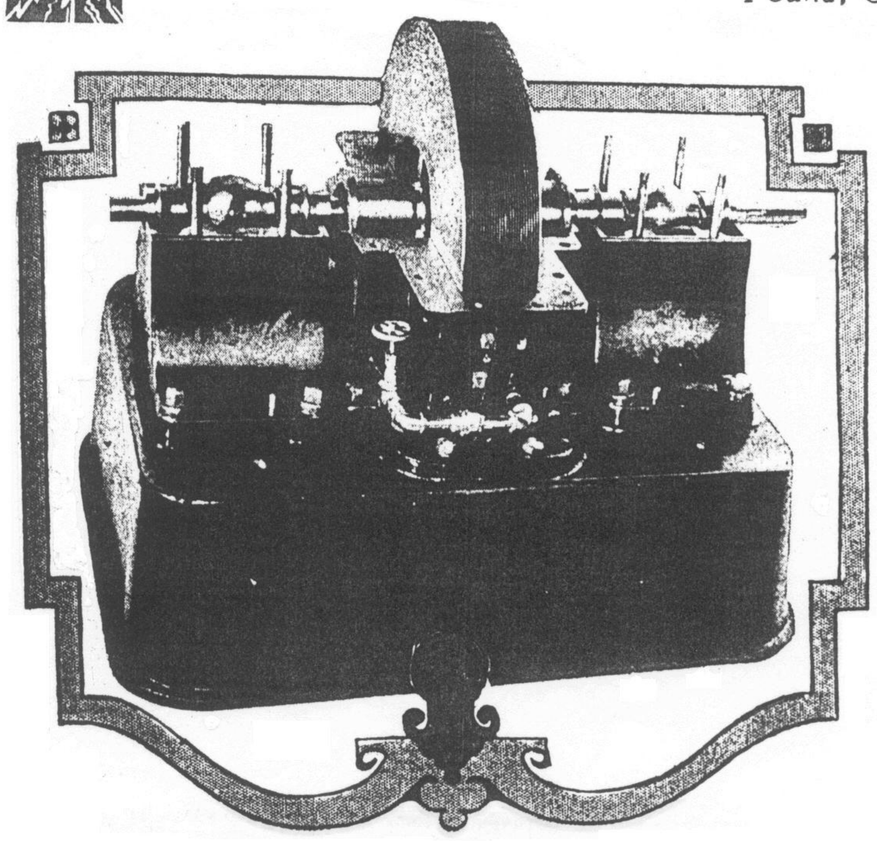
In Figs. 3 and 4, a steam turbine tested at the Waterside Station of the New York Edison Company is shown. The rotor consists of 25 disks, 18 inches in diameter. The assembled unit, Fig. 3, occupies a floor space some 20 × 35 ins. and it stands some 5 ft. high. The numerous gages seen in Fig. 3 were attached for test purposes. With steam at 125 lbs. gage and exhausting to atmosphere, 200 HP. was developed with a speed of 9,000 r. p. m. The steam consumption under these conditions was about 38 lbs. per HP.-hr.

5. A 110-HP Tesla Steam Turbine.

Mr. Tesla states that with moderate superheat and the degree of vacuum ordinarily obtainable in a turbine plant, the consumption can be reduced to 10 or 12 lbs. per HP.-hr. The weight of the unit as shown was about 400 lbs., giving a unit weight of 2 lbs. per HP.

Through refinements in design in addition to the increase of capacity secured with superheat and vacuum, Mr. Tesla expects that the weight may be reduced to as little as ¼-lb. per HP. capacity and still allow of designs which will have rotational speeds low enough for direct connecting to the majority of services.

One of the interesting possibilities of the design of turbine shown is that of self-regulation. It has already been shown how the counter pressure due to the rotation of the disks amounted nearly to that of the impressed fluid when running idle. Since the centrifugal head increases as the square of the number of revolutions, and as with available materials great peripheral velocities of the disks are possible, a turbine may be designed which will not run away, the peripheral speed being limited to that value which corresponds to the maximum velocity of the fluid which can be developed.



The main principle of design may be use for an internal-combustion motor. The small machine shown in Fig. 5 has been operated with gaseous fuel burned in an auxiliary chamber and the products of combustion cooled by injecting steam or water spray. This gives a mixture of superheated steam and gases which leave the combustion chamber under high pressure, but reduced in temperature so that they may be led directly to the disks, serving in the place of steam from a boiler. The machine shown developed 110 HP., and it is stated that only the small sized shaft prevented pushing the load higher. The products of combustion instead of being cooled by the formation of superheated steam may be expanded in an insulated nozzle, the temperature falling with the reduction in pressure and the increase in velocity. At the exit of the nozzle, the temperature could be sufficiently reduced so that the gases could be caused to impinge on the disks without injuring them.

TESLA'S NEW MONARCH OF MECHANICS

MARVELS of the Famous Inventor's Latest Triumph, the Perfect Rotary Engine, Which, Yielding Ten Horse Power to the Pound, Opens Possibilities Dreamed of for Centuries

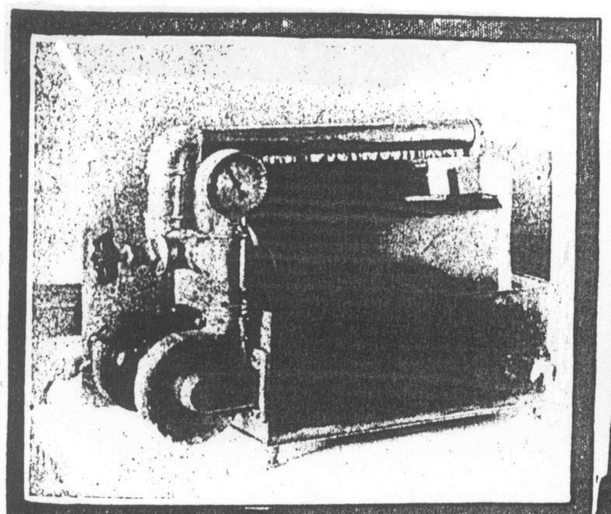
Two Hundred Horse Power Tesla Turbine with Part of Case Removed to Show Disks
By courtesy of the Scientific American

BY FRANK PARKER STOCKBRIDGE.

(Copyright, 1911, by the New York Herald Co. All rights reserved.)

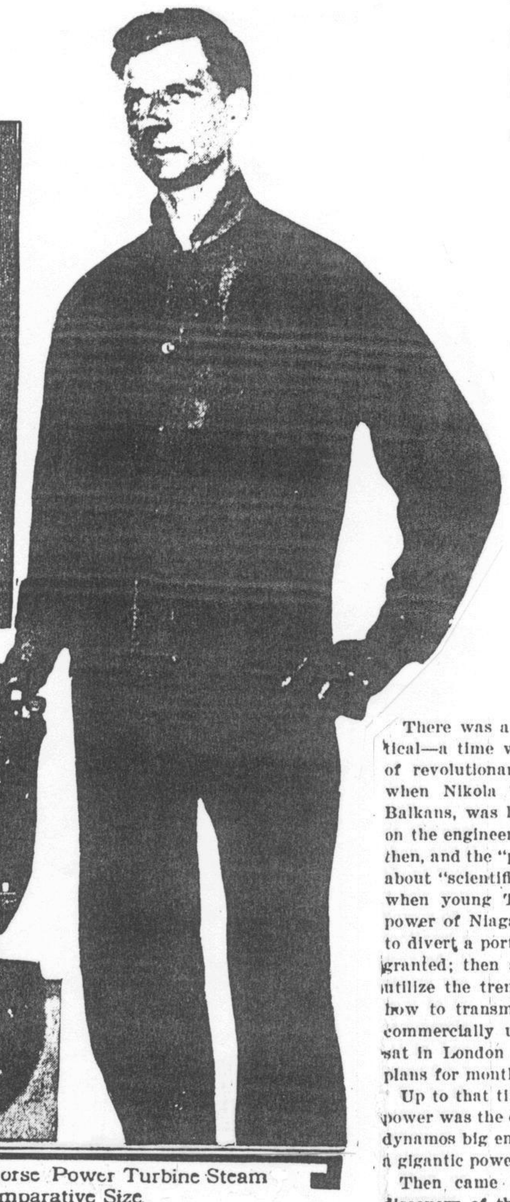
TEN horse power from a tiny engine that a man could dangle from his little finger by a string!

Five hundred horse power in a package that a man could lift easily in one hand!



A thousand horse power motor occupying hardly more space than the cardboard box in which your hatter sent your new derby home!

Marvellous? Wait until you hear the rest of it!



Suppose some one should discover a new mechanical principle—something as fundamental as James Watt's discovery of the expansive power of steam—by the use of which it became possible to build a motor that would give ten horse power for every pound of the engine's weight, a motor so simple that the veriest novice in mechanics could construct it and so elemental that it could not possibly get out of repair. Then suppose that this motor could be run forward or backward at will, that it could be used as either an engine or a pump, that it cost almost nothing to build as compared with any other known form of engine, that it utilized a larger percentage of the available power than any existing machine, and, finally, that it would operate with gas, steam, compressed air or water, any one of them, as its driving power.

It does not take a mechanical expert to imagine the limitless possibilities of such an engine. It takes very little effort to conjure up a picture of a new world of industry and transportation made possible by the invention of such a device. "Revolutionary" seems a mild term to apply to it. That, however, is the word the inventor uses in describing it—Nikola Tesla, the scientist whose electrical discoveries underlie all modern electrical power development, whose experiments and deductions made the wireless telegraph possible, and who now, in the mechanical field, has achieved a triumph even more far reaching than anything he accomplished in electricity.

There is something of the romantic in this discovery of the famous explorer of the hidden realms of knowledge. The pursuit of an ideal is always romantic, and it was in the pursuit of an ideal which he has been seeking twenty years that Dr. Tesla made his great discovery. That ideal is the power to fly—to fly with certainty and absolute safety—not merely to go up in an aeroplane and take chances on weather conditions, "holes in the air," tornadoes, lightning and the thousand other perils the aviator of to-day faces, but to fly with the speed and certainty of a cannon ball, with power to overcome any of nature's aerial forces, to start when one pleases, go whither one pleases and alight where one pleases. That has been the aim of Dr. Tesla's life for nearly a quarter of a century. He believes that with the discovery of the principle of his new motor he has solved this problem and that incidentally he has laid the foundations for the most startling new achievements in other mechanical lines.

Tesla Turbine with Disks Three Inches in Diameter Pumping Forty Gallons a Minute Against a Nine Foot Head.

There was a time when men of science were sceptical—a time when they ridiculed the announcement of revolutionary discoveries. Those were the days when Nikola Tesla, the young scientist from the Balkans, was laughed at when he urged his theories on the engineering world. Times have changed since then, and the "practical" engineer is not so incredulous about "scientific" discoveries. The change came about when young Tesla showed the way by which the power of Niagara Falls could be utilized. The right to divert a portion of the waters of Niagara had been granted; then arose the question of how best to utilize the tremendous power thus made available—how to transmit it to the points where it could be commercially utilized. An international commission sat in London and listened to theories and practical plans for months.

Up to that time the only means of utilizing electric power was the direct current motor, and direct current dynamos big enough to be of practical utility for such a gigantic power development were not feasible.

Then came the announcement of young Tesla's discovery of the principle of the alternating current motor. Practical tests showed that it could be built—that it would work.

That discovery, at that opportune time, decided the commission. Electricity was determined upon as the means for the transmission of Niagara's power to industry and commerce. To-day a million horse power is developed on the brink of the great cataract, turning the wheels of Buffalo, Rochester, Syracuse and the intervening cities and villages operating close at hand the great new electro-chemical industries that the existence of this immense source of power has made possible, while all around the world a thousand waterfalls are working in the service of mankind, sending the power of their "white coal" into remote and almost inaccessible corners of the globe, all because of Nikola Tesla's first great epoch making discovery.

To-day the engineering world listens respectfully when Dr. Tesla speaks. The first announcement of the discovery of his new mechanical principle was made in a technical periodical in mid-September, 1911. Immediately it became the principal topic of discussion wherever engineers met.

"It is the greatest invention in a century," wrote one of the foremost American engineers, a man whose name stands close to the top of the list of those who have achieved scientific fame and greatness.

"No invention of such importance in the automobile trade has yet been made," declared the editor of one of the leading engineering publications. Experts in other engineering lines pointed out other applications of the new principle and letters asking for further information poured in on Dr. Tesla from the four quarters of the globe.

"Oh, I've had too much publicity," he said, when I telephoned to him to ask for an interview in order to explain his new discovery to the non-technical public. It took a good deal of persuasion before he reluctantly fixed an hour when he would see me, and a good bit more after that before he talked at all freely. When he did speak, however, he opened up vistas of possible applications of the new engine that staggered the imagination of the interviewer.

Telling His Life Dream.

Looking out over the city from the windows of his office, on the twentieth floor of the Metropolitan Tower, his face lit up as he told of his life dream and its approaching realization, and the listener's fancy could almost see the air full of strange flying craft, while huge steamships propelled at unheard of speeds ploughed the waters of the North River, automobiles climbed the very face of the Palisades, locomotives of incredible power whisked wheeled palaces many miles a minute and all the discomforts of summer heat vanished as marvellous refrigerating plants reduced the temperature of the whole city to a comfortable maximum—for these were only a few of the suggestions of the limitless possibilities of the latest Tesla discovery.

"Just what is your new invention?" I asked.

"I have accomplished what mechanical engineers have been dreaming about ever since the invention of steam power," replied Dr. Tesla. "That is the perfect rotary engine. It happens that I have also produced an engine which will give at least twenty-five times as much power to a pound of weight as the lightest weight engine of any kind that has yet been produced.

"In doing this I have made use of two properties which have always been known to be possessed by all fluids, but which have not heretofore been utilized. These properties are adhesion and viscosity.

"Put a drop of water on a metal plate. The drop will roll off, but a certain amount of the water will remain on the plate until it evaporates or is removed

(CONTINUED ON PAGE TWO.)

Nikola Tesla's Revolutionary Invention, a Perfect Rotary Engine

(CONTINUED FROM PAGE ONE.)

by some absorptive means. The metal does not absorb any of the water, but the water adheres to it.

"The drop of water may change its shape, but until its particles are separated by some external power it remains intact. This tendency of all fluids to resist molecular separation is viscosity. It is especially noticeable in the heavier oils.

"It is these properties of adhesion and viscosity that cause the 'skin friction' that impedes a ship in its progress through the water or an aeroplane in going through the air. All fluids have these qualities—and you must keep in mind that air is a fluid, all gases are fluids, steam is fluid. Every known means of transmitting or developing mechanical power is through a fluid medium.

"Now, suppose we make this metal plate that I have spoken of circular in shape and mount it at its centre on a shaft so that it can be revolved. Apply power to rotate the craft and what happens? Why, whatever fluid the disk happens to be revolving in is agitated and dragged along in the direction of rotation, because the fluid tends to adhere to the disk and the viscosity causes the motion given to the adhering particles of the fluid to be transmitted to the whole mass. Here, I can show you better than I can tell you."

Dr. Tesla led the way into an adjoining room. On a desk was a small electric motor and mounted on the shaft were half a dozen flat disks, separated by perhaps a sixteenth of an inch from one another, each disk being less than that in thickness. He turned a switch and the motor began to buzz. A wave of cool air was immediately felt.

"There we have a disk, or rather a series of disks, revolving in a fluid—the air," said the inventor. "You need no proof to tell you that the air is being agitated and propelled violently. If you will hold your hand over the centre of these disks—you see the centres have been cut away—you will feel the suction as air is drawn in to be expelled from the peripheries of the disks.

"Now, suppose these revolving disks were enclosed in an air tight case, so constructed that the air could enter only at one point and be expelled only at another—what would we have?

"You'd have an air pump," I suggested.

"Exactly—an air pump or a blower," said Dr. Tesla. There is one now in operation delivering ten thousand cubic feet of air a minute. "Now, come over here."

He stepped across the hall and into another room, where three or four draughtsmen were at work and various mechanical and electrical contrivances were scattered about. At one side of the room was what appeared to be a zinc or aluminum tank, divided into two sections, one above the other, while a pipe that ran along the wall above the upper division of the tank was connected with a little aluminum case about the size and shape of a small alarm clock. A tiny electric motor was attached to a shaft that protruded from one side of the aluminum case. The lower division of the tank was filled with water.

"Inside of this aluminum case are several disks mounted on a shaft and immersed in a fluid, water," said Dr. Tesla. "From this lower tank the water has free access to the case enclosing the disks. This pipe leads from the periphery of the case. I turn the current on, the motor turns the disks and as I open this valve in the pipe the water flows."

He turned the valve and the water certainly did flow. Instantly a stream that would have filled a barrel in a very few minutes began to run out of the pipe into the upper part of the tank and thence into the lower tank.

"This is only a toy," said Dr. Tesla. "There are only half a dozen disks—'runners,' I call them—each less than three inches in diameter, inside of that case. They are just like the disks you saw on the first motor—no vanes, blades or attachments of any kind. Just perfectly smooth, flat disks revolving in their own planes and pumping water because of the viscosity and adhesion of the fluid. One such pump now in operation, with eight disks, eighteen inches in diameter, pumps four thousand gallons a minute to a height of 360 feet.

We went back into the big, well lighted office. I was beginning to grasp the new Tesla principle.

"Suppose now we reversed the operation," continued the inventor. "You have seen the disks acting as a pump. Suppose we had water, or air under pressure, or steam under pressure, or gas under pressure, and let it run into the case in which the disks are contained—what would happen?"

"The disks would revolve and any machinery attached to the shaft would be operated—you would convert the pump into an engine," I suggested.

"That is exactly what would happen—what does happen," replied Dr. Tesla. "It is an engine that does all that engineers have ever dreamed of an engine doing, and more. Down at the Waterside power station of the New York Edison Company, through their courtesy, I have had a number of such engines in operation. In one of them the disks are only nine inches in diameter and the whole working part is two inches thick. With steam as the propulsive fluid it develops 110-horse power, and could do twice as much.

"You have got what Professor Langley was trying to evolve for his flying machine—an engine that will give a horse power for a pound of weight," I suggested.

Ten Horse Power to the Pound.

"I have got more than that," replied Dr. Tesla. "I have an engine that will give ten horse power to the pound of weight. That is twenty-five times as powerful as the lightest weight engine in use to-day. The lightest gas engine used on aeroplanes weighs two and one-half pounds to the horse power. With two and one-half pounds of weight I can develop twenty-five horse power."

"That means the solution of the problem of flying," I suggested.

"Yes, and many more," was the reply. "The applications of this principle, both for imparting power to fluids, as in pumps, and for deriving power from fluids, as in turbine, are boundless. It costs almost nothing to make, there is nothing about it to get out of order, it is reversible—simply have two ports for the gas or steam, to enter by, one on each side, and let it into one side or other. There are no blades or vanes to get out of order—the steam turbine is a delicate thing."

I remembered the bushels of broken blades that were gathered out of the turbine casings of the first turbine equipped steamship to cross the ocean, and realized the importance of this phase of the new engine.

"Then, too," Dr. Tesla went on, "there are no delicate adjustments to be made. The distance between the disks is not a matter of microscopic accuracy and there is no necessity for minute clearances between the disks and the case. All one needs is some disks mounted on a shaft, spaced a little distance apart and cased so that a fluid can enter at one point and go out at another. If the fluid enters at the centre and goes out at the periphery it is a pump. If it enters at the periphery and goes out at the centre it is a motor.

"Coupling these engines in series, one can do away with gearing in machinery. Factories can be equipped without shafting. The motor is especially adapted to automobiles, for it will run on gas explosions as well as on steam. The gas or steam can be let into a dozen ports all around the rim of the case if desired. It is possible to run it as a gas engine with a continuous flow of gas, gasolene and air being mixed and the continuous combustion causing expansion and pressure to operate the motor. The expansive power of steam, as well as its propulsive power, can be utilized as in a turbine or a reciprocating engine. By permitting the propelling fluid to move along the lines of least resistance a considerably larger proportion of the available power is utilized.

"As an air compressor it is highly efficient. There is a large engine of this type now in practical operation as an air compressor and giving remarkable service. Refrigeration on a scale hitherto never attempted will be practical, through the use of this engine in compressing air, and the manufacture of liquid air commercially is now entirely feasible.

"With a thousand horse power engine, weighing only one hundred pounds, imagine the possibilities in automobiles, locomotives and steamships. In the space now occupied by the engines of the Lusitania twenty-five times her 80,000 horse power could be developed, were it possible to provide boiler capacity sufficient to furnish the necessary steam."

"And it makes the aeroplane practical," I suggested.

"Not the aeroplane, the flying machine," responded Dr. Tesla. "Now you have struck the point in which I am most deeply interested—the object toward which I have been devoting my energies for more than twenty years—the dream of my life. It was in seeking the means of making the perfect flying machine that I developed this engine.

"Twenty years ago I believed that I would be the first man to fly; that I was on the track of accomplishing what no one else was anywhere near reaching. I was working entirely in electricity then and did not realize that the gasolene engine was approaching a perfection that was going to make the aeroplane feasible. There is nothing new about the aeroplane but its engine, you know.

"What I was working on twenty years ago was the wireless transmission of electric power. My idea was a flying machine propelled by an electric motor, with power supplied from stations on the earth. I have not accomplished this as yet, but am confident that I will in time.

"When I found that I had been anticipated, as to the flying machine, by men working in a different field I began to study the problem from other angles, to regard it as a mechanical rather than an electrical problem. I felt certain there must be some means of obtaining power that was better than any now in use, and by vigorous use of my gray matter for a number of years I grasped the possibilities of the principle of the viscosity and adhesion of fluids and conceived the mechanism of my engine. Now that I have it, my next step will be the perfect flying machine."

"An aeroplane driven by your engine?" I asked.

"Not at all," said Dr. Tesla. "The aeroplane is fundamentally defective. It is merely a toy—a sporting plaything. It can never become commercially practical. It has fatal defects. One is the fact that when it encounters a downward current of air it is helpless. The 'hole in the air' of which aviators speak is simply a downward current, and unless the aeroplane is high enough above the earth to move laterally out of the downward current before striking the ground it can do nothing but fall. There is no way of detecting these downward currents, no way of avoiding them, and therefore the aeroplane must always be subject to chance and its operator to the risk of fatal accident. Sportsmen will always take these chances, but as a business proposition the risk is too great.

"The flying machine of the future—my flying machine—will be heavier than air, but it will not be an aeroplane. It will have no wings. It will be substantial, solid, stable. You cannot have a stable aeroplane. The gyroscope can never be successfully applied to the aeroplane, for it would give a stability that would result in the machine being torn to pieces by the wind, just as the unprotected aeroplane on the ground is torn to pieces by a high wind.

"My flying machine will have neither wings nor propellers. You might see it on the ground and you would never guess that it was a flying machine. Yet it will be able to move at will through the air in any direction with perfect safety, higher speeds than have yet been reached, regardless of weather and oblivious of 'holes in the air' or downward currents. It will ascend in such currents if desired. It can remain absolutely stationary in the air even in a wind for a great length of time. Its lifting power will not depend upon any such delicate devices as the bird has to employ, but upon positive mechanical action."

"You will get stability through gyroscopes?" I asked.

"Through gyroscopic action of my engine, assisted by some devices I am not yet prepared to talk about," he replied.

"Powerful air currents that may be deflected at will, if produced by engines and compressors sufficiently light and powerful, might lift a heavy body off the ground and propel it through the air," I ventured, wondering if I had grasped the inventor's secret.

Dr. Tesla smiled an inscrutable smile.

"All I have to say on that point is that my airship will have neither gas bag, wings nor propellers," he said. "It is the child of my dreams, the product of years of intense and painful toil and research. I am not going to talk about it any further. But whatever my airship may be, here at least is an engine that will do things that no other engine ever has done, and that is something tangible."

Will Tesla's New Monarch of Mechanics Revolutionize the World?

Noted Balkan Scientist Claims to Have Perfected an Engine That Will Develop Ten Horsepower to Every Pound of Weight, and Promises Soon to Give to the World a Flying Machine Without Wings, Propeller, or Gas Bag. Characterizes Aeroplanes of Today as Mere Dangerous Toys Compared With the Safe and Stable Appliance Which Will Be Used in a Short Time to Dash Through the Air at a Speed Now Unimagined.

BY FRANK PARKER STOCKBRIDGE.

TEN horsepower from a tiny engine that a man could dangle from his little finger by a string!

Five hundred horsepower in a package that a man could lift easily in one hand!

A thousand horsepower motor occupying hardly more space than the cardboard box in which your hatter sent your new derby home!

Marvelous? Wait until you hear the rest of it!

Suppose some one should discover a new mechanical principle—something as fundamental as James Watt's discovery of the expansive power of steam—by the use of which it became possible to build a motor that would give ten horsepower for every pound of the engine's weight, a motor so simple that the veriest novice in mechanics could construct it and so elemental that it could not possibly get out of repair. Then suppose that this motor could be run forward or backward at will, that it could be used as either an engine or a pump, that it cost almost nothing to build as compared with any other known form of engine, that it utilized a larger percentage of the available power than any existing machine, and, finally, that it would operate with gas, steam, compressed air, or water, or any one of them, as its driving power.

It does not take a mechanical expert to imagine the limitless possibilities of such an engine. It takes very little effort to conjure up a picture of a new world of industry and transportation made possible by the invention of such a device. "Revolutionary" seems a mild term to apply to it. That, however, is the word the inventor uses in describing it—Nikola Tesla, the scientist, whose electrical discoveries underlie all modern electrical power development, whose experiments and deductions made the wireless telegraph possible, and who now, in the mechanical field, has achieved a triumph even more far reaching than anything he accomplished in electricity.

Romance in Discovery.

There is something of the romantic in this discovery of the famous explorer of the hidden realms of knowledge. The pursuit of an ideal is always romantic, and it was in the pursuit of an ideal which he has been seeking twenty years that Dr. Tesla made his great discovery. That ideal is the power to fly—to fly with certainty and absolute safety—not merely to go up in an aeroplane and take chances on weather conditions, "holes in the air," tornadoes, lighting, and the thousand other perils the aviator of today faces, but to fly with the speed and certainty of a cannon ball, with power to overcome any of nature's aerial forces, to start when one pleases, go whither one pleases, and alight where one pleases. That has been the aim of Dr. Tesla's life for nearly a quarter of a century. He believes that with the discovery of the principle of his new motor he has solved this problem, and that incidentally he has laid the foundations for the most startling new achievements in other mechanical lines.

Tesla and Niagara Falls.

There was a time when men of science were skeptical—a time when they ridiculed the announcement of revolutionary discoveries. Those were the days when Nikola Tesla, the young scientist from the Balkans, was laughed at when he urged his theories on the engineering world. Times have changed since then, and the "practical" engineer is not so incredulous about "scientific" discoveries. The change came about when young Tesla showed the way by which the power of Niagara Falls could be utilized. The right to divert a portion of the waters of Niagara had been granted; then arose the question of how best to utilize the tremendous power thus made available—how to transmit it to the points where it could be commercially utilized. An international commission sat in London and listened to theories and practical plans for months.

Up to that time the only means of utilizing electric power was the direct current motor, and direct current dynamos big enough to be of practical utility for such a gigantic power development were not feasible.

Then came the announcement of young Tesla's discovery of the principle of the alternating current motor. Practical tests showed that it could be built—that it would work.

That discovery, at that opportune time, decided the commission. Electricity was determined upon as the means for the transmission of Niagara's power to industry and commerce. Today a million horsepower is developed on the brink of the great cataract, turning the wheels of Buffalo, Rochester, Syracuse, and the intervening cities and villages operating close at hand the great new electrochemical industries that the existence of this immense source of power has made possible, while all around the world a thousand waterfalls are working in the service of mankind, sending the power of their "white coal" into remote and almost inaccessible corners of the globe, all because of Nikola Tesla's first great epoch-making discovery.

Great Excitement in Engineering World.

Today the engineering world listens respectfully when Dr. Tesla speaks. The first announcement of the discovery of his new mechanical principle was made in a technical periodical in mid-September, 1911. Immediately it became the principal topic of discussion wherever engineers met.

"It is the greatest invention in a century," wrote one of the foremost American engineers, a man whose name stands close to the top of the list of those who have achieved scientific fame and greatness.

"No invention of such importance in the automobile trade has yet been made," declared the editor of one of the leading engineering publications. Experts in other engineering lines pointed out other applications of the new principle, and letters asking for further information poured in on Dr. Tesla from the four quarters of the globe.

"Oh, I've had too much publicity," he said when I telephoned to him to ask for an interview in order to explain his new discovery to the nontechnical public. It took a good deal of persuasion before he reluctantly fixed an hour when he would see me, and a good bit more after that before he talked at all freely. When he did speak, however, he opened up vistas of possible applications of the new engine that staggered the imagination of the interviewer.

Telling His Life Dream.

Looking out over the city from the windows of his office, on the twentieth floor of the Metropolitan Tower, New York, his face lit up as he told of his life dream and its approaching realization, and the listener's fancy could almost see the air full of strange flying craft, while huge steamships propelled at unheard of speeds plowed the waters of the North River, automobiles climbed the very face of the Palisades, locomotives of incredible power whisked wheeled palaces many miles a minute, and all the discomforts of summer heat vanished as marvelous refrigerating plants reduced the temperature of the whole city to a comfortable maximum—for these were only a few of the suggestions of the limitless possibilities of the latest Tesla discovery.

"Just what is your new invention?" I asked.

"I have accomplished what mechanical engineers have been dreaming about ever since the invention of steam power," replied Dr. Tesla. "That is the perfect rotary engine. It happens that I have also produced an engine which will give at least 25 times as much power to a pound of weight as the lightest weight engine of any kind that has yet been produced.

"In doing this I have made use of two properties which have always been known to be possessed by all fluids, but which have not heretofore been utilized. These properties are adhesion and viscosity.

"Put a drop of water on a metal plate. The drop will roll off, but a certain amount of the water will remain on the plate until it evaporates or is removed by some absorptive means. The metal does not absorb any of the water, but the water adheres to it.

"The drop of water may change its shape, but until its particles are separated by some external power it remains intact. This tendency of all fluids to resist molecular separation is viscosity. It is especially noticeable in the heavier oils.

"It is these properties of adhesion and viscosity that cause the 'skin friction' that impedes a ship in its progress through the water or an aeroplane in going through the air. All fluids have these qualities—and you must keep in mind that the air is a fluid, all gases are fluids, steam is fluid. Every known means of transmitting or developing mechanical power is through a fluid medium.

"Now, suppose we make this metal plate that I have spoken of circular in shape and mount it at its center on a shaft so that it can be revolved. Apply power to rotate the craft and what happens? Why, whatever fluid the disk happens to be revolving in is agitated and dragged along in the direction of rotation, because the fluid tends to adhere to the disk and the viscosity causes the motion given to the adhering particles of the fluid to be transmitted to the whole mass. Here, I can show you better than I can tell you."

A Practical Demonstration.

Dr. Tesla led the way into an adjoining room. On a desk was a small electric motor, and mounted on the shaft were half a dozen flat disks, separated by perhaps a sixteenth of an inch from one another, each disk being less than that in thickness. He turned a switch and the motor began to buzz. A wave of cool air was immediately felt.

"There we have a disk, or rather a series of disks, revolving in a fluid—the air," said the inventor. "You need no proof to tell you that the air is being agitated and propelled violently. If you will hold your hand over the center of these disks—you see the centers have been cut away—you will feel the suction as air is drawn in to be expelled from the peripheries of the disks.

"Now, suppose these revolving disks were inclosed in an airtight case, so constructed that the air could enter only at one point and be expelled only at another—what would we have?

"You'd have an air pump," I suggested.

"Exactly—an air pump or a blower," said Dr. Tesla. "There is one now in operation delivering 10,000 cubic feet of air a minute. Now come over here."

He stepped across the hall and into another room, where three or four draftsmen were at work and various mechanical and electrical contrivances were scattered about. At one side of the room was what appeared to be a zinc or aluminum tank, divided into two sections, one above the other, while a pipe that ran along the wall above the upper division of the tank was connected with a little aluminum case about the size and shape of a small alarm clock. A tiny electric motor was attached to a shaft that protruded from one side of the aluminum case. The lower division of the tank was filled with water.

"Inside of this aluminum case are several disks mounted on a shaft and immersed in a fluid, water," said Dr. Tesla. "From this lower tank the water has free access to the case inclosing the disks. This pipe leads from the periphery of the case. I turn the current on, the motor turns the disks, and as I open this valve in the pipe the water flows."

He turned the valve and the water certainly did flow. Instantly a stream that would have filled a barrel in a very few minutes began to run out of the pipe into the upper part of the tank and thence into the lower tank.

"This is only a toy," said Dr. Tesla. "There are only half a dozen disks—'runners,' I call them—each less than 3 inches in diameter, inside of that case. They are just like the disks you saw on the first motor—no vanes, blades, or attachments of any kind. Just perfectly smooth, flat disks revolving in their own planes and pumping water because of the viscosity and adhesion of the fluid. One such pump now in operation, with eight disks, 18 inches in diameter, pumps 4,000 gallons a minute to a height of 360 feet.

Pump Becomes an Engine.

We went back into the big, well lighted office. I was beginning to grasp the new Tesla principle.

"Suppose now we reversed the operation," continued the inventor. "You have seen the disks acting as a pump. Suppose we had water, or air under pressure, or steam under pressure, or gas under pressure, and let it run into the case in which the disks are contained—what would happen?"

"The disks would revolve and any machinery attached to the shaft would be operated—you would convert the pump into an engine," I suggested.

"That is exactly what would happen—what does happen," replied Dr. Tesla. "It is an engine that does all that engineers have ever dreamed of an engine doing, and more. Down at the Waterside power station of the New York Edison Company, through their courtesy, I have had a number of such engines in operation. In one of them the disks are only 9 inches in diameter, and the whole working part is 2 inches thick. With steam as the propulsive fluid, it develops 110-horsepower, and could do twice as much.

"You have got what Prof. Langley was trying to evolve for his flying machine—an engine that will give a horsepower for a pound of weight?" I suggested.

"I have got more than that," replied Dr. Tesla. "I have an engine that will give 10 horsepower to the pound of weight. That is 25 times as powerful as the lightest-weight engine in use today. The lightest gas engine used on aeroplanes weighs 2½ pounds to the horsepower. With 2 1-2 pounds of weight I can develop 25 horsepower."

"That means the solution of the problem of flying," I suggested.

"Yes, and many more," was the reply. "The applications of this principle, both for imparting power to fluids, as in pumps, and for deriving power from fluids, as in turbines, are boundless. It costs almost nothing to make, there is nothing about it to get out of order, it is reversible—simply have two ports for the gas or steam, to enter by, one on each side, and let it into one side or other. There are no blades or vanes to get out of order—the steam turbine is a delicate thing."

I remembered the bushels of broken blades that were gathered out of the turbine casings of the first turbine-equipped steamship to cross the ocean, and realized the importance of this phase of the new engine.

No Delicate Adjustment Necessary.

"Then, too," Dr. Tesla went on, "there are no delicate adjustments to be made. The distance between the disks is not a matter of microscopic accuracy, and there is no necessity for minute clearances between the disks and the case. All one needs is some disks mounted on a shaft, spaced a little distance apart, and cased so that a fluid can enter at one point and go out at another. If the fluid enters at the center and goes out at the periphery it is a pump. If it enters at the periphery and goes out at the center it is a motor.

"Coupling these engines in series, one can do away with gearing in machinery. Factories can be equipped without shafting. The motor is especially adapted to automobiles, for it will run on gas explosions as well as on steam. The gas or steam can be let into a dozen ports all around the rim of the case if desired. It is possible to run it as a gas engine with a continuous flow of gas, gasoline and air being mixed and the continuous combustion causing expansion and pressure to operate the motor. The expansive power of steam, as well as its propulsive power, can be utilized as in a turbine or a reciprocating engine. By permitting the propelling fluid to move along the lines of least resistance a considerably larger proportion of the available power is utilized.

"As an air compressor it is highly efficient. There is a large engine of this type now in practical operation as an air compressor, and giving remarkable service. Refrigeration on a scale hitherto never attempted will be practical, through the use of this engine in compressing air, and the manufacture of liquid air commercially is now entirely feasible.

"With a 1,000-horsepower engine, weighing only 100 pounds, imagine the possibilities in automobiles, locomotives, and steamships. In the space now occupied by the engines of the Lusitania 25 times her 80,000 horsepower could be developed, were it possible to provide boiler capacity sufficient to furnish the necessary steam."

"And it makes the aeroplane practical," I suggested.

Flying Machine to Supplant Aeroplane.

"Not the aeroplane, the flying machine," responded Dr. Tesla. "Now you have struck the point in which I am most deeply interested—the object toward which I have been devoting my energies for more than twenty years—the dream of my life. It was in seeking the means of making the perfect flying machine that I developed this engine.

"Twenty years ago I believed that I would be the first man to fly; that I was on the track of accomplishing what no one else was anywhere near reaching. I was working entirely in electricity then, and did not realize that the gasoline engine was approaching a perfection that was going to make the aeroplane feasible. There is nothing new about the aeroplane but its engine, you know.

"What I was working on twenty years ago was the wireless transmission of electric power. My idea was a flying machine propelled by an electric motor, with power supplied from stations on the earth. I have not accomplished this as yet, but am confident that I will in time.

The Aero a Mere Toy.

"When I found that I had been anticipated, as to the flying machine, by men working in a different field, I began to study the problem from other angles, to regard it as a mechanical rather than an electrical problem. I felt certain there must be some means of obtaining power that was better than any now in use, and by vigorous use of my gray matter for a number of years I grasped the possibilities of the principle of the viscosity and adhesion of fluids, and conceived the mechanism of my engine. Now that I have it, my next step will be the perfect flying machine."

"An aeroplane driven by your engine?" I asked.

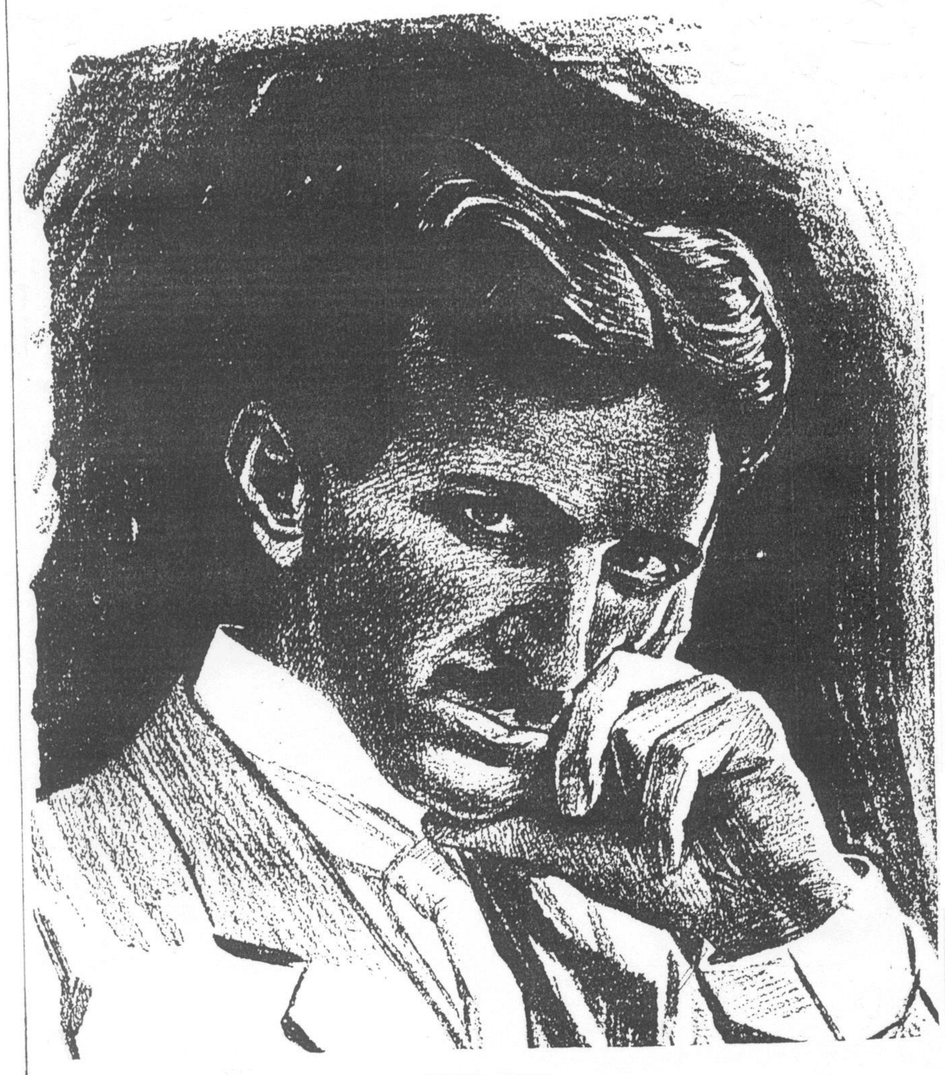
"Not at all," said Dr. Tesla. "The aeroplane is fatally defective. It is merely a toy—a sporting plaything. It can never become commercially practical. It has fatal defects. One is the fact that when it encounters a downward current of air it is helpless. The 'hole in the air' of which aviators speak is simply a downward current, and unless the aeroplane is high enough above the earth to move laterally out of the downward current before striking the ground it can do nothing but fall. There is no way of detecting these downward currents, no way of avoiding them, and therefore the aeroplane must always be subject to chance and its operator to the risk of fatal accident. Sportsmen will always take these chances, but as a business proposition the risk is too great.

"The flying machine of the future—my flying machine—will be heavier than air, but it will not be an aeroplane. It will have no wings. It will be substantial, solid, stable. You cannot have a stable aeroplane. The gyroscope can never be successfully applied to the aeroplane, for it would give a stability that would result in the machine being torn to pieces by the wind, just as the unprotected aeroplane on the ground is torn to pieces by a high wind.

Neither Wings Nor Propeller.

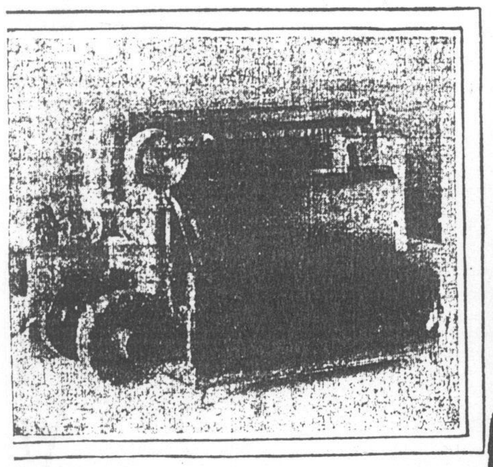
"My flying machine will have neither wings nor propellers. You might see it on the ground and you would never guess that it was a flying machine. Yet it will be able to move at will through the air in any direction with perfect safety, higher speeds than have yet been reached, regardless of weather and oblivious of 'holes in the air' or downward currents. It will ascend in such currents if desired. It can remain absolutely stationary in the air even in a wind for a great length of time. Its lifting power will not depend upon any such delicate devices as the bird has to employ, but upon positive mechanical action."

"You will get stability through gyroscopes?" I asked.



"Through gyroscopic action of my engine, assisted by some devices I am not yet prepared to talk about," he replied.

"Powerful air currents that may be deflected at will, if produced by engines and compressors sufficiently light and powerful, might lift a heavy body off the ground and propel it through the air," I ventured, wondering if I had grasped the inventor's secret.



Dr. Tesla smiled an inscrutable smile.

"All I have to say on that point is that my airship will have neither gas bag, wings, nor propellers," he said. "It is the child of my dreams, the product of years of intense and painful toil and research. I am not going to talk about it any further. But whatever my airship may be, here at least is an engine that will do things that no other engine ever has done, and that is something tangible."

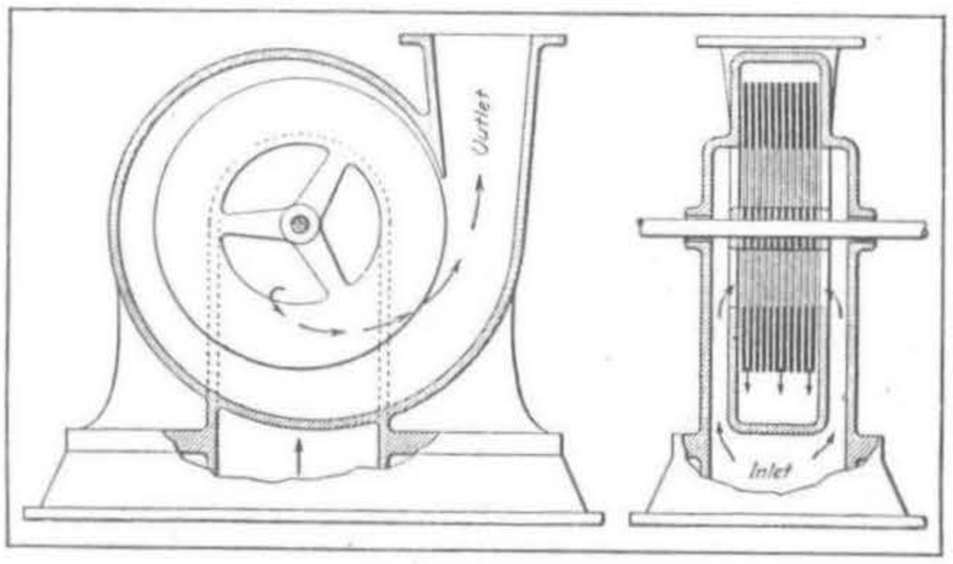
SCIENCE AND INVENTION

TESLA'S NEW ROTARY MACHINE

A MACHINE based on a new principle, for use wherever a fluid is used as a vehicle of energy, has been invented by Nikola Tesla. Apparently it is capable of a wide variety of applications, from cases where velocity is to be imparted to the fluid, as in a pump, to those where the moving fluid is itself to operate machinery, either by its velocity alone or by its expansion. The fluid may be liquid or gaseous, and its velocity may be due to simple hydrostatic or gaseous pressure or to explosive combustion. Here, then, we have evidently a device capable of use wherever engines, turbines, pumps, or power-transformers of any kind are now in use. The new principle consists simply in the utilization of the fluid's internal friction and its adhesion to a smooth surface for giving it speed or imparting to machinery its speed already acquired. This operation is thus vastly smoother than in any known pump or engine, and wasteful and injurious jerks are eliminated, as well as complicated parts. The new invention, which is in practical operation at one of the Edison Company's stations in New York, was briefly described by Mr. Tesla before the National Electric Light Association last May, and an authoritative description is now published by *The Electrical Review and Western Electrician* (Chicago, September 9). Says Mr. Tesla:

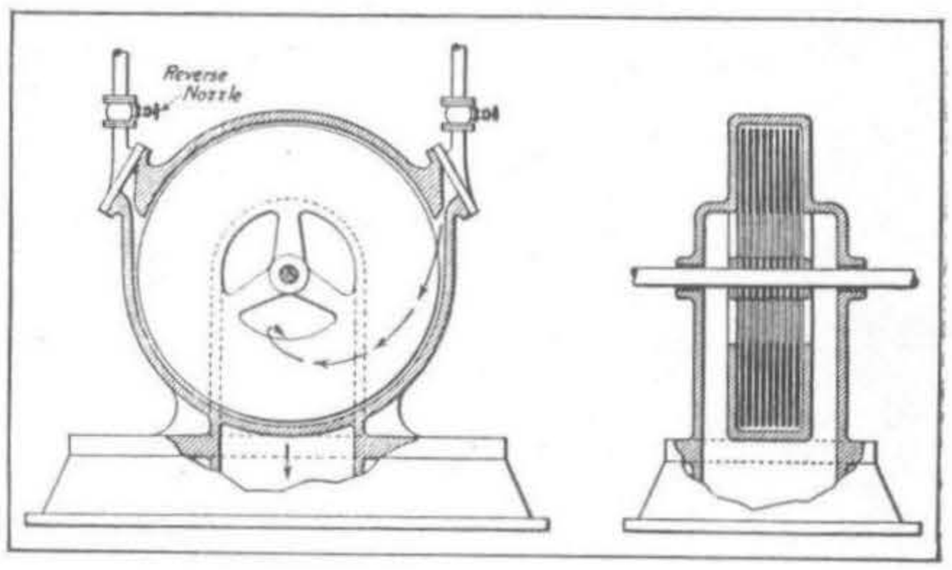
A 200-HORSE-POWER TESLA STEAM-TURBINE.



"In the practical application of mechanical power based on the use of a fluid as vehicle of energy it has been demonstrated that, in order to attain the highest economy, the changes in velocity and direction of movement of the fluid should be as gradual as possible. In the present forms of such apparatus, more or less sudden changes, shocks, and vibrations are unavoidable. Besides, the employment of the usual devices for imparting to, or deriving energy from a fluid, as pistons, paddles, vanes, and blades, necessarily introduces numerous defects and limitations and adds to the complication, cost of production, and maintenance of the machine.

"The purpose of the invention is to overcome these deficiencies and to effect the transmission and transformation of mechanical energy through the agency of fluids in a more perfect manner, and by means simpler and more economical than those heretofore employed.

"This is accomplished by causing the propelled or propelling fluid to move in natural paths or stream-lines of least resistance, free from constraint and disturbance such as occasioned by vanes or kindred devices, and to change its velocity and direction of movement by imperceptible degrees, thus avoiding the losses due to sudden variations while the fluid is receiving or imparting energy.



"It is well known that a fluid possesses, among others, two salient properties: adhesion and viscosity. Owing to these a body propelled through such a medium encounters a peculiar impediment known as 'lateral,' or 'skin resistance,' which is twofold: one arising from the shock of the fluid against the asperities of the solid substance, the other from internal forces opposing molecular separation. As an inevitable consequence a certain amount of the fluid is dragged along by the moving body. Conversely, if the body be placed in a fluid in motion, for the same reasons, it is impelled in the direction of movement. The accompanying drawings illustrate operative and efficient embodiments of the idea."

The illustrations show simply a set of smooth disks revolving in a case. When these are set in rotation and the fluid is admitted, it is dragged along in a spiral path, making possibly several revolutions, and is finally expelled through the outlet, having gradually gained in velocity during its trip. In this way the machine may function as a pump or as a device for the compression of air. The reversibility of the machine allows it also to function as a motor when a fluid under pressure or in rapid motion is fed to it. We read:

Longitudinal section. Cross-section.

TESLA DISK-IMPELLER PUMP.

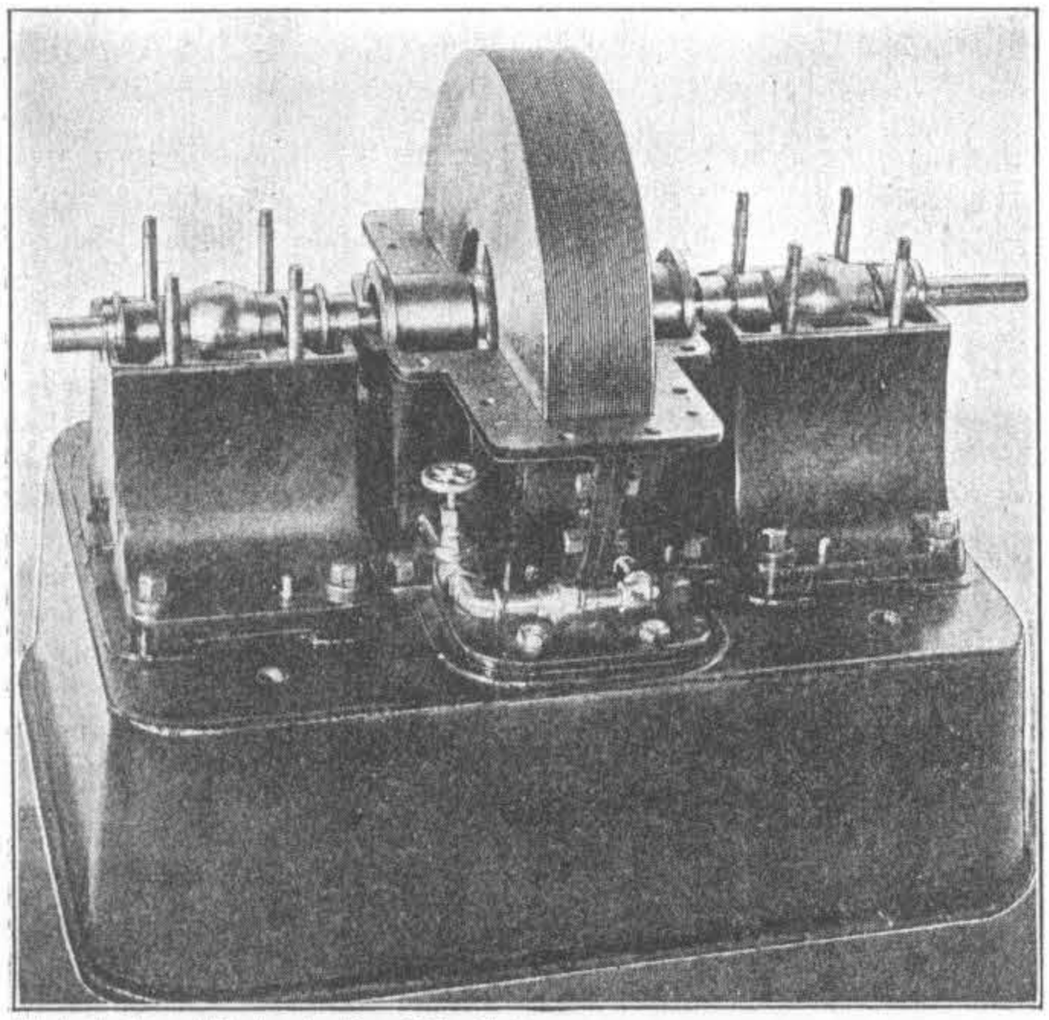
Longitudinal section. Cross-section.

TESLA DISK WHEEL IN A STEAM-TURBINE.

INTERIOR MECHANISM OF MR. TESLA'S TURBINE.

"The operation above described is reversible, for if water or air under pressure be admitted to the opening the runner is set in rotation in the direction of the dotted arrow by reason of the peculiar properties of the fluid which, traveling in a spiral path and with continuously diminishing velocity, reaches the orifices through which it is discharged. If the runner be allowed to turn freely, in nearly frictionless bearings, its rim will attain a speed closely approximating the maximum of that of the fluid in the volute channel and the spiral path of the particles will be comparatively long, consisting of many almost circular turns. If the load is put on and the runner slowed down the motion of the fluid is retarded, the turns are reduced, and the path is shortened."

If steam be admitted, the machine will work like an engine under expansion, but if the expansion be allowed to take place before admission, it will operate like a turbine, being driven by the impact of the rapidly-moving particles. Says the inventor:



"The above description of the operation is suggested by experience and observation and is advanced merely for the purpose of explanation. The undeniable fact is that the machine does operate, both expansively and impulsively.

"When the expansion in the nozle is complete, or nearly so, the fluid pressure in the peripheral clearance space is small, as the nozle is made less divergent and its section enlarged, the pressure rises, finally approximating that of the supply. But the transition from purely impulsive to expansive action may not be continuous throughout, on account of critical states and conditions, and comparatively great variations of pressure may be caused by small changes of nozle velocity.

"In the preceding, it has been assumed that the pressure of supply is constant or continuous, but it will be understood that the operation will be, essentially, the same if the pressure be fluctuating or intermittent, as that due to explosions occurring in more or less rapid succession."

One of the special advantages claimed by the inventor for his device is its ease and simplicity of reversal, which may be effected simply by turning a valve. He says in conclusion:

"It is simple, light, and compact, subject to but little wear, cheap, and exceptionally easy to manufacture, as small clearances and accurate milling work are not essential to good performance. In operation it is reliable, there being no valves, sliding contacts,

or troublesome vanes. It is almost free of windage, largely independent of nozle-efficiency, and suitable for high as well as for low fluid velocities and speeds of revolution. The principles of construction and operation are capable of embodiment in machines of the most widely different forms, and adapted for the greatest variety of purposes."

THE MACHINIST'S SENSE OF TOUCH

DESPITE the high development of automatic-machine construction, the sense of touch remains an essential factor in a large part of the operations performed in manufacturing. This is due, we are told by *The American Machinist* (New York, October 5) to the wide utilization of semi-automatic and hand-operated machinery even in the most scientifically organized plants. In the majority of shops operations are still carried on upon a scale which warrants only a limited amount of automatic machinery. So, in spite of the general departure from the earlier hand-processes, the sense of touch remains of considerable importance. We read, for instance, that

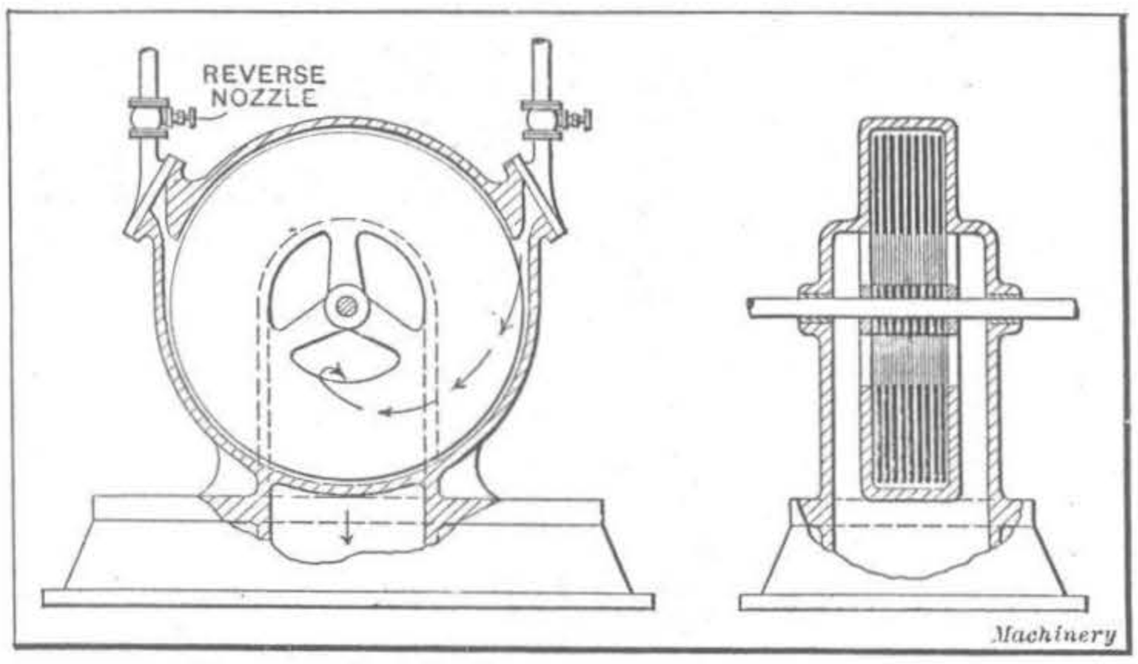
SIZE OF THE TESLA TURBINE.

A 110-horse-power machine under the hand of the man who runs it.

"The faculty known as the sense of touch that enables the operator of a hand-screw machine to follow, by the 'feel' of his lever, the cutting action of each of the tools as it is in turn run over the rotating stock, and to finish the cut with a definite pressure against the tool-slide stop, also serves as an accurate medium by which the operator of the hand-miller may gage the action of the cutter under which he feeds his work. In these cases, as with certain other machines of the hand-operated type, the practised workman can bring the tools to the work or the work to the cutter with a movement that is almost instantaneous and, throughout the extent of the cut, a feed may be maintained that is limited only by the strength of the operator or by what his sense of touch tells him is the maximum rate permissible with the speeds and tools employed.

"The dexterity of manipulation which usually develops in the hand coincident with the sense of touch, and which is an equally important consideration in modern shop practise, enables punch presses to be fed with little loss of time, and small work to be passed in and out of milling-fixtures and drilling-jigs with a similar economy of time and effort. A boy tending a certain machine of the semi-automatic type with a dial feed for carrying the work under a set of punches, has been known to develop sufficient cleverness of the fingers to enable him to drop 50,000 small blanks into holes in the dial in a day of ten hours; at the same time inspecting each blank, and this also by touch rather than visually, his attention being focused upon the general operation of the machine and not directly upon the work fed in the dial.

"Similarly, the movements of a machine-operator's foot may be developed to an extent that converts this member into a device functioning throughout the work day with the regularity of machinery itself. In fact, in certain instances on punch-press work, hand fed, and requiring foot-pressure upon a treadle to start each cycle of movements, the application of the starting pressure may occur with such clock-like regularity as to form a source of danger to the operator in that his fingers for some reason may lag for an instant and be caught under the punch, the movements of which continue as regularly as tho occurring without human intervention.



"Constituting as it does so essential a factor in modern

production, the sense of touch is likely to be developed and utilized still further, rather than dispensed with in our mechanical progress, and the legitimate field of the various hand-operated machine tools as manufacturing machines extended correspondingly along with the increase in the use of power-feed machines of both the conventional and high-power types."

THE TESLA STEAM TURBINE

Experiments with a novel design of steam turbine have been made by Mr. Nikola Tesla, who is well known in the electrical field on account of the part he has played in the developments in connection with the rotating magnetic field and other alternating current subjects. A diagrammatical section of the Tesla steam turbine is shown in the accompanying illustration. The steam is expanded in a nozzle and the heat energy is thus converted into kinetic energy. The rotor of the steam turbine simply consists of a number of thin flat disks, the inlet for the steam being at the outer periphery of these disks and the outlet being at their center, as indicated. The high velocity steam escaping from the nozzle is caused to impinge tangentially on the edges of the disks,

Diagrammatical Sections of the Tesla Steam Turbine

and in order to escape it must find a path from the periphery of the disks to the central outlet. The velocity energy of the steam produces a rotary motion of the disks, due to molecular drag on the surface, and hence the path of the steam from the outside to the inside of the disks will be a spiral one. Expressing the matter in popular terms, we may say that the action is due simply to the friction of the steam against the sides of the disks as the steam moves from the outside periphery to the center along a spiral path.

The arrangement shown in the illustration permits of easy and convenient reversal, as it is only necessary to provide a duplicate nozzle discharging against the opposite side of the disks as indicated. When the machine is at rest, or is running slowly, as in starting, the steam takes the shortest path from nozzle to exhaust, and thus develops a comparatively large torque. As the machine speeds up, the difference in velocity between the steam and the disks decreases, and the centrifugal force tends to lengthen the spiral path of the steam, so that a given amount of steam may make several revolutions with the disks before finally passing out through the exhaust opening.

A turbine of this type has been tested at the Waterside Station of the New York Edison Co. The rotor of the tested turbine has 25 disks, each 18 inches in diameter. The assembled turbine occupies a floor space of 20 by 35 inches and is about 5 feet high, completely installed. With steam at 125 pounds gage pressure per square inch exhausting into the atmosphere, 200 horsepower was developed with a speed of 9000 R. P. M. The steam consumption was 38 pounds per horsepower-hour. The weight of the turbine is 400 pounds, giving a unit weight of only 2 pounds per horsepower. While the steam consumption at present is rather high, Mr. Tesla

believes that with moderate superheat and a degree of vacuum the same as that ordinarily used in a turbine plant, the steam consumption can be reduced materially.

The principle employed is not limited to steam turbines. It can be applied as well to a type of centrifugal pump, having a series of smooth flat disks revolving in a casing, these disks having no vanes or other impelling projections. The motion of the water is produced simply by the friction or molecular adhesion between the disks and the fluid. In this case the fluid is, of course, taken in at the center of the disks and forced along a spiral path to the outside periphery.

* * *

BLADELESS TURBINES.

FROM a recent issue of the *Scientific American* it appears that Mr. Nikola Tesla has revived a method of steam-turbine construction which recalls one tried here some nine or ten years ago. The idea was patented by Mr. E. C. Thrupp in 1901, but Mr. D. J. Smith, of 58, Compton-street, E.C., informs us that at a still earlier date he assisted an Australian inventor to experiment with a similar type. The Tesla turbine is represented diagrammatically by Figs. 1, 2, and 3, which we reproduce from the *Scientific American*. As will be seen, its mechanical simplicity is extreme. The whole machine consists of a series of 25 thin discs 18 in. in diameter and $\frac{1}{32}$ in. thick mounted side by side on a shaft, with a small clearance between them. Steam is admitted tangentially through a nozzle on the right, and after flowing through the interspaces between the discs, escapes at the centre, causing the rotor to rotate by its frictional drag on the discs. To reverse the direction of rotation, the nozzle on the right is closed, and that shown on the left opened.

Mechanically nothing could be simpler, but unfortunately this mechanical simplicity is purchased at the expense of hydraulic inefficiency, as any of the various inventors, who have experimented on the device, could have ascertained had they applied to someone with a competent knowledge of theoretical mechanics. That the system is likely to be defective in this respect is obvious from the consideration that in a perfect turbine the steam must expand adiabatically. Now, in turbines of the type under consideration, the whole impelling force is due to the fact that the fluid slides over the surfaces of the discs with friction, against which it does work, and this frictional work is returned to the steam as heat. The whole impulsion of the rotor accordingly is dependent on the wasting of work by friction. If there were no friction, the steam would expand adiabatically, but would do no work, whereas, in the case of an ordinary turbine, could adiabatic expansion be secured, the efficiency would be a maximum. It can be shown, in short, that the maximum possible hydraulic efficiency of such a turbine is 50 per cent., and any experiments showing a better result than this can safely be discarded, though some allowance may be necessary for the fact that an hydraulic efficiency of 50 per cent. may, in a compound turbine, owing to the reheat factor, correspond to a somewhat higher thermodynamic efficiency, since the work wasted in friction at the high-pressure end of such a turbine is partially recoverable in subsequent stages.

Obviously, the system of maintaining a motion and doing work by the frictional drag of a fluid is not confined to cases of rotation, and the mathematical aspect of the question is, perhaps, more simply presented if we consider a case of rectilinear motion. Thus, suppose a stream of fluid moving at v ft. a second to be discharged into a tank mounted on wheels. Let the latter at the outset be held fast, then, although the jet exercises a frictional drag on the tank, no work is done, since motion of the latter is prevented. The frictional drag on the tank is equal to the momentum destroyed per second; or if W denote the weight discharged per second, the thrust on the tank is given by the relation $T = \frac{W}{g} v$.

At the same time the kinetic energy destroyed per second is $W \frac{v^2}{2g}$. Next assume the speed of the jet and the speed of the tank are both increased by the amount s. Then assuming, as before, that the fluid merely collects in the tank, the frictional drag is unaltered, since the fluid enters with an absolute velocity $v + s$, and remains there with an absolute velocity s. Hence the frictional drag impelling the tank is again $T = \frac{W}{g} v$, and the useful work done per second in propelling the tank is $T s = \frac{W}{g} v s$.

The kinetic energy supplied by the jet is now, however, $\frac{W}{g} \frac{(v + s)^2}{2}$.

Hence the efficiency of the device is

$$\frac{W}{g} v s \div \frac{W}{g} \frac{(v + s)^2}{2} = \frac{2 v s}{(v + s)^2}.$$

By differentiation, it is easily seen that this is a maximum when $v = s$, in which case the efficiency is $\frac{1}{2}$. Finally, let the speed of the jet be still further increased by an amount y, whilst the speed of the tank remains constant at s. The fluid is now delivered from the tank with an absolute velocity $s + y$, and a relative velocity y. The case, therefore, is exactly analogous to the Tesla turbine. The frictional drag remains the same as before—viz., $T = \frac{W}{g} v$, and the work done is still $\frac{W}{g} v s$.

The kinetic energy supplied is now, however, $W \frac{(v + s + y)^2}{2g}$, so that the efficiency is $\frac{2 v s}{(v+s+y)^2}$, which is less than when the whole of the fluid remained, and moved with the tank. In that case the maximum possible hydraulic efficiency was 50 per cent., so that when the fluid is delivered as it is in the case of the Tesla turbine, the hydraulic efficiency must be less than $\frac{1}{2}$. Of course, the motion in the latter is not rectilinear, but the argument above set forth applies identically, if for linear momentum we substitute moment of momentum, for frictional drag frictional torque, and for linear velocity angular velocity.

To make an efficient turbine of the device it would be necessary to provide vanes. We should then get a construction analogous to the "Jumbo" turbine patented and experimented with by Sir Charles Parsons many years ago. This was abandoned because it was found that any solid particles which might accidentally get into the turbine were kept in a constant state of flux between the rotor and the standing portion of the machine. They were carried in with the steam and flung out again by the centrifugal force, and the wear was consequently excessive.

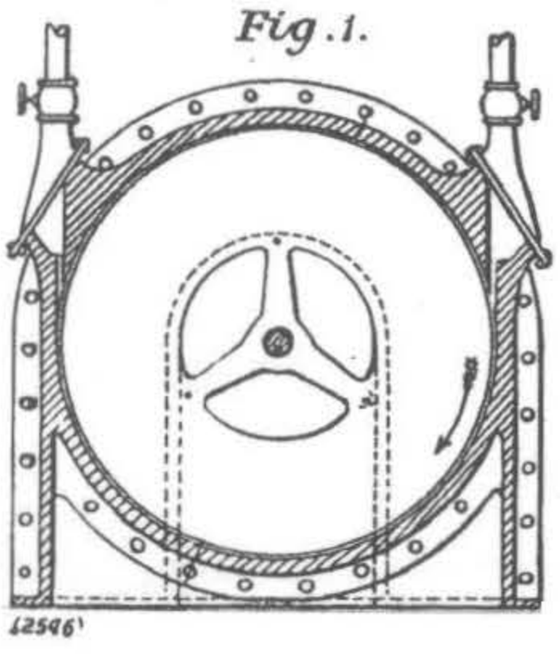

Fig. 2.

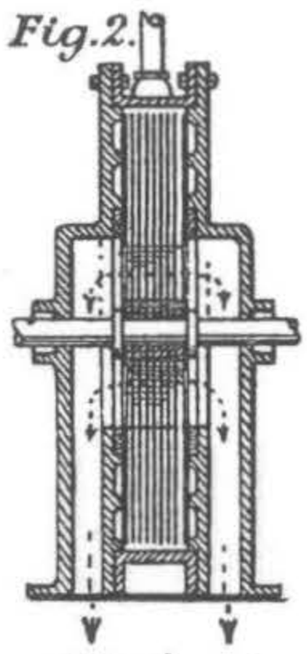

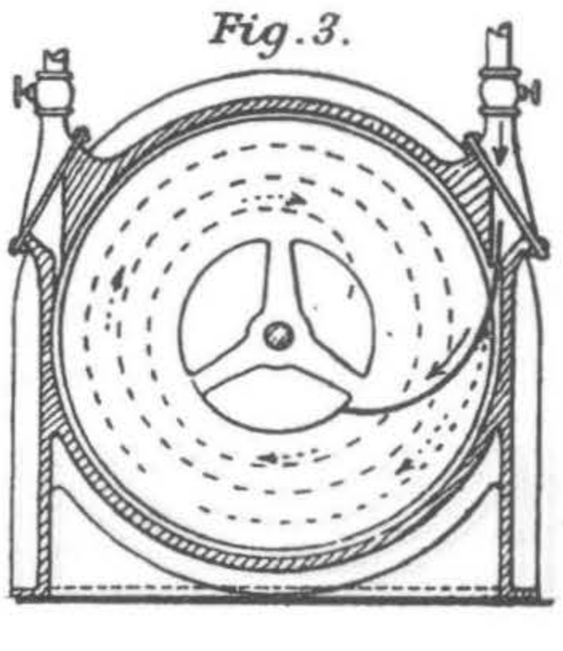

Fig. 3.

Tesla's New Mechanical Principle

Wide Field for Efficiency Increase in Motor Practice

AN engine which uses gasoline as a fuel and is capable of delivering 60 per cent. of the inherent energy of this fuel at the crankshaft instead of the customary 18 to 22 per cent. has been invented and constructed by Nikola Tesla.

"It is well known," states the inventor, "that a fluid possesses, among others, two salient properties: adhesion and viscosity. Owing to these a body propelled through such a medium encounters a peculiar impediment known as lateral or skin resistance, which is two-fold, one arising from the shock of the fluid against the asperities of the solid substance, the other from internal forces opposing molecular separation. As an inevitable consequence a certain amount of the fluid is dragged along by the moving body; conversely, if the body be placed in a fluid in motion, for the same reasons, it is impelled in the direction of movement."

Based on these observations, Nikola Tesla, the discoverer of the polyphase alternating current, has developed a new mechanical principle broadly applicable for the generation, transformation and transmission of mechanical energy. The machines constructed by Mr. Tesla are illustrated herewith, partly by photographic reproductions and partly by sectional drawings which accompanied Mr. Tesla's original treatise in the *Electrical Review and Western Electrician,* September 9.

In the development of his machines it has been the aim of the inventor to let the energated fluid *flow along its natural paths;* that is, those of least resistance, with as small a friction loss as possible. It is important to keep in mind the fact that in his, like in all other mechanical devices, *friction is inevitably equivalent to a loss in efficiency.* With these points in view Mr. Tesla uses in his construction but a few simple and economic elements creating as little resistance as possible for the fluids moving his machine or moved by them.

The machine, Fig. 1, is of simple construction and may be used as a motor or as a pump. In a steel housing, very much like to that of a centrifugal pump, is contained a runner consisting of a number of steel or bronze plates arranged in series upon a shaft, Fig. 2. Each plate or disc has three central openings A extending from the shaft to about one-third of the radius and separated by spokes. These openings are cut or stamped out of the discs and the surfaces of the latter are kept as smooth as possible.

If the device, Fig. 2, is mounted on bearings and rotated at considerable speed the following phenomenon takes place. The air, in direct touch with the metal discs, is held to them by molecular adhesion, clinging to the metal surfaces as water does to that of a solid it is brought in contact with, and therefore the air particles next to the discs are imparted motion in the direction of the rotation of the discs. Thus, some air is dragged along and its particles begin revolving about the shaft of the device. Since the movement of the air is rotary, centrifugal force causes it to move away from the central portions of the discs, the resultant between the rotary and centrifugal force being along a spiral line. This flow of air toward the periphery of the discs causes a fall of atmospheric pressure at the central regions, and these being occupied by the openings, air rushes in through the openings, and thus a continuous flow of air is maintained.

If the discs are enclosed in the casing seen in Fig. 1, and the shaft is rotated, the unit will work as a pump. In order to explain the office of the inlet and outlet pipes seen in the illustration, Fig. 3, is offered to illustrate the Tesla pump in partial end view and vertical cross-section. The air adjacent to the discs is dragged along in the direction of the arrows, approaching at the same time the periphery of the discs. In addition to this the particles not in direct touch with the discs, but with the moving air, are dragged along and imparted motion through viscosity, that is, the attraction of the particles of a fluid. The viscosity of air is about 100 times that of water. Thus, the entire body of air between the two discs—unless they are spaced too far—is transported to the peripheral portions of the interdiscular space and, after having reached the periphery, streams along the wall of the casing, which widens from the point 1 to 2, 3 and 4, until the air reaches the outlet where it is discharged. The quantity of the fluid propelled through this pump, according to tests made by its inventor, is approximately proportionate to the active surface of the runner—the total active surfaces of all the discs on the shaft—and to the effective speed of the machines; therefore, the performance of the pump is bettered with increasing size and number of revolutions per minute.

The machine, Figs. 1 to 3, has twenty-five plates 9 3-4 inches in diameter, the entire runner being 2 inches thick and the full weight including the casing of the machine being 20 pounds.

If a fluid under pressure is permitted to enter the casing

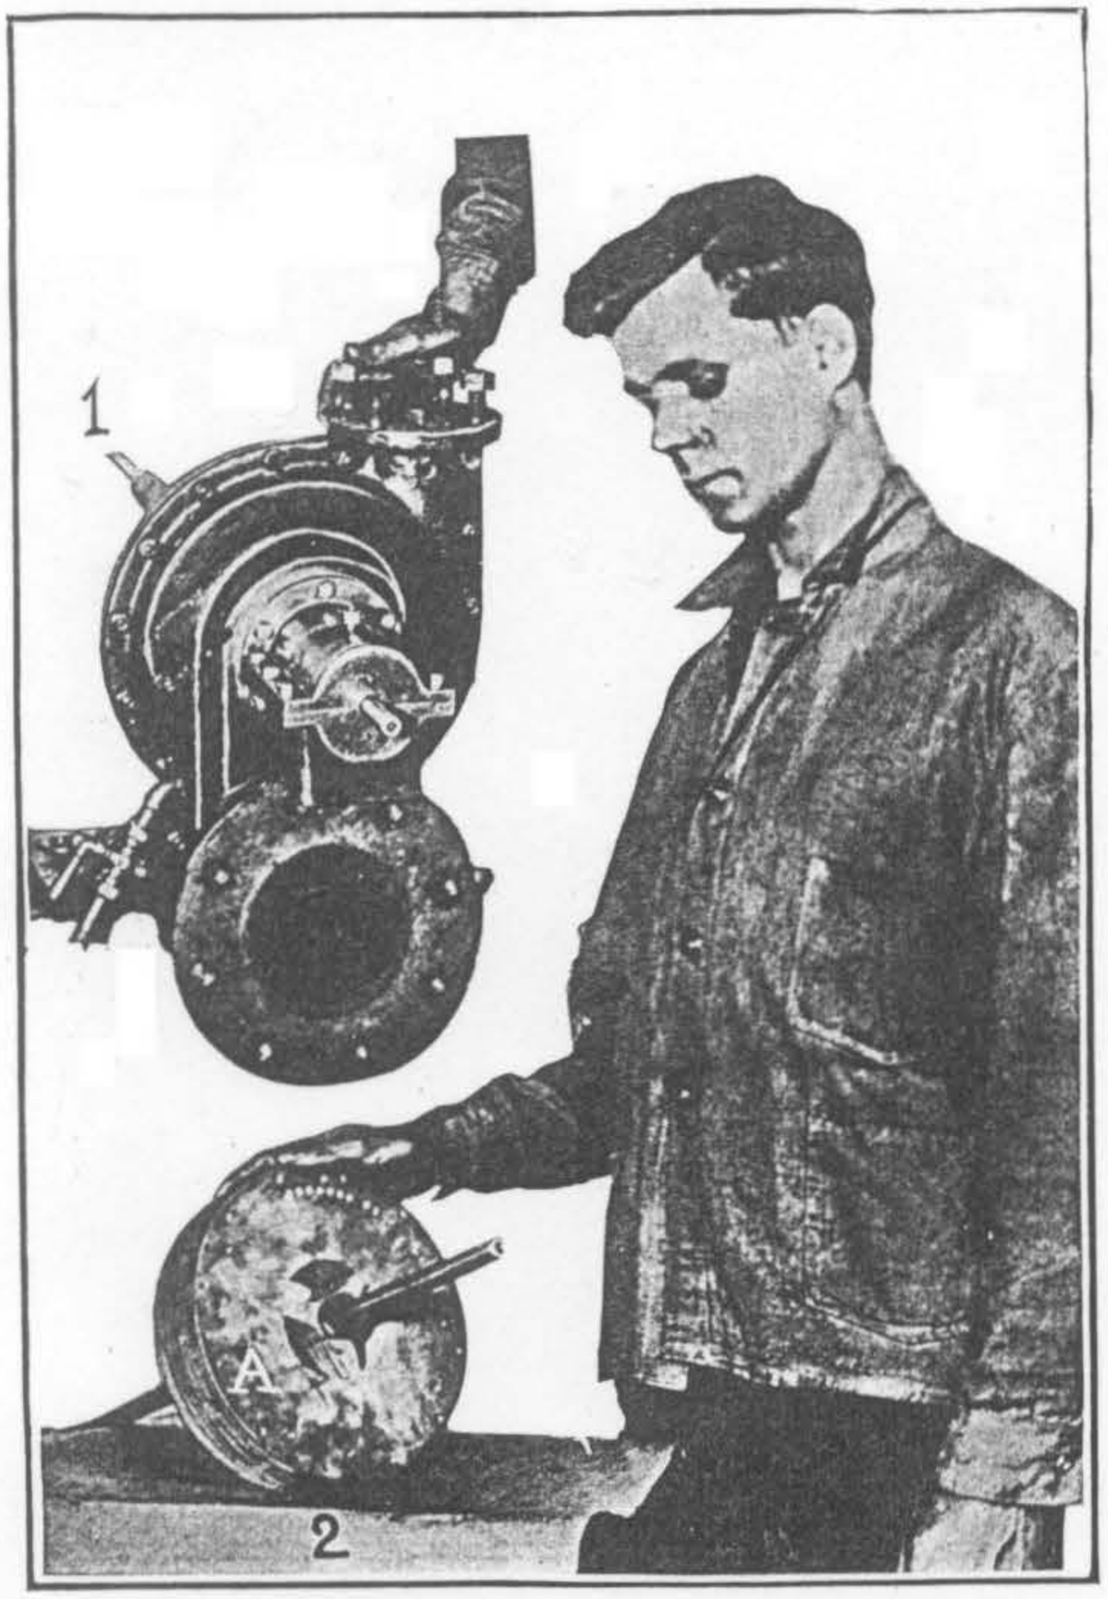

Fig. 1—110-horsepower steam-gasolene engine, weighing 20 pounds.
Fig. 2—Shaft and runner of engine

through what is marked outlet, Fig. 3, it will flow along the wall of the casing, passing the points 4, 3, 2 and 1 in the order named until, when it reaches the narrowing near the outlet, which now is the inlet, it is forced to enter the interdiscular space. In doing this the adhesion of the discs to the fluid causes the former to have motion imparted to them, so that they begin to rotate, while the fluid, which is continually giving off energy, loses in velocity. Since bodies having rotary speed imparted to them are subject to a centrifugal effect, and bodies expending energy in creating rotary motion, to a centripetal one, the fluid with decreasing speed approaches the center of rotation, and is discharged dead, without pressure, through the central openings of the discs. It is exhausted by gravity through the opening marked inlet, Fig. 3.

The engine so described, when driven by a mixture of steam and the products of a gaseous fuel burned in an auxiliary chamber showed 110 horsepower on the brake, and more load could have been sustained by it except for the small dimensioned shaft. While this instance shows that the same machine may be used as a prime mover and as a pump, it is obvious that a machine of this type specially constructed for the purpose of driving machinery may be improved upon by adapting some details to the specific needs of the situation. Thus Fig. 4 shows a Tesla rotary engine, applicable for steam or hot-air drive, having a nozzle through which the pressure of the driving steam is increased. A reversing nozzle is also provided.

As in the other engine the runner is composed of discs D, having central openings O and spokes S. The discs are held in posi-

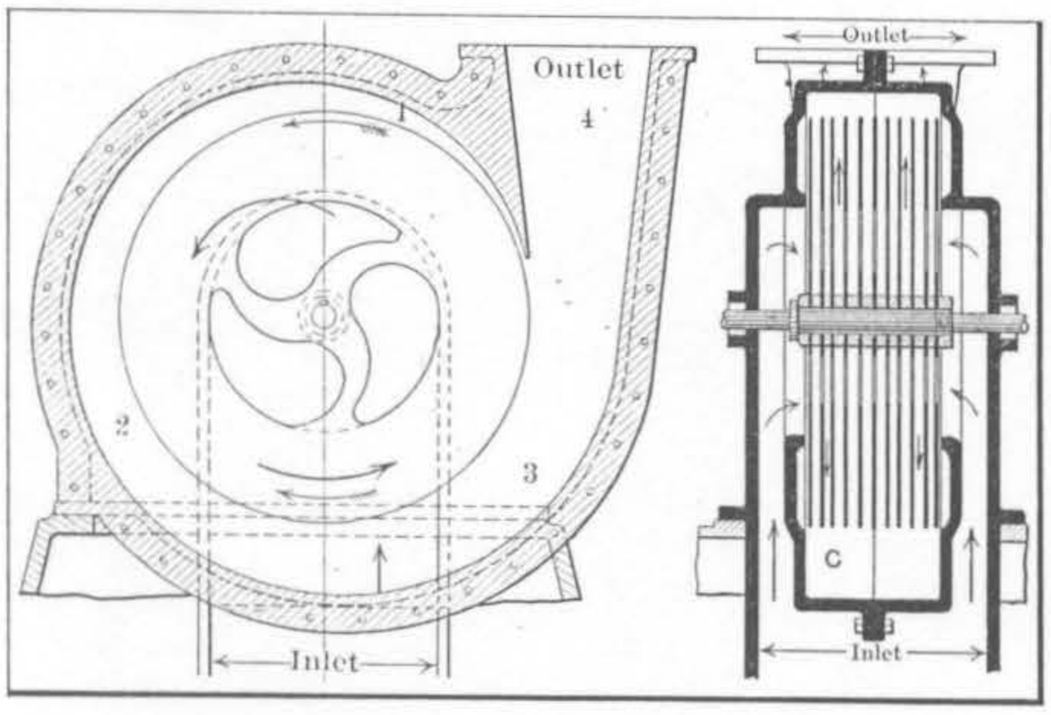

Fig. 3—Cross-section of Tesla rotary engine and pump

tion, being keyed to shaft S1 which is mounted on suitable bearings. Washers W, conforming in shape to the spokes and riveted thereto, separate the discs. For simplicity's sake, only a small number of discs is shown, with proportionally larger intervening spaces than are used in practice. The runner is mounted in a casing having two end castings S with outlets E, stuffing boxes B and a central ring R1 bored out to a circle of diameter slightly in increase of that of the discs. The ring has flanged extensions with inlets into which nozzles N are inserted. Circular grooves G and labyrinth packings P are provided on the sides of the runner.

A steam engine of this type has been installed and tested at the Waterside station of the New York Edison Company. The runner consists of twenty-five discs, diameter 18 inches, the engine base being 20 by 25 inches, and the height 5 feet. This engine developed, with steam admitted at 125 pounds pressure and exhausted at 14.7 pounds, 200 horsepower at 9,000 revolutions. About 38 pounds of saturated steam were needed per horsepower-hour, but Mr. Tesla stated that by the use of moderately superheated steam and the ordinary vacuum the consumption may be reduced to about one-third of the quantity stated.

If the motor runs without load, the fluid which enters at the periphery completes a number of circles before it has expended all its energy and it leaves through the central openings. As soon as the load is put on, the paths of the fluid are cut short, being

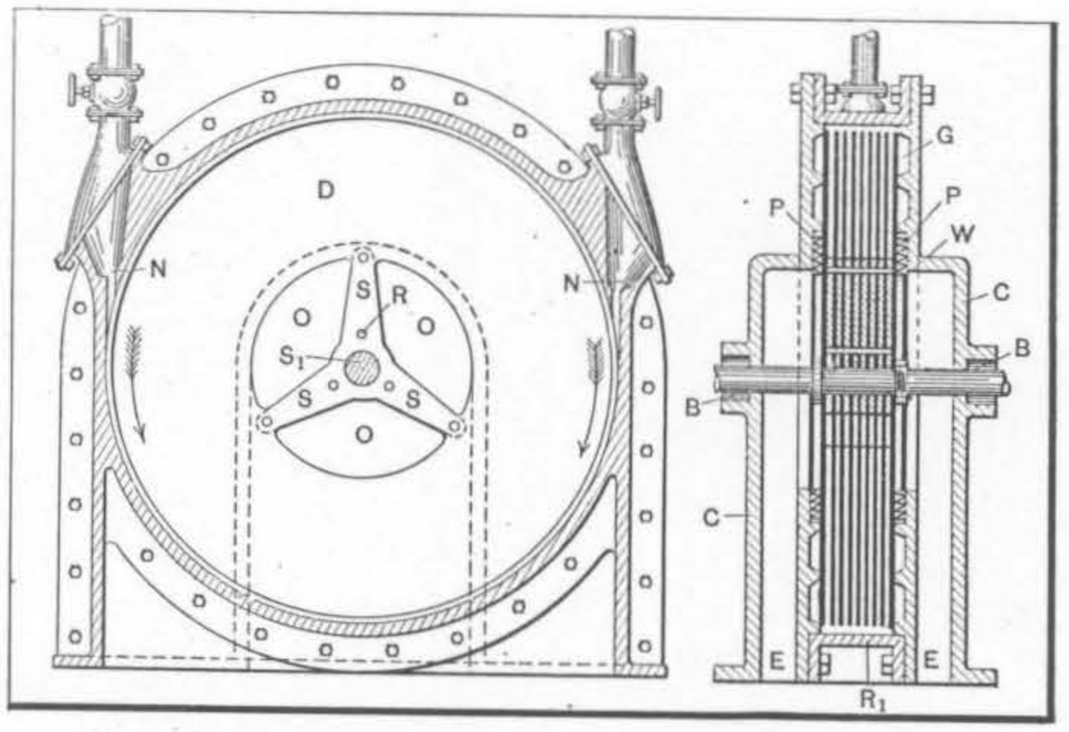

Fig. 4—Cross-section of Tesla engine for reversible steam drive

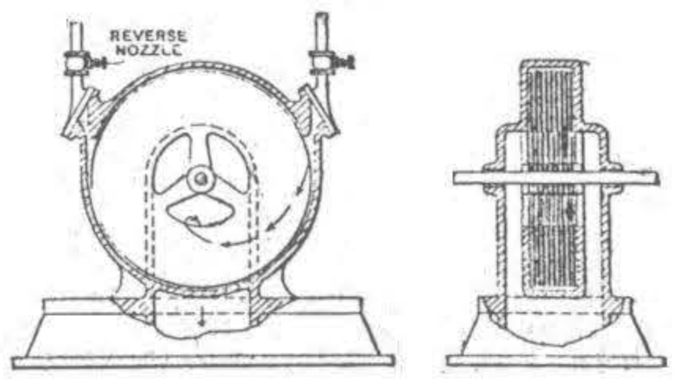
changed to a spiral with fewer turns. Despite the difficulty attending the work of determining the operating conditions in this machine, the following seems to be an established fact. The torque produced by the engine is directly proportional to the square of the velocity of the fluid relatively to the runner and to the effective area of the discs, and inversely to the distance between the individual discs. The maximum amount of work is done when the effective speed of the runner is one-half that of the entering fluid.



There is no unsurmountable difficulty in the construction of a light and practical motor of this type for the use of liquid hydrocarbon fuels. Of course, an auxiliary combustion chamber and carbureter have to be used in connection with the rotary engine described, and a very small pump to supply the air to the gasoline, if such be used. Mr. Tesla states that he has carried out numerous experiments along this line, and by the use of his motor transforms 60 per cent. of the energy of the gasoline into mechanical work available at the shaft. This may seem very high, but since with a rotary engine (compare steam engines and turbines) it is not necessary to encounter such vast cooling losses as in common gas engine practice, the high efficiency claimed by him might perhaps be obtained even in an average gasoline engine of his construction. It has been shown in THE AUTOMOBILE, July 27, 1911, pages 147-149, that the cooling losses in an automobile engine amount to 35.9 per cent., and the heat losses in the exhaust to 35.2 per cent. These heat losses together with other small expenditures of energies leave only 21.8 per cent. available at the motor shaft, that is, one-third of what is said to be recovered by an engine of the Tesla type.

The possibility of the enormous power output of Tesla engines in proportion to their weight may be understood when the great amount of active surface of these engines is considered. This fact also accounts to some extent for the large thermal efficiency. The 110-horsepower motor weighs 20 pounds, or 5.25 pounds per horsepower; the 200-horsepower engine at the Edison company's station weighs 400 pounds, or 2 pounds per horsepower, and by refinements of construction, the application of superheated steam and the use of vacuum exhaust Mr. Tesla expects to succeed in the building of an engine weighing 1-4 pound per horsepower.

A comparison between a Tesla pump and an ordinary pump may be of interest and not out of place here. In the laboratory of the inventor a small pump of the construction here illustrated is working. It is operated by a small electric motor, consuming 1-12 horsepower, and delivers 40 gallons per minute against a 9-foot head. The consumption of a good centrifugal pump rendering this work is about 1-3 horsepower, and in no case less than 1-4. This means one-third the power consumption for a given amount of work to be performed. As to the application of Mr. Tesla's principle to prime movers, it is stated by him that in large machines, by the use of superheated steam, high vacuum and the minimum of friction obtaining at these dimensions, about 95 per cent. of the fluid energy of the steam are delivered at the shaft.

THE TESLA STEAM TURBINE.

Experiments with a novel design of steam turbine have been made by Mr. Nikola Tesla, who is well known in the electrical field on account of the part he has played in the developments in connection with the rotating magnetic field and other alternating current subjects. A diagrammatical section of the Tesla steam turbine is shown in the accompanying illustration. The steam is expanded in a nozzle, and the heat energy is thus converted into kinetic energy. The rotor of the steam turbine simply consists of a number of thin, flat discs, the inlet for the steam being at the outer periphery of these discs, and the outlet being at their centre, as indicated. The high-velocity steam escaping from the nozzle is caused to impinge tangentially on the edges of the discs, and in order to escape it must find a path from the periphery of the discs to the central outlet. The velocity energy of the steam produces a rotary motion of the discs, due to molecular drag on the surface, and hence the path of the steam from the outside to the inside of the discs will be a spiral one. Expressing the matter in popular terms, we may say that the action is due simply to the friction of the steam against the sides of the discs as the steam moves

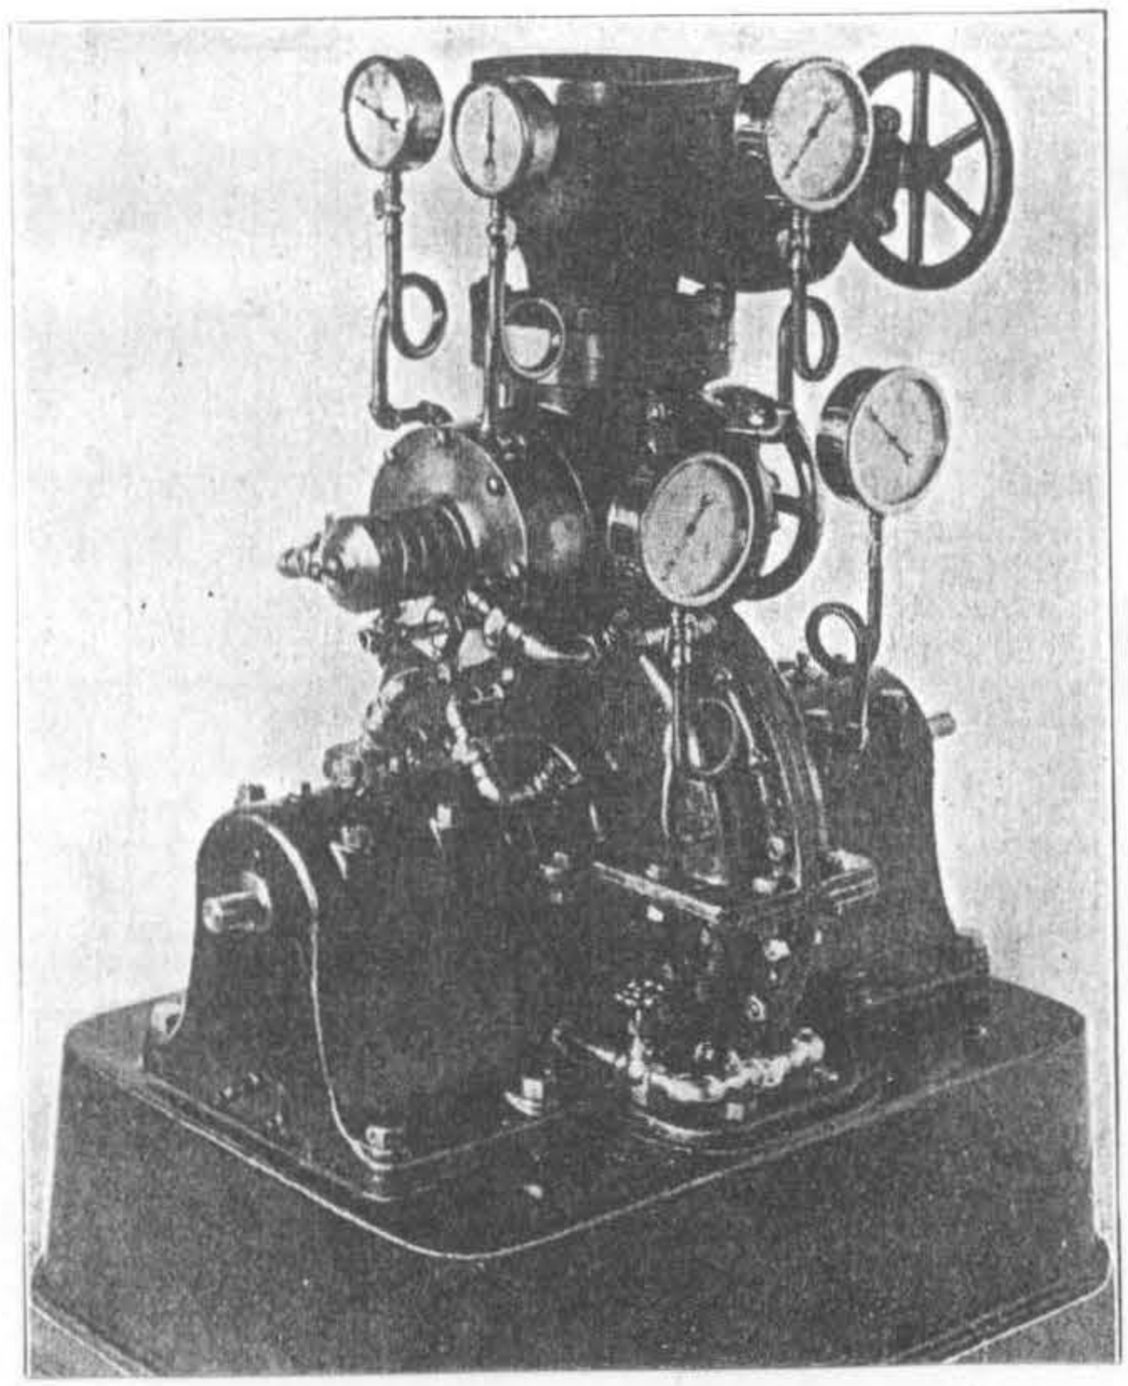
from the outside periphery to the centre along a spiral path.

The arrangement shown in the illustration permits of easy and convenient reversal, as it is only necessary to provide a duplicate nozzle discharging against the opposite side of the discs as indicated. When the machine is at rest, or is running slowly, as in starting, the steam takes the shortest path from nozzle to exhaust, and thus develops a comparatively large torque. As the machine speeds up, the difference in velocity between the steam and the discs decreases, and the centrifugal force tends to lengthen the spiral path of the steam, so that a given amount of steam may make several revolutions with the discs before finally passing out through the exhaust opening.

A turbine of this type has been tested at the Waterside Station of the New York Edison Co. The rotor of the tested turbine has 25 discs, each 18in. in diameter. The assembled turbine occupies a floor space of 20in. by 35in. and is about 5ft. high, completely installed. With steam at 125lb. gauge pressure per square inch exhausting into the atmosphere, 200H.P. was developed with a speed of 9,000 r.p.m. The steam consumption was 38lb. per horse-power-hour. The weight of the turbine is 400lb. giving a unit weight of only 2lb. per H.P. While the steam consumption at present is rather high. Mr. Tesla believes that with moderate superheat and a degree of vacuum the same as that ordinarily used in a turbine plant, the steam consumption can be reduced materially.

The principle employed is not limited to steam turbines. It can be applied as well to a type of centrifugal pump, having a series of smooth, flat discs revolving in a casing, these discs having no vanes or other impelling projections. The motion of the water is produced simply by the friction or molecular adhesion between the discs and the fluid. In this case, the fluid is, of course, taken in at the centre of the discs and forced along a spiral path to the outside periphery.—*Machinery.*

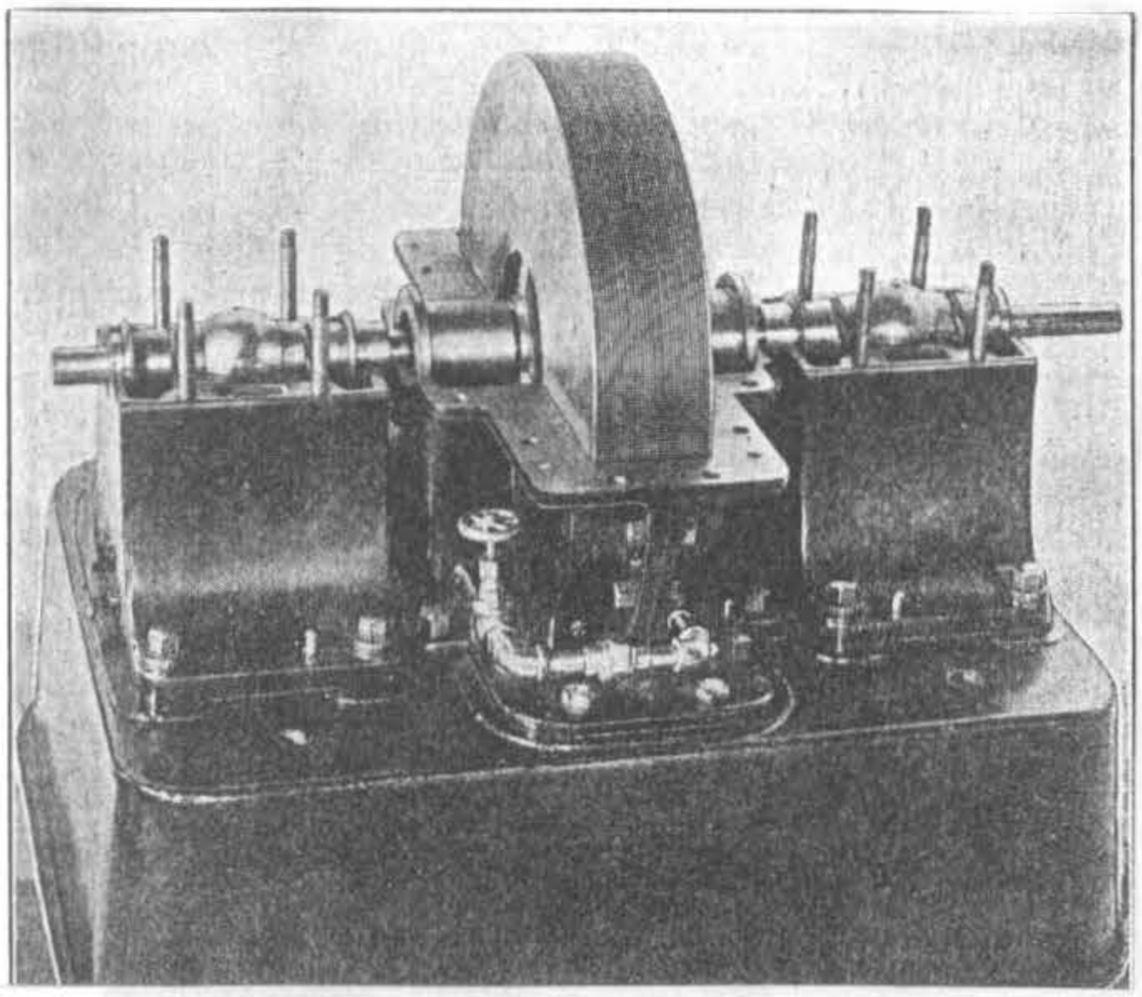
The Tesla Turbine



By E. F. STEARNS

A Complete 110-Hp. Turbine

ENGINEERS and men of science throughout the world are awaiting with unusual interest the completion of tests of a new steam turbine designed by Nikola Tesla, which preliminary experiments indicate will give enormous power from a comparatively small and extremely lightweight engine. Ten horsepower to a pound of weight has already been developed with the engines that have been tested and enthusiasts who have witnessed the work of the turbine declare the perfect rotor has at last been found. To what extent this is true, time and the construction of larger units than have yet been used must prove. At present, while the practical experimental stage has not yet been passed, the entire engineering world is profoundly interested in the work that has been done, and awaits future development with much concern.

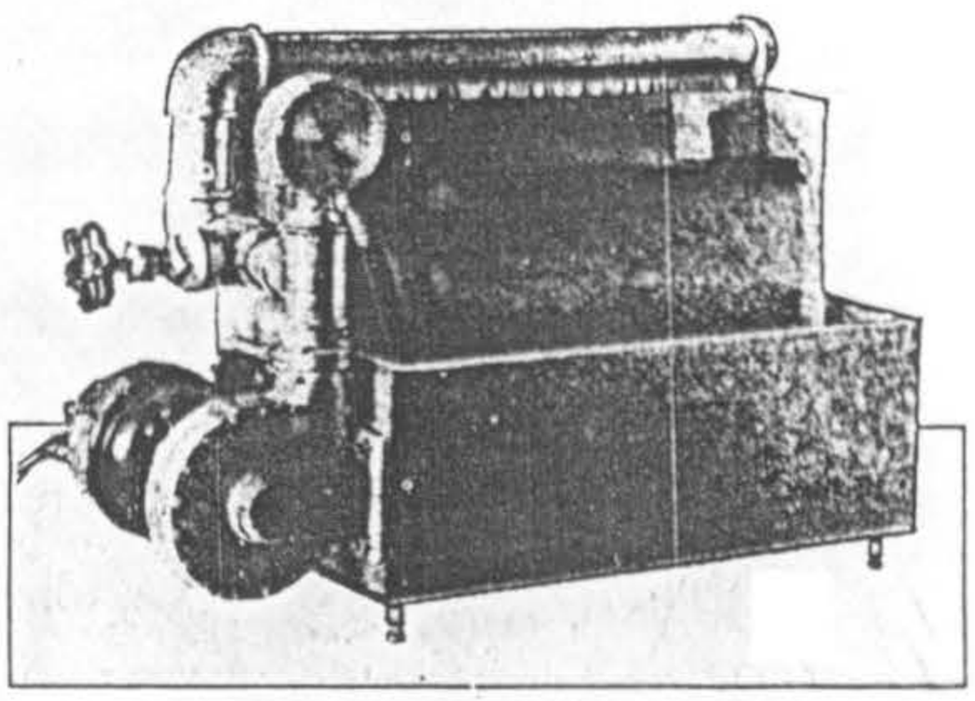


Operation of the Tesla engine depends upon two well-known properties of fluids: adhesion — the tendency, for example, of a certain amount of water to cling to a smooth metal surface, even when the bulk of the water has been shaken off; and viscosity, the resistance of fluids to molecular separation, the tendency of one drop, in a mass of fluid, to drag adjoining drops with it, if set in motion.

The Turbine, Invented by Nikola Tesla, Which is Based on a New Principle

In its simplest form, the new idea takes the shape of the inventor's little "air-diffuser." This consists of half a dozen very thin steel disks, some 9 or 10 in. in diameter, set horizontally, about ⅛ in. apart, on the upright shaft of a small, horizontal electric motor, the center of each disk being cut away in a 3-in. circle. With current switched into the motor, the disks revolve, and instantly strong suction can be felt by the hand held several inches above the axis, while a powerful current of air is blown from the spaces between the disks. The air, in short, is being sucked into the central opening and hurled out at the periphery. Consider now that disks and shaft have been inclosed in an air-tight case, with an inlet at the axis and an outlet at one point of the periphery; we have an air pump, a Tesla blower, one of which, now in operation, is delivering 10,000 cu. ft. of air per minute. Suppose again that water, instead of air, be the fluid admitted. Entering the cut-away space at the centers of the disks, the adhesion of the metal drags it, in a widening spiral, toward the spinning circumferences, there to hurl it away in a tangential direction; and since the water must now leave the case by its one outlet, we have the Tesla pump, on rather new lines.

Assume that the pumping process



The 200-Hp. Tesla Turbine, with the Upper Section of the Case Removed to Show the Disks, etc.

is to be reversed, that the disks, instead of being turned by an outside force, are to produce power themselves, that steam under pressure has been substituted for the water. The steam, admitted to the case, strikes the edges of the disks and takes the path of least resistance between them, a narrowing spiral toward the outlet through their centers. The disks themselves are dragged around, the shaft is turned and power is being generated in an entirely new fashion.

Working under the best conditions —in the experimental laboratory— a single disk of 9¾ in. diameter, with a center outlet of 3⅝ in., will develop 5 hp. Without nearly approaching the limit of strain of the materials, the pressure could be increased so that the velocity of rotation would be doubled and the power quadrupled; so that with a single steel plate, 1/32 in. in thickness, weighing about ⅜ lb., and delivering 20 hp., we have a possible 53 hp. to 1 lb. of actually working material. Or a more concrete example can be found in a double Tesla turbine, built for practical service and nearly completed. In this there are two sets of disks, arranged to revolve in opposite directions and each set developing 200 hp.

Comparison between the old and the newest is best given in the inventor's own words:

"In most engines, a very small proportion of the total amount of material is actively employed in the production of power. For example, in reciprocating engines of the older type, the power-giving portion—cylinder, piston, etc.—was no more than a fraction of 1 per cent of the total weight of material used in construction. The present form of turbine, with an efficiency of about 62 per cent was a great advance, but even in this form of machine scarcely more than 1 per cent or 2 per cent is used in actually generating power at a given moment. The new turbine offers a striking contrast, using as it does practically the entire material of the rotor (the whole surfaces of the disks) as an active source of power, and with an efficiency of 80 per cent or even 90 per cent. Owing to this, it is possible to get an enormous amount of power from a small space. Assuming sufficient boiler capacity on a vessel such as the "Mauretania," it would be perfectly easy to develop, instead of some 70,000 hp., 4,000,000 hp. in the same space—and this is a conservative statement."

A little model pump in which five disks, 3 in. in diameter, contained in the lower front, circular case, throw 40 gal. a minute when the little electric motor is started up. The water flows out of a slit at the bottom of the upper pipe and flows back to the lower tank as seen in the foreground. This model illustrates one point astonishingly: the power can be shut off when the pump is in full operation and everything stops instantly without the slightest jar. With the power switched on suddenly, the full flow is resumed so quickly that the interval between the click of the switch and the full stream of water is too small to be determined with an ordinary watch.

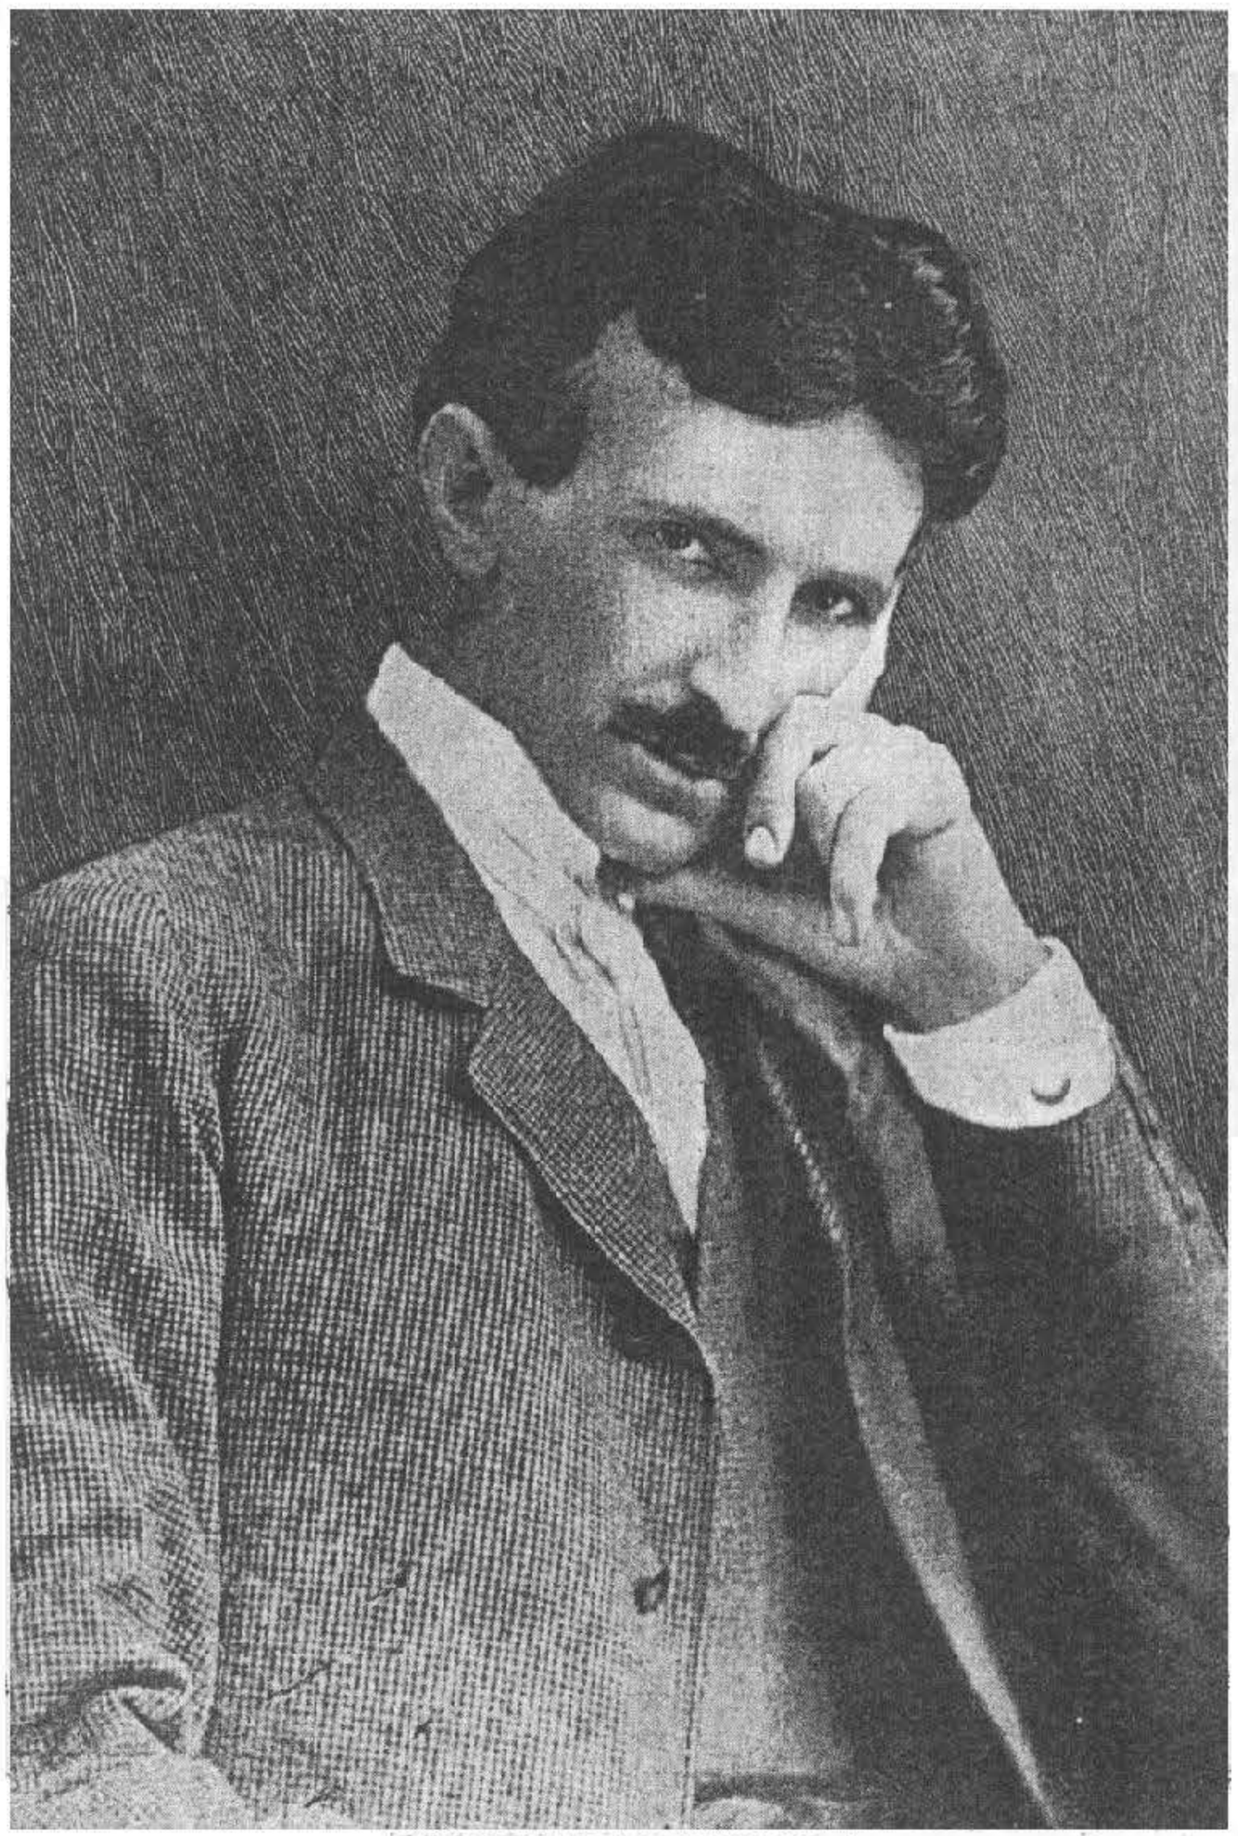
ARE FATHERS OF INDUSTRY

Men Whose Discoveries Have Created New Fields of Business.

MANY GREAT NAMES

Edison, Westinghouse, Tesla, Fritz, Acheson and Others.

(Copyright, 1911, by E. J. Edwards.)



There is a considerable company of men living today to whom the title of father of industry may be accorded—men who by their inventions and discoveries and their practical application of these have created new fields of business.

Thomas A. Edison, the father of the electric-lighting industry and the phonograph business, to mention only two of his industrial creations, is undoubtedly the most illustrious of them.

Alexander Graham Bell, the inventor of the telephone, is one of the most distinguished, although with regard to the telephone business it may be said that Theodore N. Vail, a business-man rather than a man of science, is the father of it as a great unified system.

To William Marconi belongs the honor of being the father of wireless telegraphy, only a few years ago a scientific curiosity, now a regular business.

Nicola Tesla may be regarded as the father of the commercial utilization of the alternating electric current, since he invented the apparatus by which that utilization is made safe and practicable. At the same time, from another point of view, George Westinghouse, under whose patronage Tesla achieved and perfected his great inventions, may be regarded as the father of that great branch of electric industry, since he was the inspirer of its development.

NIKOLA TESLA.
Father of the alternating current.

Popular Electricity January 1912

High Frequency Apparatus to Go with a Wireless Set

By JAMES H. DORAN

Many amateurs have undoubtedly wished to use their wireless transmitting instruments for the generation of high frequency currents. The only additional

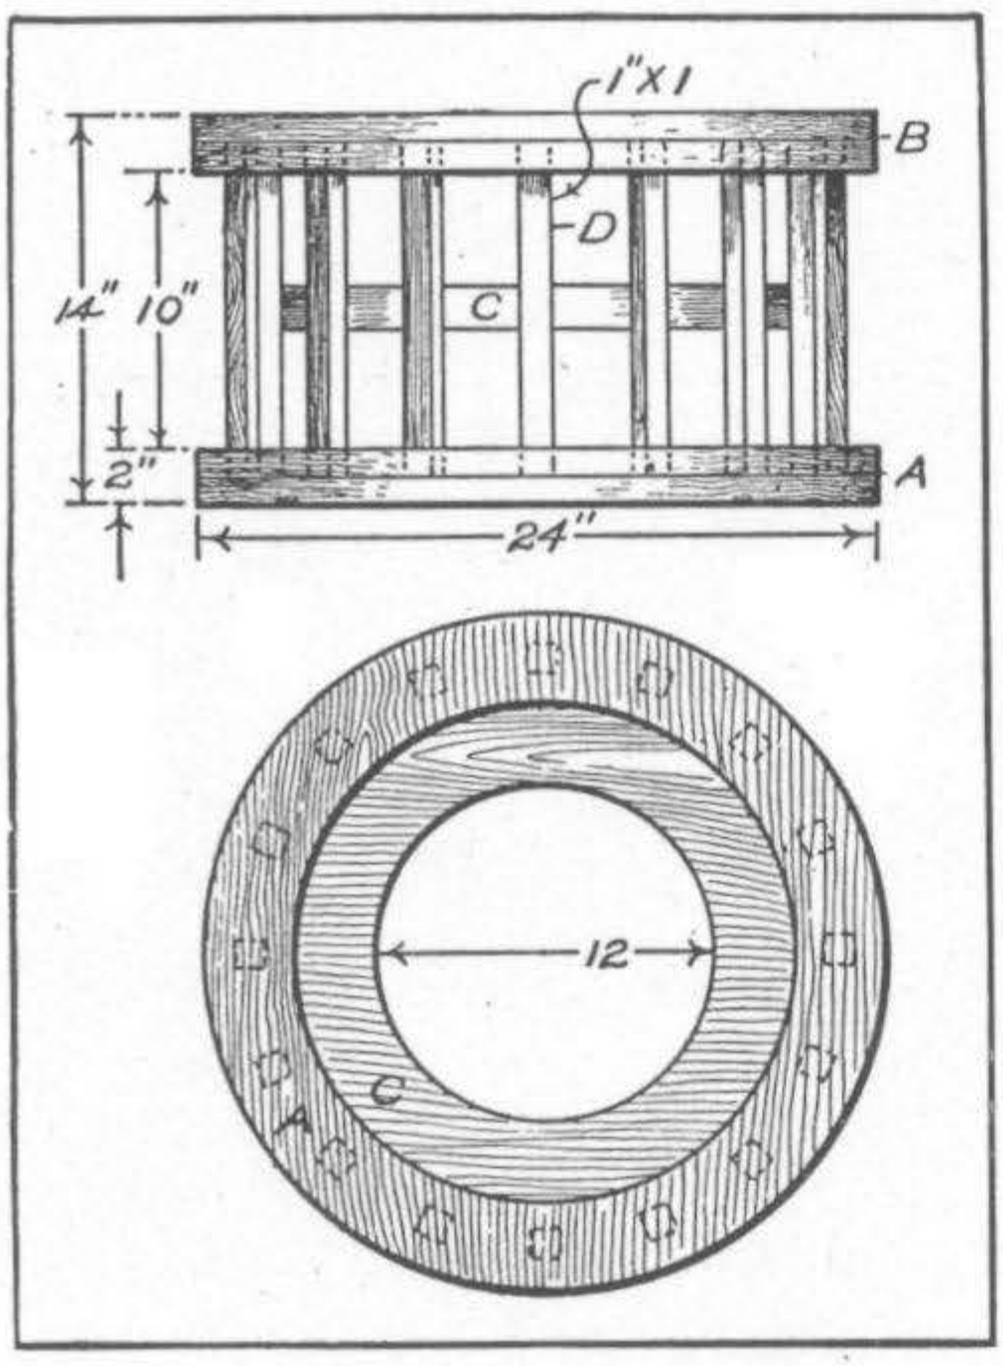


FIG. 1. PRIMARY FRAME

apparatus required is either a Tesla coil or resonator. These can be made with but little trouble and expense, and the experiments that can be performed with them are among the most instructive as well as the most spectacular in electricity.

The coils and resonators described are for use with ¾ to 1½ K. W. transformers, condensers and spark gaps.

In the construction of coils and resonators of this type the primary is placed over the secondary and is about twice the diameter of the secondary. Only one layer of wire is used on the primary, the number of turns being from five to fifteen according to size of coil and number of wire.

For the primary frame cut out of one-inch hardwood material four circular rings two feet in diameter and two inches wide. Glue these together so as to form the end pieces (A) and (B), Fig. 1. Make sixteen pieces 1 by 1 inch, in cross section and twelve inches long. These are shown by (D), Fig. 1. Fit these into recesses extending through the two inside layers of (A) and (B) and glue. This forms a cage or drum on which to wind the primary wire. Into the center of the cage fix by means of pegs a circular block (C), two inches thick and with a circular opening in the center twelve inches in diameter. This block is to hold the secondary in place inside the primary. Give the cage two coatings of oil shellac and a coating of some good stain or varnish. When dry wind on the cage twelve turns of No. 4 hard drawn bare copper wire, spacing the turns evenly apart.

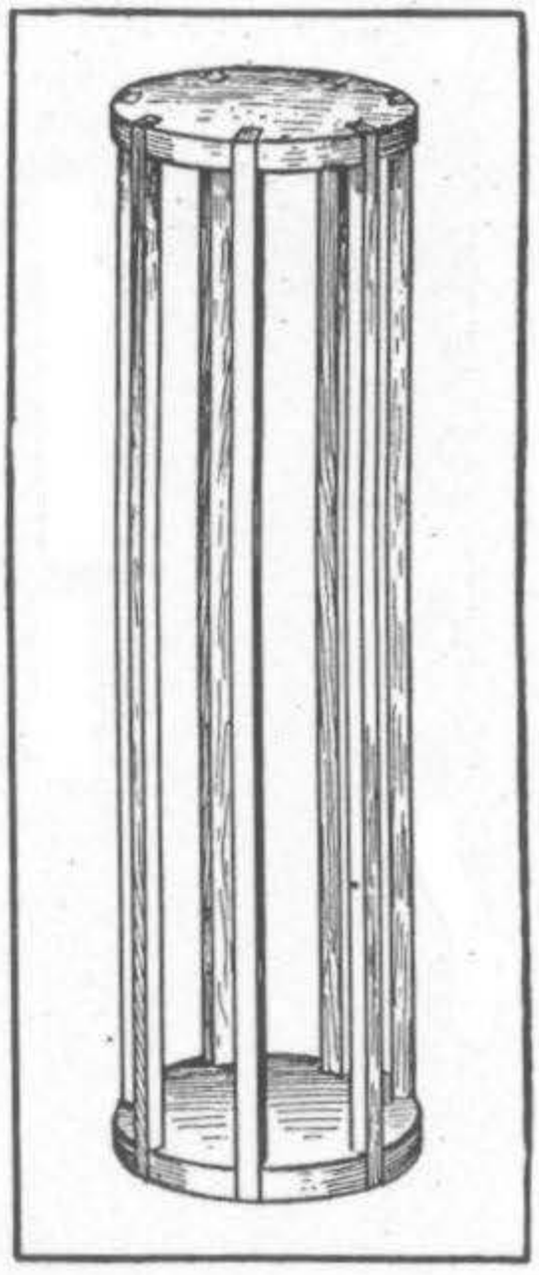

FIG. 2. SECONDARY CAGE

For the secondary make another cage 11½ inches in diameter and 50 inches long. The end pieces can be made solid and of 1⅛-inch material. The cross pieces or ribs should be 1 by 1 inches and are glued and fitted into the end pieces with the edges flush. About

ten should be used. Fig. 2 shows the complete secondary cage. Give the cage two or three coats of shellac and when dry wind on several layers of leatheroid or heavily paraffined paper so as to form a stiff drum on which to wind the secondary wire.

In the center of the end pieces bore ¾-inch holes and suspend the drum by an iron rod run through these. Wind on

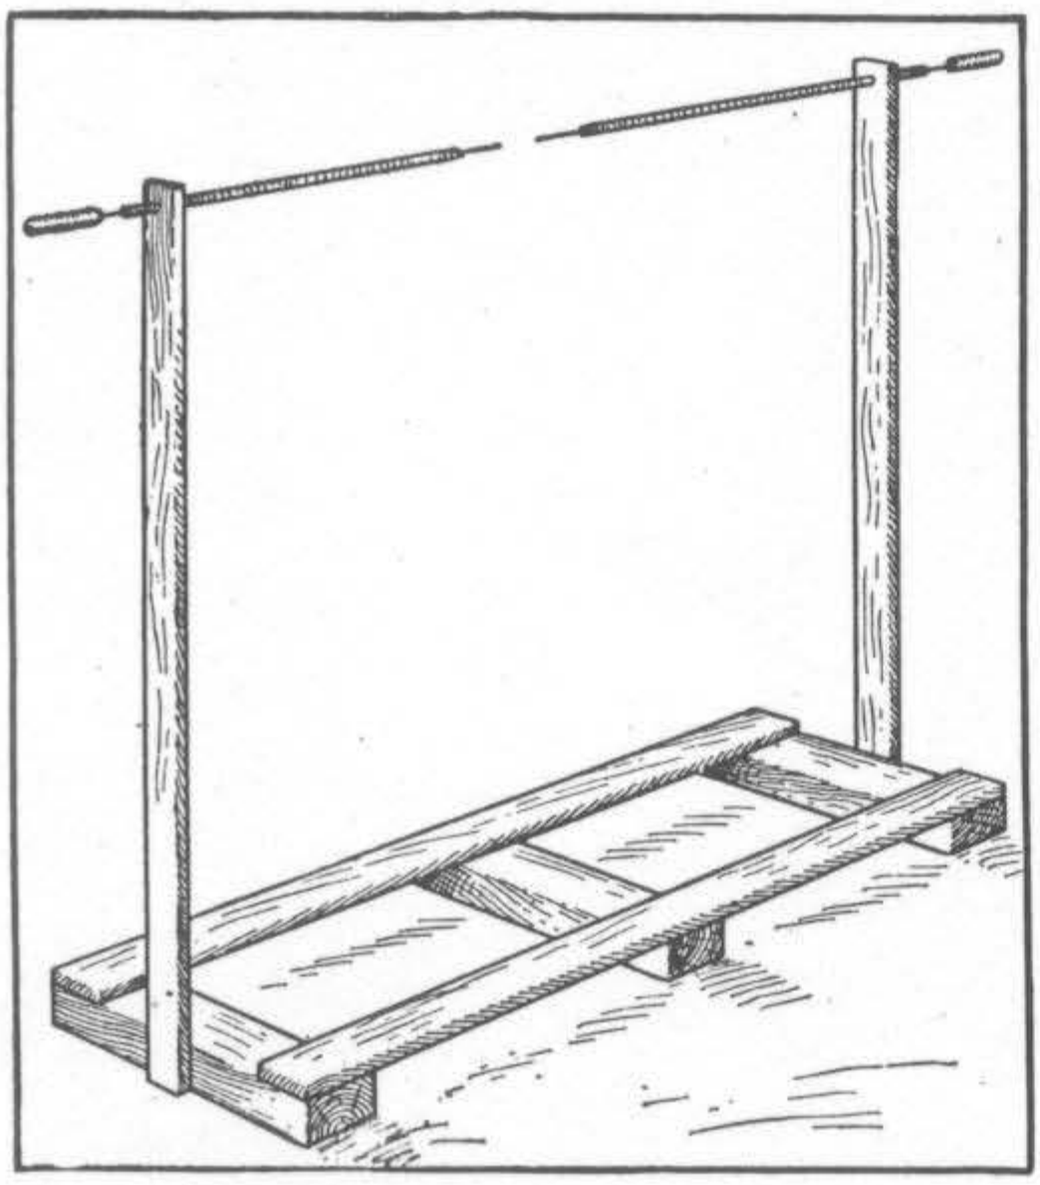

FIG. 3. BASE FOR COIL AND SUPPORTS FOR SPARK GAP

the drum 800 or 900 turns of No. 24 D. C. C. magnet wire, about five pounds will be required. Space the turns by winding in at the same time a layer of ordinary twine. When wound give the whole several coatings of shellac or micalac.

For the Tesla coil the primary should be fitted over the secondary and concentric with it. No nails or screws should be used in the construction of either the primary or secondary. The base can be made of three pieces of two by four 30 inches long and held in place by two pieces 3 by 1 inch, 50 inches long, nailed to these (see Fig. 3). To this base two uprights 3 by 1 inch, 61 inches long, are screwed and in the center of these the secondary (supporting the primary) is fastened by screws. The spark-gap is placed above the coil and is made of brass rods ¼ inch in diameter and 2½ feet long and supported by brass tubes two inches long fitted into the uprights and allowing the rods to slide freely. The ends should be filed to a sharp point, and hard rubber rods ¾ by 6 inches long should be used for handles.

The resonator is of the Oudin type. Its construction is the same as the Tesla coil except that the circular block (C) in the primary may be omitted. The secondary is placed in a vertical position and the primary at the bottom and concentric with the secondary. Instead of a spark gap of a ⅜-inch brass rod screwed into a 3-inch brass ball is used as the terminal, one end of the secondary being connected to the rod. Resonators of this kind are known as the unipolar type, the ground being used as the other terminal when two are necessary.

Fig. 4 shows the method of connecting the Tesla coil, the connections for the resonator being the same except that the bottom turn of the secondary is connected to the bottom turn of the primary and this grounded. Fig. 5 shows the resonator nearly completed.

The transformer used should give a secondary voltage of from 10,000 to 20,000, and the condenser of the best size

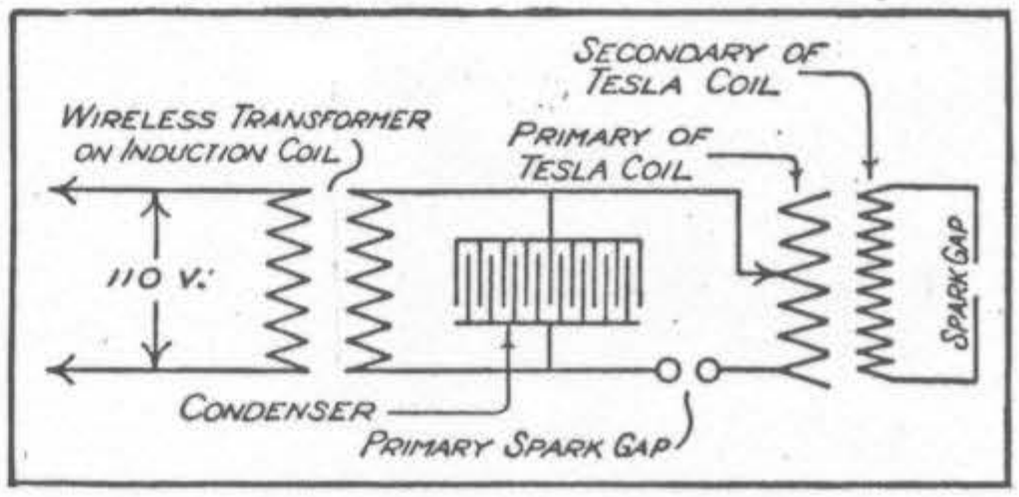

FIG. 4. METHOD OF CONNECTING TESLA COIL

suited for the transformer. The surface of the spark gap should be rather small, ½ or ¾ inch in diameter and some means should be used to keep it cool. It is preferably made of zinc disks.

The coil or resonator should be in tune with the other apparatus and this may be accomplished by varying the number of

plates or sections in the condenser and the number of turns of wire in the primary of the coil or resonator. It is best in tune when the longest sparks can be obtained from the secondary. The primary spark gap should also be carefully regulated to give the best results.

When working properly with a one to 1½ K. W. transformer, etc., the sparks should be 30 to 36 inches long for the Tesla coil and somewhat shorter for the resonator.

The frequency varies considerably according to the capacity of the condenser and the number of turns of wire used in the primary. Using a condenser of .12 M. F. capacity it varies from 225,000 to

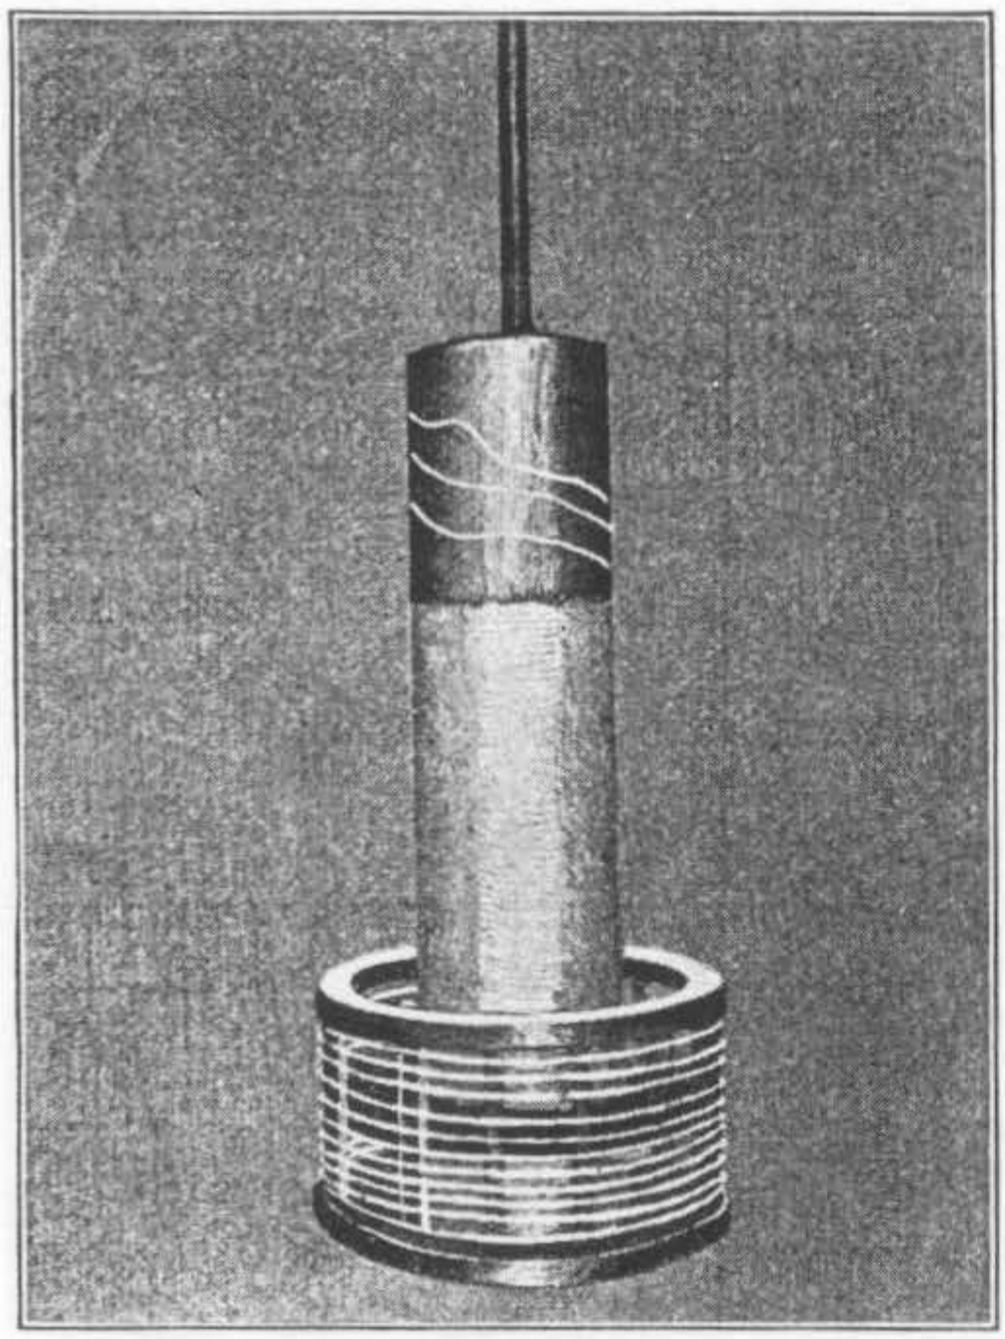

FIG. 5. RESONATOR NEARLY COMPLETED

over 1,000,000, the smaller number of turns used in the primary the greater the frequency. The voltage is difficult to calculate but runs up to about three-quarters of a million when working full force.

The above coil or resonator can be used with large induction coils (12 to 24 inch sparks) and even small ones sometimes give good results. The author has obtained sparks over 10 inches long by using a 2½ inch coil and a good electrolytic interrupter, and using about six to eight amperes on 110 volts in the primary circuit.

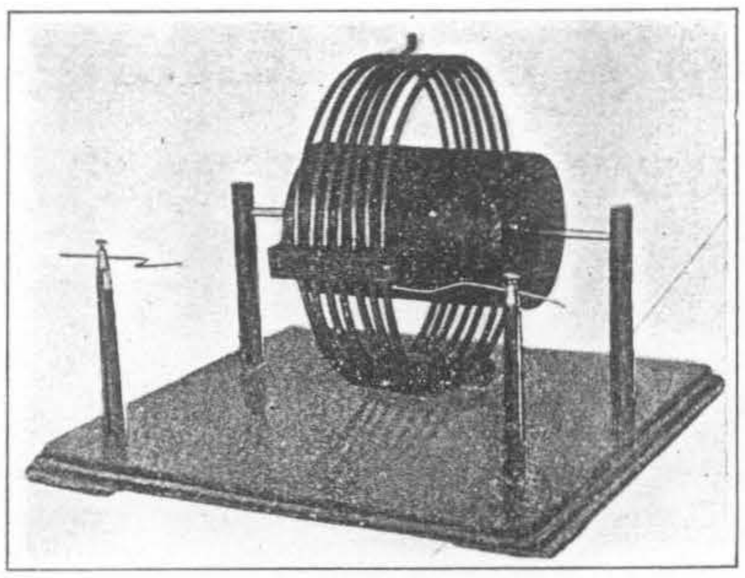
Smaller coils and resonators may be made for induction coils and ¼ to ½ K. W. transformers by making the secondary about four times as long as its diameter, and the primary twice the diameter of the secondary. The wire should be about No. 8 for the primary and No. 24 to 28 for the secondary. In resonators for small transformers and coils the length of the secondary should be about three to three and one-half times its diameter and the primary twice the size of the secondary. The wire in the primary should be about No. 8 and that in the secondary No. 28 to 32. However, the size of the wire makes little difference in either Tesla coil or resonator if not too small in the primary and if the instruments are tuned to resonance.

All the ordinary experiments can be performed with these coils and resonators and with the larger ones a great many uses will suggest themselves, and at present many of them are being used for research work in place of large induction coils.

An Easily Constructed Tesla Coil

Instructions for the Amateur Electrician

By Allan S. Dana



THE special advantage of the Tesla coil, here described, is that it is comparatively small and light. Therefore it can be readily carried from place to place. Most Tesla coils are immersed in oil but this is objectionable as the oil leaks or slops over, and also greatly increases the weight of the instrument. Although the oil-immersed coil is more efficient, a Tesla coil in air is more convenient and only slightly less efficient. The air Tesla coil to be described has the same advantage that a coil in oil has—that of having a fluid insulator between the primary and secondary coils, so that, if a spark passes accidentally between them, the air or oil immediately fills up the gap made by the spark. A solid insulator cannot be used because one spark between the primary and secondary would make a hole in the insulating material and the spark would easily travel through this hole thereafter. Hence a coil should be in either oil or air. But if it is to be portable, air must be the insulator.

Using this coil with a 4-inch induction coil, it gives a 5½-inch spark. This is the longest spark possible with this instrument, because the spark has to travel only a little over 5½ inches to jump from the primary to the secondary coil. Hence, if the rods where the spark discharge is supposed to take place are separated by more than 5½ inches, the spark will not jump there, but will take the shorter path to the primary coil.

The base of this coil is a piece of 1-inch whitewood, 16 inches by 15 inches, with its edges molded. Two and one-quarter inches from the front and 12⅝ inches apart bore two holes which will allow an 8/32 machine screw to pass through. Again, bore two holes of the same size 10 inches from the front and 12¾ inches from each other. Also two holes of the same size 10 inches from the front and 3¼ inches apart. Screw four rubber tips, such as used on furniture to avoid scarring polished floors, to the under side of the base board at the corners. These will keep it from scratching polished tables. The base may now be painted. A black varnish gives a good finish.

Next, wind six turns of No. 2 copper wire around a circular form so as to make a coil 10 inches in diameter. At each side of the coil, place two pieces of ½-inch oak, 1 by 4 inches, which are supplied with machine screws and nuts, and clamp the wires 3/16 of an inch apart by means of these. The machine screw heads should be toward the inside of the coil and must be countersunk until flush. At the bottom of the coil another strip of oak is used to clamp the whole coil to the base by means of machine screws passing through the oak strip and the holes already bored in the base board. This oak strip should be of ½-inch oak, 1 by 4 inches, with two holes for 8/32 screws, 3¼ inches apart. Flatten the ends of this primary coil and bore in each a hole which will allow the binding post from the carbon of an old dry battery to be put on and used as a terminal of the coil.

The secondary coil is wound on a cardboard tube 4¾ inches in diameter and 7¼ inches long. Cut two disks of 3/8-inch wood to fit tightly the ends of the tube and bore a ¼-inch hole in the center of each disk. Mount the tube so that it can be revolved and wind, side by side, a No. 36 single cotton-covered copper wire and a thread of 100 cotton, which has been soaked in paraffine and allowed to cool. In this manner the entire surface of the tube is covered with a coil of wire, whose adjacent turns are separated by the thickness of the paraffined thread. To the ends of this coil 10-inch lengths of No. 28 or No. 30 copper wire are soldered, and melted beeswax poured over the joint to hold it fast to the cardboard tube. Shellac the entire coil of wire, applying two coats of thin shellac. When this has dried, unwind the paraffined thread and give one

General View of the Tesla Coil.

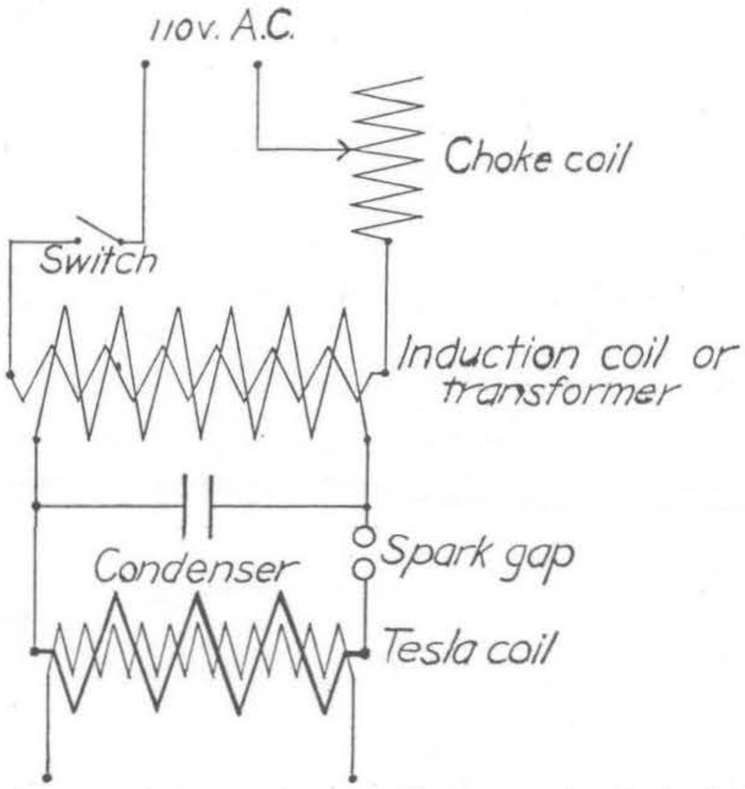


Diagram of Connections for Fitting up the Tesla Coil.

or two more coats of shellac to hold the wire onto the cardboard tube. Be sure that no two turns of the coil touch. Every turn must be separated from the next one by the width of the paraffined thread. When this is dry, pass a ¼-inch glass rod, 12¾ inches long, through the holes in the wooden disks in the end of the cardboard tube.

From a ¾-inch hard rubber rod cut two pieces 6 inches long. In one end of each bore and tap a hole for an 8/32 screw. One inch from the other end bore a ¼-inch hole half way through the rod. These last holes are to hold the ends of the glass rod, which passes through the center of the secondary coil and is used to support it. By 8/32 machine screws passing up from the under side of the base board through the holes already bored 12¾ inches apart and 10 inches from the front, these hard rubber rods are held to the base and, in turn, support the glass rod which carries the secondary coil.

Cut two 5-inch pieces of ½-inch hard rubber rod, and bore and tap each end for an 8/32 screw. At one end of each rod a binding post is screwed on, while a screw passing up from the under side of the base holds each rod perpendicular to it.

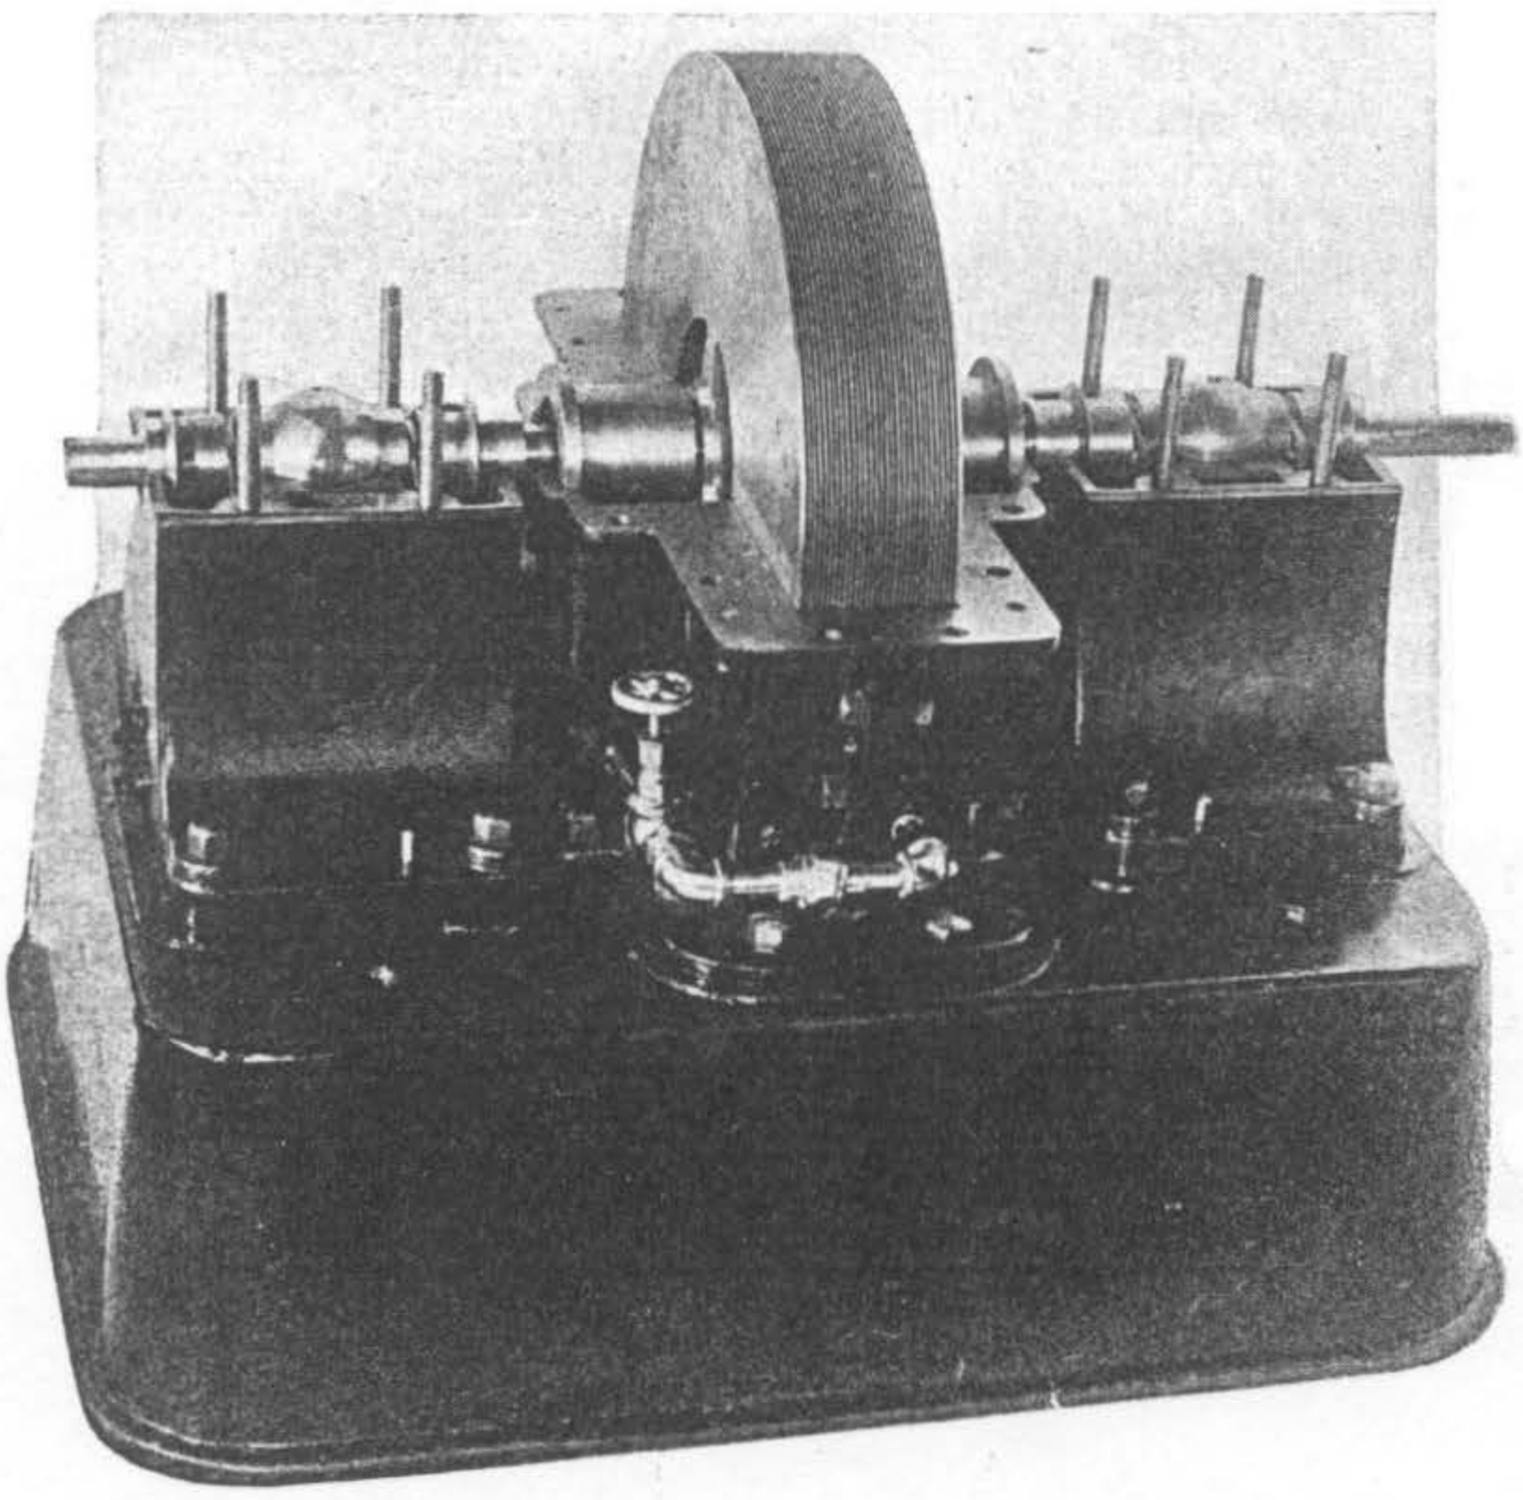
Then the ends of the secondary coil are connected to the binding posts on the top of the hard rubber rods.

The coil is now complete. If used with an induction coil on alternating current, it is best to screw the vibrator up tight, so that it will not work, and use a choke-coil in the primary circuit in order to cut down the current. Still better, a high voltage, closed core transformer, such as used to send in wireless telegraphy, may be used. The terminals of a medium-sized glass plate condenser are connected to the secondary terminals of the transformer or induction coil. Then one terminal of the transformer or induction coil is connected to one end of the coil of large wire on the Tesla coil. The other end of this coil of large wire, or primary coil, is connected to a spark gap, and the other end of the spark gap to the other end of the transformer or induction coil. When the current is turned on and the spark gap and condenser regulated, a harmless 5½-inch spark will jump between wires placed in the binding posts to which the ends of the secondary of the Tesla coil are connected.

A great many experiments may be made with this coil. Geissler tubes can be lighted by holding one end of the tube in the hand and presenting the other end to one terminal of the Tesla coil. When this is done, the electricity which lights the tube passes through the person and still does not cause any sensation. But in these days of wireless telegraphs and telephones, the most interesting experiment from the layman's standpoint is a wireless light. To make this, bend 4 feet of No. 14 B. and S. insulated copper wire to form a circle and connect a 2-volt battery lamp to the ends of this coil. If this coil is then moved near to the Tesla coil while it is in operation, the lamp will light, provided, however, that the primary coil of the Tesla and the coil of the wireless light are in the same or parallel planes.

Many other experiments can be carried out by means of this simple Tesla coil.

Technical World Magazine February 1912



POWERFUL TURBINE A MERE TOY

By

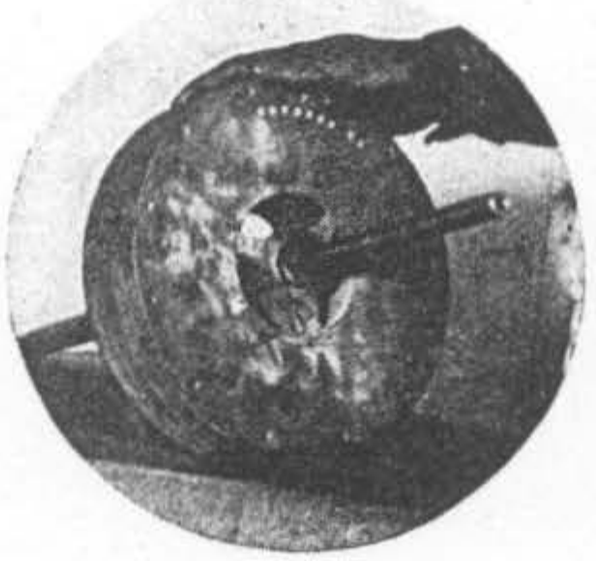
HENRY JEVONS

ALMOST any evening last fall a tall, spare man, whose discouraged looking mustache remains a glossy black without any aid from the barber in spite of the fact that its wearer is well past his fiftieth year, might have been seen wending his dignified way down East Thirty-eighth Street toward First Avenue, New York City. He was a man who would attract attention anywhere, but especially on East Thirty-eighth Street, which is not a thoroughfare one would choose for an evening stroll, unless one chanced to be hard up for strolls. If the tall man had been shadowed he would have been seen invariably to disappear within a massive brick building which covers the entire block between Thirty-eighth and Thirty-ninth streets, First Avenue and that part of Long Island Sound miscalled "East River".

Had the phenomenon been further investigated, this building would have been found to be a place of extraordinary

THE EXPERTS LAUGHED—AT FIRST—WHEN TOLD THIS TURBINE RAN 16,000 REVOLUTIONS TO THE MINUTE.

Tesla turbine of two hundred horse power. The upper part of casing is removed to show the rotor, which is 18 inches in diameter and measures 3½ inches across the face.



interest, for various reasons. Together with its twin covering, the next block north, it constitutes the Waterside Station of the New York Edison Company, the largest steam power plant in the world. Of still greater interest than its size is the fact that ever since it was built there could be found within its thick walls the living history of the evolution of the steam engine epitomized and in action. Unlike all other histories of the steam engine, the opening chapter did not begin with the exploits of Hero, of Alexandria, 120 years before Christ, but started in several pages ahead of October, 1901, on which date the plant sent out its first electrical impulse.

NIKOLA TESLA, THE HUNGARIAN SCIENTIST OF TREMENDOUS IMAGINATION, WHO HAS BUILT SOMETHING "PRACTICAL" FOR THE ENGINEERS.

When the New York Edison Company decided to build Waterside Station it took the bridles off the engineers and allowed them to go as far as they liked in designing a plant that would be the last word in steam engineering, for the plant was intended to be big enough to meet all demands for years to come. Power was furnished by vertical, three cylinder compound engines of 5,000 horse power, which were considered something marvelous both in size and economy, eleven years ago. But before steam had been turned on for the first time the Curtis turbine had thrown down the gauntlet to reciprocating engines of whatever size or kind, offering to give them cards and spades and beat them out in the matter of economy. So a turbine of 2,000 horse power was installed almost at the beginning to show what it could do. It did so well that a turbine of 10,000 horse power soon took its place beside the pioneer. All the various examples of different periods in the evolution of the steam engine worked together in harmony, sending their currents out over the same wires in one united stream to light the Great White Way and more useful, if less popular, places.

Before the plant could be started up the company realized that forty thousand horse power, instead of being enough to meet all demands for years, wasn't even enough to begin business with; so the architect was routed out of bed and told to get busy on an extension. Since then neither architect nor engineer have had time to go out to lunch, for the plant has been steadily increasing in capacity until now it aggregates approximately three hundred thousand horse power, and it is still growing night and day. At the present time the company is replacing its vertical compound engines of 5,000 horse power with Curtis steam turbines of 27,000 horse power, by far the largest steam engines the world has ever seen. A single one of these monsters would supply electric current enough to meet the requirements of a city of 250,000 inhabitants; yet one of them takes up no more space than that occupied by the vertical compound engines of one-fifth their power.

AN "INSIGNIFICANT TRIFLE."
Rotor of the tiny turbine that develops 110 horse power.

This may seem to be going some, yet the evolution of the steam engine is proceeding at such a terrific pace that even so persevering a corporation as the Edison Company might

be pardoned for feeling discouraged. In a gloomy corner of this titantic power plant a new idea has sprouted which may oblige the Edison Company to send the first of its 27,000 horse power Curtis turbines to the scrap heap before the last one can be installed. And this brings us back to the tall man.

He is none other than Nikola Tesla, whom the American Institute of Electrical Engineers, by vote of its members, placed seventh in the list of the greatest twenty-five names in electrical science. Tesla has invented a steam turbine. Of course this in itself is nothing worth mentioning, for everybody who is anybody has invented a steam turbine. And as there are steam turbines aggregating 5,166,000 horse power hard at work in the United States today, nearly all installed within the last six years, there is nothing sensational in the mere existence of such a prime mover.

But Tesla's turbine is different. Everything that Tesla does is different. Instead of studying for the priesthood as his father wished, Tesla went out to the stable at his home in far-off Hungary one day when he was very much younger than he is now and tried to fly from the roof with no other aid than that afforded by an old umbrella. The next six weeks he spent in bed. Since then he has been careful to keep his corporeal substance on solid ground; but his fancy essays some marvelous flights. It was Tesla, for instance, who proposed to signal from Long Island to the people on Mars by means of Hertzian waves of exceptional force. It was Tesla, too, who conceived the idea of wireless transmission of power, not to mention other enterprises daringly original. All this goes to show that while Tesla has a long list of practical achievements to his credit he is, in many things, decades, if not centuries, ahead of his times.

When such a man turns his attention to the things of every day life he may confidently be counted upon to produce something original. As every one who is informed upon the subject knows, the fundamental feature of the steam turbine is a wheel bearing upon its periphery a series of vanes or buckets. A jet of steam blowing upon the buckets pushes the wheel around and thus generates power. Many variations have been embroidered upon this elementary fea-

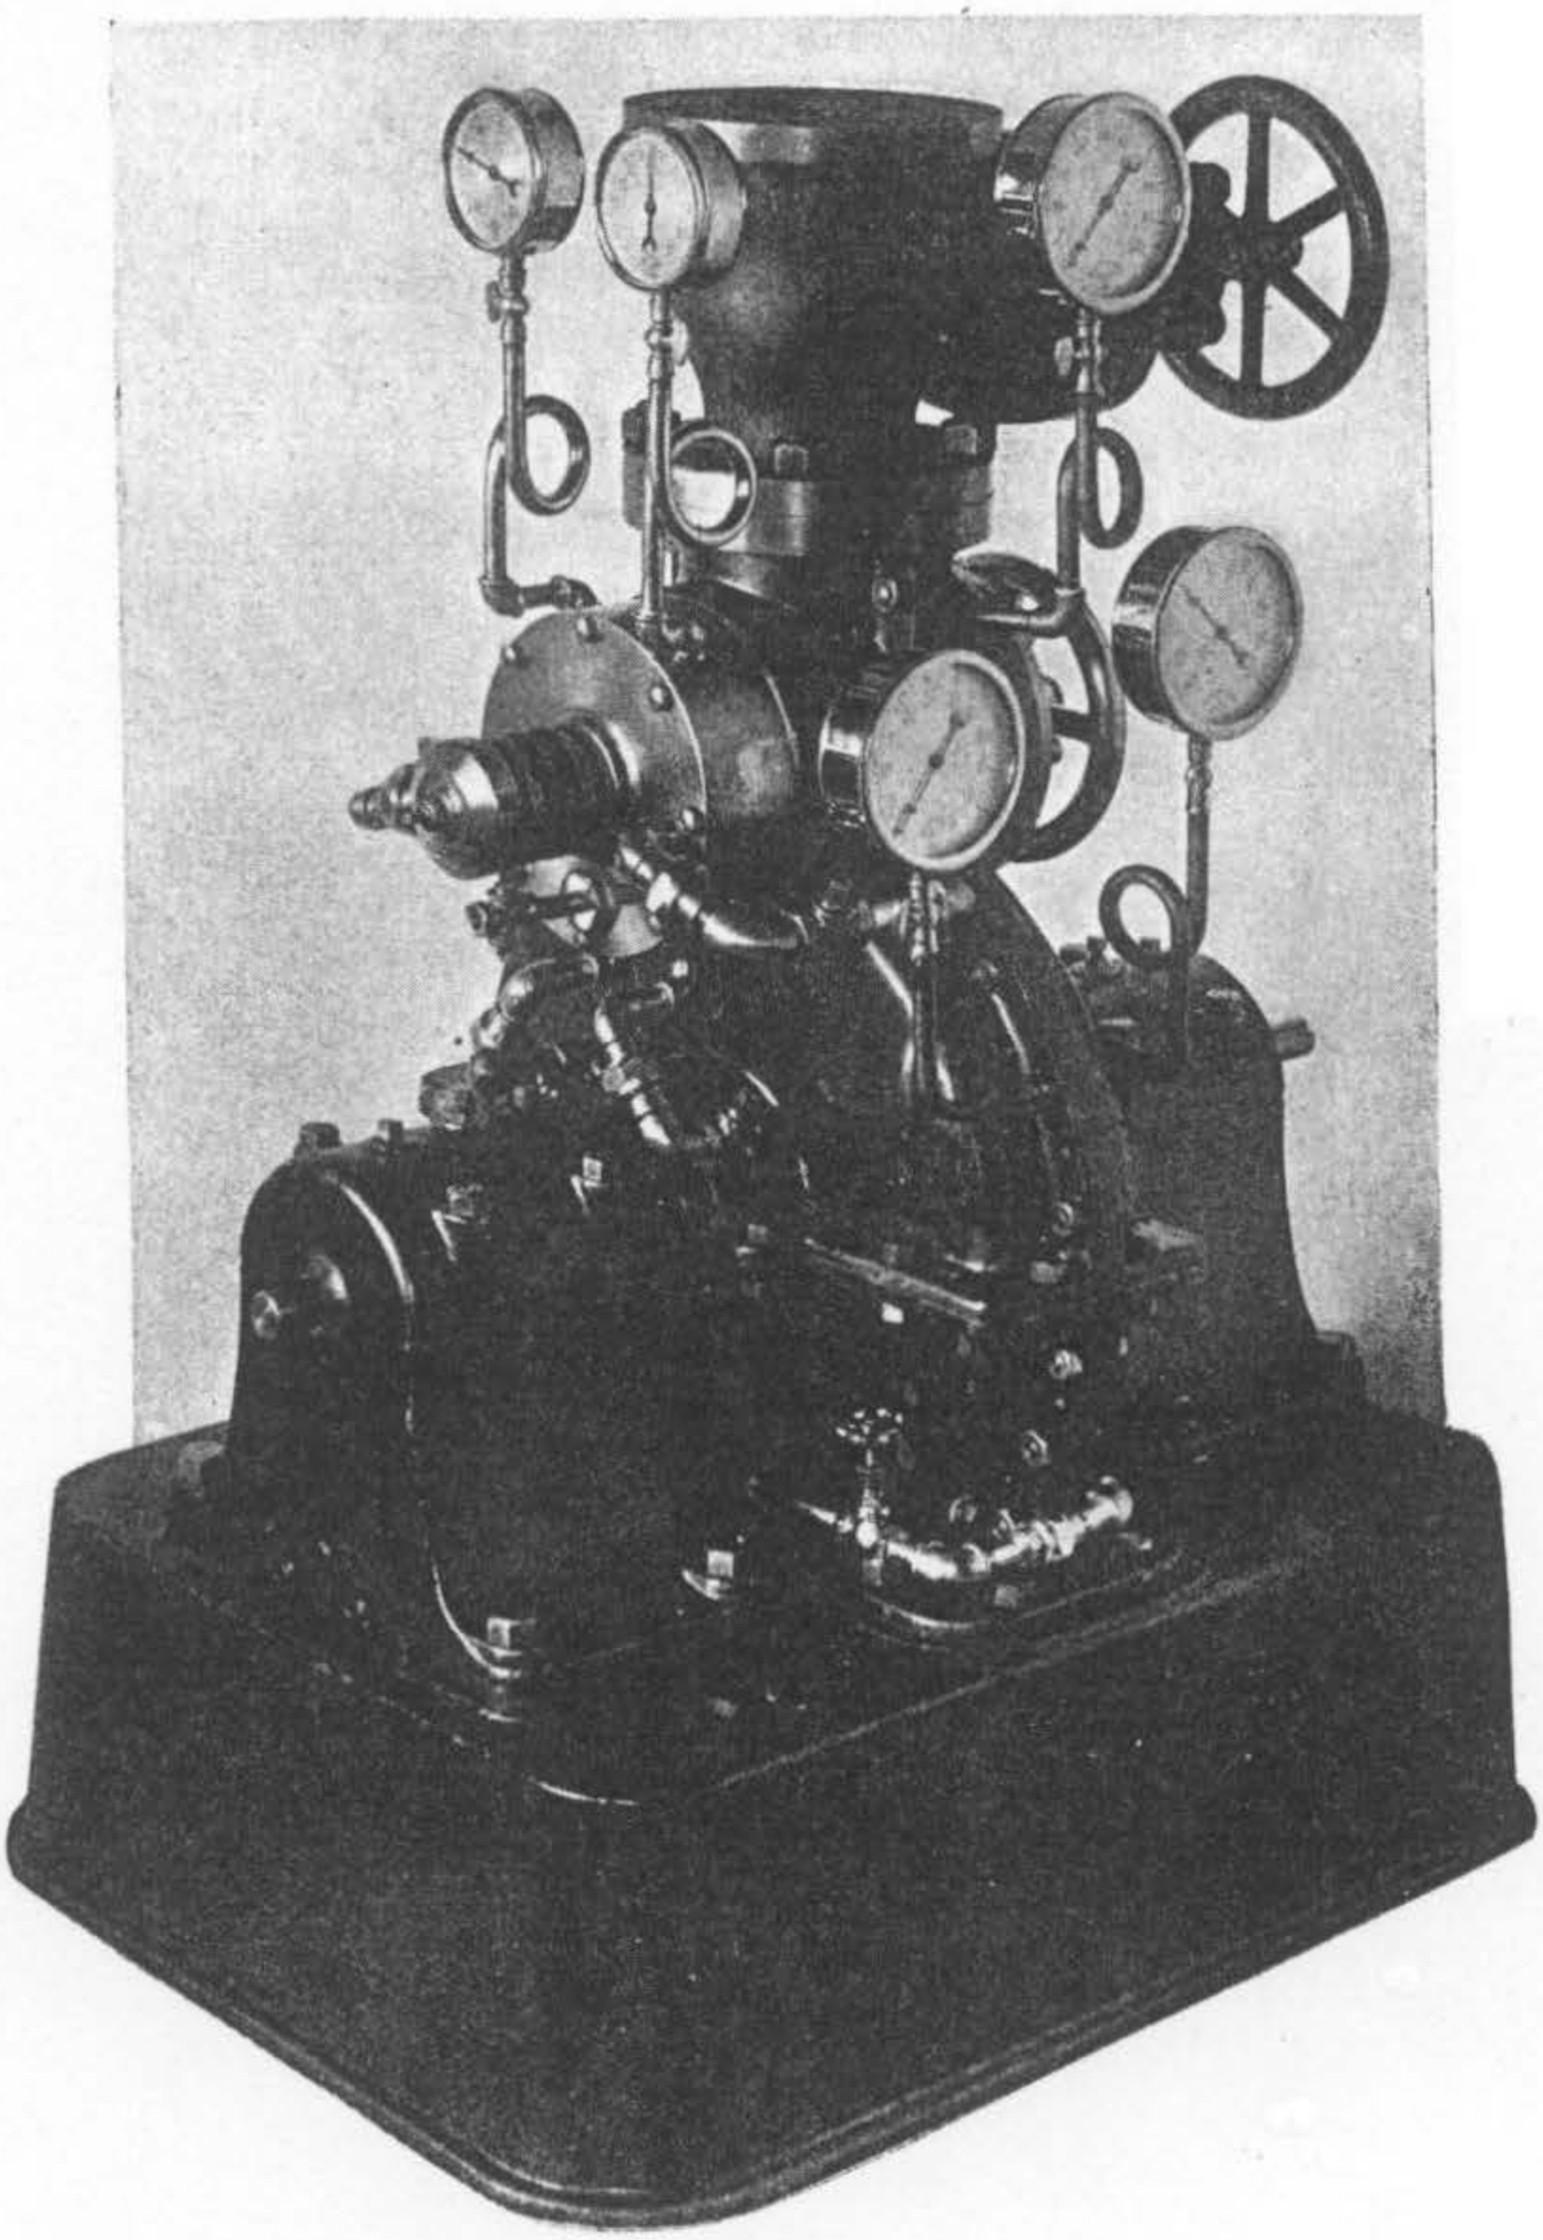
COULD BE COVERED WITH A HAT. YET IS AN ENGINE OF 110 HORSE POWER.

ture to produce the long list of turbines upon the market; but in none of them is the bucket dispensed with. It took Tesla to do that, though E. C. Thrupp, of England, tried to do it eleven years ago, and others have also tinkered vainly at the idea.

Tesla's turbine is the apotheosis of simplicity. Its working parts consist of nothing in the world but some smooth disks of steel only one thirty-second of an inch in thickness mounted about seven sixty-fourths of an inch apart upon a shaft. This assemblage of disks upon a shaft, called a "rotor," being placed within a steam-tight steel casing in which is an opening on the periphery to admit steam and another at the center of one side to allow it to escape, completes the turbine. Lacking the essential element of a turbine, the bucket, it really isn't a turbine; but as the inventor has not yet had time to think up a suitable name for it the familiar designation must answer present purposes.

To go into more minute particulars, the opening for the admission of steam is placed so that the jet strikes the periphery of the disks tangentially. As for the disks themselves, a part of their center is cut away as near as possible to the shaft so that there are three passages from side to side parallel with the shaft at equal distances apart. At one side of the casing opposite these openings is the exhaust port.

At first glance it might appear that when steam was admitted it would simply blow through between the disks and out at the exhaust port without causing the rotor to turn over. And really it almost does this, but not quite. Striking the periphery of the disks at a tangent the steam does follow a short curve to the center at first, but still the curve is long enough to allow the steam to begin to push the disks around. As the disks begin to revolve the steam follows them part way, thus increasing the distance it has to travel to reach the outlet and at the same time giving it a greater hold upon the surface of the disks. This process continues until the rotor has attained full speed, when the steam is pursuing a spiral course from inlet to outlet which takes it several times around the disks in a course six or seven feet long before it finally escapes.



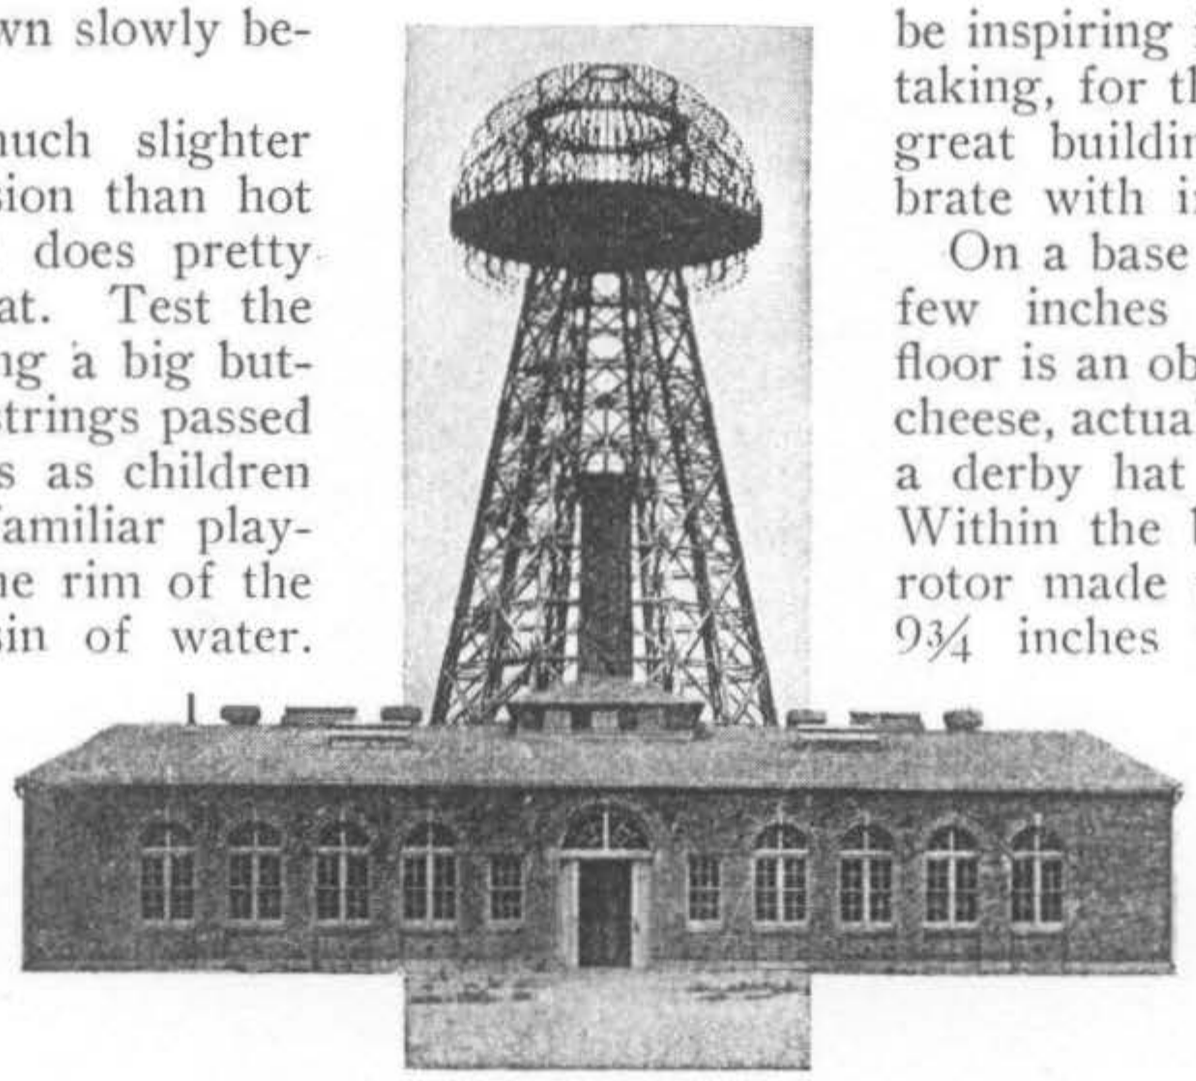
Tesla's turbine is so violently opposed to all precedent that it seems unbelievable, even when you see it at work. In the reciprocating engine the steam has the immovable cylinder head to brace itself against while it expands and pushes the movable piston ahead of it. In the reaction turbine it follows exactly the same principle, expanding between fixed buckets on the sides of a chamber and buckets on the rotor. Even in the impulse turbine there are buckets to give the steam a purchase. In the Tesla turbine there is not so much as a scratch for the steam to grip—nothing but smooth steel.

But the advantages of the earlier forms of the steam turbine and the seeming disadvantages of the Tesla motor are more apparent than real. Steam is a fluid; and when any fluid is used as the medium through which power is developed the most economical results are obtained when the changes in velocity and direction of the current are made as gradual and easy as possible. A diagram of the path followed by a jet of steam in a reaction turbine would look like the thread from an old chain stitch sewing machine ravelled out and thrown down loose. With such a zigzag course destructive eddies, vibration and shocks are inevitable. This is not saying that steam turbines are not highly efficient, for they are; but still they are a long way short of perfection. Another point that counts against the impossibility of attaining the ideal with the older forms of turbines is their delicate and difficult construction. The large ones contain many thousand blades or buckets, each one of which has to be machined and fitted separately. While turbines are much more economical than reciprocating engines in their own particular field they are, nevertheless, costly to build and maintain.

Tesla gets the cost of construction and maintenance down to an irreducible minimum by the extreme simplicity of his turbine. He can do this because he approaches the problem from an entirely new angle. Instead of developing power by pressure, reaction or impact on buckets or vanes he depends upon the properties of adhesion and viscosity

which are common to all fluids, including steam.

The characteristic of viscosity is best exemplified by cold molasses. Any one who has had to go out to the smoke house in winter to draw a pitcher of molasses for the matutinal buckwheats does not need to look in the dictionary to ascertain what viscosity is. Nor is an unduly vivid imagination required to figure out what would happen if a stream of cold molasses were directed against the rotor of a Tesla turbine. There would be such an excess of viscosity that nothing whatever would happen except the machine would be all mussed up. But by heating the molasses its viscosity would be so much reduced that the fluid



TESLA'S TURBINE OF 200 HORSE POWER EQUIPPED WITH GAUGES FOR TESTING.

It stands on a base 20 by 35 inches, and measures only five feet from floor to top of throttle valve.

might trickle down slowly between the disks.

Water has much slighter powers of adhesion than hot molasses, but it does pretty well, even at that. Test the matter by twirling a big button by twisting strings passed through the eyes as children do to make a familiar plaything, holding the rim of the button in a basin of water. The way the water will fly will show very strikingly how so thin a liquid will adhere to a smooth disk.

PLANT ON LONG ISLAND WHERE TESLA HAS MADE SOME EXTRAORDINARY EXPERIMENTS IN ELECTRICITY.

Steam is less adhesive than water, but the difference is in degree only, not in kind. When steam is admitted to the Tesla turbine a thin film of it adheres to the faces of the disks with tenacity enough to exert a pull in the direction in which the jet is moving. At the same time the steam in the thin space between the disks is also held back by the molecular attraction between its particles and those adhering to the disks, which is another way of expressing viscosity, so that all the steam between the disks is helping to drag the rotor around. Of course the disks do not move as fast as the steam, for the velocity of steam is very great.

If the disks were placed too far apart the greater bulk of the steam would flow swiftly through, like the current in a river which flows more swiftly in the center than near its banks, without doing any useful work; but the space is carefully calculated so as to make each molecule of steam exert a long pull, a strong pull and a pull all together with its neighbors, and thus do all the work it is capable of doing under the circumstances.

After Tesla had worked out the theory of his turbine he had one built, then obtained of the Edison Company permission to conduct his experiments at Waterside Station where there is an abundance of superheated steam, vacuum and all other essentials, including surroundings which might be supposed to be inspiring in such an undertaking, for the very air in the great buildings seems to vibrate with irresistible power.

On a base which raises it a few inches above the steel floor is an object shaped like a cheese, actually no bigger than a derby hat of average size. Within the black casing is a rotor made up of steel disks 9¾ inches in diameter and measuring but two inches across the face. Yet this insignificant black cheese makes a fifty kilowatt generator hump itself. Actually it is capable of developing 110 horse power. It has to be geared down, for it is too swift for any generator that ever was built.

When Tesla escorted the first installment of guests around to inspect the new turbine he remarked casually that it ran at 16,000 revolutions per minute. To ask any engineer to believe such a tall statement was putting altogether too great a strain upon credulity. The guests smiled indulgently and winked at each other behind Tesla's back. But when the inventor applied a revolution counter that bit of brass mechanism went into spasms, then calmed down enough to indicate 16,000 revolutions a minute, whereat the eyes of the visitors protruded until they were unable to wink again for a fortnight.

Beside this first Tesla turbine stand two larger ones, coupled together by a flexible shaft so that one may be used as a brake to test the power developed by the other. Taking steam at 125 pounds pressure and exhausting into the open air, making 9,000 revolutions per minute this larger turbine develops 200 horse power. At 185 pounds pressure as used by its big neighbors, it is capable of developing 300 horse power. Yet this new turbine stands on a base only 20 by 35 inches and measures but 5 feet from the floor to the top of the throttle valve. The weight is only 400 pounds, or two

pounds per horse power. The rotor is composed of 25 disks 18 inches in diameter, spaced so that they measure 3½ inches across the face. So compact is this newest of steam engines that one developing 27,000 horse power would only occupy about one-tenth of the space required for the wonderful Curtis turbines on the farther side of the room. The pair of larger turbines are thickly studded with gauges of various sorts used by the inventor in his tests and experiments.

The method of testing the capacity of the turbine is interesting. The two turbines, exact counterparts of each other, are connected by a torsion spring which has been carefully calibrated so that its strength is accurately known. Steam is admitted to the turbine used as a brake in the direction opposite to that in which the disks revolve. On the shaft of the brake turbine is a hollow pulley in which are two slots diametrically opposite each other with an electric light inside close to the rim. As the pulley revolves two flashes of light are seen which with the aid of mirrors and lenses are carried around so that they fall upon two revolving mirrors placed back to back on the shaft of the driving turbine. The mirrors are set so that when there is no torsion on the spring the light is a stationary spot at zero on a scale. As soon as a load is thrown on the spring the beam of light moves up the scale which is so proportioned to the spring that the horse power can be accurately read from it.

In various tests this turbine has consumed 38 pounds of saturated steam per horse power per hour, which is a high efficiency, considering that the steam only gave up 130 British thermal units, and that power is developed in a single stage instead of in several as in other turbines or in triple expansion reciprocating engines. This is equivalent to a consumption of less than 12 pounds per horse power per hour of the superheated steam with the high vacuum used by the monster Curtis turbines near by. Tesla declares that with a large multiple stage turbine of his own type he will be able to develop 97 per cent. of the available energy in the steam, and this with a motor weighing but a quarter of a pound per horse power capacity. Certainly he is doing remarkable things.

A notable advantage possessed by the Tesla turbine is the ease with which it can be reversed. The great drawback to the marine turbines now in use is the difficulty of reversing. It is necessary to have two turbines on each shaft: one for going ahead and one for backing. In the Tesla turbine all that is necessary is to shut off steam on one side of the casing and admit it on the opposite side. There are no ponderous levers to throw, no reversing mechanism whatever, no moving parts but the valves in the steam pipes.

Yet more marvelous is the fact that the new motor is as well adapted to the use of gas as of steam. For years dozens of inventors have racked their brains, squandered their money and sacrificed their sleep in vain efforts to produce a practical gas turbine. But the obstacles in the way appeared insurmountable. Tesla has solved the problem. He has two gas turbines now approaching completion which are to be sent to Europe. The time may not be far distant when automobile manufacturers may be announcing new models with turbine motors. The gas turbine is identical with the steam turbine, the gasoline being exploded in a separate combustion chamber and its heat reduced by a spray of steam or water when the jet is introduced at great velocity into the turbine.

As if this was not versatile enough for one invention the Tesla steam and gas turbine is also a pump and an air compressor. All that is necessary to transform the turbine into a pump is to take the rotor out of its casing and put it into another of slightly different form,—a "volute" casing, the engineers call it, and reverse the direction of the fluid. That is, the water to be pumped enters through the center of the side casing, passes through the interstices between the disks from center to circumference and flows out through the periphery of the casing.

The same molecular adhesion between the disks and the fluid and the molecular attraction between the film adhering to the disks and the fluid between them that imparts power to the steam turbine gives force to the stream of water pass-

ing through the pump or the air passing through the compressor. As the water enters at the center and as the motion of each point on the disk is circular its particles receive an impetus always at a tangent to the circular paths; and so it moves in a spiral path from center to circumference. If the outlet is wide open there is little resistance to flow in a radial direction. Pressure in the casing of the pump depends upon the velocity of the particles leaving the periphery of the rotor. By throttling the outlet the pressure is increased in proportion to the speed of the rotor, velocity being converted into pressure.

The capacity of the new pump is amazing. A nickel plated model in Tesla's office that one could carry comfortably in his overcoat pocket pumps forty gallons a minute against a head of nine feet. With a pump having disks 18 inches in diameter the inventor declares he can deliver 3,500 gallons a minute against a head of 300 feet.

But perhaps the most interesting feature about this unique invention is the use to which its proceeds are to be put. Upon being told that steps were being taken to place the turbine on the market I suggested to Tesla that he would soon be able to retire.

"Oh, no!" he exclaimed. "I shall be ready to begin work. I am going to use the money I get from my turbine to develop wireless transmission of power."

World Today Febuary 1912

Nikola Tesla, Dreamer

His Three-Day Ship to Europe and His Scheme to Split the Earth

By

Allan L. Benson

The man who lives ahead of his age is called a dreamer. Such a man is Tesla. He predicted wireless telegraphy long before it came about, and he gave the world the alternating current without which long-distance transmission of electric power would be impossible. Tesla is a man you will be glad to meet. His dreams are fascinating even if——

ALONE man dines nightly in the Rose Room at the Waldorf. For eighteen years, he has sat at the same table. The table, which stands near the wall, is just large enough for two; but it is never set for two. It is never set for more than one—and that one is Nikola Tesla.

Nikola Tesla is fifty-nine years old. Where he keeps his years, no one knows. They are not in his face, for his face looks like forty. They are not in his hair, for his hair is black. If they are anywhere, they are in his eyes, for his eyes are sad.

This lone man, who always dines across from a vacant place, has given to the world a long series of wonderful inventions. Tesla's system of electric power transmission is used by all the world, and he has a new turbine which, he says, could drive the *Lusitania* across the Atlantic at the rate of fifty miles an hour.

"That means less than three days to cross the Atlantic," he continued, "upon the same coal supply that is now used. But I have a ship in mind that my turbine could put across the Atlantic in sixteen hours.

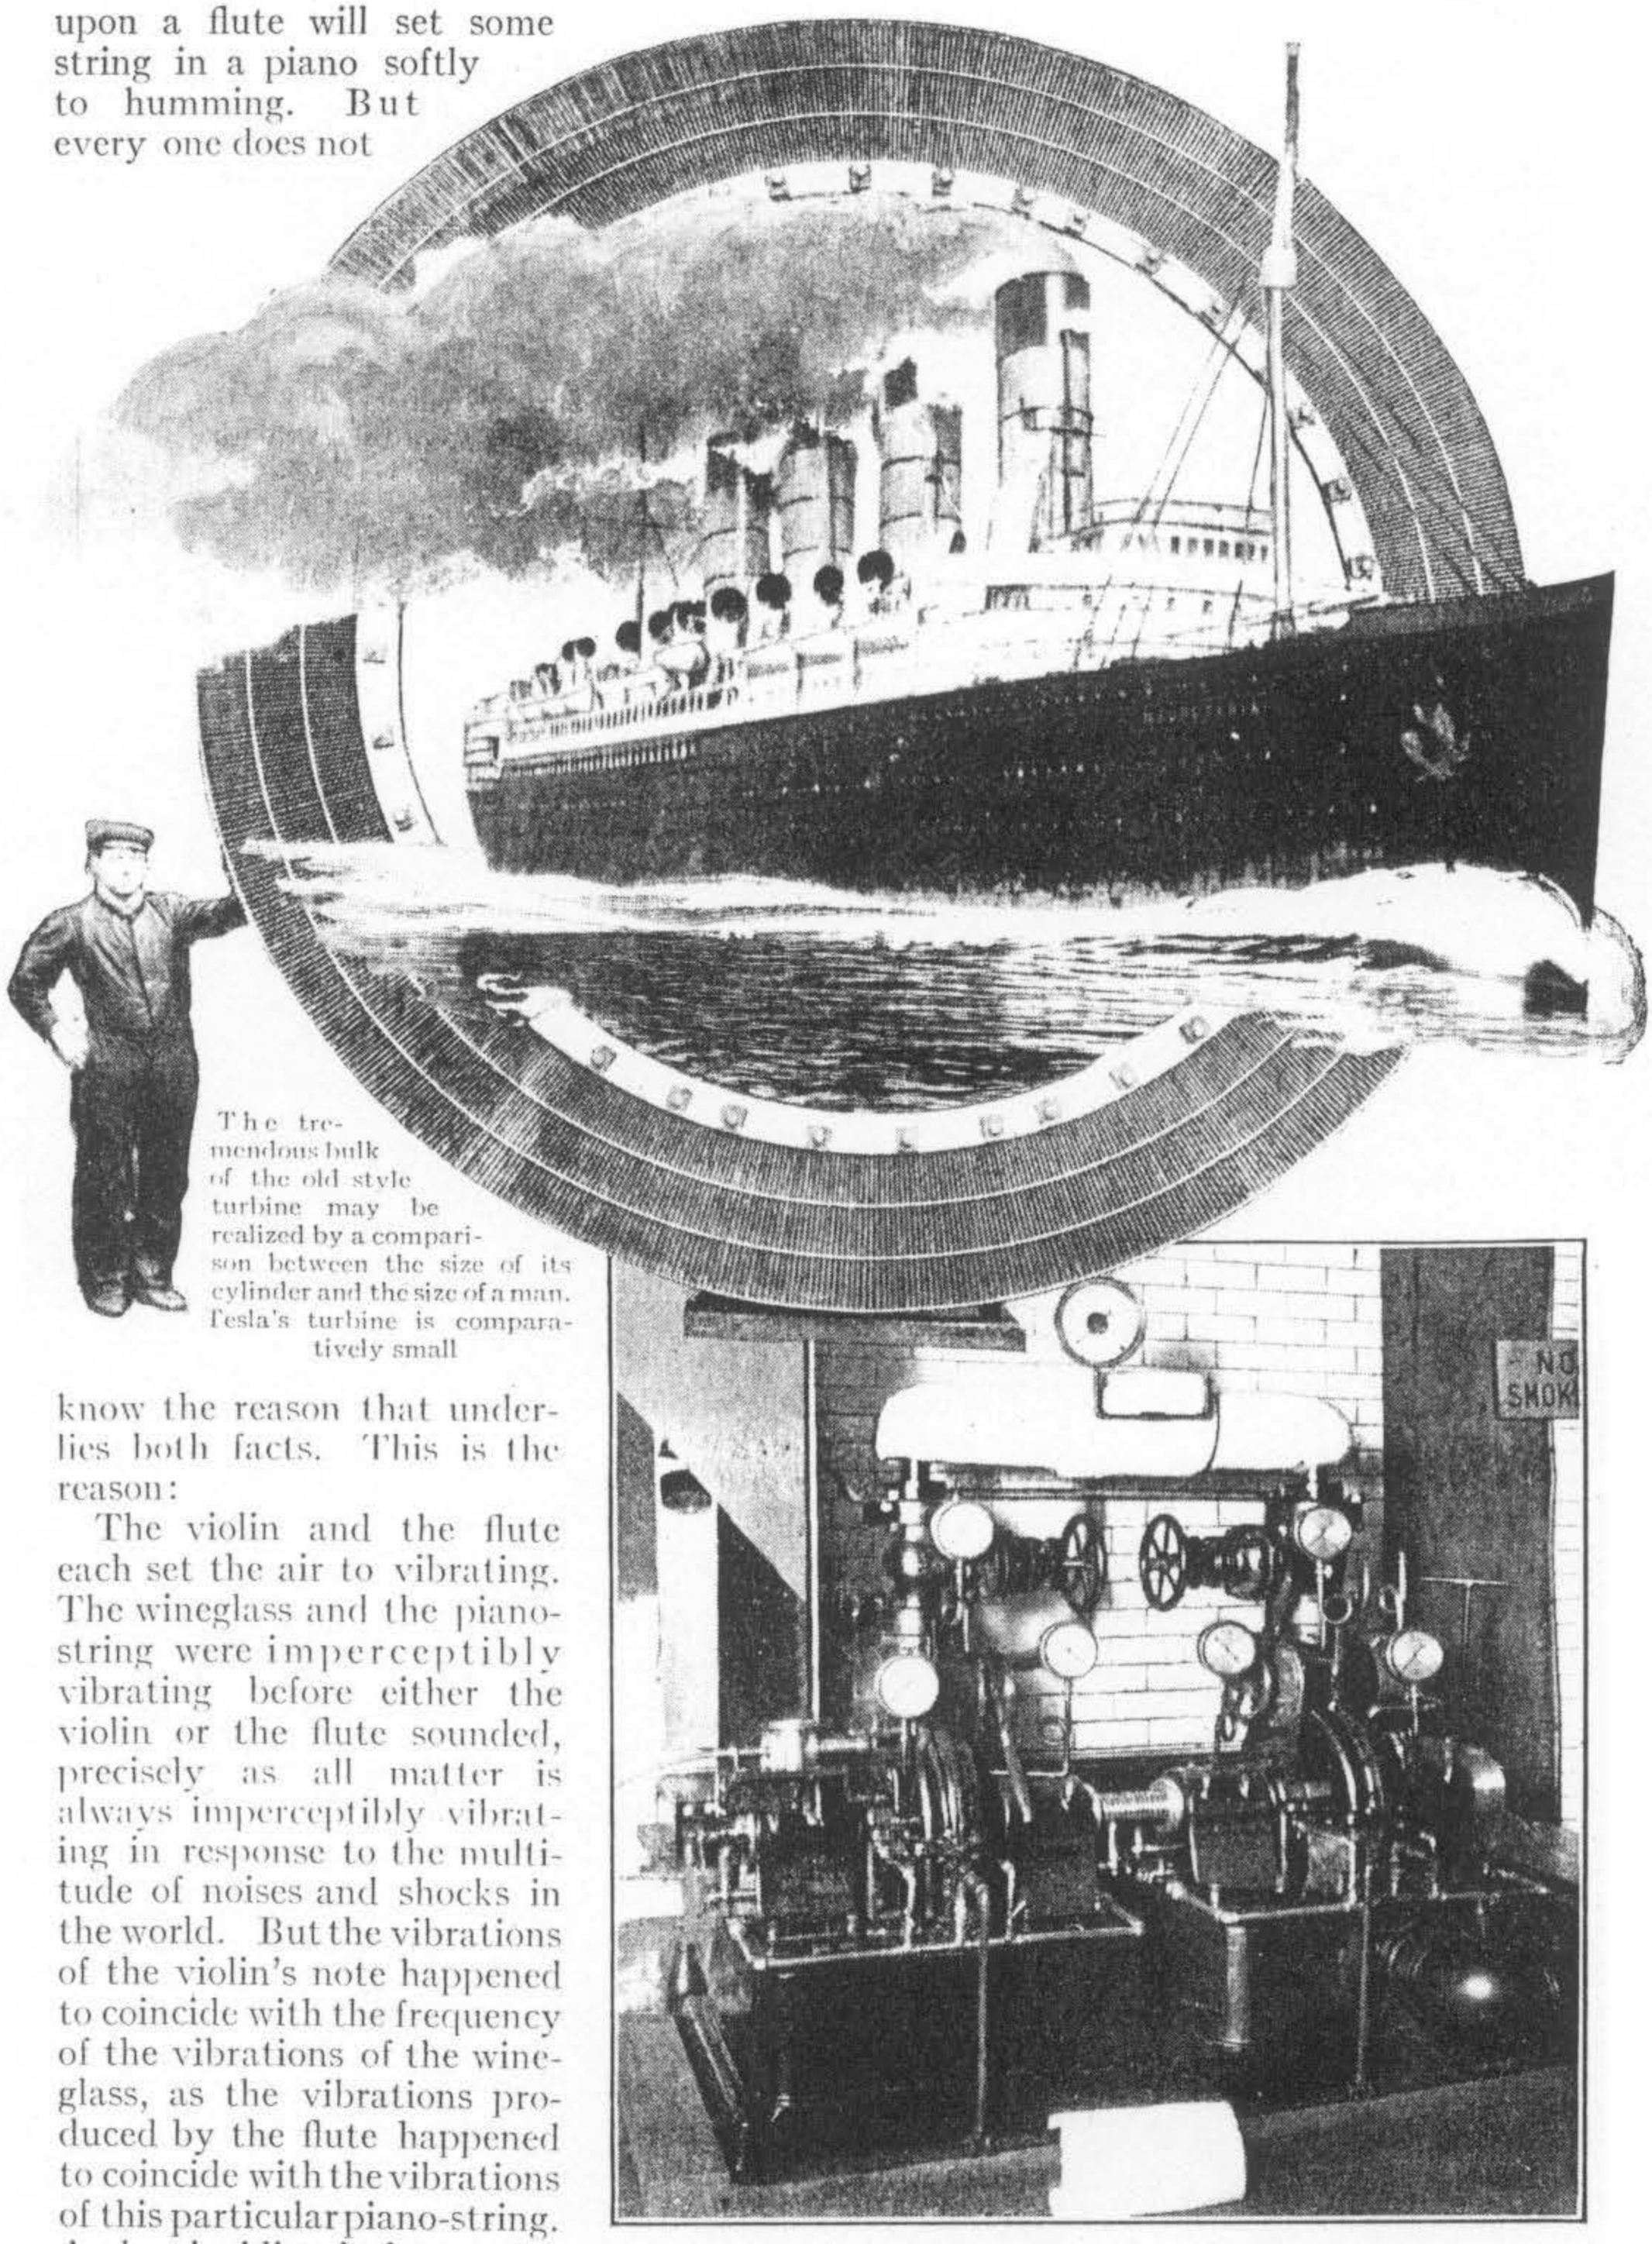
"But the world need not wait for the fifty-miles-an-hour ship. The turbine that can drive it is here. It is a simple matter of mathematics. The best type of reciprocating engine—a quadruple expansion—yields only 51 per cent. of the energy that is contained in the steam. The turbines that drive the *Lusitania* and the *Mauretania* yield 62 per cent. My turbine yields 99 per cent. This it is enabled to do because the steam goes around and around the spiral circuits, imparting energy all along its track, while in the old type of turbine, the steam goes around but once and, when it escapes, still contains much energy."

The superior efficiency that Tesla claims for his turbine is not sufficient, of course, to bring the two-and-a-half day ship. Adding 60 per cent. to power does not add 60 per cent. to speed. The law of diminishing returns prevents that. But Tesla contends that his turbine can as well be driven by steam created by gas explosions, which give enormous pressures.

This suggested internal combustion engines and aeroplanes.

"I will guarantee," said Tesla, "to put my turbine into a Wright biplane and drive it 200 miles an hour. That is to say, the turbine will furnish sufficient power. Of course, no one could sit in a Wright biplane going 200 miles an hour. I expect to develop a new type of flying-machine that my turbine will drive at almost the speed of a bullet."

The fact that Tesla dreams of such speed is not, of course, conclusive proof that such speed will soon be attained. But it should be remembered that some of Tesla's dreams have come true. I myself have seen a clipping from a New York newspaper bearing date of 1893, in which Nikola Tesla said:



"If I cannot send a message to a ship at sea, send it without wires, and make the message understood to those aboard the ship, I am willing to lay my head on the block."

No, he was not the first to send such a message. That is true. Marconi, five years later, sent the first such message. But Tesla, years before Marconi's achievement, obtained American patents upon a system of wireless telegraphy.

While on the subject of dreams, here is a Tesla dream that, so far as I know, has never been equaled by Tesla, or by any other human being, since the world began.

Every one knows that a note upon a violin will sometimes shatter a wineglass in the same room. Every one knows that a note

upon a flute will set some string in a piano softly to humming. But every one does not

The tremendous bulk of the old style turbine may be realized by a comparison between the size of its cylinder and the size of a man. Tesla's turbine is comparatively small

know the reason that underlies both facts. This is the reason:

The violin and the flute each set the air to vibrating. The wineglass and the piano-string were imperceptibly vibrating before either the violin or the flute sounded, precisely as all matter is always imperceptibly vibrating in response to the multitude of noises and shocks in the world. But the vibrations of the violin's note happened to coincide with the frequency of the vibrations of the wineglass, as the vibrations produced by the flute happened to coincide with the vibrations of this particular piano-string. And, coinciding in frequency, as they happened to do, they

Tesla's new turbine, which, he claims, could drive the *Lusitania* across the Atlantic in less than three days, upon the same coal supply that is used now

Tesla claims that in a few weeks he could set the earth's crust into such a state of vibration that it would rise and fall hundreds of feet and practically destroy civilization. A continuation of his process would, he says, eventually split the earth in two

produced the same acceleration that a boy produces when he swings some one in an old-fashioned swing. The person in the swing may weigh 200 pounds and the boy may weigh but 50 and may push but a pound. But if he times his pushes to coincide with the turn of the swing from him and keeps adding a pound each time, he will eventually have to stop to avoid throwing out the occupant of the swing. While, on the other hand, if he did not time to coincide with the movements of the swing—in other words, if he pushed a pound against the returning swing each time it came back—the swing would soon stop.

The wineglass that is broken by a violin's note is broken because the vibrations of the air that are produced by the violin happen to be of the same

"Nikola Tesla is fifty-nine years old. Where he keeps his years, no one knows. They are not in his face, for his face looks like forty. They are not in his hair, for his hair is black. If they are anywhere, they are in his eyes, for his eyes are sad"

frequency as the vibrations of the glass. In the beginning, the glass is expanding and contracting only within infinitesimally small limits. But each time that the glass begins to contract, the vibration produced by the violin gives it a little push. After thousands or millions of such pushes, the expansion and contraction of the glass are so increased that the glass breaks.

The principle embodied in this experiment interested Tesla, and he determined to try it upon a larger scale. He ordered from a steel company a steel link, two feet long and two inches thick. He was careful to specify that the steel should be of the best quality. As a matter of fact, the link was strong enough to bear a weight of hundreds of tons.

Tesla fastened to this link an electric vibrator, no larger than an alarm-clock, but so constructed that the frequency of the vibrations could be altered at will. He set the vibrator to going and then began to vary the vibrations for the purpose of getting the vibrator in "tune" with the link. For a long time, nothing happened—the vibrations of the link and of the machine did not chance to coincide. But at last he got them together, the great steel link began to tremble, increased its trembling until it dilated and contracted like a beating heart—and finally broke!

Sledge hammers could not have done it; crowbars could not have done it, but a fusillade of taps, no one of which would have harmed a baby, did it.

By means of a little electric vibrator, a steel building could be shattered as a wine-glass sometimes is by the note of a violin

Tesla was pleased. He had learned something. He wanted to learn more. He put his little vibrator in his coat pocket and went out to hunt a half-erected steel building. Down in the Wall Street district, he found one—ten stories of steel framework without a brick or a stone laid around it. He clamped his vibrator to one of the beams, and fussed with the adjustment until he got it.

"In a few minutes," he said, "I could feel the beam trembling. Gradually, the trembling increased in intensity and extended throughout the whole great mass of steel. Finally, the structure began to creak and weave, and the steel-workers came to the ground panic-stricken, believing that there had been an earthquake. Rumors spread that the building was about to fall, and the police reserves were called out. Before anything serious happened, I took off the vibrator, put it in my pocket and went away. But if I had kept on ten minutes more, I could have laid that building flat in the street. And, with the same vibrator, I could drop Brooklyn Bridge into the East River in less than an hour."

Now comes the "dream"—or whatever it is.

Tesla says that he can split the earth in the same way—split it as a boy would split an apple—and forever end the career of man.

This seems like quite a large order—but see what he says about it.

"The vibrations of the earth," said he, "have a periodicity of approximately one hour and forty-nine minutes. That is to say, if I strike the earth this instant, a wave of contraction goes through it that will come back in one hour and forty-nine minutes in the form of expansion. As a matter of fact, the earth, like everything else, is in a constant state of vibration. It is constantly contracting and expanding.

"Now, suppose that at the precise moment when it begins to contract, I explode a ton of dynamite. That accelerates the contraction and, in one hour and forty-nine minutes, there comes an equally accelerated wave of expansion. When the wave of expansion ebbs, suppose I explode another ton of dynamite, thus further increasing the wave of contraction. And, suppose this performance be repeated, time after time. Is there any doubt as to what would happen? There is no doubt in my mind. The earth would be split in two. For the first time in man's history, he has the knowledge with which he may interfere with cosmic processes."

I asked Tesla how long he thought it would take him to split the earth in two. He said he didn't know. Months might be required; perhaps a year or two.

"But in a few weeks," he said, "I could set the earth's crust into such a state of vibration that it would rise and fall hundreds of feet, throwing rivers out of their beds, wrecking buildings, and practically destroying civilization.

"The principle cannot fail. It is as powerful when applied to the earth as it is when applied to a wineglass, a swing, or a steel link. Any one who doubts should only bear in mind the illustration of the swing. A small boy, by each time adding a pound to the force with which a 200-pound man swings, can soon set the man swinging with the force of 500 pounds. It is necessary only to keep adding a little force at the right time."

There may be flaws in this theory. Others may see them. I don't. I know that some steamship companies proceed upon this theory—reversing its application, by the way—to keep their steamships in a relative state of equilibrium. Steamships sometimes roll more violently than the ocean rolls, merely because their movements become attuned to the movements of the waves. This is offset by a system of interior water-tanks, back and forth through which water is forced out of tune with the waves, thus neutralizing them. The theory works aboard a ship.

And the possibility that it might work if applied to the earth is sufficient to stimulate the imagination, even if the improbability of its application be sufficient to allay one's fears.

WHAT of the FUTURE IN ELECTRICTY

Dr. Nikola Tesla Looks Forward to the Era When One Hundred Horse Power Will Be Wireless Section Shall Spread Over the World—Tells of Other Developments That We Have Good Reason to Expect.

NIKOLA TESLA.

(Copyright, 1912, by the New York Herald Co. All rights reserved.)

"WHAT did the year 1911 contribute to the electrical progress of the world?"

"What does the year 1912 promise in the same direction?"

These questions, asked of Dr. Nikola Tesla, brought forth the following response:—

"While there has been no fundamental discovery announced during the year just past, progress has been steady and continuous. Almost insensibly great changes have been brought about in various departments.

"Probably the most important of these is the extension of electric transmission lines from hydro-electric central plants. Although the spectre of government restriction has had a deterrent effect on the development of this important industry, it has not inflicted a permanent injury.

"The technical records show that several million horse power have partly been and will soon entirely be harnessed to the service of man.

"Next in importance is the electrification of the railroads, the advantages of which are now thoroughly appreciated, even by the most conservative of railroad men. That which has been achieved in this field has conferred countless benefits on the community.

"Electric lighting has been greatly advanced through the introduction of the new type of incandescent lamp, which has been considerably improved in the last year and ocers greater possibilities.

"The storage battery is still waiting for some discoverer who will open up a new path; but while this is true, improvements have been made in the mechanical construction and arrangement of the elements, rendering the cells more suitable for practical service.

"Equally gratifying strides in telegraphy and telephony have been made, both in the extension of distance and improvement of transmission. Greater progress would have been made long ago had it not been for erroneous theories that have taken hold of the minds of electricians.

"Wireless communication has developed and has been considerably extended also, but here, too, progress is still hampered by the hypnotizing effect of the Hertzian wave theory. Some of the most able experts are still laboring under the illusion that messages are transmitted by these waves. As a matter of fact, it is the currents through the ground that affect the receiver. The Hertzian waves are extinguished within a small radius from the transmitter.

"Investigators in radio-activity have also yielded tangible results, though it must be stated that they have been drowned by impossible forecasts.

"Still another branch of applied electricity, electro-therapy—more particularly through the instrumentality of currents of high frequency—has been much enhanced, the most valuable results being the eradication of cancer and like malignant growths."

In discussing the possibilities of 1912 Mr. Tesla said:—

"I suppose that just at this time aviation commands the attention of the world more than any other field. For ages it has been the passionate desire of man to invade the domain of the bird, and finally it has materialized! The advent of a new motor, simpler, lighter, more powerful and efficient, and absolutely reliable in its operation, will convert the flying machine [illegible] apparatus [illegible] and useful vehicle.

"A promising departure has already been made by Dr. Tesla in this line, a description of his new motor having been given in the NEW YORK HERALD recently.

"Another As fascinating," Dr. Tesla continued, "are the possibilities of the discoveries that have been made by Mme. Curie. Though it may be safely predicted that the dreams of the enthusiasts will not be realized, enough has been achieved already to justify great expectations for this coming year."

"What do you think of wireless art in its various applications?" he was asked.

"The sensational exploitation of wireless telegraphy and telephony has naturally created in the public mind the idea that this is the chief if not the only field of its use. As a matter of fact, the world has not even at this moment the faintest conception of the really great and valuable results in other fields that are sure to be obtained in the near future.

"Far more important than communication is the transmission of power wirelessly, which will be done for innumerable purposes. To mention one comparatively insignificant application, a plant might be provided that would enable every vessel or vehicle either on land or the water or in the air to safely travel without compass or any other means of direction such as has heretofore been known. One such wireless plant would be sufficient for the needs of the whole world and the means of saving property and human lives.

One Central Plant.

"Remember," Dr. Tesla emphasized, "that I am now only mentioning one of the minor applications of wireless power. Just think what benefits could be derived in this particular phase of aerial development by the construction of one single plant from which all the flying machines of the world could be operated without fuel or other energy of any kind!"

Turning to other subjects he said:—

"Entirely new fields have already been opened up to scientific research and inventive application, but still greater possibilities lie before us.

"Think only what it would mean to disintegrate matter into its primary constituents, thus giving rise to new effects and phenomena and liberating forces heretofore unknown! One of the consequences, perhaps not the most important, would be the inexhaustible supply of radium emanations.

"Since advancing this idea I have spent much time attempting to realize it by the application of great electrical forces, but although I have attained tensions of 20,000,000 volts, sufficient to tear off particles from the toughest steel, they were found inadequate to break up the atomic structure. I am confident, though, that it will be done eventually.

"Another realm of infinite promise is that of intense cold, so ably and successfully explored by Sir James Dewar. The production of liquid oxygen and hydrogen, if economically effected, will be revolutionizing in its influence on industry and manufacture.

"Even some of the older electrical arts are still undeveloped. Take the storage battery, for instance. No radical departure has been made since the original demonstrations of Ritter and Plante. The time is ripe for a signal improvement. One can confidently announce the coming, and very soon, of a new principle which will mark an epoch in the development of this branch of electricity.

"Electrical progress," continued Dr. Tesla, in reply to a queation, "may be said to have begun with Gilbert and Leyden, respectively the discoverers of the earth's magnetism and the electrical condenser. From that period on the advancement, although very slow at first, was nevertheless continuous. It was greatly accelerated by the discovery of Galvani and the researches of Faraday, but the rapid growth comparable to that of the present day can be traced back only a quarter of a century.

"Nevertheless there are many facts indicating that at some earlier period electrical science was far more advanced than would appear from historical records. There is a large interval of unproductivity, but only in so far as it concerns actual accomplishment. The intellectual progress must have been more or less continuous.

"As to the utilization of fuel energy, I am glad to say that I have recently made a decided step forward through the perfection of my new gas turbine, or rotary engine, which will permit a much more economical use of fuel than heretofore possible.

Improving the Telephone.

"The energy supplied to the earth through the sun's rays is so great that if it could be cheaply stored and converted it would meet all our wants. But, although engines have already been operated by power so derived, all undertakings to this end have proved practical failures, chiefly because of the periodic character of the supply. I have long recognized that the true solution lies in a different direction.

"Telephoning through long submarine cables is possible and would have been accomplished long ago had the efforts of electricians been turned in the proper direction. The trouble lies in the transmitting and receiving instruments, especially the latter, which are still crude and require strong currents for operation, entailing great loss in the wire, as well as the surrounding insulating medium, and causing weakening and distortion of the impulses. Following the suggestion of the great mathematician Heaviside, the telephone lines are now being made of heavy wire and provided with induction coils, which have the effect of raising the tension and reducing the frictional waste in the wire.

"A further extension in the transmission has been effected by the use of the so-called phantom circuit, consisting of two separated lines. This is an ingenious and practical expedient, but the use of induction coils is only necessitated by the crudity of the instruments. In employing very sensitive receiving devices speech can be transmitted distinctly through the longest aerial lines and submarine cables without any change in their construction."

"How about the possibility of making that visible which is going on at the end of a wire as we are now able to converse over a wire?"

"We must distinguish between transmission of pictures and what has been termed television, or seeing at distance. The former is a comparatively old art now well established. Some of the early work in this direction was done in this country by Mr. Amstutz, an American engineer. Quite recently Professor Korn, of Munich, has perfected apparatus which is now being used with success.

"As regards the transmission of images, it is incomparably more difficult chiefly because of the complexity it involves. By the means which have been so far proposed thousands of wires would be necessary between two stations. An invention of mine permits the reduction of this number to but a few, or even to a single wire, so that there is a fair prospect of practical achievement at no remote date. What is more, I believe that seeing at a distance will be accomplished without wires."

"Will it be possible for electrical science to discover some means whereby such accidents as that of the Olympic and the Hawke can be avoided?"

"A perfect means for this purpose has been afforded through the discovery of the stationary waves, but unfortunately there is no plant as yet in operation. With these waves, which, as I have shown, pass from one to the other end of the globe without diminution of intensity, producing stationary loops and nodes, the danger of collisions at sea will be greatly reduced."

"Is electrical science also likely to provide quicker means of transportation than railroads or steamships?"

"Certainly. With the introduction of

(CONTINUED ON PAGE FIVE.)

The Future in Electricity.

(CONTINUED FROM PAGE ONE.)

wireless power it will be practicable to attain much greater speeds, particularly through the air, as the supply of power will dispense with the necessity of carrying fuel and lighten and simplify the flying machine. It may also be expected that by wireless supply of power vessels at sea will be made to travel faster for similar reasons."

Dr. Tesla was also of the opinion that the progress of electrical science in the days to come will do much toward promoting the peace of the world. On this subject he said:—

"Whether such a condition of human life as universal peace is at all possible is still a question. One thing is certain—that it cannot be attained by arbitration, any more than it is possible to carry out a perpetual motion scheme. Those who believe in this possibility confound effect and cause. Humanity must be so far advanced that peace is an accomplished fact when parliamentary resolutions will be the natural consequence and will have only the significance of formal procedures giving expression to the general desire.

"It is also a mistake to assume that by the coalition of a few great Powers a peaceful condition all the world over can be brought about. There is an essential difference between a family and a nation.

"If we conceive a world such as ours populated with beings perfectly alike the natural efforts of each will soon destroy the homogeneous character of the mass, and out of the multitude individuals will spring who will become centres of force, around which the others will gather, and in due course the communities so formed will clash. It is clear, therefore, that unless some new elements or forces come into play wars will be unavoidable.

"The opinions on this subject are widely different. There is, we must admit, in all of us a remnant of the barbarous instinct developed in the early struggle for existence. But while this is undeniable it does not appear that strife between nations and individuals must necessarily be accompanied by bloodshed. I believe that the primary cause of war can be traced to misunderstandings which are the result of the great distance separating individuals from each other and to the impossibility of getting into close touch. The progress of the electrical arts will enable one to come in instant touch with the rest of the world, and this should gradually lead to a peaceful understanding."

"Will wholesome food products be ultimately produced under the potency of electric affinities?"

"This may be positively expected—in fact, we are already producing some foodstuffs by electric currents. The manufacture of nitrates and other nitrogen compounds from the air is being carried on on a large scale and the productiveness of the soil has been greatly increased in some parts by this and other electrical means. The time is not distant when many kinds of food products will be manufactured by electricity, and a great number of specialists are already engaged on this problem."

"Is it likely that such an advance in electro-therapeutics may be looked for that human life may be prolonged and suffering alleviated, diagnosis and prognosis being aided by exact electrical measurements of the various organs of the human body?"

"Since 1891, when I published my first investigations with high frequency currents, they have been universally adopted in electro-therapy and wonders have already been achieved by their use. Of late the claim has been advanced that the application of such currents stimulates the mind and enhances growth, and experiments carried on for a considerable period seem to have borne out this fact.

"From personal experience I know that the daily use of high frequency currents greatly contributes to one's well being, and I cannot recommend it too highly. Electric currents have also been successfully applied as an anaesthetic in surgical operations and have proved invaluable, but as to whether human life can be materially prolonged is still open for conjecture."

LAWRRENCE MOTT.

The New York Herald February 21, 1912

INVENTOR SUES NICOLA TESLA.

Simon J. Schlenker Demands $61,000, Alleging Breach of Contract.

A suit to recover $61,000 from Nicola Tesla, the inventor, and Edward K. Stallo, capitalist, was begun in the Supreme Court yesterday by Simon J. Schlenker, through his counsel, Putney, Twombley & Putney. Mr. Schlenker alleges that he entered into an agreement with the defendants in November, 1907, to put on the market an electrical device known as the Nicola transformer.

It is alleged that Messrs. Tesla and Stallo refused to keep the agreement. Mr. Schlenker says he spent $3,500 after the contract was made, while the $58,000 represents the profit he would have made if the contract had not been broken.

The New York Tribune March 3, 1912

LETTERS TO THE EDITOR

TESLA ON WIRELESS.

Electrical Inventor Thinks Marconi's Plants Inefficient.

To the Editor of The Tribune.

Sir: In so far as wireless art is concerned there is a vast difference between the great inventor Thomas A. Edison and myself, integrally in my favor. Mr. Edison knows little of the theory and practice of electrical vibrations; I have, in this special field, probably more experience than any of my contemporaries. That you are not as yet able to impart your wisdom by wireless telephone to some subscriber in any other part of the world, however remote, and that the presses of your valuable paper are not operated by wireless power is largely due to your own effort and those of some of your distinguished confreres of this city, and to the efficient assistance you have received from my celebrated colleagues, Thomas A. Edison and Michael I. Pupin, assistant consulting wireless engineers. But it was all welcome to me. Difficulty develops resource.

The transmission across the Atlantic was not made by any device of Mr. Marconi's, but by my system of wireless transmission of energy, and I have already given notice by cable to my friend Sir James DeWar and the royal institution of this fact. I shall also request some eminent man of science to take careful note of the whole apparatus, its mode of operation, dimensions, linear and electrical, all constants and qualitative performance, so as to make possible its exact reproduction and a repetition of the experiments. This request is entirely impersonal. I am a citizen of the United States, and I know that the time will come when my busy fellow citizens, too absorbed in commercial pursuits to think of posterity, will honor my memory. A measurement of the time interval taken in the passage of the signal necessary to the full and positive demonstration will show that the current crosses the ocean with a mean speed of 625,000 miles a second.

The Marconi plants are inefficient, and do not lend themselves to the practice of two discoveries of mine, the "art of individualization," that makes the message non-interfering and non-interferable, and the "stationary waves," which annihilate distance absolutely and make the whole earth equivalent to a conductor devoid of resistance. Were it not for this deficiency, the number of words a minute could be increased at will by "individualizing."

You have already commented upon this advance in terms which have caused me no small astonishment, in view of your normal attitude. The underlying principle is to combine a number of vibrations, preferably slightly displaced, to reduce further the danger of interference, active and passive, and to make the operation of the receiver dependent on the co-operative effect of a number of attuned elements. Just to illustrate what can be done, suppose that only four vibrations were isolated on each transmitter. Let those on one side be respectively a, b, c and d. Then the following individualized lines would be ab, ac, ad, bc, bd, cd, abc, abd, acd, bcd and abcd. The same article on the other side will give eleven similar combinations, and both together twenty-two lines, which can be simultaneously operated. To transmit one thousand words a minute, only forty-six words on each combination are necessary. If the plants were suitable, not ten years, as Edison thinks, but ten hours would be necessary to put this improvement into practice. To do this, Marconi will have to reconstruct the plants, and it will then be observed that the indefatigable Italian has departed from universal engineering customs for the fourth time.

New York, Oct. 24, 1907. NIKOLA TESLA.

WIRELESS POWER

NEW YORK TRIBUNE MARCH 3, 1912

By RICHARD MAXWELL WINANS

A BOLT of lightning passing through the earth, and returning to the point of entry with undiminished force, was the astounding discovery made by Nikola Tesla, "Wizard of Electricity," inventor, scientist, scholar.

As the issue of this momentous discovery Professor Tesla has perfected a practical system of wireless power distribution. And the universal application of the wireless transmission of energy will speedily solve vast and far reaching problems in commerce and the industries, and will eventually revolutionize the whole structure of the world's social and political economy.

Already Tesla has advanced his discovery of the wireless transmission of electrical energy to the point of practical application. At his great experimental plant on Long Island he has secured actual and satisfactory results in wireless power transmission that go far toward making for its early and successful introduction into commercial and industrial uses. When all the details of his transmitting system are complete, and the world at large shall adopt wireless power in its general utilities, the wonders of science and invention, of dynamics and mechanics, the arts and the social scheme, that we employ and enjoy today will appear as the antiques of a primitive age.

The magic Lamp of Aladdin was never rubbed to such fruitful purpose, nor did it ever create such undreamed-of wonders, as will the application of the wireless transmission of energy to some of the most simple contrivances, the everyday utilities of the present; let alone the improved devices that will develop in its use, with which inventive genius will provide us for the future.

In recounting the incidents leading up to and the elemental details of the discovery that unexpectedly and unquestionably opened the way to this great realization, Tesla recites that during a systematic research, for which he had long trained himself, which he had assiduously conducted for several years, to the end of perfecting a system of wireless transmission of energy through the natural media, the earth and air, he came in 1898 to recognize three essential requirements. The first was to produce a transmitter of tremendous power; the second, to perfect a system for individualizing and isolating the energy transmitted; the third, to acquaint himself with the laws governing the propagation of electrical currents through the earth and air.

IN May, 1899, Professor Tesla selected, for various scientific reasons, a large plateau sixty-five hundred feet above sea level, in the vicinity of Colorado Springs, where the surroundings contributed ideal conditions for careful observations. Such were the climatic and other conditions that he could hear claps of thunder four to five hundred miles away; and he could have improved upon this record had it not been for the tedium of waiting for the sounds to arrive, in definite intervals, as shown by an electrical indicating device—nearly an hour before.

Having established his laboratory and adjusted the highly sensitive instruments necessary to the proposed experiments, he learned that the earth was literally alive with electrical vibrations. Colorado, with its dry and rarefied atmosphere, is famed for its natural displays of electricity; static electricity being abundantly developed. The discharges of lightning during storms are not only frequent, but often violent to an inconceivable degree. During his stay there were in the course of one electrical storm approximately twelve thousand discharges within an observed period of two hours, occurring inside a radius of less than thirty miles. Many of these discharges were so heavy that they resembled gigantic trees of fire.

About a month after his Colorado observations began Tesla was both surprised and puzzled to note that his instruments were affected more decidedly by discharges taking place at great distances than those nearby. This presented a perplexing problem, which was made the more mystifying when careful observation disclosed the fact that the differences were not due to intensity of discharges, nor varying relation between the periods of the receiving circuits and those of the terrestrial disturbances.

ONE night when meditating over these experiences," says Tesla, "I was suddenly staggered by a thought. The same thought had presented itself to me years ago; but I had then dismissed it as absurd and impossible. And that night when it recurred to me I banished it again. Nevertheless, my instinct was aroused, and somehow I felt that I was nearing a great revelation.

"It was on the third of July (1899) when I obtained the first decisive experimental evidence of a truth of overwhelming importance for the advancement of humanity. A dense mass of strongly charged clouds gathered in the west, and toward evening a violent storm broke loose which, after spending much of its fury in the mountains, was driven away with great velocity over the plains. Heavy and long persisting arcs formed almost in regular time intervals. My observations were now greatly facilitated and rendered more accurate by the experiences already gained. I was able to handle my instruments quickly, and was prepared. The recording apparatus being properly adjusted, its indications became fainter and fainter with the increasing distance of the storm, until they ceased altogether. I was watching in eager expectation. Sure enough, in a little while the indications again began, grew stronger, gradually decreased, and ceased once more. Many times, in regularly recurring intervals, the same actions were repeated, until the storm, as evident from simple computations, with nearly constant speed had retreated to a distance of about two hundred miles. Nor did these strange actions stop then, but continued to manifest themselves with undiminished force.

"When I made this discovery I was utterly astounded. I could not believe what I had seen was really true. It was too great a revelation of Nature to accept immediately and unhesitatingly. Subsequently I confided my discovery to my assistant, and he afterward confirmed it, as did also a noted engineer in a German university. Several opportunities were presented later which brought out still more forcibly and unmistakably the true nature of the wonderful phenomenon. No doubt whatever remained—I was observing stationary waves! Impossible as it seemed, this planet, despite its vast extent, behaved as a conductor of limited capacity.

"All effects diminish as the extreme line of their radius increases. For instance, sound effects would be exhausted within a given radius, which would be determined by atmospheric conditions. The general law is that at one-half the distance the intensity of the effect is fourfold. And this is also true of electrical activities. But this discovery demonstrated something that was altogether contradictory to all previous experience. Not only could an electrical current be passed through the earth with undiminished intensity, but, under certain conditions, its force would be even augmented with distance.

"Had this discovery been worked out at that time it would have given us practical wireless transmission of power on a commercial scale at least ten years ago. The world, however, was not then, and is not yet, ready to receive it. Man—that is, the layman, the man unversed in dynamic forces and scientific engineering—does not understand how one element is related to another. If I had attempted at that time to place upon the market an apparatus for the wireless transmission of power, the world would not have utilized it. It may be years before it is educated to receive these new ideas and the perfection of this discovery. It is difficult for the average citizen to comprehend or to form an adequate idea of the tremendous significance of this marvelous revelation of Nature, or the stupendous possibilities that the development and perfection of this discovery assure as a heritage to humanity."

THE full development of a possible twenty-five hundred millions of horsepower from the waterfalls and streams of the United States has been materially handicapped and restricted by the limited area over which hydroelectric energy may be practically transmitted by wire. The falls of Niagara alone could be made to supply a fifth of all the power used at present by industry and the railroads. At some remote day their power may be entirely utilized by diverting the full volume through tunnels to turbines at night, charging immense storage batteries with its energy for use during the next twelve hours, and again turning the water over the falls during the day to satisfy the sentiment of the people.

Aside from Niagara, however, most of the great power sites of the country are so distant from the centers of

population that it has been impracticable to transmit their energy to localities containing the heart of our industries, and in many instances, particularly among the Western mountains, they are so inaccessible as to make it difficult or inconvenient to establish industries about these sites or within reach of electrical power transmission. But with wireless transmission of power the energy of the waterfall of the Columbia River—which by the way, amounts to seven or eight million horsepower—can be employed to run the motors of industry, to light and heat homes and cook food on the Atlantic seaboard as readily as on the Pacific, in Portland, Maine, as well as in Portland, Oregon; or the five million horsepower from the Sacramento River, in Manila as easily as in San Francisco. There is millions more than enough horsepower going to waste in the streams of the North Pacific group to turn every wheel of industry and move the traffic of every railroad in the country; and with the advent of wireless power it will be developed, along with other millions of hydroelectric power otherwhere, as consumption creates a demand for it.

The greatest power site in the world, Zambesi Falls, was recently discovered in the until then unexplored heart of Africa. Over its brink has gone to waste thirty-five million horsepower every minute of each day for centuries, enough energy to provide a large part of the world with power, more than enough to supply the commerce and industry of the United States. Because of its isolated location it is useless to mankind, and will be until wireless power makes it possible to set the wheels of a thousand industries spinning anywhere on earth with its magnificent energy.

WHILE the general public has not been taken into Tesla's confidence concerning the progress of his work in the perfection of his system for the wireless transmission of power, scientific and electrical engineers in all countries have followed closely and with intense interest such developments as he has revealed to the technical world. For obvious reasons, however, it would not be prudent to disclose the actual working details of the system, or the specific nature of apparatus to be employed, until such time as he may elect to place his transmitter on the market for commercial purposes.

"There is," says Tesla, "much misunderstanding in regard to my wireless system. Some believe that the transmission is effected through the air, and others that the currents go only through the earth. The fact is both media serve as vehicles of energy. The current passes through the earth; but an equivalent electrical displacement also occurs in the air, exactly as when the transmission is effected through a single wire without return; a principle the practicability of which I demonstrated in my earlier investigations.

"By this system," he continues, "wireless power can be transmitted with absolutely the same facility to the antipodes as it can to a distance of a few blocks. The quantity of energy the transmitter delivers is immaterial; but, in view of the fact that the earth is immense, and that there are practical limits in the amount of energy collected in any individual receiver, it is necessary to have a very powerful transmitting plant.

"However," he explains, "the volume of energy—the indicated horsepower of the generating plant—will not in the least affect the limit of transmission. That is, a plant generating two hundred horsepower will transmit its energy to the same unlimited terrestrial distance as that of a plant generating two hundred thousand horsepower. Neither will the energy or power decrease in efficiency as the distance of transmission increases, as is the case with electrical energy transmitted by wire. The efficiency of transmission will be the same, irrespective of the distance or the amount.

"When conveying power through a wire," Professor Tesla points out, "a certain loss is incurred, due to the resistance of the conductor; but the earth is a conducting body of such enormous dimensions that there is virtually no loss, so that distance means nothing. To the average intelligence this will appear incomprehensible. We are continuously confronted with limitations, and those truths which are contradicted by our senses are the hardest to grasp. For example, one of the most difficult tasks was to satisfy the human mind that the earth rotated round the sun; for to the eye it seemed just the opposite."

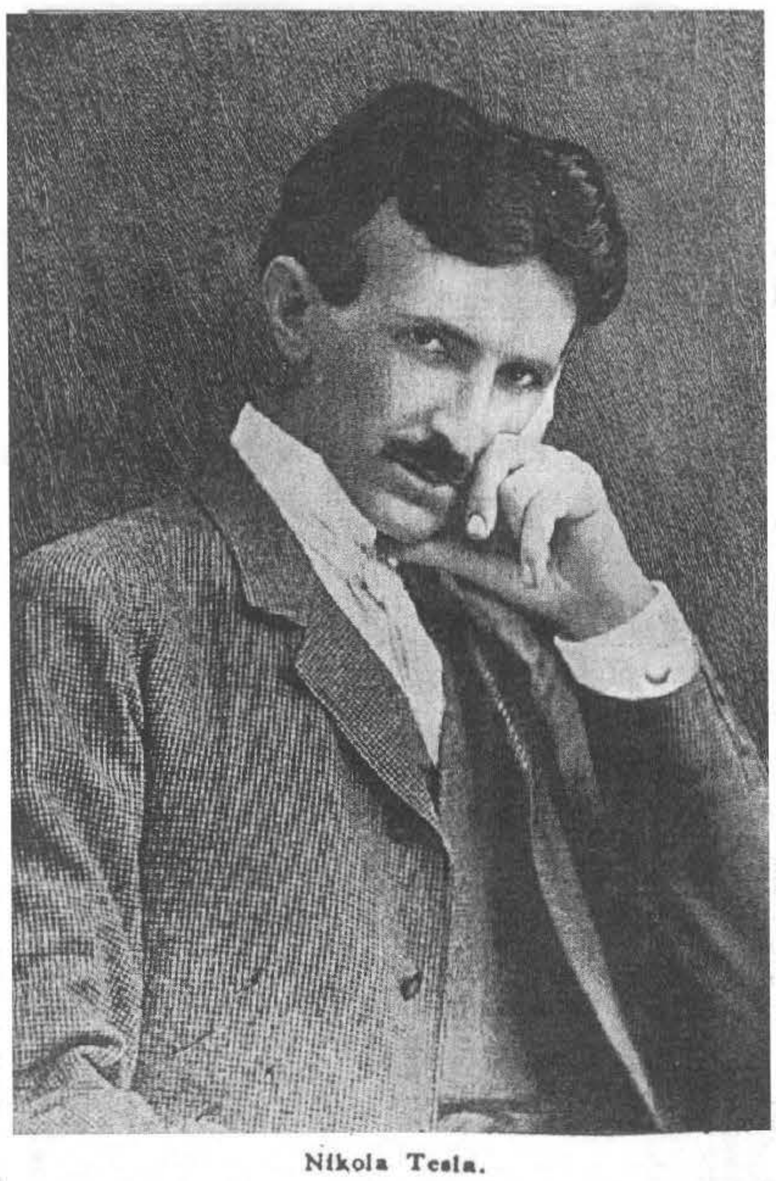
IN regard to the cost of wireless power, an estimate is made that places it at about one-sixteenth that of the present means and sources of supply. At any rate, Tesla says that it will be far cheaper than any other source known to man. "With wireless energy," he continues, "we could avail ourselves of the waste power of the present: the transmission would involve but little expense, and the apparatus would be of the simplest and cheapest."

The cost of wire transmission varies with the ratio of distance between point of generation and consumer, as determined by investment in and maintenance of conveying mains, which increases with distance. Also, over long lines, as from Niagara Falls to points some two hundred miles distant, the loss of current increases with each mile, and would, if the line were carried far enough, so decrease in volume that eventually the current would lose practical power producing energy. With the most improved means of wire transmission the limit of distance is placed by the most optimistic engineers at not much beyond five hundred miles. With wireless transmission there will be no limit, except that of terrestrial space, nor will the cost be greater in transmitting power to the antipodes than to the factory a block distant from the generating plant.

Tesla is assured that it will be absolutely unnecessary to have relay or transforming stations, since the consumer can receive the power direct, no matter where he may be situated. Also, there will be no conflict or interference of currents. Two factories situated in the same block, for instance, or two parallel railroads, or two competing steamship lines, could receive their power independently from separate sources, one from Africa, the other from Niagara. And his perfected system of positive selectivity will absolutely prevent an unscrupulous consumer from stealing his power from the air, any more than he could use the key to his barn door for manuipulating the time lock on a bank safe, so complete will be the individualization of currents. Also, this eliminates the element of power monopoly.

IN the field of transportation wireless power will work some of the greatest changes in things as they are. First among all, the steam-driven train and ship will pass into history along with the cradle, the flail, and the spinning wheel. And the noisy chugging of the smoking, foul smelling automobile will soon be a memory.

Professor Tesla has so far perfected his original system of isolation in the transmission of wireless energy that he is able to control, for instance, an automaton in the form of a miniature submarine ship, which he can readily direct and maneuver at will,—starting, stopping, speeding, turning, reversing, diving, rising, by the simple manipulation of wave impulse.



"When my system is complete," says he, "a crewless ship may be sent from any port in the world to any other port on the Seven Seas, propelled by wireless energy from a power plant anywhere on the face of the earth, and controlled and maneuvered absolutely and positively by telautomatics."

The ship in its actual position on the sea would not alone be visual to the telautomatic operator, but there also would be reproduced through the visualizing apparatus or aërocamera a detailed and faithful scene picturing her surroundings and the conditions of sea and weather.

Given wireless power and telautomatic control of ships at sea, that ever menacing *bête noire* of the mariner, the danger of collision in fog and night, or of going on the rocks or shoals, will be eliminated. For the crewless ship the operator, seated in his despatching office on land, surrounded by sensitive devices, with which any point he may elect of earth or sea may be visualized before him, would also "feel" the approach of another ship or the proximity to an iceberg or shoals, when he would easily deflect the course of his ship from danger. Ships carrying only cargo will be crewless, and they will be as water- and air-tight as a submarine, made buoyant by vacuum, and practically nonsinkable.

The future of wireless power development may render it folly for any nation to have afloat a vessel of war. The secret of another nation's scheme of selectivity might be disclosed to the enemy, when the guns of their own vessels might be turned against sister ships and a whole fleet destroyed by shells from their own guns, or their magazines might be exploded by the enemy at will. However, should there be battleships in the wireless future, they will be crewless. They will be maneuvered, their guns will be loaded, aimed, and fired, and their torpedoes discharged with unerring accuracy, by the director of naval warfare seated before a telautomatic switchboard on land.

"The time will come, as a result of my discovery," said Tesla, "when one nation may destroy another in time of war through this wireless force: great tongues of electric flame made to burst from the earth of the enemy's country might destroy not only the people and the cities, but the land itself. I realize that this is indeed a dangerous thing to advocate. At first thought it might mean the annihilation of the nations of the world by evilly disposed individuals. The public might at first look upon the perfection of such an invention as a calamity. We say that all inventions assist the criminal in his work. Today the safe burglar despises the use of dynamite, turning to electrical contrivances to cut the lock from a safe. It is fortunate for the world, therefore, that ninety per cent. of its people are good, and that only ten per cent. are evilly disposed: otherwise, all invention might be turned more greatly to evil than to good."

Nikola Tesla.

As with the ships of the sea, so also the gigantic freight ships of the aërial highways will be controlled, lifted in air, sent whizzing along at two hundred miles—the through express and mail possibly at three or four hundred miles—an hour, lowered to scheduled landing places en route, the progress of the discharge and loading being visible to the operator, and again raised and put to flight by the telautomatic control despatcher at the headquarters of the line. The possibilities of the part crewless warships of the air may play by dropping earth-rending bombs upon the cities of the enemy, is obvious.

WITH wireless propelled passenger air carriers, having decks closed or protected against the strangling, lung drowning rush through the air, traveling three or four hundred miles an hour through routes in high altitudes, one may have a six o'clock dinner in New York and breakfast next morning in San Francisco or London or Paris, or have luncheon in San Francisco and tea next day in Canton or Tokio.

The airship of Tesla's invention will be neither aëroplane nor dirigible, nor will it have wings or gasbags or propeller blades. All these things, he says, are impossible in the construction of a commercially practicable airship. The aëroplane he classes as no more than an amusing toy, a vehicle for exhibition by the venturesome sportsman; nor will it ever be anything more, because in its essential principles it has irremediable flaws that are absolutely fatal to commercial success. Tesla's airship will be proportionately as substantial, as staunch and dependable, and altogether as airworthy as the steamship of today is seaworthy. It will maintain a steady, even keel, and will not be in the least affected by air currents or any sort of weather conditions.

The size of these ships of the air may be limited only by the area of accommodations provided for their landing. Or they may be made small enough, being so easily and simply handled, that the school girl and boy may ride them to and from school, and in greater safety than walking in the city streets. The single or double or triple passenger aërocar of Professor Tesla's type will be more popular, too, for individual and independent transit, either for business or pleasure, than was the bicycle in its heyday, or the gasolene automobile at its best. Then the city commuter of the future may go and come between business and residence on his wireless aërocar, and he may go many miles farther afield, into the uncrowded hills and valleys and sea and lake shore, to make his home.

HOWEVER, before the general public is fully educated to the popular use of aërial navigation as a common utility, wireless power will have been generally, if not universally, applied to the railroads. It is very probable, in fact, aside from the industries and ocean commerce, that wireless power will find its first application to rail traffic. It will be an ideal source of power, and the resulting advantages and economies will be, more truly than tritely, too numerous to mention in anything less than a volume.

Millions of tons of coal will be saved that are now consumed in hauling fuel to coaling points. The use of hydroelectric power will conserve the coal resources. The ponderous, track wearing steam locomotive will be abandoned to the scrapheap. The smoke and soot and grime of travel will be eliminated. Direct wireless connection with the motors under each car will discard the deadly third rail and the hundred-ton electric engine. Wireless controlled safety devices will make collision impossible, and the wireless trains will provide every comfort and electrical convenience of the latest thing in hotels.

The maximum of speed will be determined by the capacity of the track to withstand strain. And wireless power will make it cheaper to cut through mountains, fill valleys and bridge cañons, than to operate on curves and grades. With these abolished and with roadbeds laid on approximate levels, straightaway as the crow flies for hundreds of miles, and with Tesla's gyroscopic mechanism to provide stability and prevent lateral impact, two or three hundred miles an hour may be maintained with safety and comfort. Then one might have breakfast overlooking the Golden Gate and attend a Broadway theater in the evening, and be home again before noon the next day.

Wireless power will make it possible to despatch crewless, light, cigar shaped steel mail cars on curveless, gradeless elevated or overhead tracks across country at an inconceivably terrific rate of speed. It may be telautomatically operated from a terminal switchboard, from where the train may be started, speeded, and stopped, or a "local" car dropped off and another taken on without pause at cities or junctions en route. Letters posted in New York in the morning may then be handed to the addressee by the postman in San Francisco on the afternoon delivery, or to the Chicago business man when he comes down to his office in mid-forenoon.

ONE of the great handicaps to the existing system of wireless telegraphy is the serious interference with messages on account of imperfect control of selectivity, secured principally by tuning. Realizing that such inter-

Continued on page 16

WIRELESS POWER

Continued from page 4

terence limited its greatest usefulness, Tesla has long since been conducting experiments along altogether different lines of transmission, in which he has developed perfect isolation and selectivity. He has discovered that any desired degree of individualization of aërograph and aërophone messages may be attained by employing a large number of coöperative elements and arbitrary variations of their distinctive features and order of succession, so that not only many thousands, but even millions, of simultaneous aërograph and aërophone messages may be sent through one conducting medium without the slightest interference.

The general term "World Telegraphy" has been suggested for Tesla's scheme of intelligence transmission, although "World Aërophony" would be as applicable, since his system will make it as practicable to talk as to telegraph through or round the globe, and as easily to a person using his aërophone at the antipodes as one in an office in the next block. Nor will it require a great, unwieldy contrivance for sending or receiving either aërograph or aërophone messages; such, for instance, as required in the present wireless system. Instead, Tesla assures us, for this purpose a small, cheap, and extremely simple device, so compact and portable that it may be carried in one's pocket, may be set up or held in one's hands anywhere on land or sea while it sends through intermediary transmitting plants messages to any part of the terrestrial universe or receives such special messages as may be intended for it, or records the news of the world as constantly despatched from the various news distributing stations.

Professor Tesla is confident that his system of intelligence transmission constitutes, in its principles of operation, means employed, and capacities of application, a radical and fruitful departure from what has been done before. "I have no doubt," he adds, "that it will prove very efficient in enlightening the masses, particularly in still uncivilized countries and less accessible regions, and that it will add materially to general safety, comfort, and convenience, and maintenance of peaceful relations. It involves the employment of a number of plants, all of which are capable of transmitting individualized signals to the uttermost confines of the earth. Each of them will be preferably located near some important center of civilization, and the news it receives through any channels will be flashed to all points of the globe. Thus the entire earth will be converted into a huge brain, as it were, capable of response in anyone of its parts. Since a single plant of one hundred horsepower can operate hundreds of millions of instruments, the system will have a virtually infinite working capacity, and it must needs immensely facilitate and cheapen the transmission of intelligence."

WITH universal aërophony available by the use of a convenient pocket instrument, the balloonist dropping into the far interior of uninhabited Canada need never be featured in the news as "lost." The explorer straving to reach the earth's poles, or venturing into the wilds of the world's untraveled regions, will be able to keep in hourly touch with his friends, to report his progress to the world, or to send out a call for relief or rescue over bleak fields of ice, the desert wastes, or jungle fastnesses. Also, the man hunting in the big woods, or on a solitary journey on land or sea, can spend an otherwise lonely evening talking with the folk at home. There will never be any reports of "line's busy" by Central on this aëroline. Nor will there be any eavesdropping on "party lines", or delays through an inattentive Central; for, lo! there will be no Central. Each instrument and its operator will constitute an aërophone central in themselves; all calls being direct from the instrument calling to the one called. And any operator with his individual pocket instrument may call any other instrument anywhere on the face of the earth, simply by adjusting the selective device on his instrument to correspond with that of the one desired.

"At my plant on Long Island," says this magician, "when all the apparatus is perfected for commercial use, I shall be able from my aërophone there to call up any 'phone in the universe, and, although apparently inconceivable, it is nevertheless true that my small voice through the delicate apparatus I am completing will be able to set the utmost confines of the whole world trembling with the vibrations of its force. As to the wireless telegraph of today and the incipient wireless telephone, they are but a puny step in the field of wireless transmission.

"Another valuable application of my wireless system," he continues, "will be the driving of clocks and watches from a master wireless time transmitter. These timepieces will be exceedingly simple, will require absolutely no attention, and will indicate rigorously correct time."

THE farmer will be one of the greatest beneficiaries of the wireless transmission of electrical energy; and through him, as a result of increased yields and decreased cost of production, the people of the cities and the public at large.

Some years ago one of the great American inventors claimed the discovery that worn-out soils could be made surprisingly productive by a more or less simple process of electrical treatment, and he rendered the world an immeasurable service in disclosing the process. But it ended there. To deliver a supply of electricity sufficient to consummate the process on the six million farms of the country was quite another problem; for in this case neither the valleys, the plains, nor the hillsides could go to Mohammed to be run as grist through his electric apparatus, but Mohammed must needs go with his equipment to wherever the land to be treated lay.

Through the perfection of his discovery Tesla will provide a way to deliver to every farm, not alone in the United States, but in the universe, enough electricity to apply the treatment effectively. And, presto! the farmer who today rides a plow behind a team of horses or draws a gang behind a tractor, may tomorrow in similar fashion ride an implement operated by wireless power, by which the soil, instead of being turned over as with the plow, will be lifted in furrow-deep slices and run through a wonderfully contrived machine in an endless ribbon, broken up into minute particles and made loose as ashes as it undergoes the necessary treatment by electricity, furnished as part of the wireless transmission, thoroughly pulverized and made firm as it leaves the implement into a perfect seed or plant bed, charged with sufficient available and soluble plant food to produce a quantity and quality of crop yield beyond the present expectations of the most sanguine of modern scientific agriculturists. It is claimed, too, as one of the advantages of wireless electricity, that it will be possible to control the weather in any locality to the extent of either preventing or producing rainfall to meet soil and crop requirements.

Of the two thousand million acres in continental United States, about half is estimated as being capable of cultivation in its present condition. Some of this is so dry you wouldn't think of raising even an umbrella on it. In 1910 our improved farm lands amounted to four hundred and seventy-five million acres. Irrigation and drainage are the principal factors that must solve the problem in the cultivation on most of the remaining vast areas that may be reclaimed and made tillable.

WIRELESS power offers the means of solution. Location presents no bar. Whether current is supplied from a power site in the community, or by a hydoelectric plant in the jungles of Africa, will be of no consequence; the cost will be the same. From distant streams or from great wells on the land the farmer may draw water in literal floods to irrigate his fields, through powerful rotary pumps, another of Tesla's inventions, which have many times greater capacity for their size and require less power than any pump heretofore produced. Or, on the other hand, he may drain semi-submerged and otherwise impossible marsh land, usually the richest of all soil in natural fertility. With the coming application of wireless power to this end, our millions of acres of parched desert lands and dismal swamps may be converted into Gardens of Eden, whence will come billions of tons of grain and fruit and vegetables and millions of cattle from knee-deep pasture lands to meet the demands of an ever growing population.

More than that, every farmstead, wherever located, may have its own individual wireless terminals to operate its field implements, to drive its machinery,—its cutters, grinders, threshers, mills,—and also to lighten the labor in the home, by running the electric washer, wringer, dryer, ironer, the sewing machine, the dough mixer and baker, the chopper, spice mills, cream separator, churn, freezer, and do all the cooking, as well as heat the house in winter and run a refrigerating plant to cool it and manufacture ice in summer.

"In each instance," says Tesla, "a small

terminal placed a little above the roof will be sufficient to furnish light, heat, and power for the isolated farm dwelling."

What farm dweller could feel isolated from the world with such conveniences, especially when there is included in the equipment of the country home a wireless "lineonews" continuously typing the important events of a universe, a wireless recordophone through which, as the operator may elect, may be heard the Sunday morning melody of the choir in St. Paul's or old Trinity, the grand operas of any city, the sermon in any church, the lecture in any lyceum, or may be seen clearly visualized the simultaneous reproduction of the best dramas, while listening to the lines of the actors who may be playing hundreds or thousand of miles distant?

With such readily available sources of entertainment, to be had by turning a switch and pressing a key, the story of the erstwhile dreary winter's eve on the still lone but far from lonely farm, will soon be among the romances to be retold; for with the advent of perfected wireless transmission the farm life of the future may be made far more alluring than life in the cities.

And old Dobbin! Framed and hung somewhere in the farm home will be the picture of a horse, in reverent memory of a noble and worthy service done, that he may not be altogether forgotten in the new age of an energy that will not consume half the crops of a farm to run it, and with better success and profit than ever before.

The World's Work March 1912

THE TESLA TURBINE

A MACHINE AS BIG AS A DERBY HAT THAT GENERATES 110 HORSEPOWER

BY

FRANK PARKER STOCKBRIDGE

WE FOLLOWED Dr. Nikola Tesla through the Waterside Power Station of the New York Edison Company —along narrow passages lined with huge electric switches, the turning of any one of which would throw a whole section of Manhattan into darkness or a blaze of light. We stumbled in the shadows of whirring dynamos, skirted great Corliss engines that seemed to rise from the very bowels of the earth beneath us and détoured past thundering

turbines. Before the largest turbine we paused for a moment.

"Here," said Dr. Tesla, pointing to the huge machine, "is a triumph of engineering skill. This turbo-dynamo, the largest ever made, developing 30,000 horsepower, was built from plans worked out on paper. It was never tested until it was erected here and it worked perfectly from the first turning on of steam. That is engineering. But that is not what we are here for."

We pressed on until we reached an open space where a mechanic in blue jeans was wiping the oil and grease from a machine so tiny in comparison with the gigantic turbine we had just inspected that it seemed like a toy.

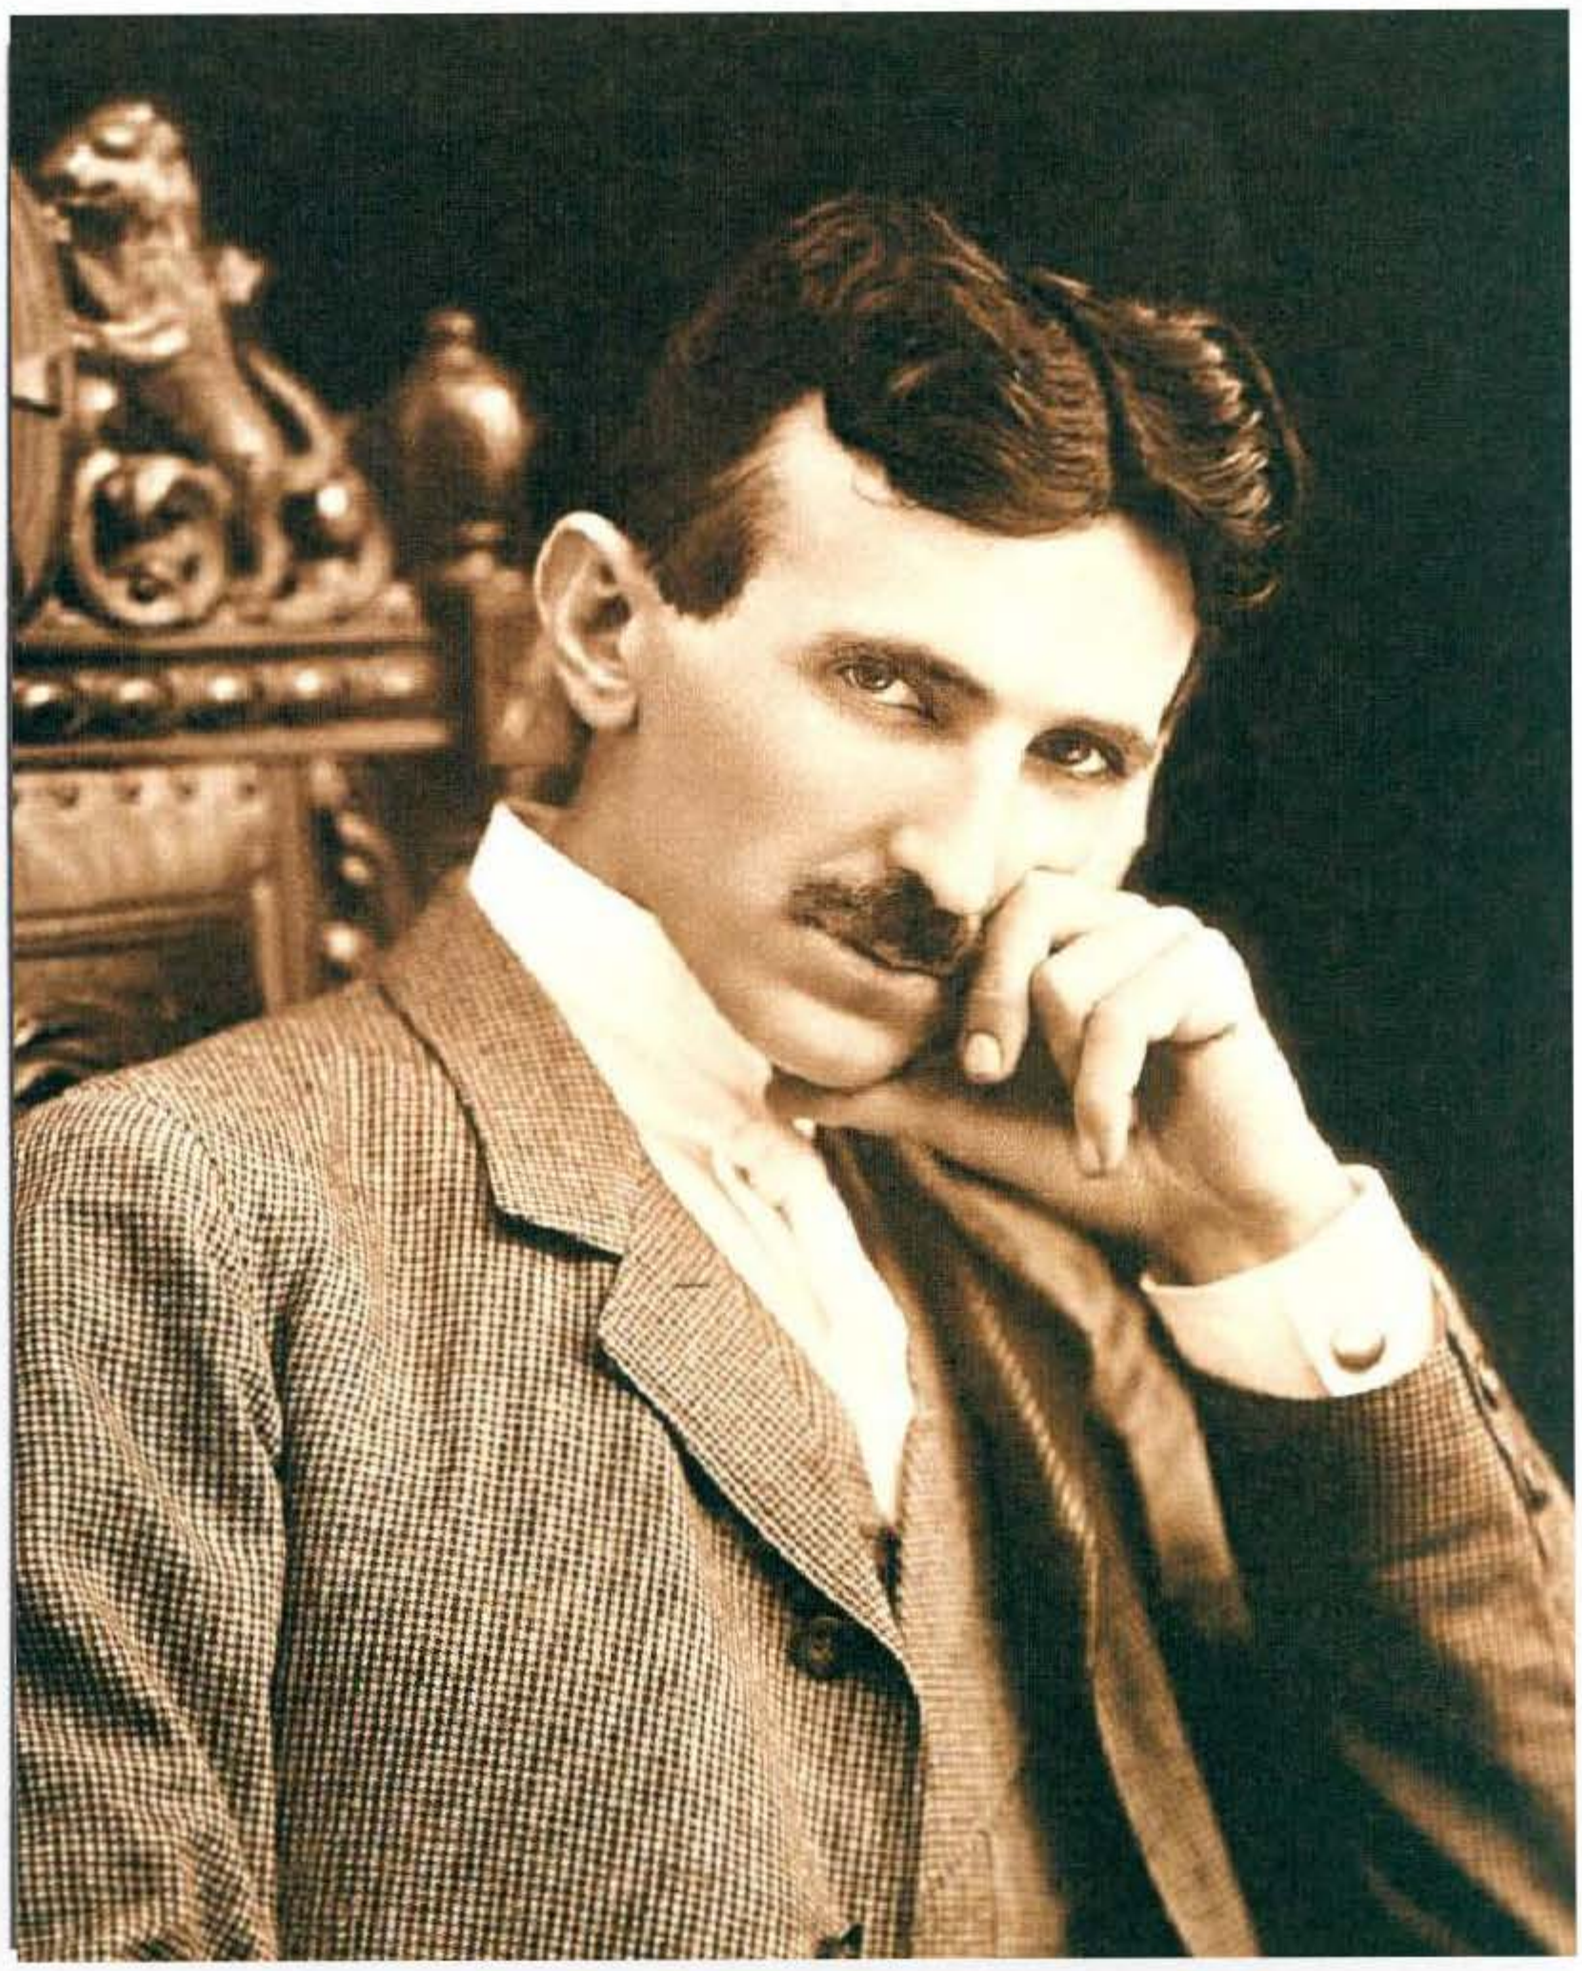
"Here it is," said the tall, thin man — or rather he shouted, for the noise of a hundred thousand horsepower of moving machinery is not conducive to free vocal expression. "Better take off your coats," he continued, "for it is a cold night and it gets pretty hot in here."

We followed his advice and example and stripped down to shirt-sleeves.

"Turn on the steam," said the inventor to the mechanic. The workman gave a valve a short turn. From inside the little machine, which seemed to be composed of two identical parts connected by a spiral spring, came a humming sound; the connecting spring began to revolve so rapidly that it looked like a solid bar of steel and the floor under our feet shook with rapid vibrations which died down. I glanced at a speed-gauge attached to what seemed to be the main shaft of the device and saw that it was registering 7,000 revolutions a minute. I looked up at the main steam gauge overhead and saw a pressure of ninety pounds to the square inch indicated.

Dr. Nikola Tesla, inventor of the alternating-current motor, and pioneer in research into high-tension electric currents generally, was demonstrating his latest invention — a steam turbine, different in principle from any heretofore in use and one which will take less room and less coal per horsepower than the best engines now running. "It's up to its normal speed now — about nine thousand revolutions," said Dr. Tesla, and the tachometer bore out his statement. "You see, for testing purposes, I have these two turbines connected by this torsion spring. The steam is acting in opposite directions in the two machines. In one, the heat energy is converted into mechanical power. In the other, mechanical power is turned back into heat. One is working against the other, and by means of this beam of light we can tell how much the spring is twisted and consequently how much power we are developing. Every degree marked off on this scale indicates twenty-two horsepower." We looked at the scale. The beam of light stood at the division marked "10."

"Two hundred and twenty horsepower," said Dr. Tesla. "We can do better than that." He opened the steam valves a trifle more, giving more power to the motive end of the combination and more resistance to the "brake" end. The scale indicated 330 horsepower. "These casings are not constructed for much higher steam pressures, or I could show you something more wonderful than that. These engines could readily develop 1,000 horsepower," he said, as we watched the turbine running smoothly, steadily, almost noiselessly except for that single clear, musical note.



Standing nearby was another and smaller machine of the same type, connected through a gear-box with a dynamo. The engine itself would almost go into an ordinary hat-box. At a signal from Dr. Tesla the mechanic turned on the steam. Instantly, without the fraction of a second's apparent delay, the dynamo was under full speed, and from the end containing the motor rose the same clear note, indicating a well-balanced machine running freely at its normal speed.

"This little turbine has developed 110 horsepower under tests," said Dr. Tesla. It was about the size of a derby hat.

"Careful tests have shown that the single-stage turbine, running at 9,000 revolutions per minute, with a steam pressure of 125 pounds at the inlet, developing 200 brake horsepower, consumes

38 pounds of saturated steam per horse-power hour," said Dr. Tesla.

"But I can do better than that by compounding," he added. "The heat-drop under the conditions I named is only 130 British thermal units, and that is less than one third of the amount available under

DR. NIKOLA TESLA

WHO, IN HIS SEARCH FOR AN ENGINE SUFFICIENTLY LIGHT AND POWERFUL TO OPERATE THE IDEAL FLYING MACHINE, HAS INVENTED A WONDERFUL LITTLE TURBINE MOTOR, FOR GENERAL USE, THAT IS AN ENTIRELY NEW APPLICATION OF MECHANICAL PRINCIPLES

modern conditions of superheated steam and high vacuum. By compounding the turbines I shall get a steam consumption of not more than eight pounds per horse-power hour.

"The most efficient steam engines in America, big, slow-moving pumping engines working under ideal conditions and constant load, use about eleven pounds. I have undertaken a contract to produce one which will consume less than nine.

"The idea on which all steam engines — gas engines, too — have been built in the past was that there must be something solid and substantial for the steam to push against. The piston of a reciprocating engine and the blades and buckets of modern turbine engines are examples of what I mean. That idea has made them rather complicated devices, requiring careful fitting for efficient operation, great expense for repairs, and, especially in the case of turbines, great liability to

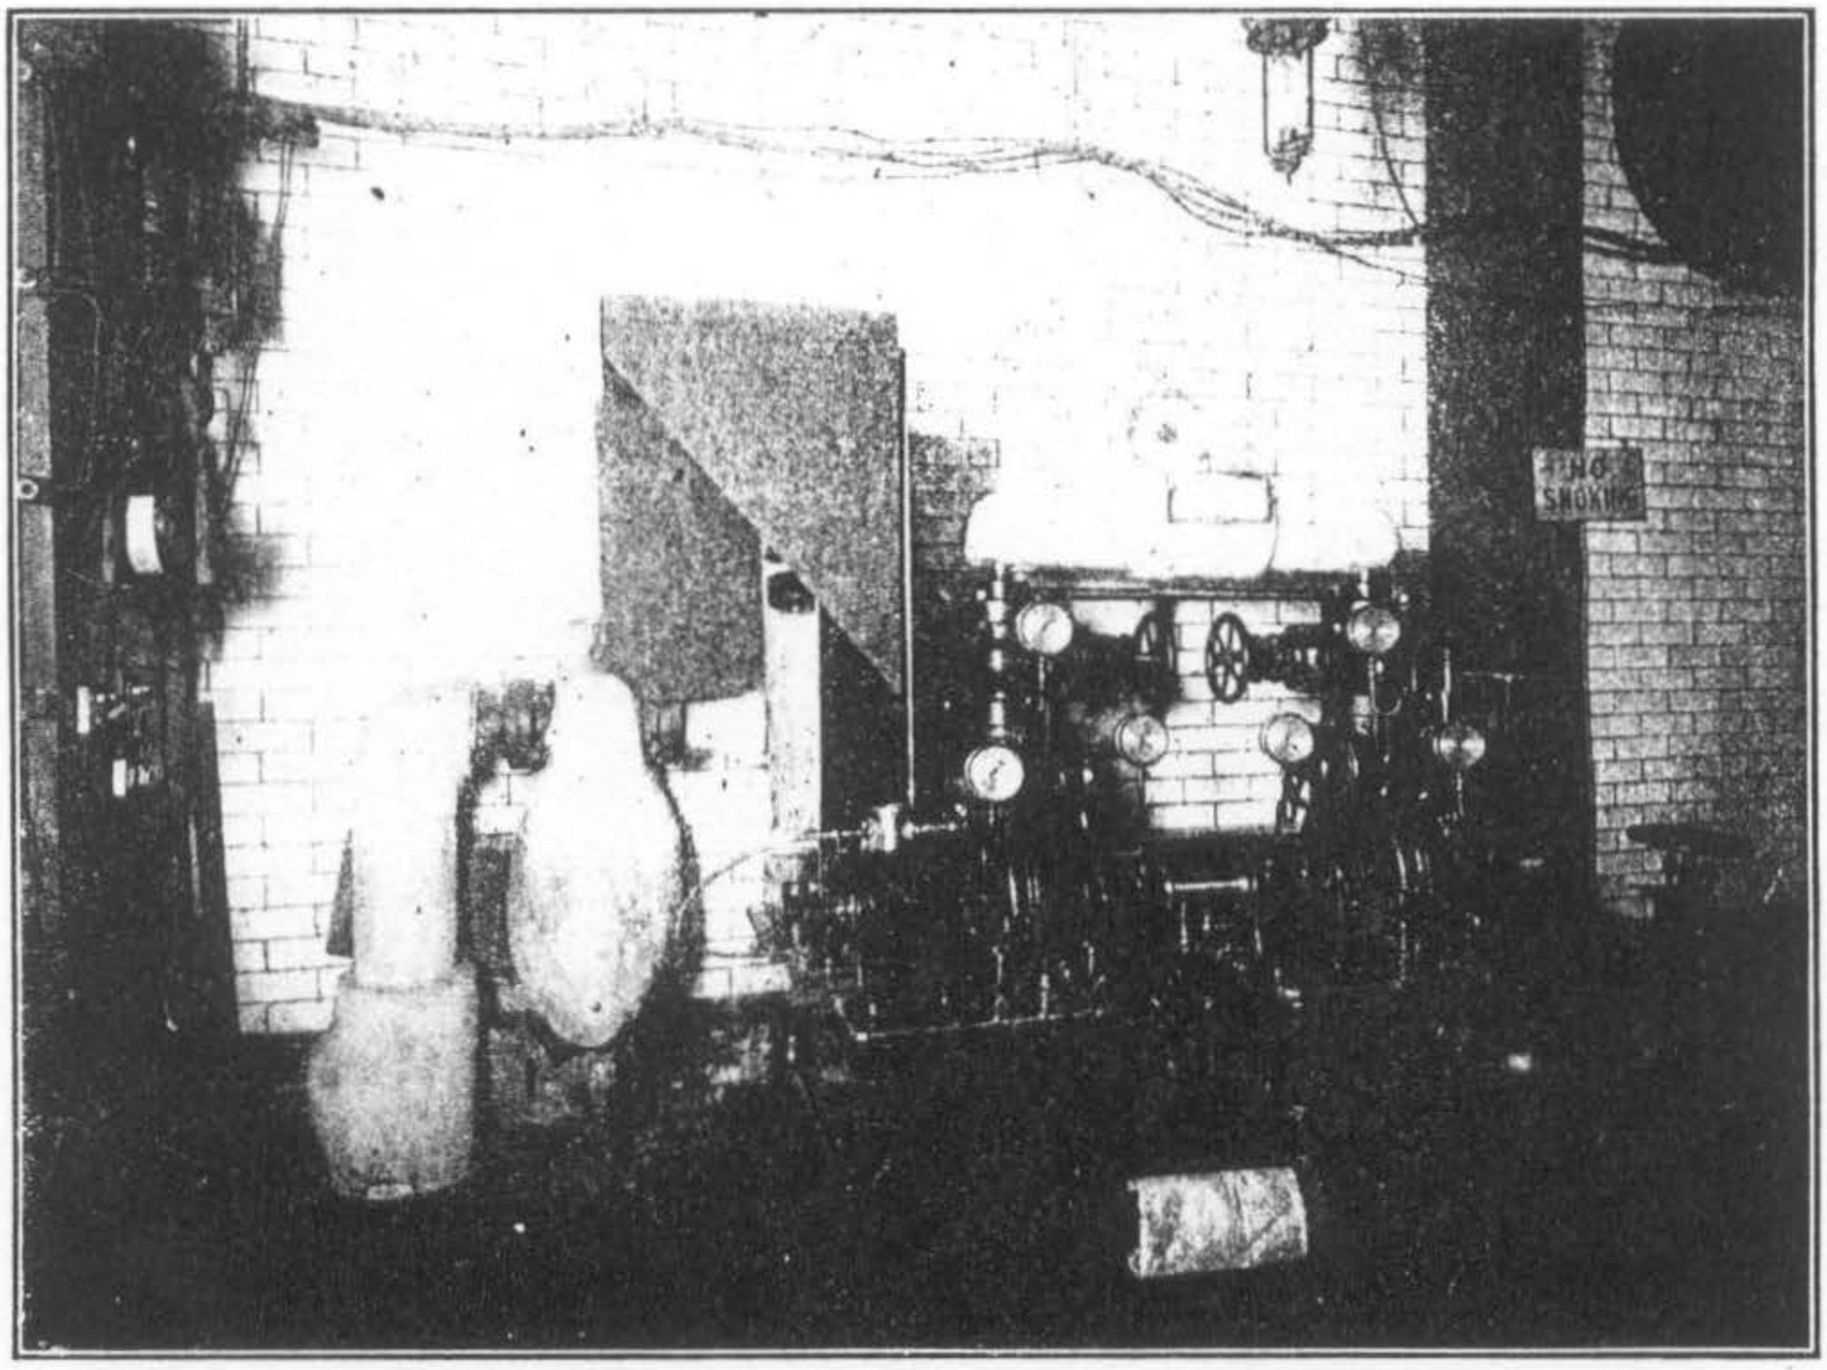
damage. It has also made them bulky and heavy.

"What I have done is to discard entirely the idea that there must be a solid wall in front of the steam and to apply in a practical way, for the first time, two properties which every physicist knows to be common to all fluids (including steam and gas) but which have not been utilized. These are adhesion and viscosity.

"You know that water has a tendency to stick to a solid surface. That is the property of adhesion which every fluid — gas, steam, water, or whatever it be — possesses. You also know that a drop of water tends to retain its form, even against a considerable force, such as gravity. That is viscosity, the tendency to resist molecular separation, and all fluids have this property, too.

"It occurred to me that if I should take circular disks, mount them on a shaft through their centres, space them a little distance apart, and let some fluid under pressure, such as steam or gas, enter the interstices between the disks in a tangential direction, the fluid, as it moved, owing to these properties of adhesion and viscosity, would tend to drag the disks along and transmit its energy to them. It happened just as I had thought it would, and that is the principle of this turbine. It utilizes the very properties which cause all the loss of power in other turbines.

THIS ABSURDLY SMALL ENGINE — TESLA'S SMALLEST MODEL — DEVELOPS 110 HORSE POWER



"Inside of the casings of those engines you saw — instead of buckets or blades or vanes on the edge of a wheel, there are simple disks of steel mounted on the shaft. In the two larger turbines these disks are eighteen inches in diameter and one thirty-second of an inch thick. There are twenty-three of them, spaced a little distance apart, the whole making up a total thickness of three and one half inches. The steam, entering at the periphery, follows a spiral path toward the centre, where openings are provided through which it exhausts. As the disks rotate and the speed increases, the path of the steam lengthens until it completes a number of turns before reaching the outlet — and it is working all the time. In the ordinary turbine the steam passes only around the periphery and the central portion of the wheel is useless. Moreover, every engineer knows that, when a fluid is used as a vehicle of energy, the highest possible economy can be obtained only when the changes in the direction and velocity of movement of the fluid are made as gradual and easy as possible. In previous forms of turbines more or less sudden changes of speed and direction are involved."

Later, in his laboratory in the Metropolitan Tower, discussing the commendations which eminent engineers, many of them with international reputations, have expressed concerning his turbine, Dr. Tesla summarized the points that make it a long step in advance in mechanical engineering.

"To say nothing of it being a new application of mechanical principles," he said; "it has many decided advantages. First of these is its simplicity. It is comparatively inexpensive to construct, be-

cause nothing but the bearings need be accurately fitted, and exact clearances are not essential. Then there is nothing in it to get out of order and the disks can easily be replaced by any competent mechanic. It can be reversed without complex or cumbersome apparatus — all that is needed is a two-way valve to let the steam in at one side or the other, as desired. Reversing an ordinary turbine is next to impossible.

"My machine occupies, as you saw

TESTING THE SPEED, POWER, AND STEAM PRESSURE OF A TESLA TURBINE

THE PICTURE SHOWS TWO ENGINES, EACH CAPABLE OF PRODUCING 330 HORSE-POWER, WORKING AGAINST ONE ANOTHER FOR TEST PURPOSES, THE TORSION SPRING CONNECTING THE TWO BEING USED TO INDICATE THE AMOUNT OF POWER DEVELOPED

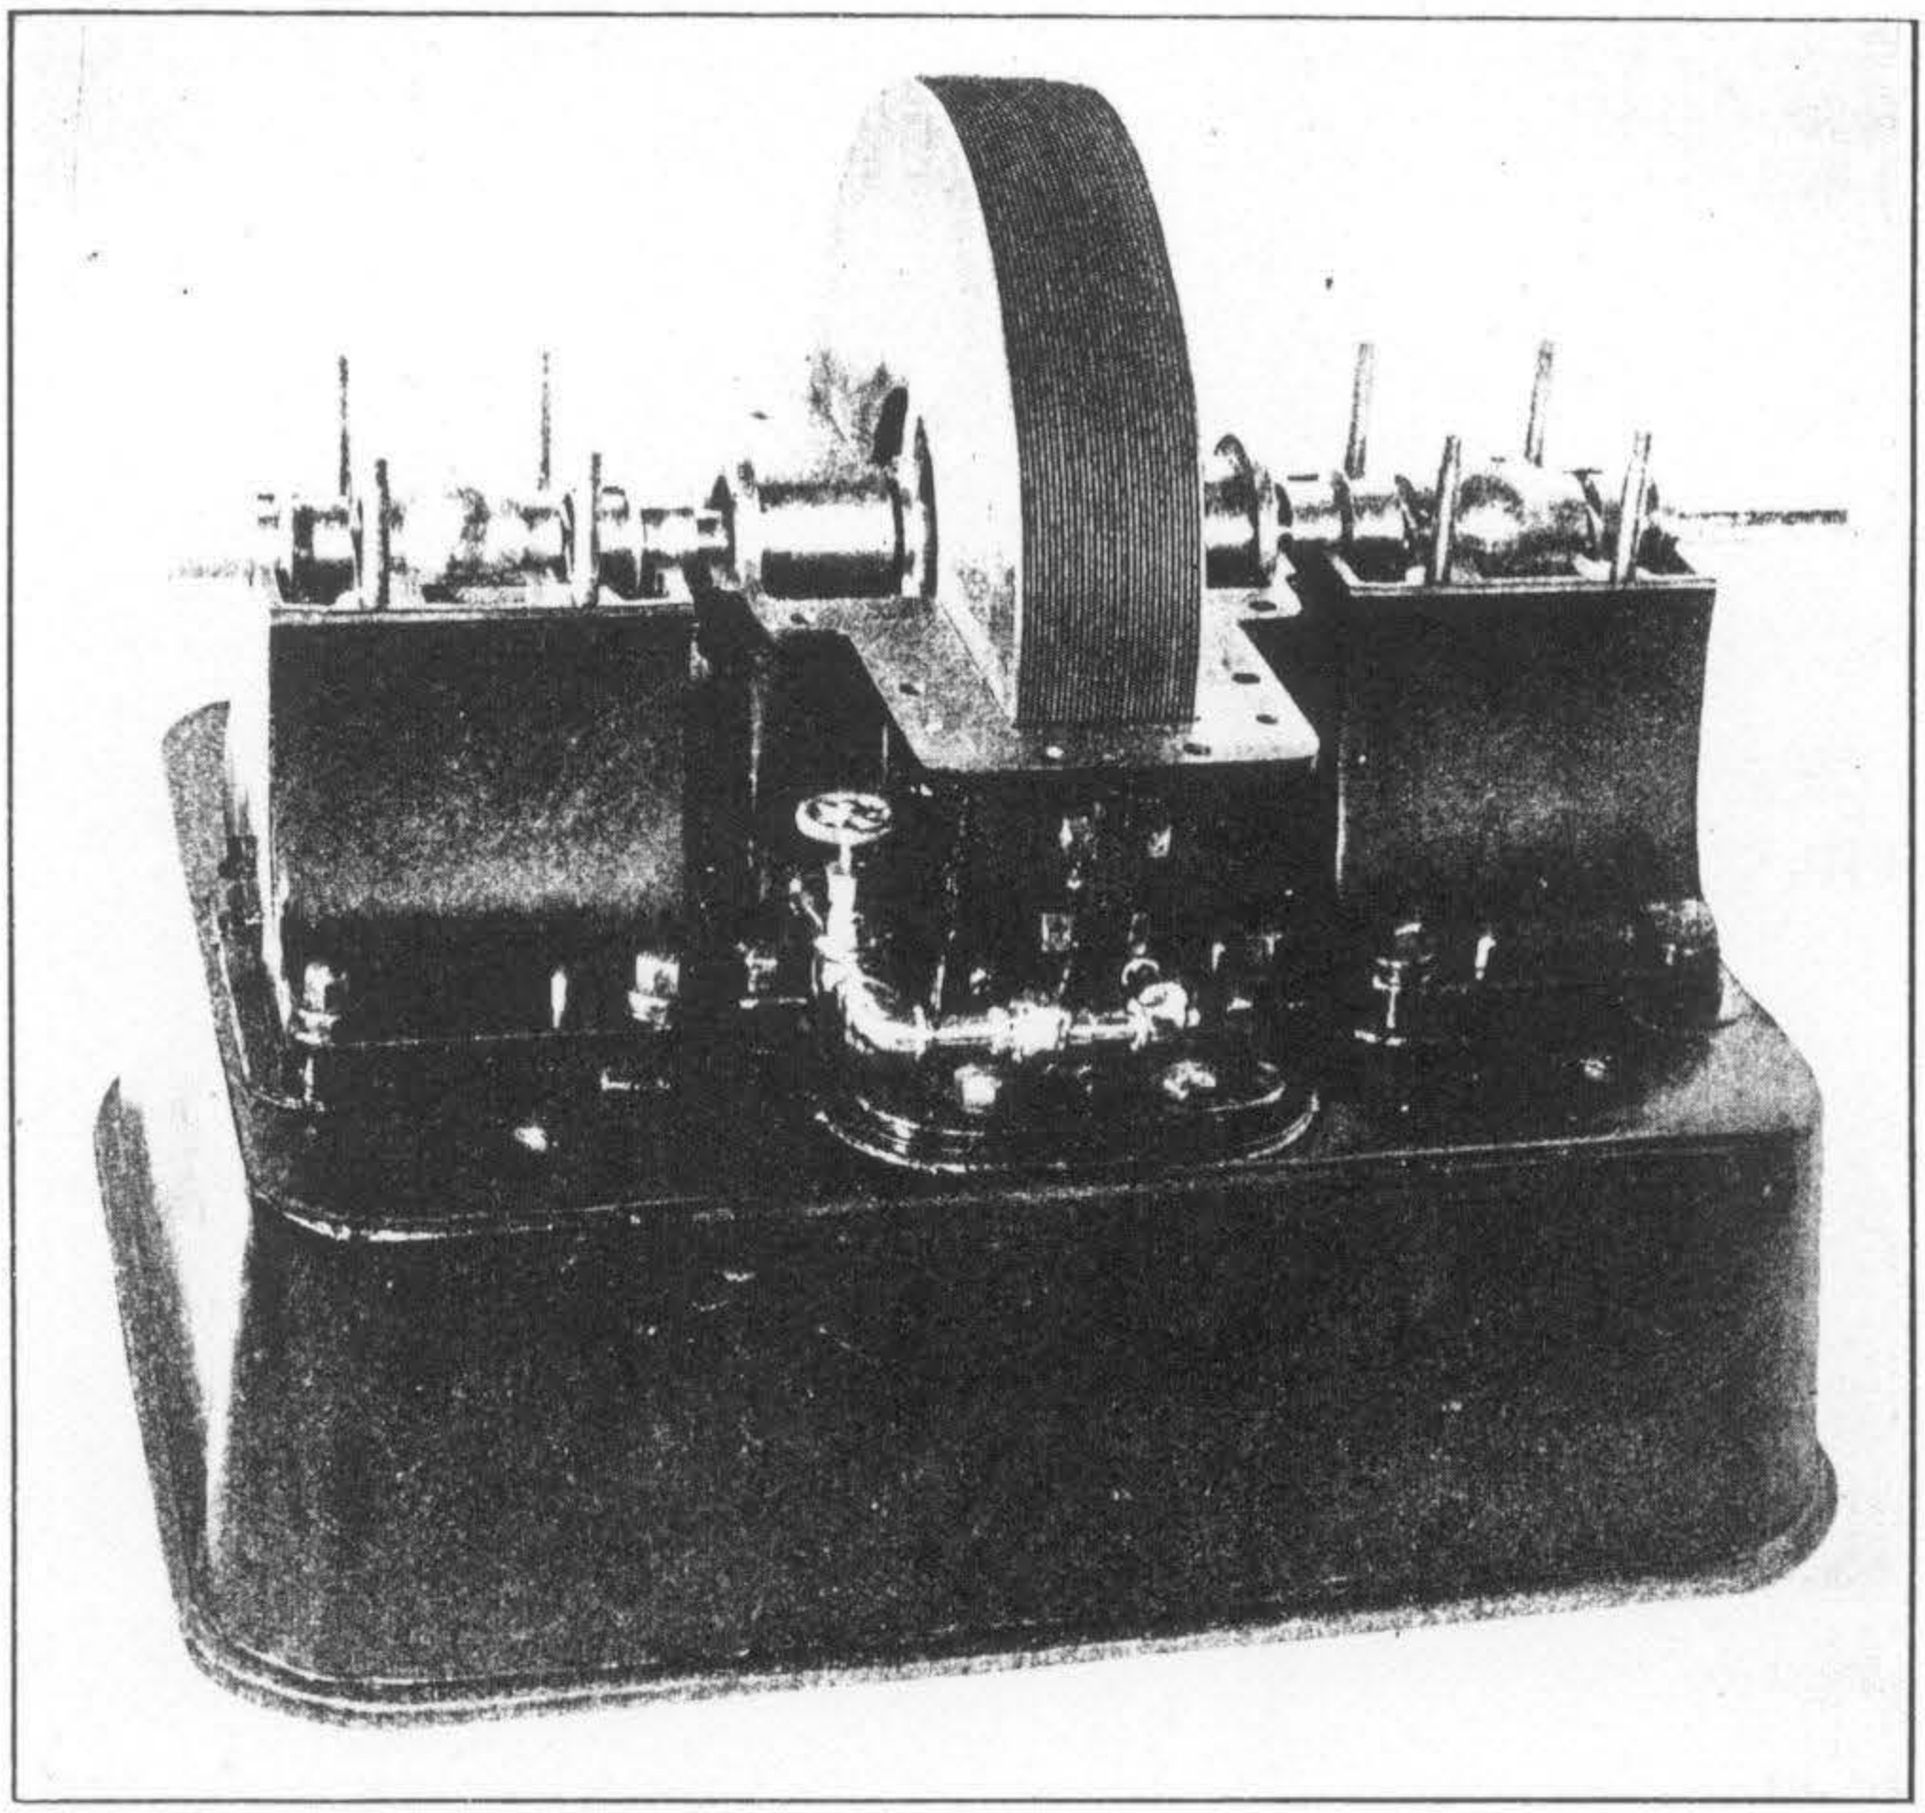
little space — the 110 horsepower turbine has disks only $9\frac{3}{4}$ inches in diameter — and in consequence it weighs very little. The lightest engines now in use weigh $2\frac{1}{2}$ pounds to the horsepower, while these, in their crudest forms, weigh less than that, and I expect to be able to produce 10 horsepower to the pound. Using gas instead of steam it gives most gratifying results, doing away with the complicated valves and springs of the prevailing types of gas engines. Another interesting application of it is as a pump, either for water or for air. The same disk arrangement is used, but the casing is so arranged, when built as a pump, that the fluid enters at the centre and is ejected at the periphery." He led the way into an adjoining room where a tiny turbine pump, with disks only three inches in diameter, operated by a one twelfth horsepower electric motor, was pumping 40 gallons of water a minute against a 9-foot head.

"How did you happen to turn your attention to mechanics instead of electricity?" I asked.

"I was a mechanical engineer before I ever took up electricity," replied Dr. Tesla. "I went into electric science years ago because I thought, in that direction, I was going to solve the problem I have been working on all my life — the production of an engine sufficiently light and powerful to operate the ideal flying machine. All my work in the wireless transmission of power, which has at-

tracted more public attention than anything else I have ever done, was toward that end. I do not expect to build that ideal machine to-morrow, any more than I expect every steam engine in the world to be thrown into the scrap-heap because of this new application of mechanical principles, but such a flying machine will come some day, and meantime I have succeeded in developing something new in prime movers. I am young yet and have plenty of time ahead of me."

I remembered that it was twenty-seven years ago that he had come over from Lika with the principle of the rotating field for alternating current motors already worked out, and began some mental calculations, which Dr. Tesla noticed.



"My age? What do you think it is?" he asked.

"If I didn't know better, I'd say around forty," I ventured. "Fifty, for a guess."

"Fifty-four," was the answer.

"And you still expect to perfect your flying machine?"

"Why not? I have half a century yet to live, if no accident happens. One of my grandfathers lived to be 118, the other past 100. One of my mother's grandfathers won a footrace at the age of 73. I hope it will not take me fifty years to perfect the flying machine, but if it does, I expect to be young enough at 104 to make a flight in it. The Tesla turbine will be on the market long before that, however."

SHOWING THE SERIES OF THIN DISKS BETWEEN WHICH THE STEAM PASSES AND WHICH, BY THE POWERS OF ADHESION AND VISCOSITY, THE STEAM DRAGS WITH IT IN ITS REVOLVING COURSE

Electric Show Ready For Week of Triumph

Exposition Will Open to he Public Again at 10 o'Clock This Morning.

Rotary Club Members We ing Full Dress to Appear Tonight.

Nikola Tesla, the Man Who "Dreamed," to Be Paid Homage Today.

Following one of the most successful opening nights in the history of the Northwestern Electric Show association, and an entire Sunday spent in perfecting and arranging belated exhibits the third annual Northwest electrical exposition will again be thrown open to the public at 10 o'clock this morning.

Electrical experts from all over the country are present and some of the most noted speakers in the electrical world will address the four electrical conventions which are being held in connection with the show.

Complete exhibits from the Edison laboratories at Orange, N. J., are being explained and demonstrated by Miller Reese Hutchinson Thomas A. Edison's chief engineer and his personal representative who arrived here Saturday, and he is assisted by a corps of Edison factory representatives, two of whom have traveled all the way to Minneapolis from the plant of the General Electric company at Schenectady, N. Y. Nelson C. Durand, second vice president of the Thomas A. Edison company at Orange, N. J., arrived Saturday to take charge of the Edison talking machine, dictagraph and dictaphone exhibits.

W. D. W. Ryan, one of the foremost illuminating engineers of the day, who has just completed an inspection of the Panama canal where he was sent by the United States government to investigate the illuminating possibilities of the great inter-oceanic highway, will come to the show direct from Colon.

He was slated to address the convention of the American Institute of Electrical Engineers today on "Lighting From the Early Ages to the Present Time," but a telegram from his received last night by Manager Clark announced that he had missed train connections in New Orleans and would not reach here until tomorrow morning. His address will be delivered at tomorrow afternoon's session.

Many Visitors Here.

The many electrical conventions and the electric show are filling the hotels with electrical visitors and there are already delegations here from Chicago, Duluth, Superior, Milwaukee, La Crosse, Winona, Red Wing and all of the vicinity cities, while every train is bringing electricians from the East, from Canada and far Western points.

Miss Blanche Mehaffey, soprano soloist from Cincinnati who opened her engagement at the show Saturday afternoon, spent yesterday with the First regiment and at the Armory rehearsing the special St. Patrick's day music which will be a feature of today's program. Miss Mehaffey will sing two numbers both afternoon and evening and there will be special cornet solos by Professor Carl Carcifini. The band numbers will include such appropriate selections as Bennett's "Irish Echoes," "The Green Flag," by Claus, Bennett's "Wearing of the Green" and similar numbers.

Tonight will also be Rotary club night at the show, 200 members of the organization having decided to visit the show with their families. They will wear full dress. This action was decided upon at a dinner of the club held at the Hotel Radisson Friday, when Manager Clark and Mr. Burns of the Flour City Iron Works addressed the members on the value of the electrical exposition from an educational standpoint. There are six exhibitors at the Armory show who are members of the organization.

Nikola Tesla Honored.

Nikola Tesla, the man who "dreamed" of the wireless telegraph and announced its possibilities to the world more than 10 years before the time of Marconi, the man who proved his ability to wreck tall buildings by the vigrations of an electric machine of his own invention, the "dreamer" who declared he was able to split the earth in twain by similar vibration, is the man honored by the electrical exposition today. Today is named Tesla day after him.

Mr. Tesla gave to the world the alternating current, without which long distance transmission of power would have been impossible. He now is working on the transmission of power by wireless, and says if he cannot accomplish his purpose he is willing to lay his head upon the block. He is again "dreaming," but in his dreams are as well founded as those he previously made public, the next 10 years will show an electrical revolution which will far outshine anything to date.

Demonstrations of Tesla's wonderful coils and inventions will be the order of the day, and his message to the people will be received by Archbishop John Ireland.

Archbishop Praises Electric Exposition

Stamp of Approval Is Placed on the Show by St. Paul Prelate.

Messages Exchanged With Tesla, Who Makes Prophecies for Future.

Night Is Turned Over to Rotary Club and St. Patrick Program.

TUESDAY, WESTINGHOUSE DAY.

Afternoon.

March, "Italian Songs" ..... Panella
Overture, "Light Cavalry" ..... Suppe
Waltz, "Artist's Dream" ..... Vollstedt
Chilian dance ..... Missud
Vocal selection, with orchestra .....
Miss Blanche Mehaffey.
Fantasia, "Napolitana" ..... Boccalari
Characteristique, "The Dawn of Love" .. Bendix
Barn dance, "Mandy, How Do You Do?" . Lampe
Finale, "The Old Town Is Looking Good Tonight" ..... Mills

Evening.

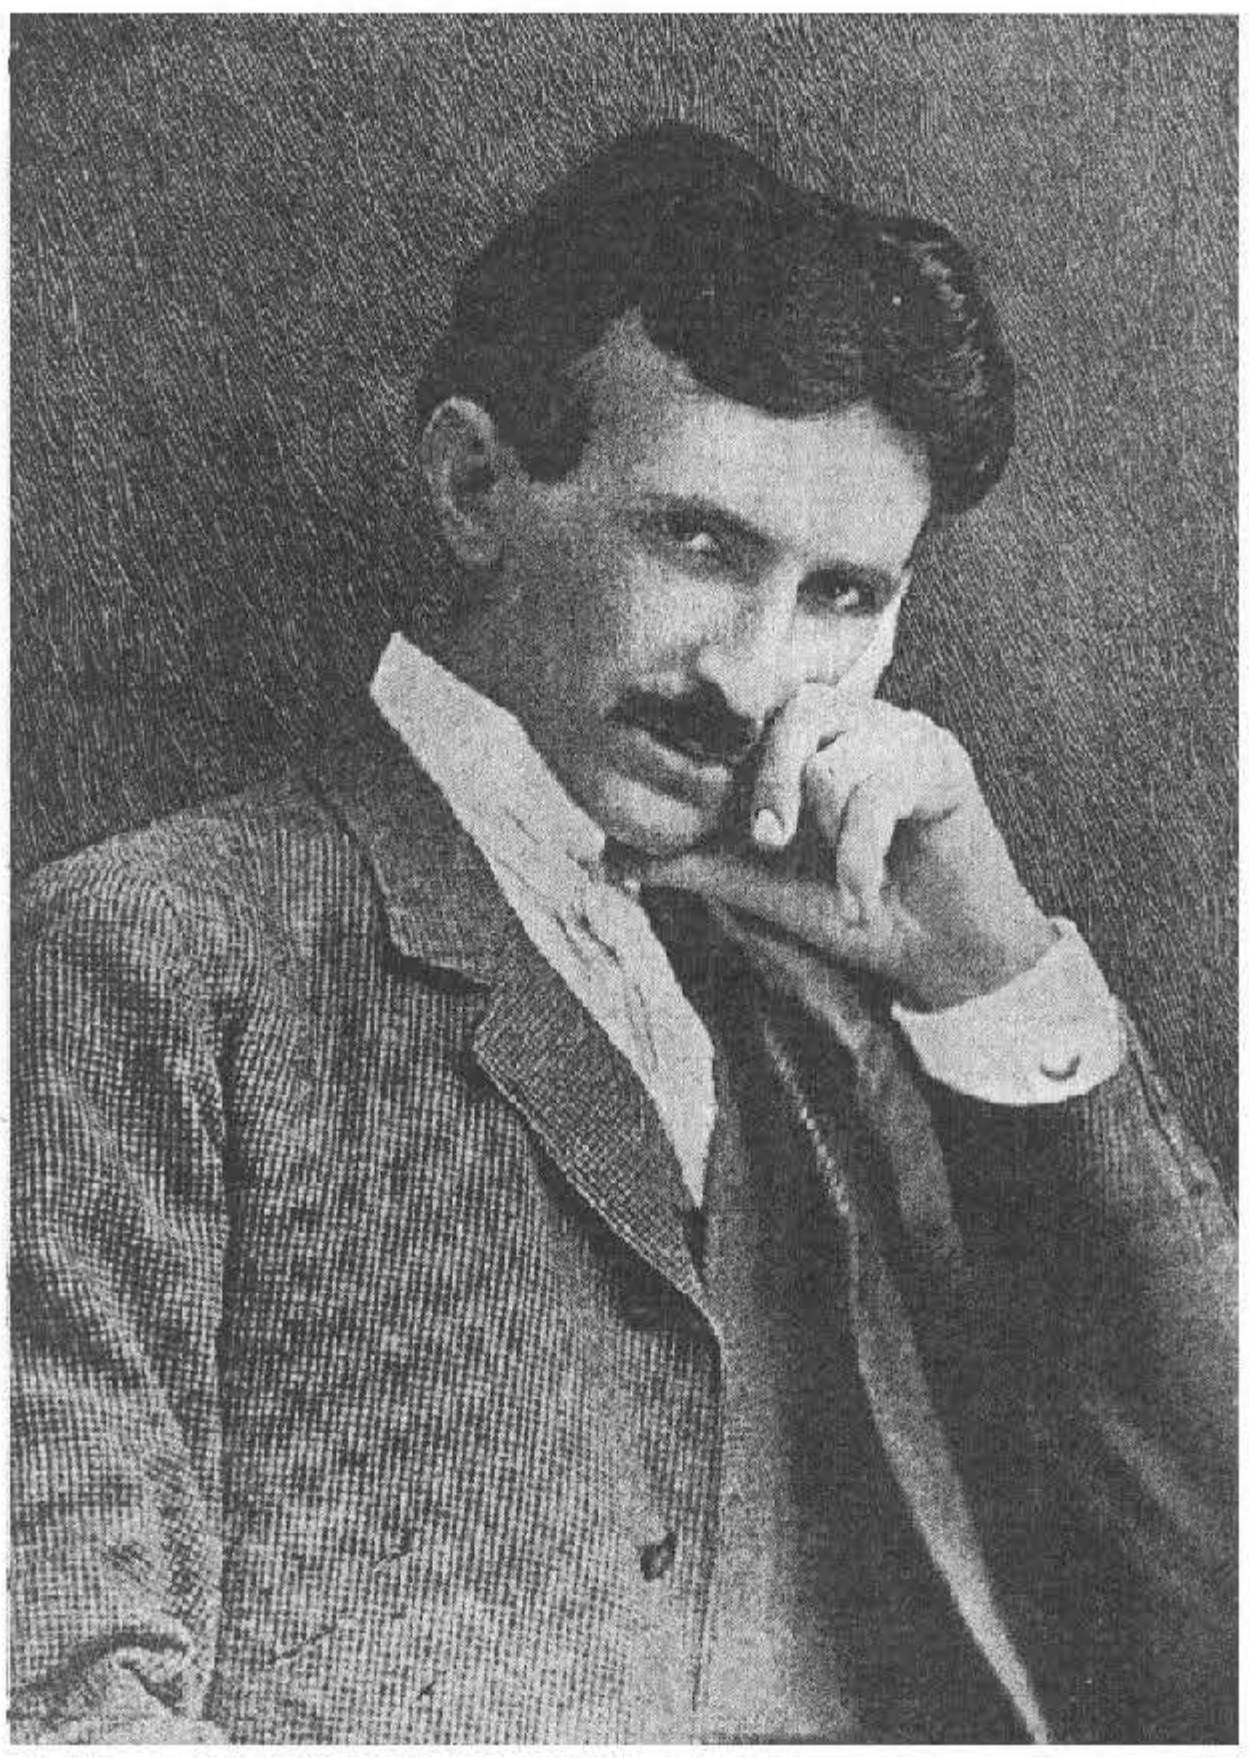
Maren, "Nieblungen" ..... R. Wagner
Waltz, "Don't Be Cross" ..... Zeller
Overture, "Les Dragons De Villars" .. Hilbrecht
Selection, "Chocolate Soldier" ..... Strauss
Vocal selection, with orchestra .....
Miss Blanche Mehaffey.
Selection, "Lucretia Borgia" ..... Donezitti
Idyl, "The Mill in the Forest" ..... Ellenberg
Patrol, "Southern" ..... Voelker
Finale, "The Red Rose Rag" ..... Wenrich

Archbishop John Ireland, of St. Paul, put his stamp of approval on the Northwestern Electrical Exposition yesterday by presiding at the opening of the afternoon show and receiving in person the message of the great inventor, Tesla, which he read from the rostrum.

Despite the fact that it is Lent the Archbishop very willingly consented to open the afternoon's exposition, declaring that on account of its educational value the show deserved the cooperation of every resident in the great Northwest which had produced it.

Mr. Tesla's message, which was directed personally to Archbishop Ireland, made great promises for the future of electricity. He said in part: "Mysterious as ever before, nature yields her precious secrets more readily and the spirit of man asserts his mastery over the physical universe. The day is not distant when the very planet which gave him birth will tremble at the sound of his voice; he will make the sun his slave; harness the inexaustable and terribly intense energy of microcosmic movement; cause atoms to combine in predetermined form; he will draw the mighty ocean from its bed, transport it through the air and create rivers and lakes at will; he will command the wild elements; he will push on and on to greater deeds, until with his intelligence and force he will reach out to spheres beyond the terrestial."

Religion Salutes Science.



Commenting on the message, the Archbishop said: "It is pleasing to listen to the prophecies of so great a man as Tesla. It shows what man with persistent effort and application can do. The laws of nature are wondrous but what are laws without the Law Giver? The more we know of nature the more we admire the Great Being who fashioned the world, and so religion salutes science and bids it go forward. As a representative of religion I bid all success to science—true science is a tribute to the immortal God."

Last night was Rotary club night, more than 200 members of the club, in full dress, with their families attending the exposition as a tribute to six members of the club who are exhibitors at the show. Last night, also, was St. Patrick's night and the "Wearing of the Green" was not only a feature of the St. Patrick's day musical program, but also was characteristic among visitors at the show.

The American Institute of Electrical engineers opened their convention at the Armory yesterday afternoon when Miller Reese Hutchinson delivered a paper on the "Edison Storage Battery."

NIKOLA TESLA

Eminent Electrical Engineer, Physicist and Inventor, Whose Work Has Attracted World-wide Attention.

Nikola Tesla, whose name is familiar in every part of the globe where scientific research is conducted, was born in 1857, in Smiljan, Lika, border country of Austria-Hungary; the son of a distinguished clergyman and orator, and of Georgiana Mandic, a famous woman and inventor, whose father was also an inventor. His education began in the elementary school of his native place, continued four years in the public school in Gospic, Lika, four years in Lower Real school in Gospic, and three years in Higher Real school, Carlstadt, Croatia, where he was graduated in 1873. Originally destined for the clergy, he prevailed upon his parents to send him to the Polytechnic School in Gratz, where, for four years, he studied mathematics, physics and mechanics, following with two years of philosophic studies at the University of Prague, Bohemia. He started on his practical career in 1881, in Budapest, Hungary, where he made his first electrical invention, a telephone repeater, and conceived the idea of his rotating magnetic field; thence he went to France and Germany, where he was successively engaged in various branches of engineering and manufacture. Since 1884 he has been a resident of the United States, of which he is a naturalized citizen, and here his subsequent inventions originated.

Among his inventions and discoveries are: System of arc lighting, 1886; Tesla motor and system of alternating current power transmission, the "Tesla coil" of transformer, which has proved an indispensable adjunct in many electrical arts, 1891; investigations of high-frequency effects and phenomena, 1891-93; system of wireless transmission of intelligence, 1893; mechanical oscillators and generators of electrical oscillations, 1894-95; researches and discoveries in novel radiations, material streams and emanations, were published in a series of papers in the "Electrical Review," New York, 1896-1898, in which he announced all the salient phenomena later attributed to radium; high-potential magnifying transmitter, 1897; system of transmission of power without wires, 1897-1900; economic transmission of energy by refrigeration, 1898; art of Telautomatics, 1898-99; discovery of stationary electrical waves in the earth, 1899; burning of atmospheric nitrogen, and production of other electrical effects of transcending intensities, 1899-1900; method and apparatus for magnifying feeble effects, 1901-1902; art of individualization, 1902-1903. The development of his system of world-telegraphy and telephony and of the transmission of power without wires has engaged much of his attention since that time. His most important recent work is the discovery of a new mechanical principle, which he has embodied in a great variety of machines, as reversible gas and steam turbines, pumps, blowers, air compressors, water turbines, mechanical transformers and transmitters of power, hot-air engines, etc. This principle enables the production of prime movers capable of developing ten-horsepower, or even more, for each pound of weight. By their application to aerial navigation, and the propulsion of vessels, high speeds are practicable.

TESLA PREDICTS MORE WONDERS

Annihilation of Space Will Be Work of the Coming Generation.

WIRELESS WILL DO IT

Transmission of Intelligence and Energy and Transport of Materials.

EXTENSION OF SIGHT

One Person Will See Another as Though That Other Were by His Side.

SOLUTION FOR AIR TRAVEL

Inventor Also Declares Electricity Will Cure Mental Ills of Children

A past generation saw the invention of the steam engine and the epochal change which it wrought in the world of industry. Methods and appliances which were regarded as permanent as the mountains passed with the coming of steam. Many of them are remembered only as curious remnants of a cruder mechanical age.

Then came the introduction of electricity to practical purposes. Now the world depends on this invisible agent as the nerve force sustaining it on its onward march. Scientific primers that were printed within the recollection of older men and women speculated about this development of electrical force and guardedly discussed its possibilities. Predictions made as to the future use of the electric current and its commercial possibilities seem absurdly conservative now, when scientists reread them in the light of actual developments.

What is to be the big change of the coming age? Has science reached the limit of its resources? Along what line will the next developments come?

Man has overcome many of his physical limitations, scientists explain, by chaining the forces of nature and making the earth and the air work for him. He has multiplied his muscular strength a billion times, but there is one problem the solution of which will be the great work of the coming generation. That is the annihilation of distance. Wireless will do this, says Nikola Tesla, the inventor.

"In the last few years many wonderful possibilities have presented themselves," explained Mr. Tesla, "but, in my opinion, none will be of such far reaching consequence as the complete annihilation of space. This will be accomplished in three fields, the transmission of intelligence; the ransport of bodies and materials and the conveying of the energy necessary to the sustenance of modern life.

"If carefully analyzed all the clashes between individuals and nations and their disastrous results can be traced to the physical impossibility of getting into close contact. Annihilate distance in thought and action and you will give unbounded opportunities to the economic, healthful and peaceful development of mankind. This annihilation of distance will be brought about by the transmission of energy without wires.

"As regards intercommunication a great step has already been made, but a fuller realization will come when a system is introduced enabling any person to reach any other on the globe, and not simply through a spoken word, but visually. I mean by this that not only must there be a telephone connection from one to any other point, but also a perfect transmission of images which will enable one person to see another as though that other were by his side.

"The next step will be the transportation of bodies and materials through the medium of flying machines operated from wireless plants. The introduction of power for this purpose will do away with all the limitations that now confront aerial navigation and make travel through the air entirely safe and comfortable. The third step will take a much longer time for realization but will ultimately be accompliahed by the general introduction of wireless power for all necessities."

Mr. Tesla pictured an age where the great operations of commerce and industry would be vitalized by central distributing wireless stations. There are in the world many natural sources of tremendous power. The falls of Niagara alone might be made to supply a fifth of all the power used in the United States. The present difficulty is that of electrical transmission by wire. It is not only the heavy cost of long lines of copper wire that hampers the distribution of the energy that might be generated at the great falls, but power can only be carried over wires for a comparatively limited distance. Wireless transmission would take that power and carry it to the ends of the earth with little loss.

The scientist points out that the power that could be derived from the waterfall of the Columbia River and the great falls of Zambesi in the heart of Africa could be brought to New York city and made to run the subway trains.

Ocean going boats would no longer need to carry their thousands of tons of coal. This fuel might be consumed in a central station, where the expense and waste of a dozen different handlings would be eliminated. If the ship were delayed by accident to her machinery in midocean there would be no fears that the coal supply might not hold out. The ship would be in constant touch with her source of enrgy supply as well as in communication with the outside world at every point of her course.

The possibilities of airship travel have so far been limited by the fact that aeroplanes and airships have no room or carrying capacity for the fuel necessary to an extended trip where there was no possibility of reaching a base of supplies. Such a trip would be a flight over the ocean. Wireless power would end this difficulty, Mr. Tesla explains. The aeroplane would be drawing energy from a central source, and it would make no difference whether it remained in the air an hour or a year so far as power supply went. Such airships might be controlled from the land as easily as though the operator were seated at the steering wheel. This, however, would not be as satisfactory an arrangement, Mr. Tesla thinks, as to have an engineer with the machine at all times.

But why tranamit power when the sun gives it so abundantly at every point? Why not harness sunlight?

"It is true that the sun's energy might be captured and made useful at any spot," said Mr. Tesla, "but it does not take long to see that it would not be as useful as the transmission of energy from a central plant, for the former would lead to individual independence, while the latter would tend to bring about a close union of interests and harmonious cooperation. It would make war impossible."

Anybody whose imagination is vivid enough can make a prediction. It is easy enough to think up situations which would be pleasant and make for the betterment of the world. Mr. Tesla states his forecasts are founded on a sound experimental basis.

"These are not forecasts," he replied in response to this objection, "they are facts. Experiments and demonstrations to this effect have already been made by me, and if it were not for the unavoidable inertia of human movement the idea would have materialized and I would be telling you of still greater wonders.

"I have demonstrated in actual tests that a powerful current from a wireless transmitter properly organized sets the entire plant into vibration like a wire, with the result of producing stationary nodes and loops. To the electrician this means that the current wave traverses the globe without appreciable loss and that, therefore, all kinds of impulses from the feeble electrical tremors caused by the human voice and affecting the sensitive diaphragm of a telephone to the powerful waves of a trolley wire can be transmitted integrally from one end of the globe to the other.

"For some years this discovery has been ready for commercial application, but you must understand that any idea so revolutionary as this one must meet with a proportionate resistance. his is the law of nature. Every effort in a new direction creates antagonism, which can only disappear when the world as a whole grasps the new truth and learns to appreciate it. Take the Panama Canal as an example. What troubles and delays have occurred and are still happening and retarding the undertaking's successful termination!

"One thing of great practical value that is being done now is the training of wireless experts, without whom such results as I have forecast would be impossible. There are 100,000 wireless amateurs in the United States. Some of these will develop into men who will bring these new ideas to their full fruition.

"In the meantime wireless communication is being extended and plans are being perfected for transmitting energy on a larger scale. I should think it would be safe to say that in the next three years a word spoken in New York city will be carried around the world. With proper instruments it could be made audible at any other point of the globe and intensified so as to be heard for miles.

"An objection is raised that the wireless art is fatally limited in the number of the signals transmissible and in their liability to interference. But this is a great popular mistake. It is true that in conveying signals through the earth we are availing ourselves of only a single medium, but it is infinitely more perfect than any artificial channel. The privacy of a message over a wire is solely based on the isolation of the conductor in space, which can be broken down. In the transmission through the earth the secrecy of the transmission is resting on the much safer basis of an arbitrary combination, which can be so intricate that it is as inscrutable as thought. Far from being less perfect, the wireless in its highest perfection is ever so much superior to the wire.

"As to the question of what effect wireless transmission of energy would have on the burning and transportation of coal it is hard to give a definite answer. One cannot tell to what perfection the means of transportation may be brought. Of course we shall never be able to overcome the inertia of mass and, therefore, limits to speed will forever be imposed even in transportation through the air. But we may learn how to concentrate the energy of coal and multiply the rate of transported energy.

"Water power alone is not sufficient for the needs of man, although it will go far toward increasing his opportunities. Coal is still our chief source of power, and a small part of its wasted energy is greater than all the water power available in the world. For instance, the manufacture of iron and steel in this country entails, according to my computation, an annual loss of power which would yield if properly exploited an annual income of not less than $300,000,000. I feel that a solution has been found, and in the near future a new resource will be opened up which will be of incalculable effect."

Nikola Tesla does not think that Prof. Ramsay's notion of burning coal in the mines or as it is found in the earth would be practical.

"The idea is ingenious," Mr. Tesla went on, "and not at all unrational, but on careful computation it will be found that more power can be derived by mining coal and burning it under proper conditions than by using it in the manner proposed by Prof. Ramsay. Another problem presented by his scheme would be that of finding employment for countless thousands who are now earning their living in mining."

He believes high frequency currents will have an important use in the future. He explains he has noticed that he has derived great physical benefit in working with them. The suggestion is made that here is a possible means for improving the mental makeup of children. The problem of the defective child has been one that has long baffled social workers, Mr. Tesla points out.

Will it be possible by these very currents which are used for wireless purposes to increase these children's mental powers and give them a fairer chance in life? Mr. Tesla thinks so.

On this point there have been already a series of experiments. Prof. Svante Arrhenius, the noted physicist of Stockholm, it is announced, has completed a series of investigations to prove that electricity has a marvellous effect on the growth of children. Two groups of children, it is stated, of about the same physique, age and mentality were placed in two rooms which were exactly alike except that in the walls of one of the rooms there were wires concealed which carried high frequency, alternating electrical currents. This was done at a school, and neither the teachers nor the pupils knew any such experiment was being conducted.

Despatches from Stockholm state that at the end of six months the electrically treated children had grown 2 inches on an average and the children who were not subjected to the electrical influence had grown only 1.16 inch. Making twenty the standard of perfection, the electrified children reached in their studies an average of 18.4 and fifteen attained a perfect mark. The unmagnetized children attained an average of 15 and only nine of them got perfect marks. When questioned the teachers who had classes in the electrically influenced room said their faculties were quickened and their powers of endurance increased.

"Ever since my first demonstration with these currents, which attracted world-wide interest, I have noticed their beneficial action," said Mr. Tesla, referring to the Stockholm experiment. "They are undoubtedly destined to create a great revolution in theraphy and medical treatment. Dr. Arrhenius is a skilful experimenter and his announcements may be relied upon. I have long been convinced that high frequency currents are useful in certain nervous afflictions and that they assisted mental effort. But that growth can be increased through their agency is an entirely new observation.

"If what already has been done can be used as safe foundation in predicting what is to come we are certainly on the verge of realizations which may completely change our mode of life. I am a little pessimistic, however, as to the part that radium is to play in the new advancement. Believing as I do that radium is much the same sort of an illusion that phlogiston was a century ago, I am forced to this conclusion. It was the accepted belief at that time that a social element designated as phlogiston was involved in combustion and the error persisted until Lavoisier discovered oxygen and showed the part it played in this phenomena.

"In my papers published in the *Electrical Review* in 1896 and 1897, several years before the discovery of radiferouse ores, I described radiations of this sort, although produced in a different manner, and pointed out their salient properties, and I still hold the same opinion, believing radium to be due to a process akin to combustion in which not oxygen but an all pervading medium much finer is involved. According to this view, there is no virtue in the radium ore itself, but it is merely the result of its combination with a medium. I think one may safely discount many of the claims made for the future uses of radium."

Mr. Tesla says he has perfected a practical system of wireless power transmission and that he has secured actual results at his experimental plants in Colorado and Long Island. He holds that he has made satisfactory demonstrations which guarantee its commercial application. This has been the cumulative work of years.

"When I was a boy," Mr. Tesla said, "I lived near a mountain and one of my pleasures was to build small water wheels and set them in motion in the streams that came down the sides of the mountain. I would use the power from these wheels for turning small machines. It was always my ambition to see the power of a waterfall chained and made to work. I used to tell my uncle that some day I would see the greatest falls in America. He laughed at me and said I would probably never get to America, let alone see Niagara Falls.

"That was a good many years ago and I thought of it again when I delivered an address at Buffalo at the introduction of Niagara power and saw in actual operation what I had dreamed of when I was a boy."

There has been a good deal said, Mr. Tesla explains, about electrical treatment of soil, which scientists claim will reclaim land. The inventor points out that with

TESLA PREDICTS MORE WONDERS

Continued from First Page.

wireless power transmission it would be an easy matter to reclaim vast tracts of land. Nikola Tesla was born at Smiljan, Lika (border country of Austria-Hungary), in 1857, the son of a Greek clergyman. After his elementary school training, he spent four years at the Lower Realschule at Jospic. He was graduated from the Higher Realschule at Carlstadt in Crotia in 1873. He took his mathematical course at the Polytechnic School at Gratz and afterward spent two years at the capital in Prague. He began his practical career at Budapest in 1881, where he invented a telephone repeater and then conceived the idea of his rotating magnetic field. Since 1884 he has lived in the United States.

The theory that sight can be made to accompany the electrical wave was advanced by Mr. Tesla in an interview published in 1896.

"This problem of transmitting sight by wires or otherwise to any distance is as difficult as it is fascinating," he says. "It must not be compared as to its technical difficulties with the transmission of pictures or even colors by such means. These are comparatively easy tasks.

"The solution of this problem has been attempted very many times and more recently a further stimulus has been given to research in this direction by the magnificent inventions of Alexander Graham Bell. As soon as it became possible to transmit the strains of an entire opera over a wire the mind jumped immediately to the conclusion that seeing by similar methods will also become an accomplished fact. This appeared the more reasonable as Bell succeeded in transmitting speech through the medium of no more than a ray of light. The activities in this direction have not abated, but on the contrary have increased, especially since we have learned more about the nature of light through the discoveries of Heinrich Hertz.

"I could hardly name two or perhaps three other problems or lines of investigation which have taxed my own powers of thinking as much as this. As yet, while in these other lines I have realized considerably, as regards this problem of transmitting sight I am still very far from positive demonstration by experiment. You should not infer from this that all my efforts to find a solution have been futile, only experience has made me more exacting and even pessismistic as to the final carrying out of my ideas; why, I am happy to say, I have remained as optimistic as ever I was in their first conception. Very often during the day I conceive ideas which give me pleasure and hope, but in the clam retirement of the night my practical sense deals mercilessly with the projects I have formed."

MR. TESLA ON THE FUTURE

On Tesla Day, at the Northwest Electric Show, held at Minneapolis, Minn., March 16th to 23rd, Mr. Tesla sent, through Archbishop Ireland, the following message to the people of the Twin Cities and the Northwest:

New York, N. Y., March 18, 1912.

His Grace, The Most Reverend Archbishop Ireland:

I bespeak your Grace's far-famed eloquence in voicing sentiments and ideas to which I can give but feeble expression. May the exposition prove a success befitting the cities of magical growth, the courage and energy of western enterprise, a credit to its organization, a lasting benefit to the communities and the world through its lessons and stimulating influence as a bewildering, unforgetable record of the triumphant progress of the art. Great as are the past achievements, the future holds out more glorious promise. We are getting an insight into the essence of things; our means and methods are being refined, a new and specialized race is developing with knowledge deep and precise, with greater powers and keener perceptions. Mysterious as ever before, nature yields her precious secrets more readily and the spirit of man asserts its mastery over the physical universe. The day is not distant when the very planet which gave him birth will tremble at the sound of his voice; he will make the sun his slave, harness the inexhaustible and terribly intense energy of microcosmic movement; cause atoms to combine in predetermined forms; he will draw the mighty ocean from its bed, transport it through the air and create lakes and rivers at will; he will command the wild elements; he will push on and on from great to greater deeds until with his intelligence and force he will reach out to spheres beyond the terrestrial.

I am your Grace's most obedient servant.

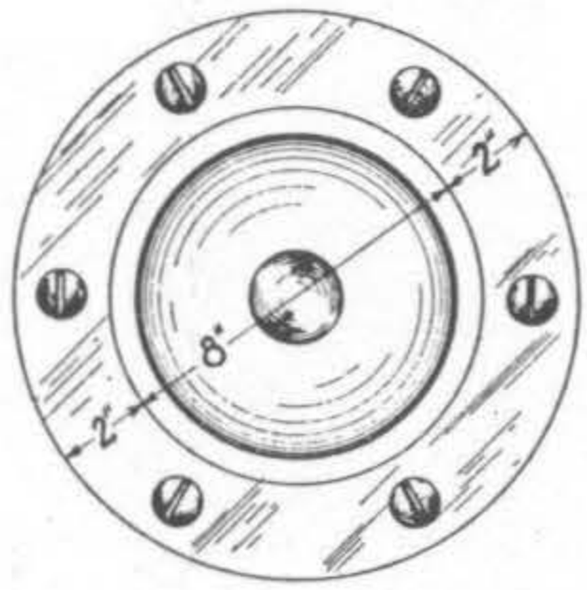
NIKOLA TESLA.

An Adjustable Tesla Coil

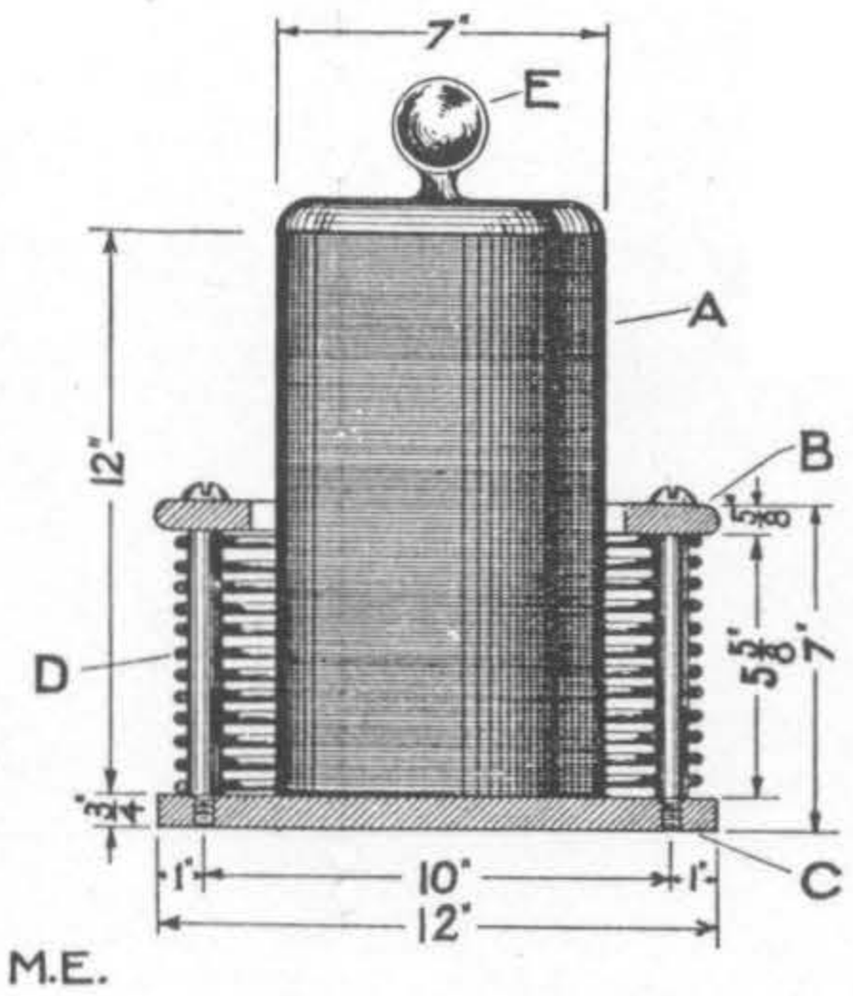
By Moore Stuart.

Every so often there appears an article on how to make a Tesla coil, of approved construction. Not one of the many articles which the writer has seen to date has described a coil which is in the least adjustable, consequently the secondary voltage must be regulated directly from the primary of the high tension transformer, by regulating the voltage supplied, either by resistance or by means of an adjustable choke coil. Both methods are very wasteful of the current.

The writer has the coil described herewith in operation on a 1½ K. W. transformer and same is easily controllable, directly from the Tesla Coil primary. The output from such a coil may be varied within large limits.



The core, A, must be of hard wood, thoroughly seasoned and varnished. Wound with as many turns as possible of No. 32, or thereabouts, enameled wire. If it is impossible to get the use of a lathe to turn this core out of wood, same may be made up of several thicknesses of heavy wrapping paper and thus forming a cylinder of the required size and thoroughly shellacking and drying. With this form of cylinder there is much more trouble in winding, as there is no way in which it can be placed on the lathe or winding machine. Winding the core is really the only difficult part in the making of this Tesla Coil.



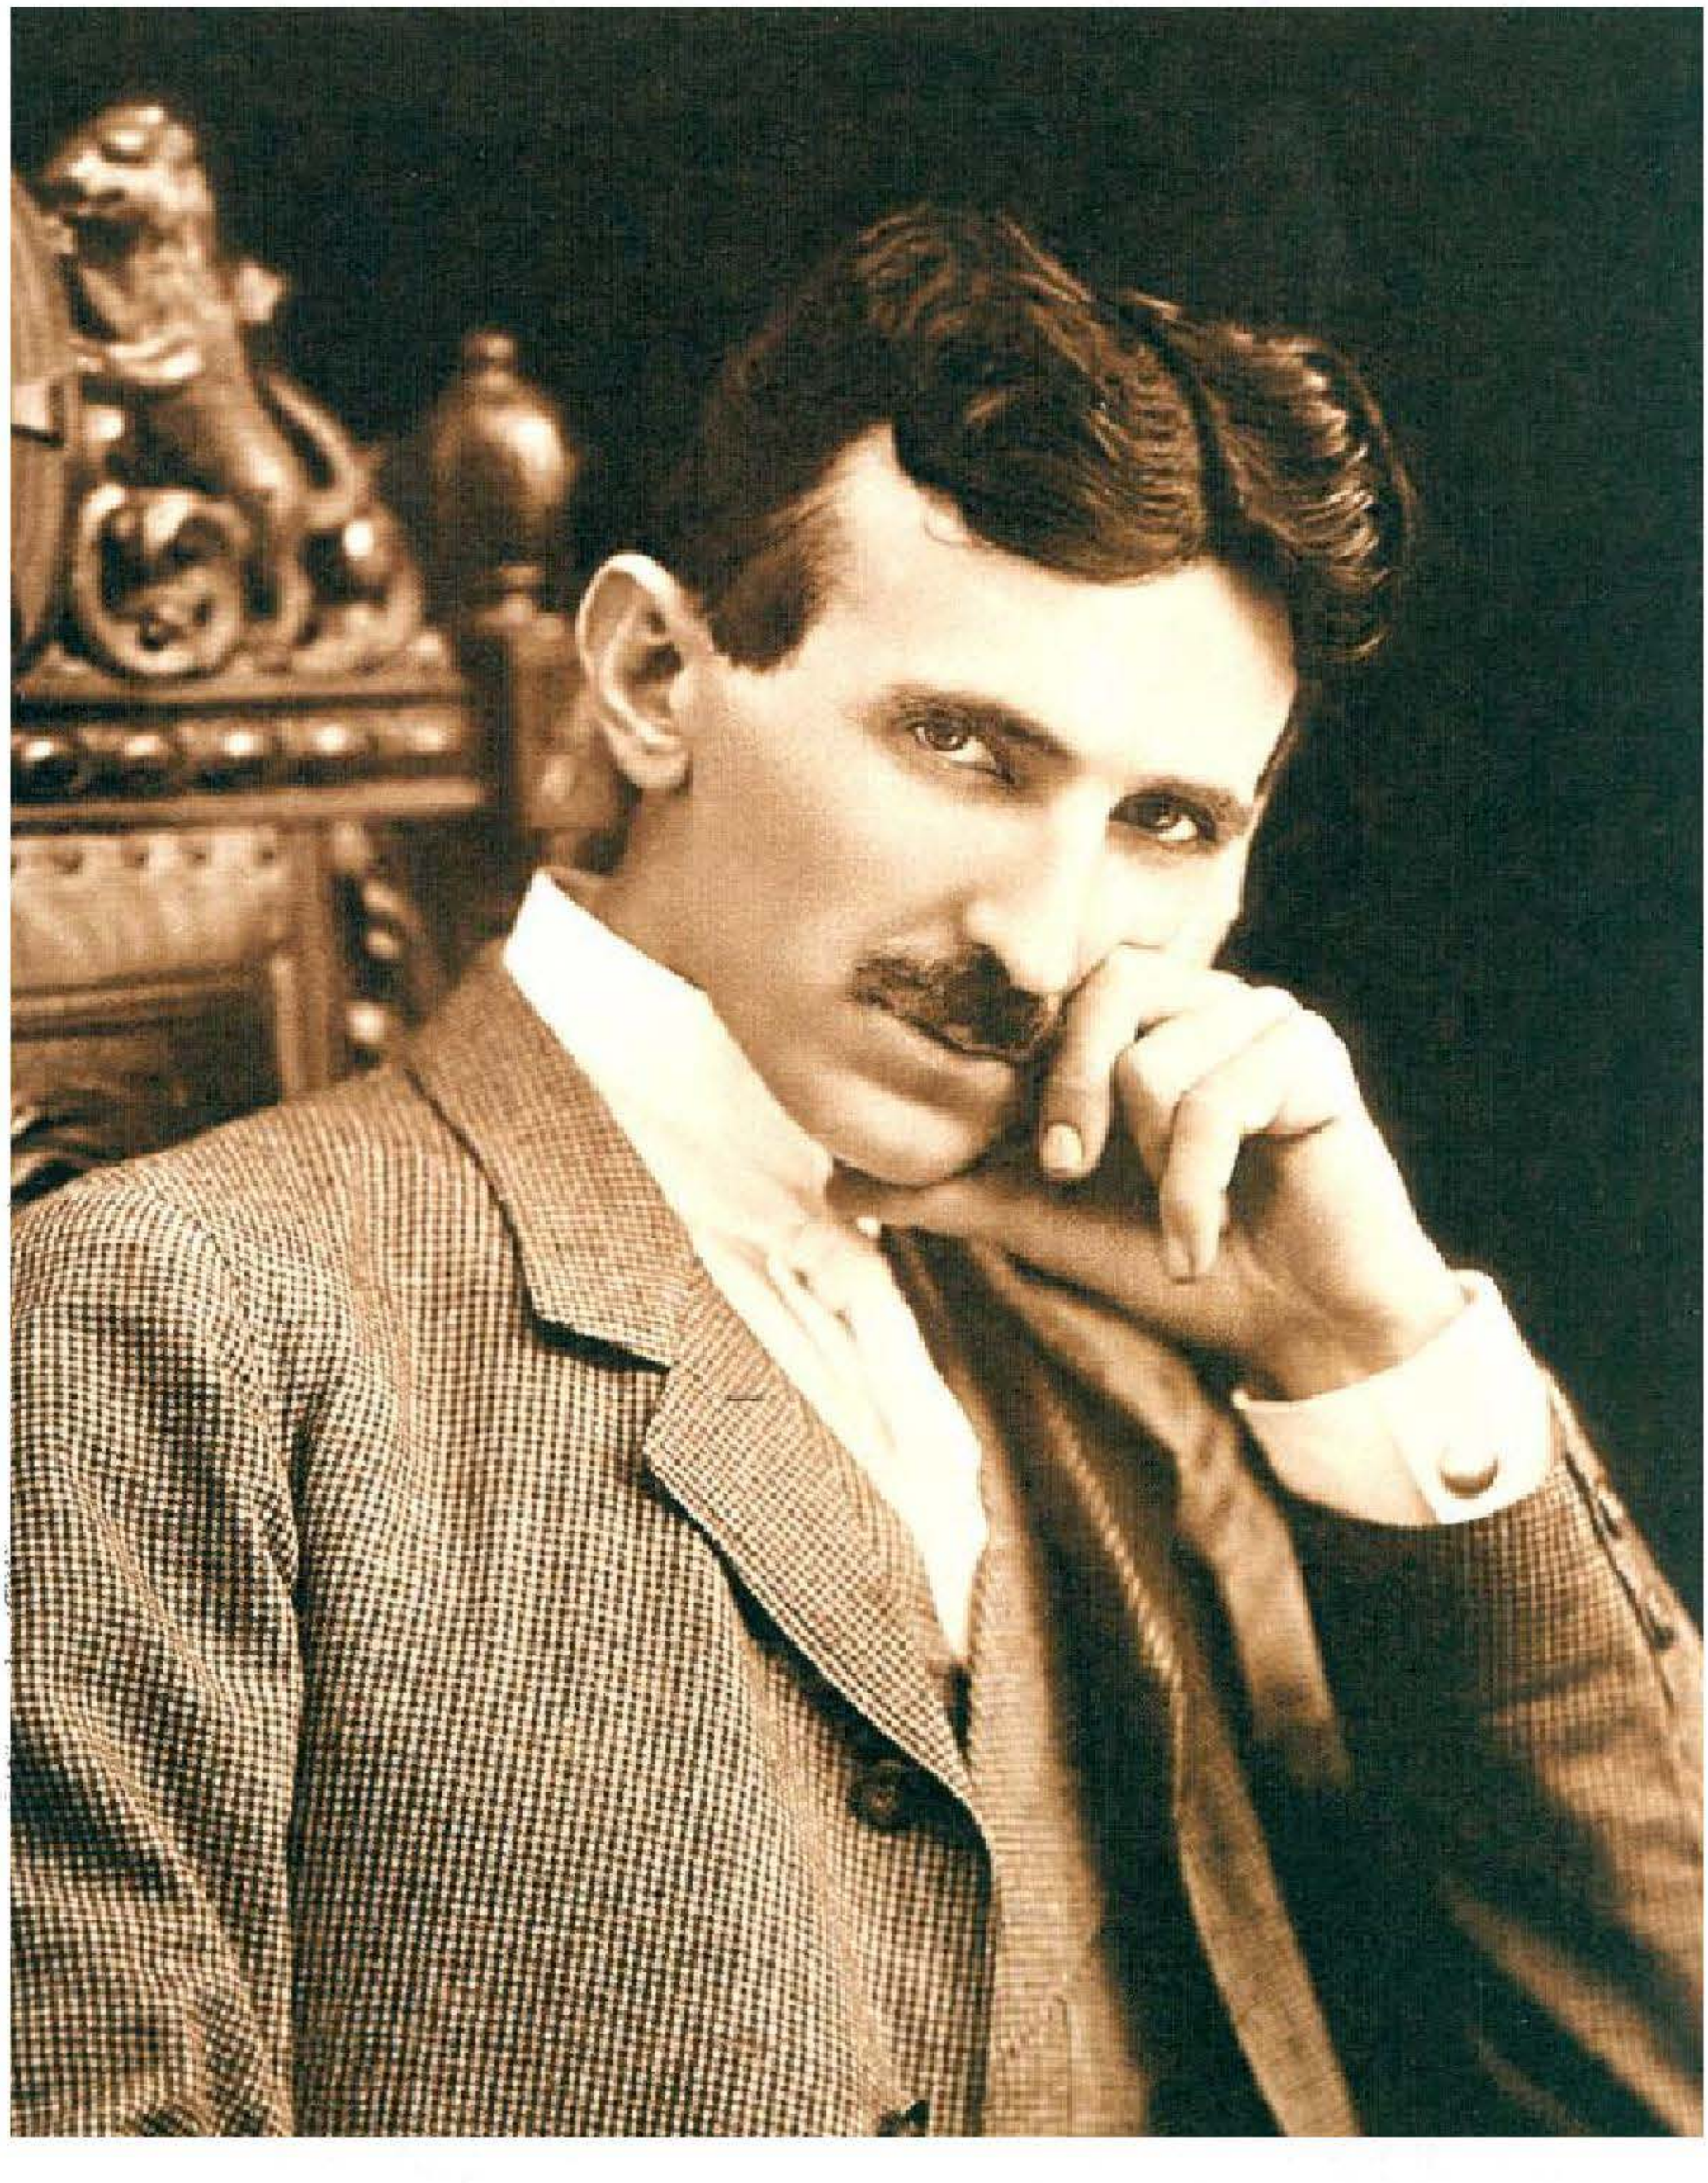
The top flange of the Primary should be turned up out of ⅝ inch stock, in either mahogany or walnut and polished. It is 12 inches outside diameter, with a hole 8 inches in diameter in the centre for the Secondary Coil to pass through.

The Base, C, should be of the same material as the top flange and should be finished and polished the same. There is no hole in this base, as the core of the secondary is screwed directly to this. The rods, D, are also screwed to this by means of flat head wood screws, counter sunk from the under side of the base. Round head brass wood screws are used to hold the rods in position from the top for the sake of appearances, although flat head may be used with the same results as to strength.

The primary winding should be about 12 turns of heavy copper wire, approximately ¼ inch in diameter. About twenty-two feet will be required. The ends should be drilled to receive a small wood screw to hold the wire in position after once winding. The screws may be screwed into the rods at either end of the coil.

The ball, E, should be of metal, or if that is not obtainable a wooden ball may be turned and covered with tin foil. The top end of the secondary winding should

M.E.



be soldered to this ball. A metal spike may also be used in place of the ball. The other, or lower end of the secondary winding may be soldered to the lower end of the primary winding, or may be taken out through the bottom, depending upon the use to which the completed coil will be put. Clips may be used to connect the primary winding with the secondary of the transformer. It will be readily seen that a connection may be made at any point of the winding after the manner of a wireless helix.

The completed coil should be mounted

on four insulators to insulate it from the earth.

This coil may be adapted to be used for wireless telephonic purposes by merely placing a slider upon the secondary for the adjustment of same. It will be readily understood that this winding should not be adjusted while working the coil, especially if used for wireless purposes with a large condenser, as the number of oscillations per second will be so low as to be dangerous to human life.

If used as a Tesla Coil, many weird and interesting experiments may be carried out. If used with a small condenser on a 1 K. W. transformer, with the entire circuit in resonance, an 8 inch spark may easily be drawn to the hand, if a small piece of metal is held in the hand, without any sensation whatever. However, it is not well to try and receive the current from such a coil unless one is experienced in the action and use of such apparatus, as there are so many factors to be considered, before the current from the secondary is not dangerous to life. Even though the voltage from such a coil be enormous, it will be remembered that but 250 milliamperes or ¼ ampere is generally conceded to be enough to destroy the heart action of a man in average condition, and sometimes very much less current will have the same destructive effect.

Nikola Tesla

Supplement to Modern Electrics. May 1912

Nikola Tesla

NIKOLA TESLA, whose name is familiar in every part of the globe where scientific research is conducted, was born in 1857, in Smiljan, Lika, border country of Austria-Hungary; the son of a distinguished clergyman and orator, and of Georgiana Mandic, a famous woman and inventor, whose father was also an inventor. His education began in the elementary school of his native place, continued four years in the public school in Gospic, Lika, four years in Lower Real school in Gospic, and three years in Higher Real school, Carlstadt, Croatia, where he was graduated in 1873. Originally destined for the clergy, he prevailed upon his parents to send him to the Polytechnic School in Gratz, where, for four years, he studied mathematics, physics and mechanics, following with two years of philosophic studies at the University of Prague, Bohemia. He started on his practical career in 1881, in Budapest, Hungary, where he made his first electrical invention, a telephone repeater, and conceived the idea of his rotating magnetic field; thence he went to France and Germany, where he was successively engaged in various branches of engineering and manufacture. Since 1884 he has been a resident of the United States, of which he is a naturalized citizen, and here his subsequent inventions originated.

Mr. Tesla is the author of numerous scientific papers and addresses, and honorary or regular member of many scientific societies, institutions and academies in the United States and abroad; he is a life member of the British Association for the Advancement of Science and a member of the Royal Institution of Great Britain, M. A. of Yale, L. L. D. of Columbia, and Doctor of Science of the Vienna Polytechnic School, the latter distinction being conferred upon him in acknowledgment of his discoveries of the rotating, magnctic field and principles of wireless energy transmission; the Elliott Cresson gold medal was awarded him in recognition of his original work first presented before the Franklin Institute and the National Electric Light Association in 1893, in which one of the most important chapters was devoted to a description of his wireless method. Mr. Tesla's rank among those who have led in advance in knowledge and appreciation of electrical forces is among the foremost.

Among his inventions and discoveries are: System of arc lighting, 1886; Tesla motor and system of alternating current power transmission, popularly known as two-phase, three-phase, multi-phase, or poly-phase systems, which have created a revolution in electrical engineering and are now universally adopted, 1888; system of electrical conversion and distribution by oscillatory discharges, 1889; generators of high-frequency currents and effects of these, 1890; transmission of energy through a single wire without return, 1891; the "Tesla coil" or transformer, which has proved an indispensable adjunct in many electrical arts, 1891; investigations of high-frequency effects and phenomena, 1891-93; system of wireless transmission of intelligence, 1893; mechanical oscillators and generators of electrical oscillations, 1894-95; researches and discoveries in novel radiations, material streams and emanations, published in a series of papers in the "Electrical Review," New York, 1896-1898, in which he announced all the salient phenomena later attributed to radium; high-potential magnifying transmitter, 1897; system of transmission of power without wires, 1897-1905; economic transmission of energy by refrigeration, 1898; art of Telautomatics, 1898-99; discovery of stationary electrical waves in the earth, 1899; burning of atmospheric nitrogen, and production of other electrical effects of transcending intensities, 1899-1900; method and apparatus for magnifying feeble effects, 1901-1902; art of individualization, 1902-1903. The development of his system of world-telegraphy and telephony and of the transmission of power without wires has engaged much of his attention since that time. A number of discoveries in the electrical field, made by Mr. Tesla, which he has not yet announced, he considers of greater moment than any electrical work he has so far done. His most important recent work is the discovery of a new mechanical principle, what he has embodied in a great variety of machines, as reversible gas and steam turbines, pumps, blowers, air compressors, water turbines, mechanical transformers and transmitters of power, hot-air engines, etc. This principle enables the production of prime movers capable of developing ten-horsepower, or even more, for each pound of weight. By their application to aerial navigation, and the propulsion of vessels, high speeds are practicable.

The Solar Eclipse and Radio-telegraphy.

During the recent solar eclipse an interesting test was undertaken between the radio station of the Royal Dock Yard in Copenhagen and the Blaavandshuk station on the coast of Jutland, so as to ascertain the effect of the eclipse upon wireless transmission. It transpired that the telegraphing became more distinct and reliable as the eclipse progressed, and that it was most distinct shortly after the culmination of the eclipse. The view that it is the effect of the solar light upon the atmosphere which is the cause of radio-telegraphy being much better at night than during the day was thus confirmed.

WIRELESS TRANSMISSION.

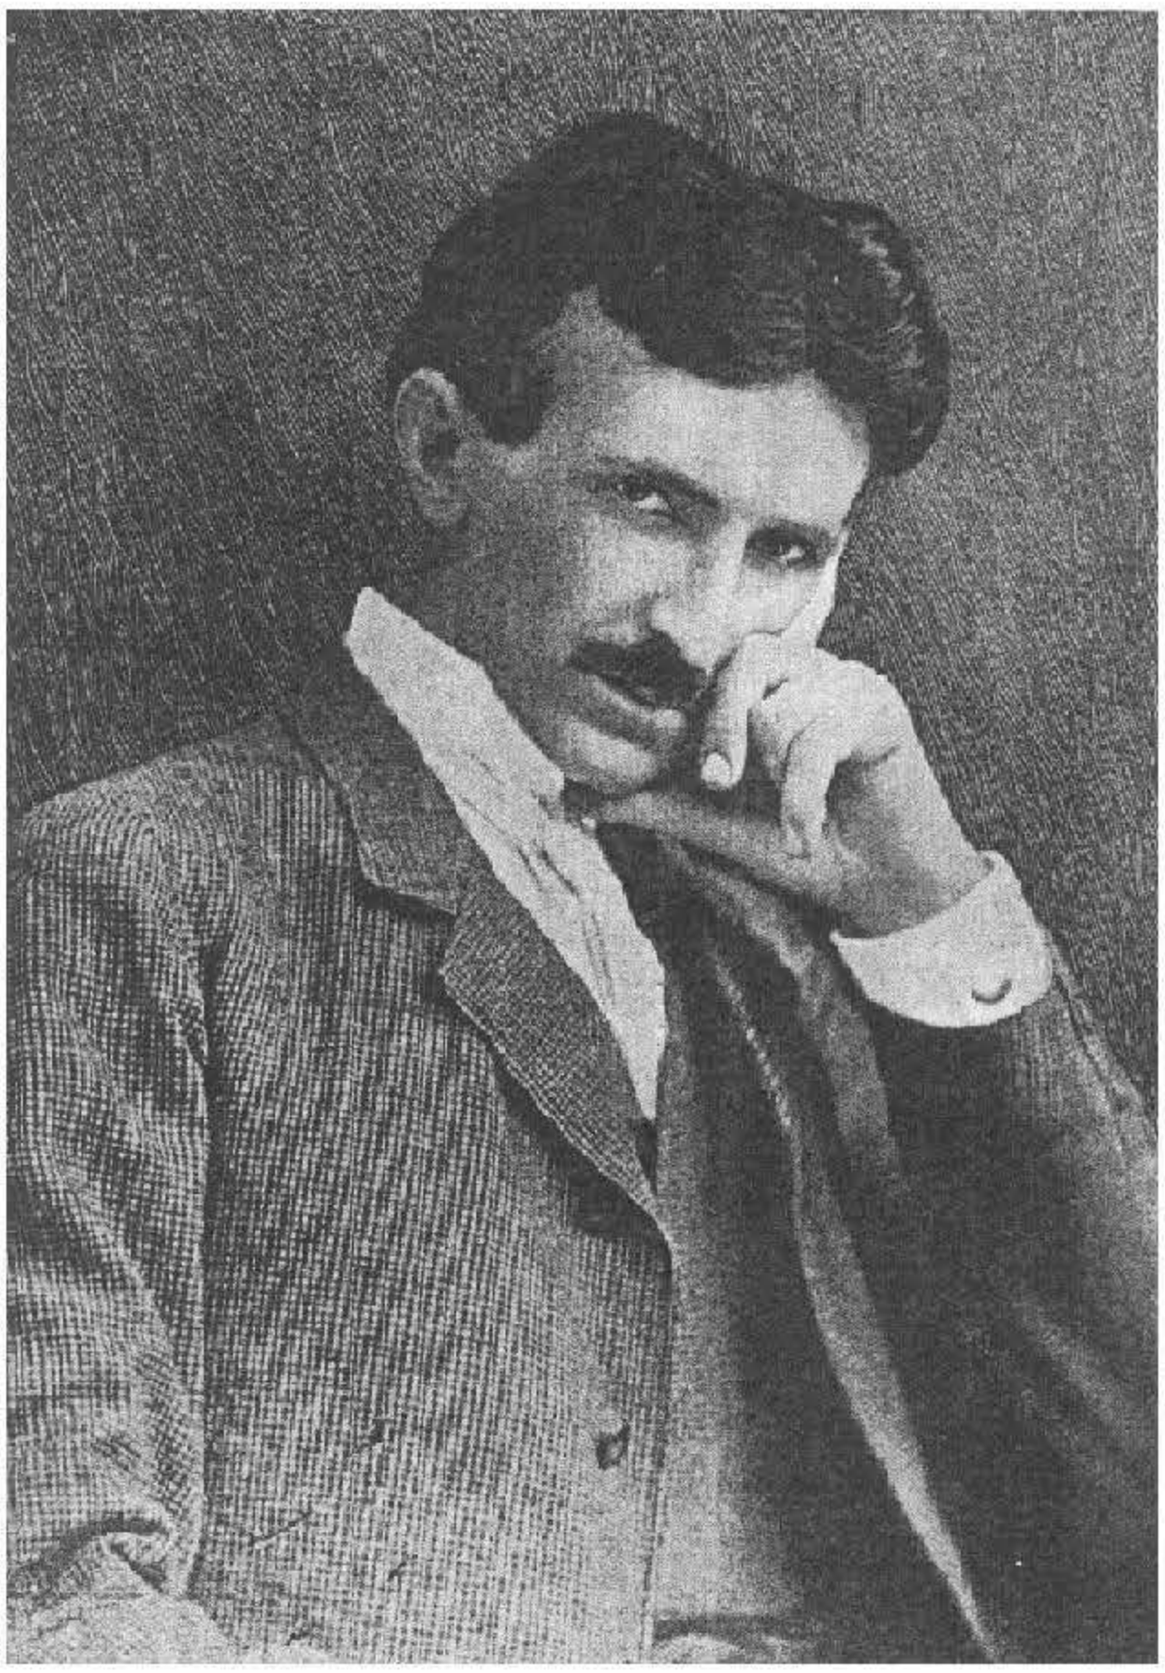
Ever since the celebrated experiments of Heinrich Hertz, the possibility of radiating electric energy from an oscillator to a receiving apparatus was realized. At first it seemed as if the feebleness of such radiation would prevent its transmission to any considerable distance, but the persistent work of Marconi and other investigators showed that transmission to a considerable distance is quite possible by this method. With the further developments of the art it was found, however, that the practical results in wireless transmission did not entirely agree with the laws which were theoretically derived on the basis of the Hertz-wave theory.

Another phenomenon which has puzzled experimenters and practical operators in wireless telegraphy is the fact that the distance of transmission of wireless signals, which of course depends upon the rate of attenuation, depends upon atmospheric conditions and most notably upon the time of day; that is to say, whether the portion of the earth over which the signals are being transmitted is experiencing day or night.

There has been an attempt to connect the latter phenomenon with the state of ionization of the atmosphere, which is naturally assumed to be different when the sun is shining upon it than at night time. The ionization effect of ultra-violet light is well known and the radiation of the sun is known to contain a considerable proportion of these important wave-lengths. There has been no satisfactory relation established, however, between the conditions of ionization and the strength of the received signals.

In an article which will be found upon pages 34 and 35 of this issue, Dr. Nikola Tesla has propounded a theory, which is supported by his experimental observations, to account for the practical results which have been observed. He has come to the conclusion that the Hertzian waves are responsible for but a small part of the energy which is transmitted from a wireless antenna, the main consideration in such transmission being conduction through the earth. Of course it is not maintained that signals cannot be and are not transmitted by Hertzian waves, as in some cases, notably in transmission to and from balloons and aeroplanes, earth currents are eliminated and dependence must be placed entirely upon radiation through the atmosphere. In most cases of long-distance signaling, however, earth connections are found essential to the best results and it cannot be doubted that the currents flowing into and out of the earth at the point of connection of the antenna or the auxiliary apparatus are important incidents in the operation.

Regarding the effect of sunlight upon transmission, Dr. Tesla presents a unique explanation which experts in this field would probably not be willing to accept without further demonstration. He attributes the change in facility of transmission to the evaporation of moisture from the earth's surface in places which are exposed to the sun's rays. Of course such evaporation is increased by the heat absorbed from the sun's radiation, a phenomenon which affects the conditions in the superficial layer of the earth's crust. Conduction through the earth could itself scarcely be effected in this way, but the explanation given by Dr. Tesla is that the evaporated particles of moisture carry off with them an electrical charge which affects the electrical distribution on the earth. He states that the dissipation of energy is proportional to the cube of the frequency, which would indicate that the best condition for transmission would be a low frequency and consequently large wave-length.



Dr. Tesla promises at some future time to contribute a more extensive discussion of this subject, disclosing the lengthy investigations which have led him to these important conclusions. The scientific and technical world will eagerly await a fuller demonstration of the truth of this theory.

Nikola Tesla.

In the realm of electricity and physics few men have striven for such mighty achievements and attained such prominence through the working out of ideas greatly in advance of current thought as has Nikola Tesla, the subject of this sketch.

Nikola Tesla was born at Smiljan, Lika, the border country of Austria-Hungary, in 1857, the son of a Greek clergyman and orator, and Georgina Mandic, who was an inventor, as was her father. Tesla was educated for a year in the elementary schools, for four years at the lower Realschule, Gospic, Lika, and for three years at the higher Realschule, Carlstadt, Croatia, graduating in 1873. He was a student for four years at Polytechnic School, Gratz, in mathematics, physics and mechanics. After this he studied two years in philosophic studies at the University of Prague, Bohemia. He has received the honorary degree of Master of Arts, from Yale, in 1904, and Columbia, N. Y., conferred the degree of L.L.D. in 1894.

Nikola Tesla began his practical career at Budapest, Hungary, in 1881, where he made his first electrical invention, a telephone "repeater," and conceived the idea of his rotating magnetic field. He later engaged in various branches of engineering and manufacture, and, since 1884, has been a resident of the United States, becoming a naturalized citizen. Dr. Tesla is the author of numerous scientific papers and addresses, and his inventions and discoveries cover a wide range. Speaking chronologically, his chief work may be summed up as follows: systems of arc lighting, 1886; Tesla motor and system of alternating-current power transmission, 1888; system of electrical conversion and distribution by oscillating discharges, 1889; generation of high-frequency currents and effects of these, 1890; transmission of energy through a single wire without return, 1891; Tesla coil or transformer, 1891; investigations of high-frequency effects and phenomena, 1891-1893; system of wireless transmission of intelligence, 1893; mechanical oscillators and generators of electrical oscillations, 1894-1895; researches and discoveries in radiations, material streams, and emanations, 1896-1898; high-potential magnifying transmitter, 1897; system of transmission of power without wires, 1897-1905; economic transmission of energy by refrigeration, 1898; art of "Telautomatics," 1898-1899; burning of atmospheric nitrogen and production of other electrical effects of transcending intensities, 1899-1900; method and apparatus for magnifying feeble effects, 1901-1902; art of individualization, 1902-1903. Since 1903, Dr. Tesla has been chiefly engaged in the development of his system of world telephony and telegraphy, and the design of a large plant for the transmission of power without wires. He has also devoted a great deal of energy to the development of a perfected system for the electrical production of nitrates from the atmosphere and quite recently announced the development of a remarkable form of turbine, the perfecting of which when realized will mean practically a revolution in our application of mechanical principles. In the current issue of the ELECTRICAL REVIEW AND WESTERN ELECTRICIAN Dr. Tesla discusses with characteristic candor and vigor some new ideas with regard to the propagation of electrical impulses through the air without wires.

Nikola Tesla,
Noted Electrical Inventor and Scientist.

THE DISTURBING INFLUENCE OF SOLAR RADIATION ON THE WIRELESS TRANSMISSION OF ENERGY.

By Nikola Tesla.

When Heinrich Hertz announced the results of his famous experiments in confirmation of the Maxwellian electromagnetic theory of light, the scientific mind at once leaped to the conclusion that the newly discovered dark rays might be used as a means for transmitting intelligible messages through space. It was an obvious inference, for heliography, or signalling by beams of light, was a well recognized wireless art. There was no departure in principle, but the actual demonstration of a cherished scientific idea surrounded the novel suggestion with a nimbus of originality and atmosphere of potent achievement. I also caught the fire of enthusiasm but was not long deceived in regard to the practical possibilities of this method of conveying intelligence.

Granted even that all difficulties were successfully overcome, the field of application was manifestly circumscribed. Heliographic signals had been flashed to a distance of 200 miles, but to produce Hertzian rays of such penetrating power as those of light appeared next to impossible, the frequencies obtainable through electrical discharges being necessarily of a much lower order. The rectilinear propagation would limit the action on the receiver to the extent of the horizon and entail interference of obstacles in a straight line joining the stations. The transmission would be subject to the caprices of the air and, chief of all drawbacks, the intensity of disturbances of this character would rapidly diminish with the distance.

But a few tests with apparatus, far ahead of the art of that time, satisfied me that the solution lay in a different direction, and after a careful study of the problem I evolved a new plan which was fully described in my addresses before the Franklin Institute and National Electric Light Association in February and March, 1893. It was an extension of the transmission through a single wire without return, the practicability of which I had already demonstrated. If my ideas were rational, distance was of no consequence and energy could be conveyed from one to any other point of the globe, and in any desired amount. The task was begun under the inspiration of these great possibilities.

While scientific investigation had laid bare all the essential facts relating to Hertz-wave telegraphy, little knowledge was available bearing on the system proposed by me. The very first requirement, of course, was the production of powerful electrical vibrations. To impart these to the earth in an efficient manner, to construct proper receiving apparatus, and develop other technical details could be confidently undertaken. But the all-important question was, how would the planet be affected by the oscillations impressed upon it? Would not the capacity of the terrestrial system, composed of the earth and its conducting envelope, be too great? As to

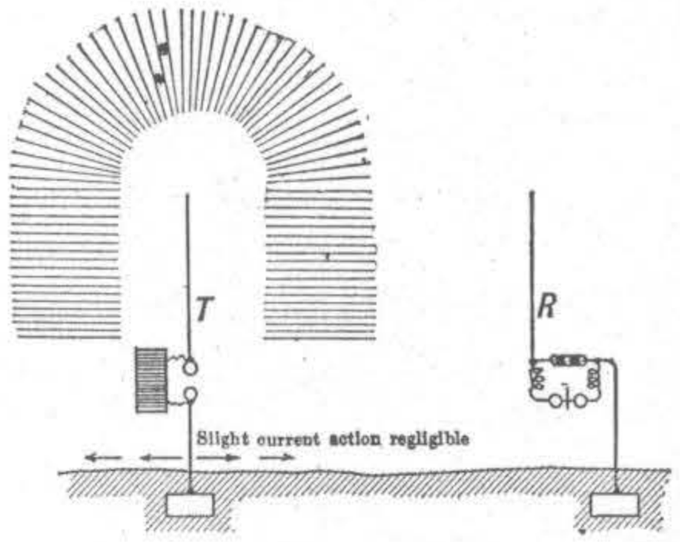


Fig. 1.—Hertz Wave System.

this, the theoretical prospect was for a long time discouraging. I found that currents of high frequency and potential, such as had to be necessarily employed for the purpose, passed freely through air moderately rarefied. Judging from these experiences, the dielectric stratum separating the two conducting spherical surfaces could be scarcely more than 20 kilometers thick and, consequently, the capacity would

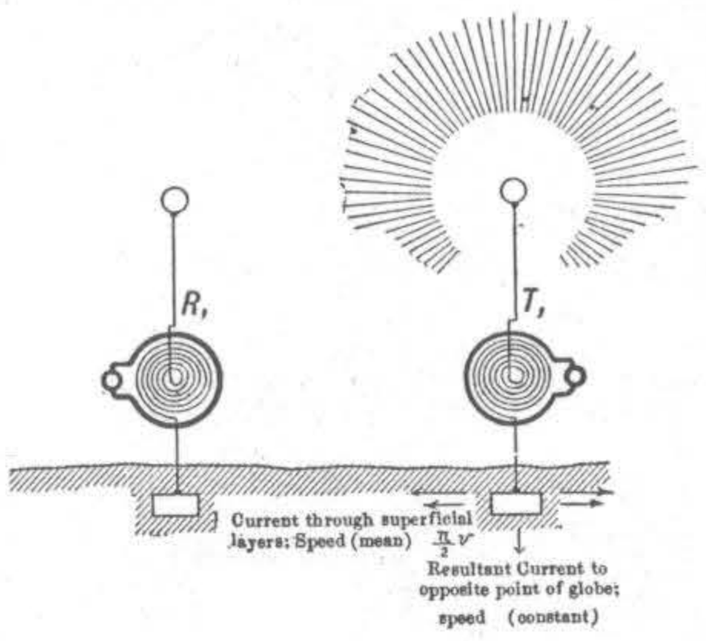

Fig. 2.—System Devised By Tesla.

be over 220,000 microfarads, altogether too great to permit economic transmission of power to distances of commercial importance. Another observation was that these currents cause considerable loss of energy in the air around the wire. That such waste might also occur in the earth's atmosphere was but a logical inference.

A number of years passed in efforts to improve the apparatus and to study the electrical phenomena produced. Finally my labors were rewarded and the truth was positively established: the globe did not act like a conductor of immense capacity and the loss of energy, due to absorption in the air, was insignificant. The exact mode of propagation of the currents from the source and the laws governing the electrical movement had still to be ascertained. Until this was accomplished the new art could not be placed on the plane of scientific engineering. One could bridge the greatest distance by sheer force, there being virtually no limit to the intensity of the vibrations developed by such a transmitter, but the installment of economic plants and the predetermination of the effects, as required in most practical applications, would be impossible.

Such was the state of things in 1899 when I discovered a new difficulty of which I had never thought before. It was an obstacle which could not be overcome by any improvement devised by man and of such nature as to fill me with apprehension that transmission of power without wires might never be quite practicable. I think it useful, in the present phase of development, to acquaint the profession with my investigations.

It is a well known fact that the action on a wireless receiver is appreciably weaker during the day than at night and this is attributed to the effect of sunlight on the elevated aerials, an explanation naturally suggested through an early observation of Heinrich Hertz. Another theory, ingenious but rather fine-spun, is that some of the energy of the waves is absorbed by ions or electrons, freed in sunlight and caused to move in the direction of propagation. The ELECTRICAL REVIEW AND WESTERN ELECTRICIAN of June 1, 1912, contains a report of a test, during the recent solar eclipse, between the station of the Royal Dock Yard in Copenhagen and the Blaavandshuk station on the coast of Jutland, in which it was demonstrated that the signals in that region became more distinct and reliable when the sunlight was partially cut off by the moon. The object of this communication is to show that in all the instances reported the weakening of the impulses was due to an entirely different cause.

It is indispensable to first dispel a few errors under which electricians have labored for years, owing to the tremendous momentum imparted to the scientific mind through the work of Hertz which has hampered independent thought and experiment. To facilitate understanding, attention is called to the annexed diagrams in which Fig. 1 and Fig. 2 represent, respectively, the well known arrangements of circuits in the Hertz-wave system and my own. In the former the transmitting and receiving conductors are separated from the ground through spark gaps, choking coils, and high resistances. This is

necessary, as a ground connection greatly reduces the intensity of the radiation by cutting off half of the oscillator and also by increasing the length of the waves from 40 to 100 per cent, according to the distribution of capacity and inductance. In the system devised by me a connection to earth, either directly or through a condenser, is essential. The receiver, in the first case, is affected only by rays transmitted through the air, conduction being excluded; in the latter instance there is no appreciable radiation and the receiver is energized by currents conducted through the earth while an equivalent electric displacement occurs in the atmosphere.

Now, an error which should be the focus of investigation for experts is, that in the arrangement shown in Fig. 1 the Hertzian effect has been gradually reduced through the lowering of frequency, so as to be negligible when the usual wave-lengths are employed. That the energy is transmitted chiefly, if not wholly, by conduction can be demonstrated in a number of ways. One is to replace the vertical transmitting wire by a horizontal one of the same effective capacity, when it will be found that the action on the receiver is as before. Another evidence is afforded by quantitative measurement which proves that the energy received does not diminish with the square of the distance, as it should, since the Hertzian radiation propagates in a hemisphere. One more experiment in support of this view may be suggested. When transmission through the ground is prevented or impeded, as by severing the connection or otherwise, the receiver fails to respond, at least when the distance is considerable. The plain fact is that the Hertz waves emitted from the aerial are just as much of a loss of power as the short radiations of heat due to frictional waste in the wire. It has been contended that radiation and conduction might both be utilized in actuating the receiver, but this view is untenable in the light of my discovery of the wonderful law governing the movement of electricity through the globe, which may be conveniently expressed by the statement that the projections of the wave-lengths (measured along the surface) on the earth's diameter or axis of symmetry of movement are all equal. Since the surfaces of the zones so defined are the same the law can also be expressed by stating *that the current sweeps in equal times over equal terrestrial areas.* (See among others "Handbook of Wireless Telegraphy," by James Erskine-Murray.) Thus the velocity of propagation through the superficial layers is variable, dependent on the distance from the transmitter, the mean value being $\pi/2$ times the velocity of light, while the ideal flow along the axis of propagation takes place with a speed of approximately 300,000 kilometers per second.

To illustrate, the current from a transmitter situated at the Atlantic Coast will traverse that ocean—a distance of 4,800 kilometers—in less than 0.006 second with an average speed of 800,000 kilometers. If the signalling were done by Hertz waves the time required would be 0.016 second.

Bearing, then, in mind that the receiver is operated simply by currents conducted along the earth as through a wire, energy radiated playing no part, it will be at once evident that the weakening of the impulses could not be due to any changes in the air, making it turbid or conductive, but should be traced to an effect interfering with the transmission of the current through the superficial layers of the globe. The solar radiations are the primary cause, that is true, not those of light, but of heat. The loss of energy, I have found, is due to the evaporation of the water on that side of the earth which is turned toward the sun, the conducting particles carrying off more or less of the electrical charges imparted to the ground. This subject has been investigated by me for a number of years and on some future occasion I propose to dwell on it more extensively. At present it may be sufficient, for the guidance of experts, to state that the waste of energy is proportional to the product of the square of the electric density induced by the transmitter at the earth's surface and the frequency of the currents. Expressed in this manner it may not appear of very great practical significance. But remembering that the surface density increases with the frequency it may also be stated that the loss is proportional to the cube of the frequency. With waves 300 meters in length economic transmission of energy is out of the question, the loss being too great. When using wave-lengths of 6,000 meters it is still noticeable though not a serious drawback. With wave-lengths of 12,000 meters it becomes quite insignificant and on this fortunate fact rests the future of wireless transmission of energy.

To assist investigation of this interesting and important subject, Fig. 3 has been added, showing the earth in the position of summer solstice with the transmitter just emerging from the shadow. Observation will bring out the fact that the weakening is not noticeable until the aerials have reached a position, with reference to the sun, in which the evaporation of the water is distinctly more rapid. The maximum will not be exactly when the angle of incidence of the sun's rays is greatest, but some time after. It is noteworthy that the experimenters who watched the effect of the recent eclipse, above referred to, have observed the delay.

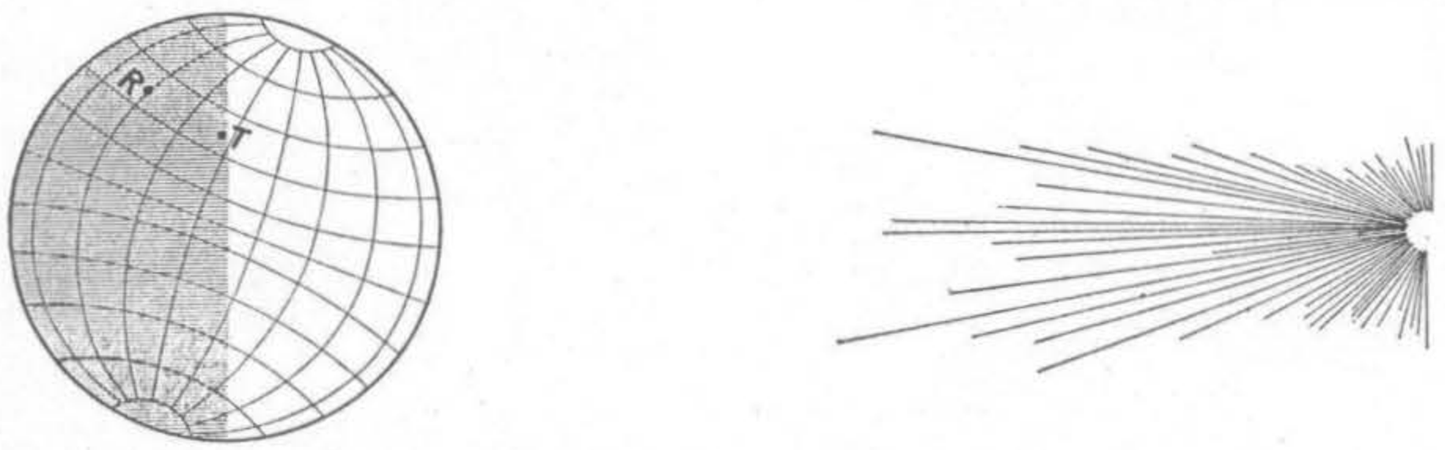

Fig. 3.—Illustrating Disturbing Effect of the Sun on Wireless Transmission.

The New York Sun July 7, 1912

WHY WIRELESS DOES BEST WORK AT NIGHT

Nikola Tesla Says Solar Radiation Causes the Air to Lose Moisture.

ELECTRIC ENERGY LOST

Evaporation Lessens the Power of the Earth in Aiding Transmission.

Nikola Tesla believes he has discovered the reasons for the phenomena long noticed by wireless folks that the wireless receiver is appreciably weaker in the day than it is at night.

In the *Electrical Review and Western Electrician* of Chicago, published yesterday, appears an article by the electrical inventor on "The Disturbing Influence of Solar Radiation on the Wireless Transmission of Energy." In this article Tesla accounts for this condition on the theory that as moisture in the air is dissipated by the sun's rays, and as particles of water in evaporating carry with them charges of electricity, the earth is thus deprived of some of the electrification which resides upon its surface at night. This, he claims, causes a dissipation of energy which necessarily interferes with the transmission of the electrical signals and prevents them from being observed at so great a distance as in the night time.

Tesla has long maintained that the earth plays as important a part in wireless transmission as the air and has contended as the results of demonstrations, he says, that the results accomplished are not due merely to Hertzian waves, whose existence was discovered by Heinrich Hertz, the German physicist. Tesla writes:

"Bearing, then, in mind that the receiver is operated simply by currents conducted along the earth as through a wire, energy radiated playing no part, it will be at once evident that the weakening of the impulses could not be due to any changes in the air, making it turbid or conductive, but should be traced to an effect interfering with the transmission of the current through the superficial layers of the globe.

"The solar radiations are the primary cause, that is true, not those of light, but of heat. The loss of energy, I have found, is due to the evaporation of the water on that side of the earth which is turned toward the sun, the conducting particles carrying off more or less of the electrical charges imparted to the ground.

"At present it may be sufficient for the guidance of experts to state that the waste of energy is proportional to the product of the square of the electric density induced by the transmitter at the earth's surface and the frequency of the currents. Expressed in this manner it may not appear of very practical significance. But remembering that the surface density increases with the frequency it may also be stated that the loss is proportional to the cube of the frequency."

GREAT INVENTIONS AND THEIR ORIGINATORS

NIKOLA TESLA, the noted physicist, electrician and inventor, was born at Smiljan, Luka, in Austro-Hungary, in 1857.

Tesla's father was a distinguished clergyman and orator, and his mother was the daughter of an inventor and herself an inventor. His father intended to educate Nikola for his own profession, but the boy prevailed upon his parents to send him to the Polytechnic school in Gratz, where for four years he studied mathematics, physics and mechanics. Two years of philosophic studies at the University of Prague followed.

It was in 1881 that he began his practical career in Buda-Pesth, and here he made his first electrical invention, a telephone repeater, and first conceived the idea of the rotating magnetic field.

A few years later he was led to come to this country, where he desired to develop motors on the basis of his own discovery of the rotating magnetic field. This he completed in 1888.

Among his inventions are a number of methods and appliances of electrical vibrations aiming at the production of efficient light with lamps without filaments and the production and transmission of power without wires.

It was on his discovery of the action of air on gaseous matter when subjected to rapidly alternating electrostatic stresses that the modern art of insulating currents of very high tension is based.

Among his other achievements is the construction of steam engines and electrical generators or oscillators with which results otherwise unattainable have been achieved.

He is now a citizen of the United States,

NIKOLA TESLA

and is an ardent advocate of the country under whose flag most of his inventions were originated.

He has written a number of scientific works and has addressed many scientific societies.

The New York Times July 21, 1912

NICOLA TESLA SUED.

Shlenker Claims $61,500 Interest in Inventor's Transformer.

Nicola Tesla, the inventor, and Edmund K. Stallo, son-in-law of the late Alexander McDonald, the Standard Oil man, were sued yesterday in the Supreme Court by Simon Shlenker, who claims an interest in the "Tesla transformer," a machine which was patented by the inventor.

Mr. Shlenker alleges that he invested $61,500 in the machine, on the understanding that it was to be placed on the market and the prifits shared. Instead of doing as he had contracted, Shlenker accuses Tesla of having used his investment for personal experiments and of having failed to finance the enterprise.

The New York Evening Sun July 30, 1912

PLAN TO QUICKEN DULL CHILDREN

School Authorities Consider Electrical Experiment.

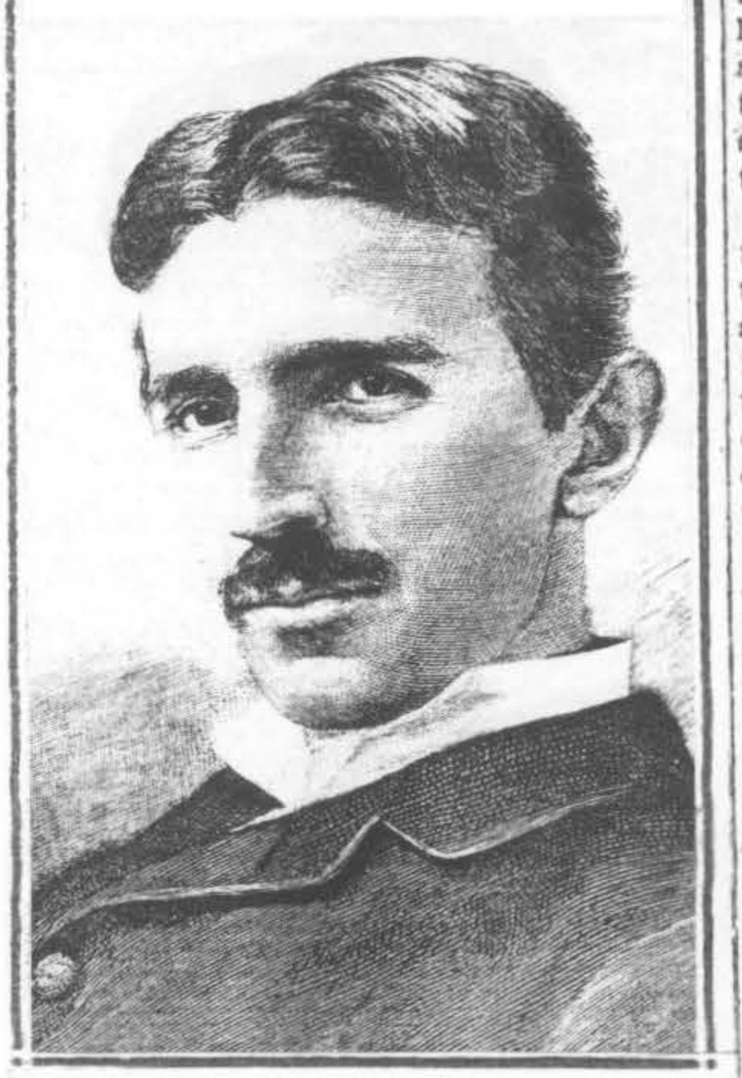
MAY WIRE CLASSROOM

Remarkable Results From Trial in Sweden.

A novel experiment in the classes of defective children in the public schools of this city is to be tried this fall, provided the sanction of the Board of Education is obtained. This experiment consists of electrifying a school room, which process, it is maintained by experts, arouses the children to greater mental and physical ability and tends to make them brighter in every respect. It is proposed to experiment with the subnormal pupils first, since they have more need of a brain stimulator.

Provided the school commissioners are willing to allow the tests the work is to be in charge of Nikola Tesla, the inventor. The scientist, City Superintendent of Schools William H. Maxwell and Dr. L. B. Blan have had several conferences on the matter, and when the subject was thoroughly explained to Dr. Maxwell he expressed his willingness to have the scheme tried out. It is likely that the proposition will be put up to the Board of Education at an early fall meeting, perhaps the first, on Sept. 11.

City Superintendent Maxwell said that since the electrifying process is still in the experimental form, his first demand was an assurance from Mr. Tesla that, let alone helping the pupils, the test would in no wise be detrimental.



"Mr. Tesla stated that there is no possibility of the experiments having anything but a good effect on the pupils. If this electrification of school rooms will improve the ability of the children it should be thoroughly tried out. The inventor told me that the process has been used with great success in Europe and after a number of conferences with him I came to the conclusion that the system should be tested in the New York schools."

The European experiments with the electrifying machine have taken place in Stockholm, Sweden. The work in that city was carried on under the supervision of Prof. Svante Arrhenius, the noted physicist. Mr. Tesla followed the tests across the water and then consulted with Dr. Maxwell. The scientist claims that the main apparatus used in the foreign experiments was originally devised by him. Mr. Tesla explained that it was reported another man was responsible for the invention.

The machinery used in the electrification consist of a series of wires hidden in the walls of the school room. It is proposed to take two rooms, as nearly alike as possible, and at the end of the proper period compare the

SUPERINTENDENT MAXWELL.

NIKOLA TESLA

results obtained in the electrified and unelectrified rooms. About fifty pupils will make up the classes and the tests are to be conducted without the knowledge of the children or the teachers.

Mr. Tesla has volunteered to take charge of the installation of the apparatus and conduct the tests himself. The wires, concealed in the walls of the class room, are to be charged with high frequency currents.

"I am certain," said Mr. Tesla, "that the experiment will prove that these currents will assist cerebration and arouse the children to greater ability. The stimulation of the nerve cells helps the physical as well as the mental condition of the child. With Dr. Maxwell's cooperation very thorough tests of the process are likely to be made. The only thing remaining is to get the sanction of the Board of Education."

It is estimated that the proper appli-

(Continued on Fourth Page.)

PLAN TO QUICKEN DULL CHILDREN

(Continued From First Page.)

cation of the currents will necessitate the expenditure of $10,000. This matter, however, will be settled later. It is thought quite unlikely that a lack of funds will hinder the work.

The Stockholm experiment with the electrifying process has been closely watched by scientists throughout the United States. The novelty of the plan aroused considerable interest, but through Mr. Tesla's services, New York will probably be the first American city to try it. It is said that the local test will follow closely along the lines of the foreign experiment.

For the work abroad two sets of fifty children, each averaging the same age and physical condition, were placed in separate class rooms, exactly alike except for the concealed wires installed in the walls of one room. The regular school work was taken up and the test lasted for six months. Frequent observations of the pupils were recorded to ascertain the effect of the high tension wave on the children under electrical treatment.

At the end of the experimental period the children in the magnetized room, the official report of the tests says, showed an increase in stature of two inches, while in the unmagnetized room the average increase was only one and one-fourth inches. The pupils in the electrified room likewise showed a weight increase and proportionate physical development greater than the children in the other. Then the investigators looked to the mental side of the question.

According to the report this examination showed that the children exposed to the electrical waves averaged 92 per cent. in their school work, fifteen being marked 100 by the teacher, while in the unmagnetized room the pupils were credited with an average of 75 per cent. and only nine obtained perfect ratings.

The electrified children, so the report says, appeared generally to be more active during the experiment and less subject to fatigue than those in the other room. The instructors likewise benefited by the treatment, it is said, and positively attested to the fact that their faculties were quickened and their powers of endurance stimulated by the waves.

Experimental psychologists, however, recommend cautious tests with the new process. Prof. W. C Bagley, head of the department of psychology of the University of Illinois, said on the subject:

"Such tests would certainly need to be repeated under carefully controlled conditions before we reached any conclusion. Not only this, but one would necessarily have to wait some years to see whether there were any deleterious results with the children subjected to the experiments. It would be the height of folly to encourage a wholesale application of this treatment prior to a most cautious and prolonged investigation within restricted areas."

This statement from Prof. Bagley was presented to Mr. Tesla. On reading it carefully the scientist said:

"After experimenting on myself and my assistants steadily during the past ten years, employing my most powerful coil, very much stronger than that used in the Stockholm test, I noted absolutely no ill after effects. On the contrary, many beneficial physiological effects of a lasting nature were recorded."

SUNDAY, AUGUST 18, 1912.

ELECTRIFIED SCHOOLROOM TO BRIGHTEN DULL PUPILS

Experiment Will Be Tried in New York with Superintendent Maxwell's Consent to See if High Potential Currents Will Help Defectives---Remarkable Results Reported Abroad.

Supt. W. H. Maxwell of New York's Public Schools.

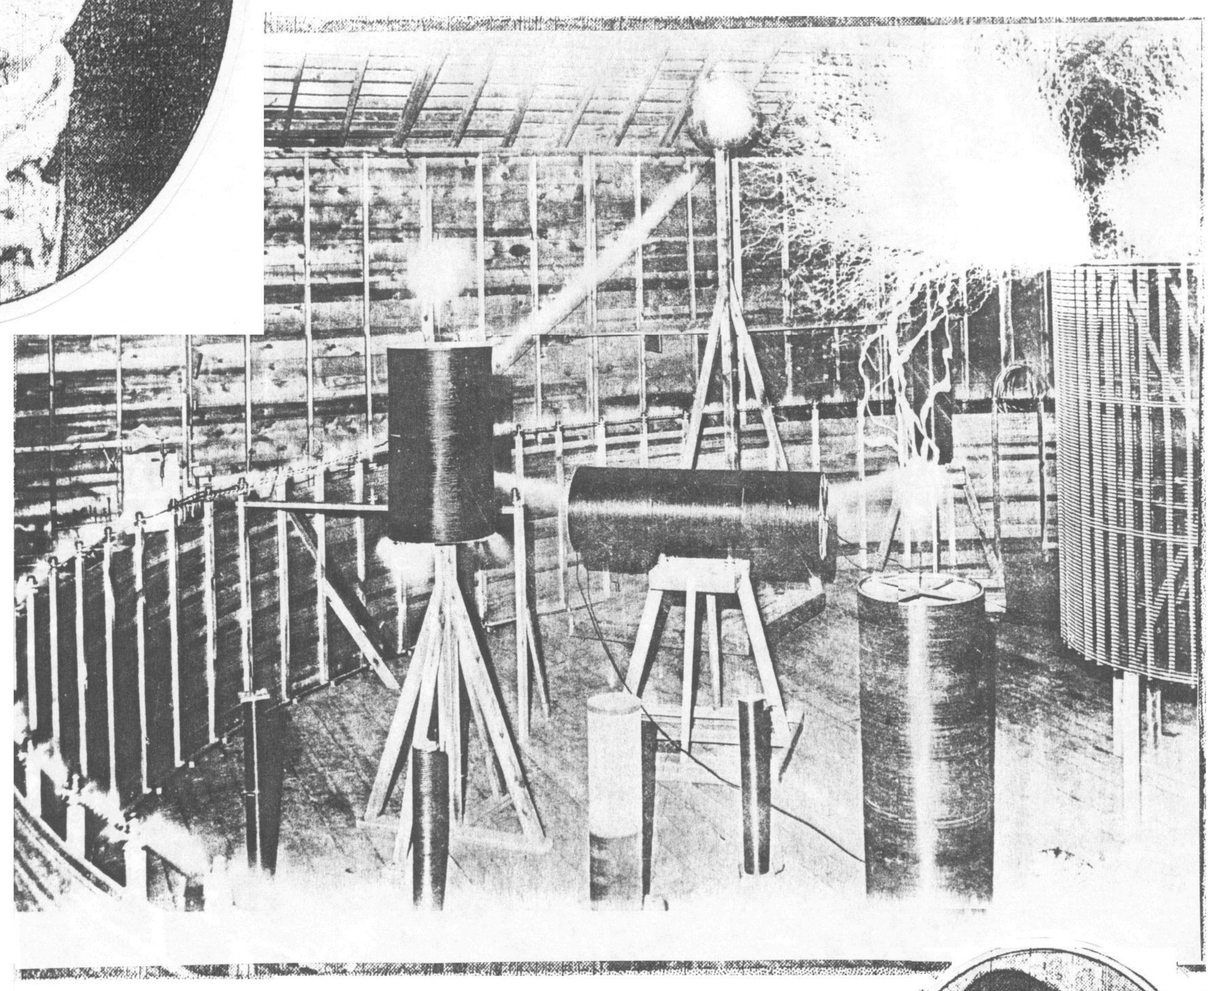
NEW YORK will try an experiment next Fall which, if successful, will completely overturn all methods hitherto applied in its schools and introduce a new era in education.

It is so sensational that at first sight, it seems like the impossible dream of a mad inventor. Yet it has the thorough approval of men who are by no means identified with anything sensational and unpractical, among them Superintendent of Schools William H. Maxwell and Dr. Louis Blan of Columbia University while the inventor of the scheme, Nikola Tesla, can point for corroboration of what he claims, to the extremely successful results already obtained by means of his invention in the schools of Stockholm, capital of Sweden.

Currents in the Walls.

Fifty mentally defective school children will be the first subjects of the experiment. They will enter and seat themselves in what will look, to all intents and purposes, like an ordinary schoolroom. But it will be far from that. Through the walls invisible electrical currents will run, by means of which, it is declared, the brains of the children will receive artificial stimulation to such an extent that they will be transformed from dunces into star pupils.

Six months is the time limit set for the experiment. At the end of that period, if the inventor and those who have studied his work are to be believed, the fifty backward pupils will leave the electric schoolroom and hold their own thenceforth with ease against their cleverest comrades, whom they had never even dreamed of emulating six months before.



The work is to be in charge of Mr. Tesla, who, by means of the Tesla electric coil, secreted in the walls of the classroom, will permeate its atmosphere with high frequency electric currents. It is expected that Dr. S. H. Monnell of Chicago, famous as an electro-therapist, will volunteer his services in carefully examining the children before, during, and after their exposure to the high-voltage current. Dr. Blan will assist him by making a record of the progress of each case.

City Superintendent of Schools William H. Maxwell said in confirming the report that the experiments are to be made.

"I am convinced that the high-frequency current has no deleterious effect; that, on the contrary, it is positively beneficial, and that the experimental tests should be and in all probability will be carried out in the Fall."

Cost of the Apparatus.

The cost of installing the apparatus and properly applying the tests is $10,000. Several men, including a New York philanthropist, have offered the amount. At the same time Mr. Tesla hopes himself to be able to finance this first experiment, and when its advantages are demonstrated, to then allow some interested person to step in and install appliances in every schoolroom of the city. All school children both normal and defective, would then be subject during their classroom periods to the stimulation of this pervasive high-frequency current. When asked about the cost of such a project, Mr. Tesla replied that it would be very moderate, about $100 to install the apparatus in each room.

Coils for the Transmission of the High Frequency Current. Photograph Represents a Powerful Machine. Effect Will Be Much Modified in a Schoolroom.

Use May Become General.

According to the inventor this experiment in the schools will be merely an opening wedge, a suggestion to the people that by the use of high potential electricity they may do away with the use of bromides, phosphates, pepsin tablets, and all kinds of drugs taken for disorders of the nervous and digestive systems. If his dream comes true, ten years from now people will inquire when renting an apartment or a house "Is it electrified?" Every one will have at least one room in his house furnished with a coil generating high frequency currents. By that time the appliances will be inexpensive, so that at a moderate cost people will be able to obtain superb health and mental brilliancy. Ordinary conversation will then be carried on in scintillating epigrams, and the mental life of the average adult will be so quickened as to equal the brain activity of the most brilliant people living before the time when a generator of high-frequency currents was a household essential.

Leading experimental psychologists assert that the high-frequency current intensifies cerebration. It is a mental stimulant, just as alcohol is a mental stimulant, the difference being that the electricity is harmless and confers lasting benefits. It is related that during certain high-frequency tests performed by Mr. Tesla one of his assistants was exceedingly stupid in carrying out instructions concerning the laboratory adjustments. The laboratory was equipped with a coil generating high voltage currents. After a time Mr. Tesla noticed that the man grew brighter and did his work better. He supposed for a time that this was because the man was learning, but after watching him closely he discovered that his assistant's quickness was much deeper than merely learning to make the tests. His mental life had been stimulated and instead of being slow to learn, as at first, he now showed remarkable acumen.

Form of Apparatus to be Used in a Schoolroom.

The tests made on school children in Europe were with the Tesla apparatus, and were carried on under the supervision of Prof. Svante Arrhenius at Stockholm, Swedep. The results were watched with keen interest by scientists, especially psychologists, in the United States, for, although scientific experimenting with school children is customary in Europe, it has as yet been untried in this country.

Suspicion of Experiments.

As Dr. Blan pointed out, over here there has until recently been a suspicious attitude on the part of people with reference to experiments of an elaborate nature performed on school children. Fear of deleterious effects has had something to do with this, as well as a general skepticism, on the part of educators, of the value of such tests. In this respect we in America have been far behind Europe, and especially Scandinavia, which is one of the most advanced countries in the world in its educational methods. The experiment about to be performed in the Fall in New York City will be the first of its kind in the United States, and so marks an epoch in our methods of handling school children.

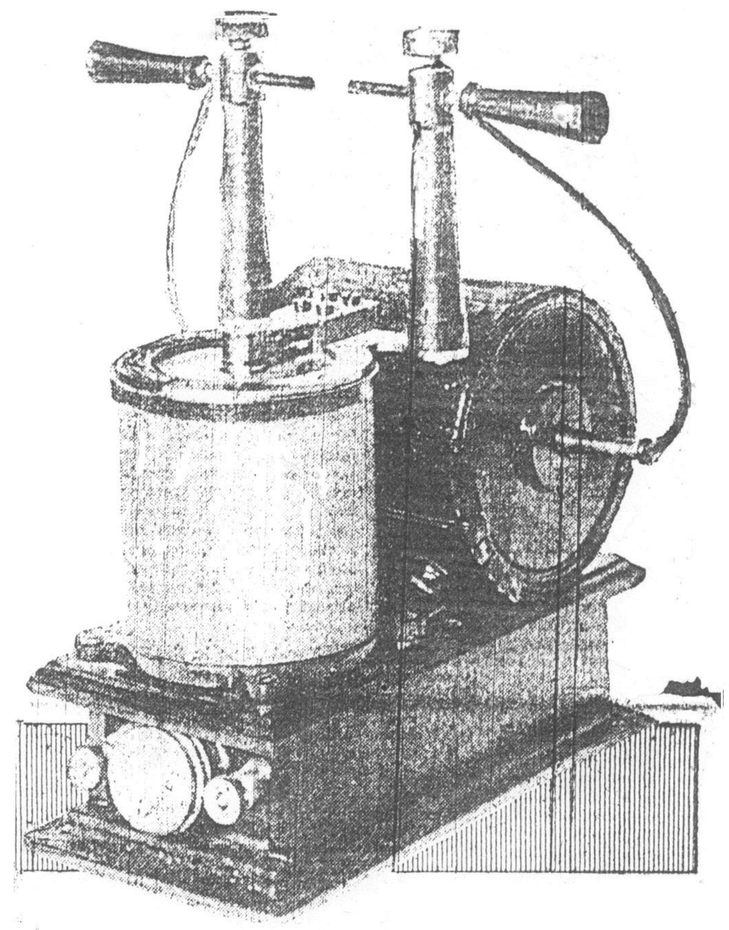
The question of a possible deleterious after-effect has, of course, been the crucial one on which opposition to the work has hinged. However, it is the consensus among psychological experts and electro-therapists that there is absolutely no danger attending such experimentation.

The Stockholm Experiment.

In Stockholm two sets of fifty children, each, averaging the same age and physical condition, were placed in separate class rooms exactly alike except for the concealed wires installed in the walls of one of the rooms. The regular school work was pursued and the test lasted for six months. Frequent observations of the children were recorded to ascertain the effect of the high-frequency waves upon them. At the end of the experimental period the children in the magnetized room, according to the official report, showed an increase in stature of two and a half inches, while in the unmagnetized room the average increase was only one and one-fourth inches. The pupils in the electrified room likewise showed a weight increase and proportionate physical development greater than that of the children in the other.

On the mental side, according to this report, the children exposed to the electric waves averaged 92 per cent. in their school work, as opposed to an average of 75 per cent. in the children of the other room. Fifteen pupils in the electrified room were marked 100 by their teacher, while only nine obtained perfect ratings in the other class.

The report continues that the electrified children appeared generally more active and less subject to fatigue than those that were not electrified, and that the teachers also experienced from the treatment a quickening of the faculties as well as an increase of powers of endurance.



Abroad these scientific tests are as likely to be made on average children as on defectives. In fact, the tests in Sweden were applied on normal pupils. "Here," comments Dr. Blan, "the custom seems to be to try everything on the goat first, and so sub-normal or defective children are to be used, whereas it would be just as well, perhaps even better, to electrify normal children and note the results."

When asked if there were any injurious effects whatsoever from high frequency electricity, Mr. Tesla replied that the effects of the rays of light issuing from the ordinary incandescent lamps in our houses were positively more harmful than those proceeding from the high potential coil. He added that the increasing prevalence of baldness may be largely due to the effect on the scalp of the electric rays from incandescent lamps.

Details of the Apparatus.

The apparatus is called the Tesla coil from its inventor. It consists of a primary made up of a few turns of coarse wire, and differs from the official coil of the X-ray machine largely in this coarseness of the primary. Whereas, using the X-ray coil, one may obtain from 50 to 150,000 volts, with the Tesla coil millions of volts may be generated. Carefully insulated wires will be inserted in the walls of the experimenting classroom and the tests will be carried on without the knowledge either of the teachers or the pupils. The air of the room will be completely saturated with incalculable millions of infinitesimal electric waves vibrating at a frequency so great as to be unimaginable and capable of measurement only by a most delicate volt meter.

The experts find that the higher the voltage and the lower the amperage the less harmful is the electric wave. High frequency currents never kill.

Instrument for Electrification Used by Physicians.

The low frequency currents with high amperage are the kind used in executions. The X-rays, produced by high-frequency currents, but through specially devised tubes, are, as is well known injurious. They are of lower frequency than the currents generated by the Tesla coil. The X-ray passes through the body like a bullet and actually makes microscopic holes. The high frequency currents from the Tesla apparatus do not pass through the body, but bathe it and permeate it very much as does alcohol when rubbed on the skin.

The fifty defective New York children who will be subjected to the experiment will in reality have an electric bath lasting for six months.

Dr. J. P. Sutherland, Dean of the Boston University School of Medicine, says: "I have been interested for some time in the subject of high frequency electricity, particularly in the effect of high frequency currents on metabolism, (that is, tissue-change.) My work has been confined almost wholly to adults. High frequency currents produce ozone, the properties of which as a tonic and a stimulant are well known. Although the effect of the current on the human body is not thoroughly understood as yet, it has a decided effect on its chemical processes."

Prof. Sutherland also predicts that one of these days the high frequency current will be a commonplace in the home. He says further that it is now possible to imbue persons with this electric tonic without their coming in contact with any apparatus whatever, or their even knowing that they are being exposed to the electrifying process.

Electricity's Effect on Women.

The effect of electricity upon women as compared to men calls to some interesting comments from Dr. Blan. "Women," he says, "are more sensitive to the electric wave than are men because of their inherent organic constitution. Women's hearts are smaller and pulsate more rapidly; their brains are smaller and their skin is thinner, which explains their shorter time reaction to electric stimulus.

"Further, women in their mental traits are more variable than men. This has been demonstrated by leading psychologists throughout the country, among them T. B. Thompson, a brilliant woman psychologist from the University of Chicago, who has written a book on 'The Mental Traits of Sex.' This means that in any random choice or select[illegible] of a group of men and women, the men are the most stupid and the brightest. In the scale of mental ability the women will occupy an average position.

In a series of tests carried out last year by Dr. Blan on school children of the City of New York, he discovered this new fact with respect to the position of women in the scale of mental ability by taking as his criteria the records of promotion and repetition for the boys and the girls. He found that on the average boys were brighter than girls, and that they were also more stupid. Girls occupied a middle position between the two extremes of intelligence represented by the two divisions of the group of boys.

In relating this fact to the application of high frequency currents, Dr. Blan said that in so far as the girls are more sensitive to the electric wave than the boys, the electric friction by means of high frequency currents will tend to raise the girls from their average position in the scale of intelligence into the class occupied by the exceptional boys.

Mr Tesla was asked to make a statement as to the manner in which his electrical experiments with the school children were to be carried out. He replied:

"The high frequency currents can be applied in three distinct ways. One is to pass the currents directly through the body, bringing the part to be treated in contact with the terminal or source of the current. Another way is to establish an electrostatic field in the room and expose the person to the influence of the alternating stresses of high potential. The third way is to act on the person by induction.

"When the experiment is made in this city the electricity will be applied in all three ways, but the third method will in all probability be given greatest prominence." In this case a cable will be laid around the room and high frequency currents passed through the same, creating a rapid-changing electro-magnetic field. The experiment in Stockholm was performed in this manner. The apparatus was in all essentials the same as the one I used in this city many years ago when I had an installment of that kind in continuous use."

Mr. Tesla said further that it was not essential to the, success of the tests that the wires be hidden or that the work be done without the knowledge of the teachers and the pupils, but nevertheless it would be done secretly so as to properly compare results with the experiment of Prof. Arrhenius.

No Danger to the Pupils.

When asked if there would be danger if for some reason or other the current passing through the cable were too strong, the inventor said no, and continued: "The apparatus is so designed that this will never happen. Yet, even if the current were a thousandfold increased, no untoward effect would result. I have frequently, in the presence of visitors in my own laboratory, energized a loop of wire with high frequency currents so strongly that when a piece of metal, such, for instance, as a sheet of tin, was approached to the loop, it was melted instantly, and the process of melting was so instantaneous that the metal would explode with the report of a gun. Into this same loop of wire so energized that the metal near it would come to white heat, melt, and burst with a report, I have repeatedly thrust my head and felt no inconvenience. My explanation is that human tissues act as electrical condensers, which means that the heating effect such as is produced in a conductor is excluded."

The New York Times August 26, 1912

ELECTRIFIED SCHOOLROOMS.

Reader Has No Faith in Fads That Promise Royal Road to Learning.

To the Editor of The New York Times:

With a somewnat deep-seated distrust of new-fangled devices in school keeping, I read the full-page article on electrified schoolrooms in SUNDAY'S TIMES. The Montessori method, exploded by a visit to Rome of a committee sent thither by Columbia for the express purpose of investigating it, promised, just as the new device from Sweden does, to make dull pupils bright and bright pupils superlative. Not a single new device has been brought out these twenty years, and they have been numerous, that did not promise wonders in the same words with which Rome and Stockholm now cajole us. "With our device," so evefybody with one has been saying, "we can get the child to attain 20 per cent, more in lessons and in less time." And when each new device has been favorably reported on (Page 251, Eleventh Report,) quite regardless of facts, and has served its purpose of advancing the "professional" fortunes of its sponsors, it is quietly dropped and another taken up.

If this new device is really tried, it is safe to say that it will be done in a school whose Principal (a title always printed with small letters in annual reports for years past) knows enough to report favorably, (XI., 251,) on new devices regardless of facts and for the purpose of seeking favor at headquarters—the exact words of the page quoted.

What in the world do we want of more improvement, anyhow? The promotions are now 92 per cent. of all pupils, (Page 82, Thirteenth Report,) and dozens of schools promote the pupils to the extent of 95 per cent. and more and, mirabile dictu, no less than seventeen promote from 99 per cent. to 110 per cent. of their pupils, (or victims.) These figures are official and may be read on Pages 410-470 of the Thirteenth Report. What per cent. of promotions may we anticipate if we advance on those figures? Surely we who went to school in the bad old times and were told there was no royal road to learning have a grievance so great that we should join the Bull Moosers to have it redressed. They alone can do it.

ROBERT P. KNOX.

New York, Aug. 20, 1912.

"The solar radiations are the primary cause, that is true, not those of light, but of heat. The loss of energy, I have found, is due to the evaporation of the water on that side of the earth which is turned toward the sun, the conducting particles carrying off more or less of the electrical charges imparted to the ground.

"At present it may be sufficient for the guidance of experts to state that the waste of energy is proportional to the product of the square of the electric density induced by the transmitter at the earth's surface and the frequency of the currents. Expressed in this manner it may not appear of very practical significance. But remembering that the surface density increases with the frequency it may also be stated that the loss is proportional to the cube of the frequency."

Why Wireless Does Best Work at Night

Nikola Tesla believes he has discovered the reasons for the phenomena long noticed by wireless folks that the wireless receiver is appreciably weaker in the day than it is at night.

In the *Electrical Review and Western Electrician* appears an article by the electrical inventor on "The Disturbing Influence of Solar Radiation on the Wireless Transmission of Energy." In this article Tesla accounts for this condition on the theory that as moisture in the air is dissipated by the sun's rays, and as particles of water in evaporating carry with them charges of electricity, the earth is thus deprived of some of the electrification which resides upon its surface at night. This, he claims, causes a dissipation of energy which necessarily interferes with the transmission of the electrical signals and prevents them from being observed at so great a distance as in the night time.

Tesla has long maintained that the earth plays as important a part in wireless transmission as the air and has contended as the results of demonstrations, he says, that the results accomplished are not due merely to Hertzian waves, whose existence was discovered by Heinrich Hertz, the German physicist. Tesla writes:

"Bearing, then, in mind that the receiver is operated simply by currents conducted along the earth as through a wire, energy radiated playing no part, it will be at once evident that the weakening of the impulses could not be due to any changes in the air, making it turbid or conductive, but should be traced to an effect interfering with the transmission of the current through the superficial layers of the globe.

The Disturbing Influence of Solar Raditaion on the Wireless Transmission of Energy

By Nikola Tesla

Editorial Note.—In the following interesting article, Dr. Tesla presents a theory to account for the diminished intensity of wireless signals on account of bright sunlight, which differs radically from the commonly accepted assumption that the effect is due to the ionization of the upper layers of the atmosphere by the ultra-violet rays of the sunlight. It will also be noticed that he does not accept the notion that the signals are transmitted by means of Hertzian or electro-magnetic waves, but explains the phenomenon on an altogether different basis.

When Heinrich Hertz announced the results of his famous experiments in confirmation of the Maxwellian electromagnetic theory of light, the scientific mind at once leaped to the conclusion that the newly discovered dark rays might be used as a means for transmitting intelligible messages through space. It was an obvious inference, for heliography, or signalling by beams of light, was a well recognized wireless art. There was no departure in principle, but the actual demonstration of a cherished scientific idea surrounded the novel suggestion with a nimbus of originality and atmosphere of potent achievement. I also caught the fire of enthusiasm, but was not long deceived in regard to the practical possibilities of this method of conveying intelligence.

Granted even that all difficulties were successfully overcome, the field of application was manifestly circumscribed. Heliographic signals had been flashed to a distance of 200 miles, but to produce Hertzian rays of such penetrating power as those of light appeared next to impossible, the frequencies obtainable

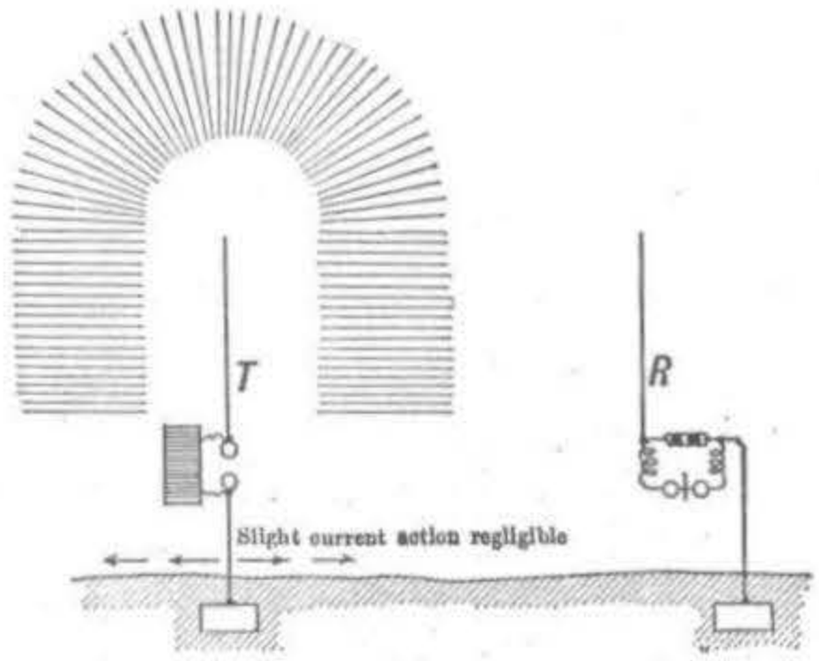


FIG. I.

through electrical discharges being necessarily of a much lower order. The rectilinear propagation would limit the action on the receiver to the extent of the horizon and entail interference of obstacles in a straight line joining the stations. The transmission would be subject to the caprices of the air and, chief of all drawbacks, the intensity of disturbances of this character would rapidly diminish with the distance.

But a few tests with apparatus far ahead of the art of that time satisfied me that the solution lay in a different direction, and after a careful study of the problem I evolved a new plan, which was fully described in my addresses before the Franklin Institute and National Electric Light Association in February and March, 1893. It was an extension of the transmission through a single wire without return, the practicability of which I had already demonstrated. If my ideas were rational, distance was of no consequence and energy could be conveyed from one to any other point of

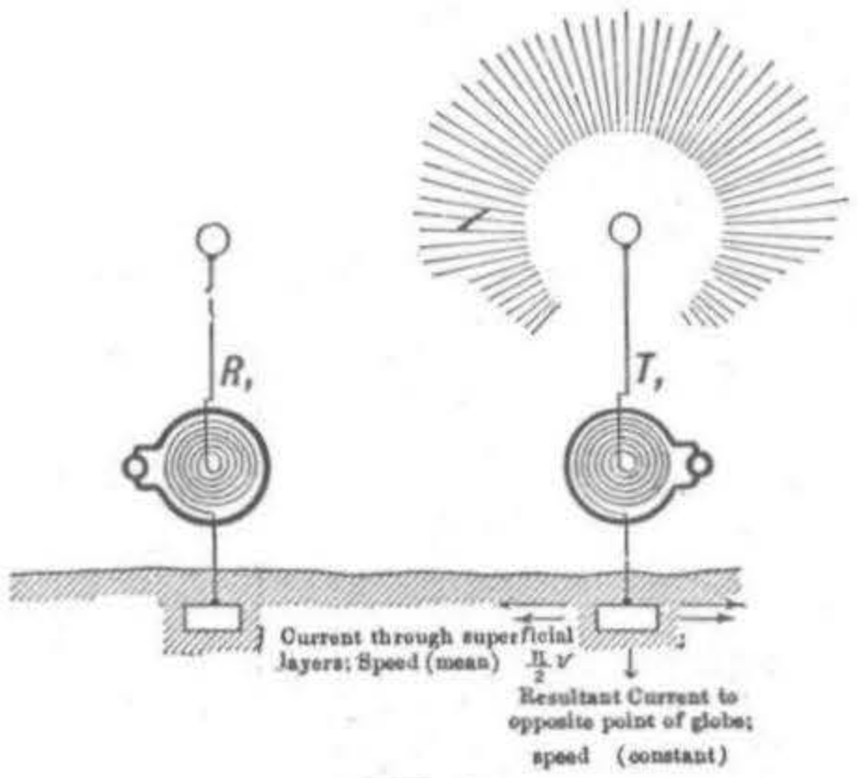

FIG. 2.

the globe, and in any desired amount. The task was begun under the inspiration of these great possibilities.

While scientific investigation had laid bare all the essential facts relating to Hertz-wave telegraphy, little knowledge was available bearing on the system proposed by me. The very first requirement, of course, was the production of powerful electrical vibrations. To impart these to the earth in an efficient manner, to construct proper receiving apparatus, and develop other technical details could be confidently undertaken. But the all-important question was, how would the planet be affected by the oscillations impressed upon it? Would not the capacity of the terrestrial system, composed of the earth and its conducting envelope, be too great? As to this, the theoretical prospect was for a long time discouraging. I found

that currents of high frequency and potential, such as had to be necessarily employed for the purpose, passed freely through air moderately rarefied. Judging from these experiences, the dielectric stratum separating the two conducting spherical surfaces could be scarcely more than 20 kilometers thick and, consequently, the capacity would be over 220,000 microfarads, altogether too great to permit economic transmission of power to distances of commercial importance. Another observation was that these currents cause considerable loss of energy in the air around the wire. That such waste might also occur in the earth's atmosphere was but a logical inference.

A number of years passed in efforts to improve the apparatus and to study the electrical phenomena produced. Finally my labors were rewarded and the truth was positively established: the globe did not act like a conductor of immense capacity and the loss of energy, due to absorption in the air, was insignificant.

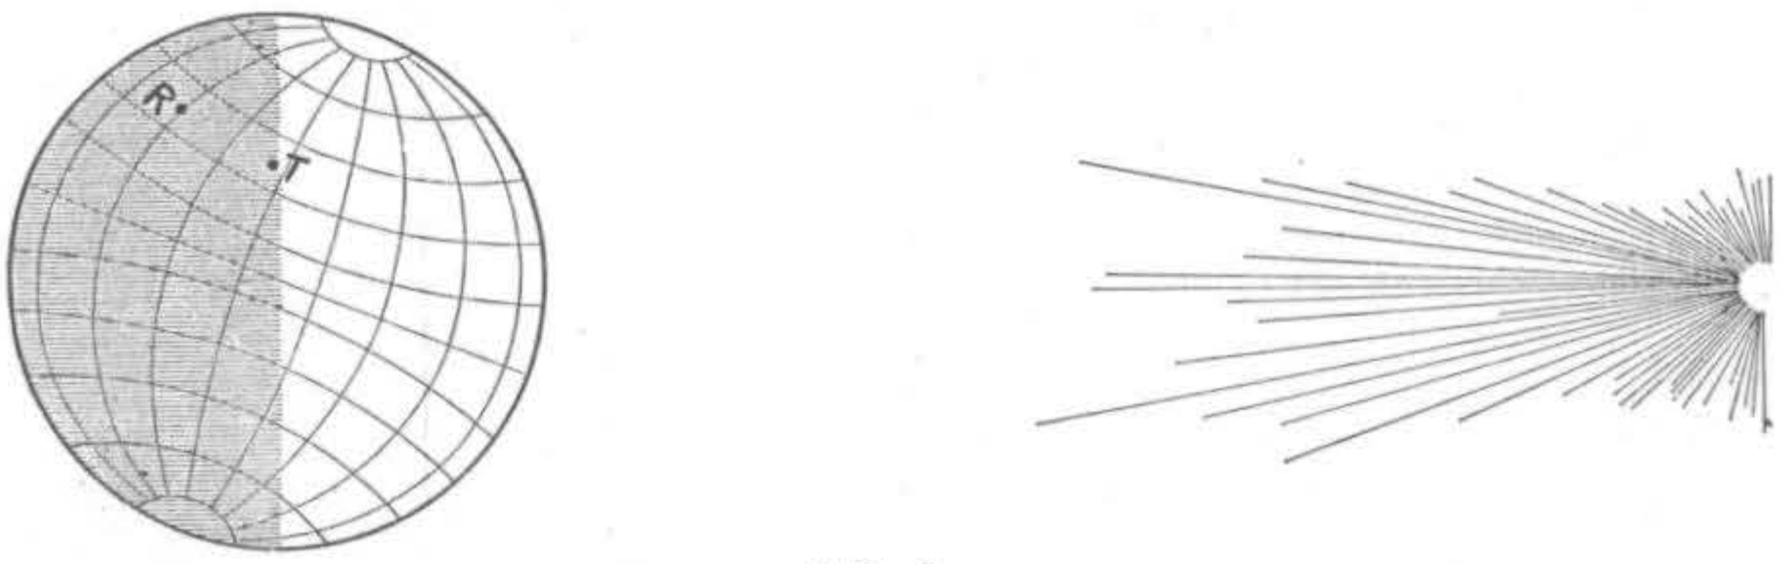

FIG. 3.

The exact mode of propagation of the currents from the source and the laws governing the electrical movement had still to be ascertained. Until this was accomplished the new art could not be placed on the plane of scientific engineering. One could bridge the greatest distance by sheer force, there being virtually no limit to the intensity of the vibrations developed by such a transmitter, but the installment of economic plants and the predetermination of the effects, as required in most practical applications, would be impossible.

Such was the state of things in 1899 when I discovered a new difficulty of which I had never thought before. It was an obstacle which could not be overcome by any improvement devised by man and of such nature as to fill me with apprehension that transmission of power without wires might never be quite practicable. I think it useful, in the present phase of development, to acquaint the profession with my investigations.

It is a well known fact that the action on a wireless receiver is appreciably weaker during the day than at night, and this is attributed to the effect of sunlight on the elevated aerials, an explanation naturally suggested through an early observation of Heinrich Hertz. Another theory, ingenious but rather fine-spun, is that some of the energy of the waves is absorbed by ions or electrons, freed in sunlight and caused to move in the direction of propagation. The *Electrical Review and Western Electrician* of June 1, 1912, contains a report of a test, during the recent solar eclipse, between the station of the Royal Dock Yard in Copenhagen and the Blaavandshuk station on the coast of Jutland, in which it was demonstrated that the signals in that region became more distinct and reliable when the sunlight was partially cut off by the moon. The object of this communication is to show that in all the instances reported the weakening of the impulses was due to an entirely different cause.

It is indispensable to first dispel a few errors under which electricians have labored for years, owing to the tremendous momentum imparted to the scientific mind through the work of Hertz, which has hampered independent thought and experiment. To facilitate understanding, attention is called to the annexed diagrams, in which Fig. 1 and Fig. 2 represent, respectively, the well known arrangements of circuits in the Hertz-wave system and my own. In the former the transmitting and receiving conductors are separated from the ground through spark gaps, choking coils, and high resistances. This is necessary, as a ground connection greatly reduces the intensity of the radiation by cutting off half of the oscillator and also by increasing the length of the waves from 40 to 100 per cent., according to the distribution of capacity and inductance. In the system devised by me a connection to earth, either directly or through a condenser, is essential. The receiver, in the first case, is affected only by rays transmitted through the air, conduction being excluded; in the latter instance there is no appreciable radiation and the receiver is energized by cur-

rents conducted through the earth while an equivalent electric displacement occurs in the atmosphere.

Now, an error which should be the focus of investigation for experts is, that in the arrangement shown in Fig. 1 the Hertzian effect has been gradually reduced through the lowering of frequency, so as to be negligible when the usual wave-lengths are employed. That the energy is transmitted chiefly, if not wholly, by conduction can be demonstrated in a number of ways. One is to replace the vertical transmitting wire by a horizontal one of the same effective capacity, when it will be found that the action on the receiver is as before. Another evidence is afforded by quantitative measurement, which proves that the energy received does not diminish with the square of the distance, as it should, since the Hertzian radiation propagates in a hemisphere. One more experiment in support of this view may be suggested. When transmission through the ground is prevented or impeded, as by severing the connection or otherwise, the receiver fails to respond, at least when the distance is considerable. The plain fact is that the Hertz waves emitted from the aerial are just as much of a loss of power as the short radiations of heat due to frictional waste in the wire. It has been contended that radiation and conduction might both be utilized in actuating the receiver, but this view is untenable in the light of my discovery of the wonderful law governing the movement of electricity through the globe, which may be conveniently expressed by the statement that the projections of the wave-lengths (measured along the surface) on the earth's diameter or axis of symmetry of movement are all equal. Since the surfaces of the zones so defined are the same the law can also be expressed by stating *that the current sweeps in equal times over equal terrestrial areas.* (See among others "Handbook of Wireless Telegraphy," by James Erskine-Murray.) Thus the velocity of propagation through the superficial layers is variable, dependent on the distance from the transmitter, the mean value being $\pi/2$ times the velocity of light, while the ideal flow along the axis of propagation takes place with a speed of approximately 300,000 kilometers per second.

To illustrate, the current from a transmitter situated at the Atlantic Coast will traverse that ocean—a distance of 4,800 kilometers—in less than 0.006 second with an average speed of 800,000 kilometers. If the signalling were done by Hertz waves the time required would be 0.016 second.

Bearing, then, in mind that the receiver is operated simply by currents conducted along the earth as through a wire, energy radiated playing no part, it will be at once evident that the weakening of the impulses could not be due to any changes in the air, making it turbid or conductive, but should be traced to an effect interfering with the transmission of the current through the superficial layers of the globe. The solar radiations are the primary cause, that is true, not those of light, but of heat. The loss of energy, I have found, is due to the evaporation of the water on that side of the earth which is turned toward the sun, the conducting particles carrying off more or less of the electrical charges imparted to the ground. This subject has been investigated by me for a number of years, and on some future occasion I propose to dwell on it more extensively. At present it may be sufficient, for the guidance of experts, to state that the waste of energy is proportional to the product of the square of the electric density induced by the transmitter at the earth's surface and the frequency of the currents. Expressed in this manner it may not appear of very great practical significance. But remembering that the surface density increases with the frequency it may also be stated that the loss is proportional to the cube of the frequency. With waves 300 meters in length economic transmission of energy is out of the question, the loss being too great. When using wave-lengths of 6,000 meters it is still noticeable though not a serious drawback. With wave-lengths of 12,000 meters it becomes quite insignificant, and on this fortunate fact rests the future of wireless transmission of energy.

To assist investigation of this interesting and important subject, Fig. 3 has been added, showing the earth in the position of summer solstice with the transmitter just emerging from the shadow. Observation will bring out the fact that the weakening is not noticeable until the aerials have reached a position, with reference to the sun, in which the evaporation of the water is distinctly more rapid. The maximum will not be exactly when the angle of incidence of the sun's rays is greatest, but some time after. It is noteworthy that the experimenters who watched the effect of the recent eclipse, above referred to, have observed the delay.

PRINCESS SEEKS AID FOR SERBS

American Actress Whose Husband Is of Old Balkan Family Asks for Subscriptions.

Among the Servians who have arrived in New York from the West is Prince Lazarovich-Hrebellanovich. He came from Los Angeles, Cal., accompanied by his wife. Although he says his title is only a courtesy one, Prince Lazarovich takes pride in an ancestral tree which he traces back to the rulers of the Servian Empire before the advent of the Turk.

The Princess was Miss Eleanor Calhoun, the American actress. They were married in London. When in California she began to raise money to aid the Balkan allies. In New York she contemplates a similar undertaking. Her idea is to have some well known bank undertake to receive funds which could be transmitted directly to banking institutions in the Balkans. In this matter she has obtained the co-operation of Mr. Nikola Tesla, the inventor, himself a Serb by birth, though for many years an American citizen. Mr. Tesla said yesterday that he is enthusiastic for the work on behalf of Servia which Prince and Princess Lazarovich have done and are doing, and said he believes that the Servian cause will be materially aided by some of his American friends.

Several hundred Montenegrins and Servians are expected to leave New York to-day. A number of them will go on board the steamship La Touraine, of the French line. A party of two hundred young men came from Bisbee, Ariz. There are two organizations of Serbs there and, together with subscriptions from individuals, they raised $5,000, which is being spent in providing transportation for this contingent.

Showing that the enthusiasm to go back and fight for their country continues unabated among the Greeks and Montenegrins as well as the Servians and Bulgarians, the steamship Sant' Anna, of the Fabre line, which leaves port this morning, will take out 1,200 Greeks in one party. Reservations for 200 more men who could not be accommodated on board that steamship have been made for the Niagara, of the French line, which, it is expected, will take a total of 1,000 men for the Greek army.

Though there are not many of them in this country, the Montenegrins are polling their full strength, 600 of them going out of the country to-day on board steamships of French, Italian and American lines. Three hundred more natives of that country are to arrive in this city to-day from various points in the Western States and Canada. All are paying their own way and are doing so enthusiastically.

Funds that have been started by natives of the four warring Balkan States are being rapidly increased, not only by subscriptions received from persons of their own nationality, but by Americans. The fund in aid of the Greek Red Cross Society, which is being collected by Miltiades Melachrino and Anthony P. Ralli, of No. 15 William street, was increased yesterday by subscriptions which totalled $2,200, bringing the total sum received up to date to about $7,200. This money is cabled directly to Athens.

The Daily Atlantis, the Greek daily newspaper, has a subscription list open to aid the Greek army's field hospital and cables the money directly to Crown Princess Sophie of Greece. Several large subscriptions, totalling $2,000, were received yesterday.

Funds in aid of the Bulgarian field hospital service are coming in slowly to the committee, of which Mr. Angelinoff, Consul General, is in charge. This is explained by the fact that the circulars that have been mailed extensively throughout the Western portion of the United States, where the greatest Bulgarian population in this country resides, have not yet been received by them.

The New York Herald November 15, 1912

MR. TESLA FEARS A EUROPEAN WAR

Says Balkan Struggle Was Made Possible by Diplomacy of His Uncle, Metropolitan Nikola.

Mr. Nikola Tesla, the electrician and scientist, who was born in Smiljan, on the borders of Austria-Hungary, and who has made a close study of European conditions, declared to a reporter for the HERALD last night that the situation created by the present war in the Balkans was one of extreme danger to the European Powers.

"If it comes to a clash of the Powers," said Mr. Tesla, "the result will be a war compared to which the greatest wars of history will be mere skirmishes. The improvement in the machines of war and the power of destruction which science has given to these engines would make such a war appalling. It is difficult to predict what the result would be, but one fact is certain—Germany would get the lion's share.

"Any one who knows of German science, thoroughness, discipline and the marvellous organization of its war force will concede that no two European Powers combined could fight Germany successfully. Russia, with its immense territory and resources, might be impregnable on the defence, but a battle on the open field between these two great Powers would undoubtedly be decided in favor of Germany."

Mr. Tesla asserted that the present war would not have been possible except for a stroke of diplomacy on the part of his uncle, the metropolitan Nikola, many years ago. He declared that the Balkan provinces would have been absorbed by Austria in 1878, when Servia was their enemy, except for the work of the metropolitan Nikola. He refused to discuss the fate of Constantinople, although he said that he had received confidential advices from friends in the war zone. He strongly advocated liberality to the Turks.

"The Balkans," said Mr. Tesla, "are not opposed to Austria, but to its policies. How can Austria be opposed when the majority of the Austrian population is Slav? But Austria has maintained its unity through the popularity of the House of Hapsburg. With the death of the present Emperor the bond that has kept the branches together will be dissolved. I believe that Austria, without a revolution and without bloodshed, will then fall apart. The Slav population will drift to the Slav centre, the German provinces will be absorbed by the German Empire and the Hungarians will win independence. It will be a Hungarian kingdom.

"Servia should have a seaport, and, in the event that the Powers should interfere, that much undoubtedly will be granted to her. In so far as England is concerned, there is only one opinion, and its attitude is significant. The United States should naturally have a voice in the proceedings, and very likely this country will be invited to mediate because there are so many Servians here. It is considered by all races that the Americans are fair.

"I do not believe in harsh measures, advocated by so many with prejudice against the Turks. The Balkan allies have now won great victories, but the greatest victory would be to show that they are dealing in the twentieth century and consider human beings all alike, Turk or Christian. I believe it best for the world that the Powers should interfere at this moment. Among intelligent persons there is only one opinion, and that is that the war should be over. If a hundred years had elapsed without this war civilization would have pushed the Turks out of Europe without any war."

Tesla's Plan of Electrically Treating School Children

By E. Leslie Gilliams

Nikola Tesla believes he has found an electrical way of lessening the burdens of school life and the difficulties of acquiring education. A few months ago Mr. Tesla laid before the superintendent of the schools of New York, William H. Maxwell, a plan for making dull pupils bright by saturating them unconsciously with electricity.

Mr. Maxwell, an eminently progressive and practical man, after a careful investigation of Mr. Tesla's plan, arrived at the conclusion that the experiment could not possibly do the pupils any harm, seemed feasible, and to promise the accomplishment of great good.

Therefore he endorsed it for a six months' trial.

News of the new electrical project has leaked out in the school world, and the eyes of progressive schoolmasters all over the United States are now turned towards New York, and many inquiries have been received by Mr. Maxwell, requesting particulars regarding this novel electrical educational experiment.

Nothing in detail, however, will be furnished for awhile, as after the test has been made, careful calculations must be undertaken and conclusions and deductions drawn therefrom. It has been announced that the experiment is first to be conducted on a class of mentally defective children, the most difficult of all pupils to handle, and the bane and trial of every school teacher's life.

Mr. Tesla's plan for the arrangement of the experimental electrical school room, which has received Mr. Maxwell's approval, calls for the installation in this

room of a number of insulated cable wires through the walls. These wires will be so carefully concealed as not to be noticeable to the pupils. Every effort will be made to keep the knowledge of the experiment from them. In general appearance the room will not differ from the ordinary bright, sunny, cheerful school room with its desks and other useful fixtures.

A high frequency current of millions of volts will be generated in an apartment properly arranged for the purpose outside of the school room. When school begins, by simply turning a switch, the high frequency current will be turned on, by one of the instructors, and shortly afterwards the school room will become completely saturated with infinitesimal electrical waves vibrating at high frequency. The whole room will thus, Mr. Tesla claims, be converted into a health giving and stimulating electro-magnetic field, or "bath."

When the inventor's plan was first brought to the attention of the Board of Education in New York, a lively controversy over the benefits of the proposition ensued. A fear existed on the part of some of the members of the board that the stimulation of the defective children, during the experimental period of six months, might be followed by a more or less prolonged or permanent reaction. These educators based their view upon the position taken by Professor W. C. Bagley of the Department of Physiology of the University of Illinois, who has made the statement that it would be years before it could be determined whether bad effects followed such an electrical experiment. Mr. Tesla and other noted electrical experts, who have had great experience with high frequency currents, claim that Professor Bagley is at fault in his presumption.

As proof they point to the fact that Mr. Tesla's project is more than a plan as, in Stockholm, it has already been carried out by Professor Savante Arrhenius with school children and proved most successful. No after effects except those of a beneficial nature have been observed, although they have been carefully looked for.

According to Tesla the high frequency current sets up in the body what he describes as a sort of molecular massage or tissue gymnastics. The tiny particles of which the body is composed are constantly in motion, and the high frequency current causes them to move about in a livelier fashion and increase in number. This unusual activity of the molecules of the human body brings about increased oxidation—the burning up of the waste product of the body by oxygen.

He acknowledges that his plan of stimulating dull pupils by saturating them with electricity is based on the well known theory of stimulating plant growth by electricity—a theory which has been successfully carried out in England by Sir Oliver Lodge, and has also been tried with favorable results by scientists in Denmark and Belgium.

The up to date home of the near future, Mr. Tesla believes, will not only be a place of rest, ease and comfort, but a health resort and a sanitarium as well, making seaside vacations unnecessary.

It will be equipped with high frequency electrical apparatus which will without the knowledge of the inmates keep them constantly charged with electricity, thereby warding off many ills and aches now common, and making the workers always fit for the battle of life. By means of the high frequency currents, he says, all the benefits of the seashore may be obtained right in the crowded city. Instead of spending a few weeks by the sad sea waves every summer, a man and his family may derive all the benefits of the seaside in his own home all the year around.

The New York Times September 4, 1912

SERVIAN PRINCE DEFENDED.

Nikola Tesla Denounces Attack on Lazarovich-Hrebellanovich.

To the Editor of The New York Times:

I am in receipt of a printed statement purporting to express the sentiments of the Serbs of New York. It is an attack on Prince Lazarovich-Hrebellanovich, so vulgar and libelous that its distribution through the mails constitutes a flagrant crime. I understand that thousands have been sent out, and that all the papers in the city have received them. While publicity was refused, much harm has been done, and this is the reason for my asking you the privilege of saying a few words in your columns in the interest of fairness and truth. My motive, however, is not only the just indignation of a man who has done so much for the Balkan cause and the pain and injury inflicted upon a noble American woman, his wife, but the discredit which is cast on my countrymen. I maintain that few of them will be found willing to indorse such an act, and that all those who are endeavoring to live up to Servian ideals will condemn it as emphatically as I do myself.

To make these malicious attacks which have unfortunately found some reflection in the papers effective, misinformation is designedly spread in regard to the status of Servian nobility. On this point it is necessary to enlighten the American public. The political and social changes in Servia bear no semblance to those which took place in America, because of the radically different racial and national traits, customs, and traditions. At the close of the fourteenth century, when the great Servian Empire, under Lazar-Hrebellanovich, fell, the rights of the dynastic family and those of nobility were not lost, although this privileged class was shorn of its worldly power and influence. In the succeeding few hundred years of Turkish rule it almost disappeared through assimilation and emigration. At the beginning of the nineteenth century, when Servia obtained freedom through a revolution, a law was passed forbidding the sovereign to bestow distinctive titles, but nobility still existed, and no special article provided for its extinguishment. Moreover, the modern free State of Servia comprised only a very small part of the mediaeval empire, and any law to this end would be limited to its own territory, and, in any event, would not be retroactive and of effect on those who had emigrated after the battle of Kossovo Polje. So it comes that there are still a few families in Austria, France, Russia, and other countries who can trace their ancestry back to the old Servian nobility, and if they choose to use their titles they can do so with full propriety.

As regards Prince Lazarovich-Hrebellanovich, his title matters little, for he has won a better claim to distinction through his labors and rare intelligence. In his capacity as publisher, editor, lecturer, and author he has rendered great services to the Servian people, which I trust will be fittingly recognized, despite all intrigue and opposition.

NIKOLA TESLA.

New York, Dec. 2, 1912.

Nicola Tesla Talks of the Future of the Greatest Problems Now Confronting the Scientific World.

TO begin, will you tell me, Mr. Tesla, which of the modern discoveries or inventions do you think will have the greatest effect on the future development of human interests?

There is no limit to human ingenuity and the possibilities of accomplishment. New advances, one more astonishing than the other, are being announced in rapid succession, each contributing to our comfort, convenience and safety of our existence. It is not impossible that some stupendous discovery might be made of greater effect on human life than any that has gone before, but, judging from what we know at present, I have no doubt that the perfection of the wireless art and its application for innumerable purposes to which it lends itself will be of greater significance in our future development than any other technical advance. This departure naturally means to me more than most others, for just at this moment I am enjoying the supreme satisfaction and happiness in seeing the principles I discovered and the ideas for which I fought, against the most violent opposition generally recognized and adopted.

Q. This new invention is certainly wonderful, but why should it be so much more important than others?

It is not new, and it is not an invention, in the ordinary acceptance of the term. The art is as old as the memory of man; only the methods and devices are novel. It is not a single invention, as commonly believed, but the result of a number of discoveries and improvements. It is revolutionary and far-reaching because of the fact that the greatest impediment to human progress is the immensity of the globe on which we live and consequent difficulty of bringing individuals in close contact, conducive to mutual understanding and harmony. In this is to be found the principal cause of most of our troubles and conflicts. This also is the chief reason for our limitations and the existence of conditions retarding our advancement. The telescope has enabled us to explore other worlds. The microscope has revealed to us many of nature's mysteries. The benefits we have derived from these inventions are inestimable. The wireless art gives still greater promise. It will be the means of completely annihilating distance and thereby affording unprecedented opportunities for intellectual and material advancement.

Wireless Art In Its Infancy.

Q. Would you not more clearly indicate how this is to be brought about?

By its universal application for all purposes in the three great departments of human activity which are: The transmission of intelligence, the transport of our bodies and materials and the transmission of energy necessary to our existence. Such great change will naturally consume considerable time. So far we have seen only the first and crude beginnings, confined to the field of intelligence transmission. But the experts have now freed themselves of illusionary ideas, which have delayed practical consummation, and it may be confidently expected that the time is not distant when signals, written characters, pictures, musical plays and spoken words will be conveyed from one to any other point of the globe and our facilities of communication and exchange of thought immensely improved. As regards transportation, the applications will come more slowly because they involve installments of plants on a large scale and the vanquishing of greater engineering difficulties. With the increasing skill and number of experts and commercial encouragement, which will naturally come when the rationality of such undertakings is practically demonstrated and their possibilities appreciated, the obstacles will be finally overcome and a new epoch in transport and travel will be inaugurated.

It is in the third department that the greatest revolution will be wrought, however, for cheap power will become available at any place in the world. This will put an end to a sinful waste of energy which is now going on in this country perhaps more so than in any other. Think only that in the manufacture of iron and steel in America the coke ovens and blast furnaces discharge through the flues excellent fuel sufficient to develop at least 20,000,000 horse power, which could yield a revenue of $300,000,000 a year. The natural gas and oil wells are another instance of such barbarous waste, particularly the former. In many places enormous quantities of gas are permitted to escape uselessly into the air when they might be employed for the production of power and manufacture of valuable compounds. In the mining, transportation and use of coal, on which we are now absolutely dependent, the losses incurred are appalling. But, however great the economies effected through the extensive use of this art they are of small consequence as compared with its advantages in connection with a great many problems for which it offers ideal solutions.

To Illumnate The Ocean.

Q. Can you illustrate this by specific examples?

Certainly. Consider, for instance, the safety of ocean travel. In the terrible disaster of the Titanic wireless messages have proved instrumental in saving life. This is gratifying enough, but the calamity might have been entirely avoided through the scientific application of the same underlying principles. Numerous devices have been proposed to prevent collisions with icebergs, and I have myself invented not a few, but after years of thought and reflection, with due consideration of these later developments, I have come to the conclusion that the best, if not the only radical remedy, is to illuminate the ocean. This can be done through wireless transmission of power. It is my earnest hope that in the near future a concerted effort will be made to this end. To name another instance, I may refer to the operation of aeroplanes and dirigibles by this method. The purely mechanical solution of the problem, on which all experts are concentrating their efforts, can lead to but limited success on account of the necessity of carrying fuel or other store of energy. A wireless flying machine, besides being simpler, could maintain itself indefinitely in the air. The civilizing potency and practical importance of this improvement alone are inestimable.

To mention other examples, I might dwell on various uses of a stationary waves. This unique terrestrial phenomenon was discovered some years ago. Popularly explained, it is based on the sympathetic response of the earth to electrical oscillations of great intensity and definite pitch. The phenomenon manifests itself through the presence of electrical forces or activities in perfectly fixed positions in space. When such conditions obtain, distance, in the transmission of electrical energy, ceases to have a meaning and many results of the greatest scientific and commercial importance become readily attainable. Vessels can be guided along any route without a compass and with unfailing precision, the speed of a moving object and its distance with reference to another point can be determined, and the diameter of the earth and many other geographical data ascertained with great accuracy and without the employment of the usual means of observation and measurement.

To Fight Wars With Electricity.

Q. What do you think will be the effect of the dirigible balloon and the aeroplane on warfare? Will advance in this direction ultimately result in doing away with wars?

For many years, and especially since the development of the more practical types of aerial machines, I have carefully followed the articles and discussions of experts in endeavoring to form my own opinion on this subject. Some military authorities belittle the possibilities of the aerial vessel in this respect, but we have seen in the recent conflicts that the aeroplane has already exercised a marked influence on the tactics and general conduct of war. There can no longer be any doubt that a vessel on the plan of the Zeppelin dirigible would be a formidable instrument in a battle between armies as well as encounters at sea.

I believe, though, that there is absolutely no reason for a panic on that ground, for it should be borne in mind that in the same measure as we are perfecting aerial machines we are likewise improving the instruments for their destruction. There are already guns especially constructed for this purpose. Remember, however, that aerial machines will be equally available to both combatants, thus leaving the equilibrium undisturbed. It is difficult to say what the outcome will be in the next few years, but we may feel sure in making one prediction, namely, that the means of defense will always outstrip the means of attack. This is in the very nature of things, for it is a fundamental law that it takes less effort to disintegrate than to put in form.

Personally, I believe that wars in the distant future, if they do come, will be decided not by mechanical appliances but by electrical forces. I can see the day when it will be possible to direct from a power plant to any point on the globe, destructive energy of such intensity that the most terrible engines of war so far invented will be mere playthings in comparison. When this becomes possible, wars should cease. In the meantime, the enormous cost and sacrifice involved in warfare will be a powerful deterrent, compelling nations to choose the peaceful course.

Predicts New Storage Battery.

Q. Is there any prospect that the electric motor will in the end displace the gasoline engine in the operation of automobiles?

That, of course, is a woman's question. You are afraid of complication and believe that to simplify the apparatus is an essential requirement. The mechanical engineer does not look upon this in the same light. Although the present gasoline engine is far from being ideally simple, it has proved itself eminently practical, as is evidenced by the enormous extent of the automobile industry founded on its use. To replace this engine, and particularly the much improved type which is surely coming, will call for a new principle in primary or storage batteries. In these fields we have advanced but little since the discoveries of the early pioneers, but the announcement of a new principle may come any day, and it will be the death knell of the heat automobile engine, for no such machine can ever equal the electric motor in simplicity, safety and ease and perfection of control.

Q. Do you believe that printing will ever be replaced by a photographic process?

Photography, from its first inception, was a great triumph of invention. It has been of immense assistance in the study of all the phases and phenomena of nature. But while wonders have been achieved in this department, we are still far from replacing printing by photography. Printing machinery has been perfected to an incredible degree, as is well exemplified in the production of the daily papers. It is conceivable that by the use of a photographic method records could be made much quicker and cheaper. Photography seems to lend itself more especially to the reproduction of pictures, and in this particular line much is being done at present. A far-reaching improvement achieved of late years is color photography, and it is now a burning problem to devise a cheap and simple process for the reproduction of color photographs. The task is very difficult, but it will be undoubtedly accomplished.

Radium as Power Factor, a Dream.

Q. How about the dictagraph?

This is not a great invention, though a very useful instrument. It is popular with people who are not worrying about the form of expression, but it will never supplant an intelligent secretary or stenographer. My interest in this and similar devices resides chiefly in the possibility of their use in connection with the wireless system. Very soon it will be possible to make such records at any distance, and then the full value of this improvement will be demonstrated.

Q. What do you think of radium and the prospect it opens for the future?

My views on the subject are probably not in agreement with those of many men of science who have devoted themselves to this branch of investigation. It may not be generally known that in my papers published in the Electrical Review of New York from 1896 to 1897, long before the discovery of radium by Mme. Curie, I demonstrated the existence and described the salient properties of emanations of the same nature. My views were received with skepticism at that time, but I am glad to say that now they are adopted in their entirety. I see no reason for changing the opinions I then expressed. The so-called radium emanations are not an isolated phenomenon, but are universal. There is, according to my ideas, no such element as radium or polonium, although spectral analysis, the theory of Mendeleff, and various experimental observations, support this modern view. I believe, that as to this, scientific opinion is in error, as it was a century ago, in assuming that there was such a substance as phlogiston concerned in combustion until Lavoisier discovered oxygen. Similarly the radium manifestations are, in all probability, due to the action of a universal medium on certain volatile substances. Much of the speculation based on Mme. Curie's discovery is necessarily erroneous, being in direct contradiction to well established principles. The claims of some enthusiasts that in radium lies the possibility of future power development are nothing but a dream. But solid fact is that we are in the presence of new and wonderful effects the study of which is leading us gradually to a better and deeper understanding of the mechanism of the universe.

Harnessing Nature

Can the Free Energy of Space be Utilized?

By Waldemar Kaempffert

IN a few centuries the world's coal mines will be exhausted. Whence shall we derive the energy to turn the wheels of industry? By harnessing nature, is the answer. Long before we took stock of our fuel supply and found that we must husband what little we have left, scientific dreamers wondered whether natural forces could not in some way be utilized. To be sure, the potential energy stored up in every combustible is a natural force; however artificial our engines may seem, their power is nevertheless ultimately obtained from the sun. But that power is released and applied only by complicated and cumbrous mechanism that wastes many times more energy than it delivers. Why should it not be possible to tap the free energy of space, the energy with which the sun, for example, incessantly bombards us? Can not some engine be devised to transform and make available the apparently inexhaustible supply of energy liberated by every atom of radium? To answer questions such as these with anything like satisfaction is impossible. Yet they are discussed by the most distinguished physicists of the day, and therefore they acquire a dignity with which they might not otherwise be invested. At the fourth annual meeting of the British Science Guild, for example, the whole vast subject of harnessing nature was considered and a committee of seventeen was appointed to report upon it. Among the members of that committee were such distinguished scientific men as Sir William Ramsay, Hon. R. J. Strutt, Prof. Vivian B. Lewes, Sir Charles A. Parsons, Mr. Dugald Clerk, and Dr. Hele Shaw. The committee has not yet handed in its final report, but it has done enough to show how wonderful are the possibilities of engineering when combustibles will no longer be available and along what lines the investigator must work if success is to be attained.

Water Power.

The only natural source of free energy that engineers have thus far successfully utilized is water power. How they have gone to work is so old a story that it need not be retold here. Their task was simple. The crudest kind of bladed wheel ground corn centuries ago. The great turbines of Niagara Falls are merely improvements upon it.

A water fall is a ready-made solar engine, the only commercial solar engine that man has succeeded in utilizing. No machine has ever been designed or ever will be designed that will surpass the water fall in efficiency. The sun pumps the water of ocean, lake and river on mountain tops, and the force of gravity drops the water again to its original level. The cycle is endless. Because there are no valves, no shafts, no connecting rods, no thermal losses, the efficiency is one hundred per cent. It has been calculated that the total energy of these atmospheric deposits amounts to 100,000,000 horsepower. With the advent of electricity and its introduction into industry part at least of this energy is being used—the sole example of the successful use of nature's free energy.

Putting the Sun to Work.

But why not go directly to the sun? Its radiation has been measured and expressed in engineering units. In his Royal Institution lectures of 1911, Sir J. J. Thomson stated that, shining from a clear sky, the sun sends to the earth energy at the rate of 7,000 horsepower an acre. Moreover, as the temperature of the sun is at least 6,000 deg. Cent. this energy must arrive in a highly available condition; theoretically it ought to be almost wholly convertible into mechanical work. No wonder that the construction of a commercial solar engine has been one of the most fascinating problems that ever engaged the attention of inventors.

Up to within recent years the most elaborate experiments on record were those of Capt. John Ericsson, designer of the famous "Monitor." On a rainless strip eight thousand miles long and one mile wide, extending almost continuously from Africa into Asia and from South America into the United States, solar heat enough is wasted, he figured, to drive 22,300,000 solar engines of one hundred horse-power each, nine hours a day.

In endeavoring to utilize a very small part of this truly staggering amount of wasted energy, Ericsson worked persistently from 1865 to 1878 and built in that time no less than seven sun engines. He adopted the rather obvious method of concentrating the sun's rays on a boiler when he was driving his engine by steam, and on an air chamber when he employed one of his "caloric" engines. Eventually he succeeded in obtaining about one horse-power for every one hundred square feet of reflecting surface. Finally he came to the conclusion that the scheme was impracticable. "The fact is," he frankly admitted, "that although the heat is obtained for nothing, so extensive, costly and complex is the concentration apparatus that solar steam is many times more costly than steam produced by burning coal."

Since Ericsson's day other attempts have been made along different lines. Readers of the SCIENTIFIC AMERICAN are familiar with the proposals of Mr. Frank Shuman, Prof. Reginald Fessenden, and Messrs. Willsie and J. Boyle, Jr. Because their apparatus has been described in these columns at sufficient length it is unnecessary to dwell upon it again. In all these three solar power plants, the "hot box" of de Saussure, Langley and other pioneer solar physicists is employed. In other words, a film of water is heated in a glass-covered trough. The heat impounded by the trough is sufficient to raise the water to the boiling point, or very near it. Mr. Shuman has designed a low-pressure steam engine in which this hot water is flashed into steam. Messrs. Willsie and Boyle employ their hot water to vaporize a liquid, which has a boiling point lower than that of the water, a liquid such as sulphur dioxide. The vapors which are given off from the sulphur dioxide at a pressure of 215 pounds to the square inch drive a specially designed engine and are then returned to be used over again. The water which has given up its heat to the sulphur dioxide is sent through the hot-box again to absorb more heat from the sun.

Since the sun does not shine by night even in the desert of Sahara, a storage system must be devised—a piece of apparatus that can be charged with excess power and tapped at will in sunless periods. Compressed air tanks, storage batteries charged by dynamos driven by the solar engine, water pumped into a reservoir by a solar pump and used later to drive a water wheel, have all been proposed. Messrs. Willsie and Boyle store their hot water in a well insulated tank, so that it retains its heat over night and is always hot enough to vaporize sulphur dioxide. Mr. Shuman has also designed an insulated tank or boiler for storing hot water.

Prof. Fessenden, in the solar power scheme described and illustrated in the SCIENTIFIC AMERICAN two years ago, considered it more expedient to pump water into a reservoir and let it drop a considerable height against a water wheel. He, too, heats his water in a thin film under glass, causes the steam thus generated to drive a low-pressure pump directly, and thus fills his reservoir with water. In the plant illustrated in the SCIENTIFIC AMERICAN he showed a way of lifting Channel water to the top of the Dover Cliffs, so that it would flow back through a pipe and drive a water turbine at the bottom of the cliff. In conjunction with each solar plant a windmill is to be operated, so that, as he explains, "much better all-day and all-year efficiency will be obtained, because the wind is, as a rule, more effective during cloudy weather and at night time, i. e., when solar radiation is diminished or absent."

If we can extract heat from anything we can perform work. Water can be boiled without fire simply by reducing the pressure of the atmosphere. Since the atmosphere contains a certain amount of heat, why not extract it, as it were, and drive an engine? That is a proposal which Mr. Nikola Tesla has made. The direct utilization of the sun's heat after the manner of Ericsson, Shuman, and others seems to him commercially hopeless, however practicable it may be on an experimental scale. Moreover, he cannot reconcile himself to the idea that the entire manufacturing interests of the world must be transplanted to Arizona, southern California, Egypt, or the Sahara desert when the world's coal supply is exhausted and the solar engine is at last realized. Industry seems to be identified with the temperate zones, where sunshine is intermittent. The periodicity of sunshine, with which all solar engineers must reckon, he finds an insuperable difficulty. Moreover, it seems inept to him to convert the intense heat of the sun into low-temperature heat, of which only a small fraction can ever be recovered as mechanical work. In his opinion, the only direct way of converting solar energy into work is to tap the heat units of the atmosphere, heat units available at all times, in fair weather as well as foul, in summer as well as in winter. There is no need to invent storage systems; for the atmosphere is its own storage tank. This is, to be sure, but a thermodynamic dream as yet, but a dream which, however wild it may seem, is nevertheless worthy of at least academic discussion.

The Photo-chemical Power Transformer.

Every living organism is a crude kind of solar engine. We are all dependent on the product of the soil for our existence, and that product in turn represents so much solar energy chemically stored up. A grazing cow is a living engine that converts solar energy into work. The solar energy that has caused grass to grow is turned to practical account whenever she flicks a fly from her back. Prof. V. Coblentz has suggested that perhaps a chemical substance may be discovered, which, when exposed to the sun, is transformed into a stable substance capable of giving up its energy for subsequent consumption, a substance more highly efficient than grass and capable of releasing its energy perhaps in an electrical way.

This idea was further developed in a profound analysis of photo-chemical problems before the recent International Chemical Congress by the distinguished Italian chemist, Prof. Ciamician. An obvious cycle, he suggested, was the use of mineral fertilizers to raise a harvest, which, dried by the sun, could be converted entirely into gaseous fuel, the ammonia being fixed and returned to the soil as fertilizer, together with the ash. He also deemed it possible to produce the things we need directly without the intervention of much factory machinery. If ammonia can be directly obtained from atmospheric nitrogen and hydrogen—the recent technical achievement of a great German chemical manufacturing company—why should it not be possible, he asks, to utilize solar energy in connection with catalytic substances and thus artificially reproduce plant processes on an unprecedented scale? A photochemical laboratory in northern Africa might thus produce immediately useful substances now supplied only after much coal-burning, engine-driving and mechanical handling of raw material. A meadow is not a highly efficient transformer of solar energy, but the manner in which it synthesizes the chemical elements stored up in the earth with the aid of sunshine might well be artificially reproduced, and the solar engine itself abandoned except for purely thermodynamic purposes. If a plant can reverse the process of combustion, if it can transform the carbon dioxide of the atmosphere into starch, simultaneously setting free oxygen, why can't man adopt the same principle with success? At all events, Prof. Ciamician holds that it lies within our power to make plants produce abundantly the things we need. The possibility is indicated when we consider the ease with which we have increased the amount of sugar in the sugar beet and the percentage of protein in wheat.

The Energy of the Rotating Earth.

In an introductory lecture to the engineering classes at University College, London, Prof. J. A. Fleming, in considering the sources of energy available to mankind, pointed out that the earth is a great flywheel. It whirls along in its orbit with a velocity of about twenty miles a second or 1,200 times that of an express train. Its rotational energy is a hundred thousand million billion horse-power hours; but the total orbital energy or energy of motion in its orbit is ten thousand times greater. "Suppose," said Prof. Fleming, "suppose we could in some way or other slow down its rotation so as to make the day just five minutes longer. . . . This would decrease the earth's angular velocity by about one third of one per cent and decrease the angular energy by about two thirds of one per cent, or say by 1/150 part. If then we could capture and store up the difference in the rotational energy in the two cases, it would give us about six million billion horse-power hours, or a billion horse-power for seventy thousand years. The energy we can obtain by the combustion of all the one thousand million tons of coal at present raised per year, sinks into insignificance compared with the enormous energy which would be set free by an almost imperceptible lengthening of the earth's diurnal rotation."

Prof. Fleming was not rash enough to indicate in what manner this unthinkable amount of energy could be utilized. Those who will attempt that will find themselves engaged in the mad task of designing perpetual motion machines.

The Energy of the Atom.

If Ramsay is correct in stating that copper and lead can be disintegrated, have we not here a source of energy? Sir William Ramsay has himself effectually disposed of that possibility. First, all metals, except gold and platinum, he has pointed out, are produced by the combustion of fuel, or, it may be, by electric power derived from turbines and dynamos. Hence they must be more costly than the means used in their produc-

tion; to produce them, not merely must energy be used, but also some must be degraded, and lost as heat. Labor, too, is expended in their production. On the supposition of change with evolution of energy, they would give out no more than has been put in, in converting the ores into the metals. Lastly, supposing that this compound can be induced to change, under the action of ultra-violet light for example, the change is too slow to be effective as a source of energy; and ultra-violet light itself is produced only after much energy is expended.

Experiments conducted by Mr. Nikola Tesla with electromotive forces of 20,000,000 volts have convinced him that if 100,000,000 volts could be produced it might be possible to break down the atomic structure of any element and thus liberate a certain amount of energy. "But," he told the writer of this article, "even if the feat could be accomplished and sufficient energy set free, there still remains the enormously difficult problem of devising a means of utilizing the energy in a practical way."

Prof. J. A. Fleming suggests a somewhat similar course. "It is now pretty generally recognized," he argues, "that an atom is a complicated structure, a sort of solar system in miniature composed of revolving electrons. It may be possible to break down the structure by the action of impulses due to concentrated electric waves of the right period, setting up vibrations, which are resonant with some natural period of the atom, just as it is possible to break down a suspension bridge by a number of men jumping on it in time with its natural period of oscillation. If then the atom were to break down, the energy liberated might be far greater than that applied to it in the form of the resonant impulses."

Sir William Ramsay is undoubtedly right in maintaining that no source of energy, capable of being converted into work on a large scale, can be looked for, so far as the transmutation of matter is concerned. "The question is not—can it be done? but—does it pay to do it? And to the last question the answer is emphatically *no*."

Radium as a Source of Energy.

So minute a quantity of pure radium as one gramme (one twenty-eighth of an ounce) yields 118 calories an hour, 2,900 a day, or nearly one million a year. A ton of radium, according to Sir William Ramsay containing a million grammes, would give one million million calories per year. As one gramme of coal in burning evolves about 8,500 calories, one ton would evolve one million times as much, or 8,500,000,000, which is only the 117th part of that evolved by the radium in a year. Moreover, the radium after the year has suffered merely a minute loss of weight; roughly speaking, about 1/3,500th of its weight has disappeared; hence before it was all "consumed" it would have evolved $117 \times 3{,}500 = 460{,}000$ times as much heat as an equal weight of coal. Add to this the fact that coal is utterly consumed in a few hours, but that rate of change of radium is all but imperceptible, and the superiority of radium over coal, weight for weight, is still more apparent.

Unfortunately, radium is about the scarcest producer of energy in the whole world. Radium is the offspring of uranium; it does not occur apart from uranium. Sir William Ramsay places the supply of uranium in its ores at about one million tons. Since the amount of uranium contained in the "kulm" shale of Sweden is under 0.5 per cent he concludes that the amount of radium metal in the whole world is not more than 500 pounds—too insignificant, in a word, for serious consideration as a substitute for coal. Not more than 125,000 tons of coal would be saved by utilizing the energy in 500 pounds of pure radium. The railway locomotives of the United States burn more than that quantity of fuel in a year. Besides, the energy in the five hundred pounds of radium cannot be liberated quickly, but must be spread over a period of centuries. The late Prof. Curie once remarked that he would not venture into a room containing only a pound of radium, so extraordinarily intense is its action. Hence, even if it were possible to hasten the discharge of radioactive energy, the engineers of a radium power plant would have to be recruited from the members of Stevenson's Suicide Club.

The Internal Heat of the Earth.

It is a matter of common knowledge that in sinking mining shafts there is a rise in temperature of about 1 deg. Fahr. for every 69 feet, down to a certain depth. Active volcanoes afford still more striking evidence of the earth's internal heat. Have we not here an inexhaustible source of energy? We have, but it is difficult, if not impossible, to utilize it. If the prime requisite in making use of any source of heat is to obtain good conditions of thermal interchange with it, an insuperable obstacle would be found in the poor conducting qualities of rock. Only by fluid convection would it be remotely possible to obtain communication with the earth's stores of heat. In considering these possibilities, the Hon. R. J. Strutt points out that hot springs, while they have been utilized from time immemorial, are too diminutive. The perpetual streams of molten lava that flow into the sea in certain localities, as at Stromboli, might perhaps be utilized, he ventures, "but the opportunities for applying the method would scarcely be extensive enough to encourage inventors."

Why not pump water down to the heated interior and return it to the surface at a high temperature? Here again Strutt sees no possibilities. The pipes would have to be kept immersed in molten lava; no sufficiently rapid transference of heat to them from solid rock would be possible. For the same reason, he states, the pipes must not be cooled down by the water flowing through them sufficiently to cause the surrounding lava to congeal. Can the pipes endure the prolonged action of molten basalt? Wrought iron might in Strutt's opinion. "On the other hand, the margin of difference between the melting point of basalt and of iron is not very great, and lack of stiffness in iron pipes at such temperatures would undoubtedly introduce the most serious difficulties." Even if the attempt be made by directly attacking a volcanic crater the engineering difficulties would be enormous.

Similar conclusions were reached by Sir Charles A. Parsons in a presidential address to the engineering section of the British Association for the Advancement of Science. He discussed the feasibility of constructing a bore hole twelve miles deep. While the feat could be accomplished, and while the temperature of the rock at that depth is probably 272 deg. Fahr., the undertaking would involve an expenditure of millions.

HIGH-FREQUENCY CURRENTS.[1]

By W. D. Duddell.

The methods of producing high-frequency currents may be divided broadly into three classes, namely: (1) alternator methods; (2) methods based on the oscillatory discharge of a Leyden jar; (3) arc methods.

In a little special machine which I have here there are 15 magnets—that is to say, 30 poles alternately north and south—and it runs at 8,000 revolutions per minute or 133.3 revolutions per second, so that frequency in this case is 2,000. The peripheral speed of this machine is just over three miles per minute. From this example it will be pretty obvious that if I attempt to obtain high frequencies—that is to say, frequencies well above 10,000—I shall have to run either at enormous speeds or have a very large number of poles. One of the very earliest high-frequency machines ever constructed in this country, and following shortly after Tesla's high-frequency machine, was made by Messrs. Pyke and Harris for Sir David Salomons.

The machine ran at 1,500 revolutions per minute, but as both the armature and the field magnets are free to move, their relative rate was 3,000 revolutions per minute, or 50 revolutions per second. The number of pairs of poles is 174, so that frequency is 8,700.

At about the same date that Sir David Salomons had his machine constructed, Mr. Parsons constructed for Professor Ewing at Cambridge University a high-frequency alternator in which the high frequency—namely, 14,000—was obtained by using a high speed of 12,000 revolutions per minute.

If, instead of moving the wires across the faces of the magnets, or moving the soft iron cores on which they are wound, the wires be wound on the poles of the magnets and a piece of soft iron moved past the magnet poles, an alternating current will be produced as before, with this difference—that for a given number of poles and a given speed this type of alternator will produce twice the frequency of the previous type. Alternators depending on this principle are usually called inductor alternators. Many high-frequency alternators have been constructed on this principle by using 204 polar projections or teeth and a speed of 35,400 revolutions per minute. I have obtained a frequency of no less than 120,000 in a machine I constructed in the laboratories of the Central Technical College, but the output of the machine was microscopic.

Turning to modern high-frequency machines, we have the alternator designed by Mr. Alexanderson, with which frequencies as high as 200,000 have been obtained.

A high-frequency alternator on quite a different principle is due to Dr. Goldschmidt. I have mentioned in Sir David Salomon's early machine that the two disks forming the field and armature were rotated in opposite directions. It is possible, however, to produce a rotating field electrically without the disk moving at all. When this is accomplished the frequency of the machine depends as before upon the relative speed of the rotating field and the armature.

Consider for simplicity, a machine having only two poles, so that it gives one complete cycle per revolution, and suppose I supply the fixed part or stator with an alternating current of 100 frequency and so connect it that it will produce a rotating field (we will assume the alternating current to be three phase for the sake of simplicity), if now I rotate the rotating part in the opposite direction to that of the rotating field I shall have induced in the rotor an alternating current whose frequency will depend on the relative speeds. For instance, if the speed of the rotor is such that with a stationary field it would give 100 frequency, then as my field is actually rotating in the opposite direction at 100 frequency the actual frequency produced will be 200 per second. Using this 200-per-second frequency by means of another machine running at the same speed one could increase it to 300, and so on indefinitely. This would, however, lead to a very complicated machine, and Dr. Goldschmidt has arranged matters so that instead of requiring a number of machines the successive additions to the frequency can all go on in the same machine.

The simplest way to explain this is to suppose that the alternating current at 200 frequency obtained from the rotor is passed back into the stator of the same machine so as to produce a rotating field of 200 frequency without in any way interfering with the original rotating field of 100 frequency. This rotating field of 200 frequency will induce an alternating current of 300 frequency in the rotor, which could in turn be transferred back to the stator and produce a rotating field having 300 frequency, and so on.

This is what Dr. Goldschmidt calls the electrical method of transferring the currents from the rotor to the stator. He has also devised a magnetic method which is simpler. Turning again to our two-pole machine whose stator is supplied with current at 100 frequency, there will be induced in the rotor a current of 200 frequency. Now, if the rotor be short-circuited there will be produced in it a rotating field having 200 frequency, which will induce in the stator a current having 300 frequency, which in turn can be short-circuited and will induce in the rotor a current having 400 frequency, and so on. I have spoken of the machine as if the rotating field was produced by a three-phase current. A single-phase field may be looked upon, theoretically, as two rotating fields in opposite directions, one of which will have no effect as far as we are concerned, and therefore a single-phase machine will do just as well. Further, it is not really necessary to supply the stator of the machine with an alternating current. If it is excited with a direct current it will induce an alternating current in the rotor which will react on the stator, and backwards and forwards in the same way as I have already described.

It would seem at first sight as if by this means an indefinitely high frequency could be very easily obtained. There are, however, certain practical difficulties.

By this method Dr. Goldschmidt has obtained 12 kilowatts at a frequency of 30,000, and at high frequencies a lesser output.

The present position of the generation of high-frequency currents by means of alternators may be stated by saying that it is now practically possible to generate by means of a machine alternating current up to and over 200,000 frequency. At frequencies of 100,000 several kilowatts are obtainable, and at the lower frequencies machines can be built for greatly increased outputs. Where large amounts of power at high frequencies are required, such as in wireless telegraphy, the question is now becoming a commercial one as to the efficiency of the different types of alternator, their cost and their reliability. Is it possible to run these machines continuously day in and day out and to supply power at high frequencies? If so, how much does it cost per kilowatt-hour to produce this high-frequency power, taking into account not only the coal consumption, but also the wear and tear on the machine and all the other running and capital charges?

Leyden-Jar Discharges.

Turning next to the second method of producing high-frequency currents—namely, by the discharge of a Leyden jar—it was quite early inferred by Helmholtz and Henry that the discharge of a Leyden jar did not always flow in the same direction, and we owe to Lord Kelvin the mathematical investigation of this subject, and to Feddersen its experimental demonstration. If I charge a Leyden jar, or any other condenser, and allow it to discharge through a very high resistance, a current will flow, which gradually dies away as the jar discharges. If, however, I discharge the condenser through a sufficiently low resistance, it will be found that the current continues to flow in the same direction after the jar is completely discharged, and then charges it up in the opposite direction, the current gradually getting smaller.

1. Portion of an address to the Royal Institution of Great Britain.

When the jar is charged to a certain extent in the opposite direction to its original direction it starts to discharge again, this time in the opposite direction. The current again continues to flow after the jar is discharged, and charges it up in the original direction. This cycle of operation is repeated, the energy of the charge in the jar gradually getting less and less, until it dies away. The frequency of these oscillations is determined by the capacity of the condenser and the self-induction.

It is quite easy to obtain by this method almost any frequency—for instance, anything between 1 and 100,000,000 are comparatively easily obtainable, and I have even demonstrated frequencies as low as one-half.

The fundamental difference between these high-frequency currents and those generated by alternators is that they die away—that is to say, that the amplitude gradually decreases and comes to zero. The condenser then has to be re-charged, and the process repeats itself. Now, a single discharge of this sort is not of much practical use. It is necessary to charge the condenser and repeat the discharges in rapid succession if any useful work is to be done. Many methods have been proposed for this purpose. Some of the early successful experiments were those of Tesla.

The condenser is allowed to discharge through a circuit which consists of the necessary self-induction and a spark gap in series. The spark gap will stand a certain electrical pressure, and then let the electricity pass. When once the electrical pressure or voltage has been raised to a sufficiently high value to break down the spark gap, the spark gap changes from being an insulator which prevented the flow of electricity to being a comparatively good conductor, and it remains conducting in the ordinary way until the current finally ceases. If the condenser be charged to a sufficiently high voltage, the spark gap will break down, a spark will take place, and during the time that the gap is conducting, oscillations will take place. In order, therefore, to produce the repeated sets of discharges of the condenser, all we have to do is to repeatedly charge the condenser to a sufficiently high voltage, and this is easily accomplished by charging it from a transformer connected to an ordinary low-frequency alternator.

This is the usual method of producing high-frequency currents. It will be evident, however, that the high-frequency currents obtained by this means differ fundamentally from those obtained from an alternator; for instance, with an oscillation frequency of 1,000,000 per second, such as I am using, and 50 oscillations for each discharge of the jar, the whole discharge will last 0.00005 second. As we are only obtaining 170 discharges per second, there is something like 0.005 second between the end of one discharge and the beginning of the next, which is a comparatively long time, about 100 times as long as the oscillations last.

It is obvious that if the discharges can be caused to take place with greater rapidity by using a higher-frequency alternator to charge the jars, the gaps will be closed up, and this is the method originally used by Tesla, and which is now being used in many of the wireless transmitters, though in this case there is another reason for using a greater number of discharges per second. For instance, the Marconi Company, in their musical spark transmitters, use a frequency of some 300—that is to say, some 600 discharges per second—and the Telefunken Company as many as 1,000 discharges per second.

I now come to another class of method which still depends upon the discharge of a condenser. If I have a body like a pendulum or a spring capable of oscillations, I can make it oscillate by pulling it away from its position of rest and then letting it go. I can also make it oscillate by giving it a blow or shock, and I can make it oscillate by applying to it a number of impulses at properly timed intervals. All three of these methods are employed in the production of high-frequency currents. The first is the simple discharge of the Leyden jar without any auxiliary apparatus; the third is the method usually employed in wireless telegraphy for obtaining and maintaining a long series of oscillations in the aerial by tuning it and loosely coupling it to the Leyden-jar circuit in which the discharge takes place. The second method also involves a discharge of a condenser. In this case the spark gap is so arranged that it suppresses the oscillations of the condenser—that is to say, it breaks down, allows a larg rush of current, and then becomes insulating and stops anything further from happening.

It might be thought at first that in this method of producing oscillations there was no relationship between the nature of the swing in the first, or discharge, circuit and the frequency of the oscillations in the second circuit. Without going into the theory of coupling, which would take me too far, I would point out that for the best result there is a relationship, and this can be easily seen if one considers the question of starting oscillations in, say, a short and a long pendulum. The long pendulum will be set swinging easier with a blow which comes on and off comparatively slowly, whereas the short pendulum will require a short, quick tap to start it swinging.

This method of shock excitation, due to Max Wien, is employed by the Telefunken Company in its wireless transmitter, and also in its therapeutic apparatus; a special type of spark gap being used consisting of large flat metal plates, a very short distance apart, the object being to suddenly cool the spark to cause it to go out, and the gap to become insulating again at the earliest possible moment.

A spark gap of this type connected to a condenser and self-induction can be supplied in the ordinary way, when the frequency of the spark will naturally depend upon the frequency of the alternator.

If an attempt be made to employ the successive discharges of a condenser when charged from continuous current, a difficulty is encountered if large powers are dealt with. This difficulty seems to reside in the properties of the spark gap, which tends to become completely conducting, or, what is technically called "arcs," when large powers, say 10 kilowatts or over, are employed.

Mr. Galletti set himself to get over this difficulty by employing a number of such circuits, each with its own spark gap, and connecting these together so that they would all help to produce the oscillations.

By combining a number of circuits and using the high-voltage continuous current supplied by the Moutier-Lyons transmission—some 40,000 volts—Mr. Galletti was able to deal with many kilowatts, the spark frequency being very high, about 10,000 per second. Corresponding to each of these sparks there is a series of oscillations, so that in this case the oscillations must be completely joined up, and the result almost the same as if an alternator were employed.

Mr. Galletti has been able to employ still larger numbers of sparks per second, up to 100,000. In this case one arrives at the interesting result that the oscillations can be maintained by impulses from the condenser circuit every other oscillation, or even each individual oscillation. This should maintain a true alternating current, such as is produced by an alternator, with no waste intervals.

Arc Methods.

If an ordinary direct-current arc is produced between solid carbon or metal electrodes, it is unstable—that is to say, it cannot be burnt unless a resistance is placed in series with it. The current can be kept at any desired value by putting sufficient resistance in series with the arc, so that when the current is increased the potential difference between the terminals of the arc and the resistance taken together increases, and the circuit as a whole becomes stable. If such an arc be shunted with a capacity and self-induction in series oscillations will be set up in this shunt circuit, the frequency of the oscillations being mainly determined by the periodic time of the shunt condenser circuit.

When the oscillations are taking place, the oscillatory current flows through the arc, and consequently tends to increase and decrease the arc current. Any increase in the current tends to make the

vapor column of the arc larger, and any decrease makes it smaller, so that the vapor column of the arc pulsates in size. This pulsation in the size of the vapor column moves the air in the neighborhood of the arc, and, if the frequency is suitable, produces sound; hence this experiment is known as the musical arc. By varying either the capacity or the self-induction, the frequency of the oscillations can be varied, and hence the pitch of the notes given out by the arc, and by this means a tune can even be played on it.

The frequency of the currents produced when using an ordinary arc between solid carbon electrodes is comparatively low, at the most a few thousands per second. The reason for this is that the characteristic of the arc—that is to say, the relationship between the potential difference and the current—depends to some extent on how quickly the current is varied. If the current is varied very quickly, then an increase of current is accompanied by an increase in the potential difference; the arc is no longer an unstable conductor, and oscillations cannot be produced.

There are various ways of rendering the arc unstable, even when the current varies rapidly. One of these consists in using very small currents. For instance, metal arcs using currents under one-half ampere are extremely unstable, and remain so even under high frequencies.

Another method is to energetically cool the electrodes; for instance, to make one of the electrodes consist of a vessel containing water, or squirt a jet of water through the arc. The third method, due to Mr. Poulsen, consists in placing the arc in hydrogen, or some hydrogen compound, such as coal gas or alcohol vapor. By this means high-frequency oscillations can easily be produced up to about a million per second, and at the lower frequencies of, say, 100,000, considerable powers can be dealt with.

To render the arc still more unstable, Mr. Poulsen places it in a strong transverse magnetic field. With an apparatus of this sort I am informed that 30 kilowatts or more can be dealt with by a single arc, and if several arcs are placed in series, large powers can be transformed.

If the apparatus is properly adjusted the high-frequency currents produced are very nearly true alternating currents, such as are obtained from an alternator.

The only difficulty I find in working the apparatus is to maintain the frequency absolutely constant, as it appears that the frequency depends to a small extent on the current through the arc and on the arc length. In the actual apparatus employed for wireless telegraphy the electrodes are kept in rotation so as to ensure a greater constancy in the arc length.

In using a generator of this sort for wireless telegraphy, messages have been transmitted and recorded from a distance of about 1,000 miles at the speed of over 100 words per minute.

A large number of modifications of the arc method have been produced, practically all of which consist in changing the nature of the electrodes or the surroundings of the arc, so as to try and make it still more unstable at high frequencies and large currents. Most arcs seem to lose their stability after the current has passed a certain limit. For this reason there is generally a best working current for any arc. If it is required to deal with more power than one arc can transform, it is better to put the arcs in series.

A very interesting generator of high-frequency currents is that invented by S. G. Brown. It is difficult to say whether it is an arc or a spark or what. The unstable conductor which takes the place of the arc consists of an aluminum wheel, on the edge of which a copper block rests. The wheel is kept rotating, and the contact is shunted by a condenser and self-induction. This arrangement produces high-frequency currents quite easily, but I have never been able to make it deal with any large powers.

In conclusion, it is of interest to review in general terms the present position of the three main methods of producing high-frequency currents. The most important application at the moment for high-frequency currents is wireless telegraphy. For this purpose frequencies in the range between 30,000 and 1,000,000 are required. A few kilowatts of high-frequency energy is generally sufficient for practical purposes at the higher frequencies. At the lower frequencies, which are mainly used on long-distance working, large amounts of power are required. In fact, one of the great problems in long-distance wireless telegraphy is to produce several hundred kilowatts of high-frequency energy with certainty and regularity, and at a reasonable price.

The alternator method, as far as the information at my disposal goes, has never yet been applied to very large powers. There is no doubt that it is from many points of view an ideal method.

The spark method has been successfully employed over a wide range of frequency and up to very large powers, and there is no doubt that it is capable of satisfactory operation. The spark method used with very-high-frequency sparks and continuous current, as proposed by Mr. Galletti, is still in its experimental stage. There seems no reason why the principle should not be extended so as to deal with larger powers. The practical difficulties may be great, but I think they should be able to be overcome.

The arc method is in a much more advanced condition. A large amount of work has been done, and practically all the details have been worked out. There is no doubt that fairly large powers can be successfully generated and utilized.

The position is therefore a very interesting one. No one of the methods seems at the moment to have so many advantages as to make it *the* one method above all others for producing high-frequency currents. The final decision as to which is the best will probably in the end be determined by the regularity with which the apparatus works, and by that governing factor in all commercial enterprises—the cost of production.

APPRAISEMENT OF ESTATE REVEALS ASTOR'S PERSONALITY

Interesting Sidelights Thrown on the Character of Victim of the Titanic Disaster by the Record of His Effects. Comparatively Modest in His Personal Luxuries, an Inventor and a Good Investor.

THE appraiser's report of the estate of Col. John Jacob Astor, filed in the Surrogate's Office last Monday, throws a flood of light on a great American fortune in a way which can hardly be paralleled in court records of the sort. The dimensions of this fortune of $87,000,000 and over, the importance to New York City of the Astor real estate holdings, the intricate system of trusts and a fabric of family tradition which amounts to a rule of primogeniture among the Astors for five generations, and the picturesque interest attaching to Col. Astor and his stripling heir excited public attention and found a response in elaborate newspaper reports of the appraisal. Yet these reviews, owing to the intricacy of the subject, could not touch upon details which, when segregated and analyzed, form a fascinating character study of the man whose enjoyment of three millions ended with the Titanic disaster. John Jacob Astor seemed to be an obvious personality to those who read of the appraiser's report. The obvious was most deceptive. Behind the summary of millions lurked another man, neo-philosopher and mystic, bound as completely by family tradition as some Spanish prisoner of simple tastes, though with surroundings that might be called regal—a span who could have been a scientist if he had been given a chance—the dreams of the poet traveling, by this case, that of the multimillionaire.

Such is the story told in legal documents which seem to be, at first glance, as dry as dust, though found on closer scrutiny to embody a unique human document.

The simplicity of Col. Astor's personal, intimate surroundings is one of the most forceful impressions gathered from the appraisal. With a fortune of more than $87,000,000 and an income estimated at not less than $3,000,000 a year, his immediate belongings, including wearing apparel, jewelry and dressing requisites, did not rise above more than $10,000.

At Fernehff, his estate on the Hudson, Col. Astor slept in a room that could be furnished for $1,625, in an enamelled bed appraised at $85. He walked on a $75 carpet, looked from walls ornamented with pictures worth $35 to the most costly ornament of the room, a "grandfather's clock," appraised at $150. All of his apparel, desk and toilet utensils and other personal effects at Fernehff, said the appraisers, could be duplicated for $412.

No Pomp in His Rooms.

More elaborate surroundings might be expected in Col. Astor's residence in upper Fifth Avenue. Yet here his personal appointments were the least costly of any occupied by the Astor family. A $5,000 Japanese screen in the library would more than pay for the furniture of his bedroom and the dressing closet adjoining. The Hotel St. Regis, when he finished it, gained notoriety from reports of a $10,000 bed. Col. Astor was sleeping in one worth $450. The most valuable thing in his bedroom is a Persian rug valued at $500. All of the furnishings, said the appraiser, would be purchased for $3,000.

These figures might be confusing unless a distinction were made between the things that entered intimately into Col. Astor's daily life and those which came to him on the death of his mother, Mrs. William Astor, and passed from him to his wife and eldest son, in accordance with a well-defined family tradition. Col. Astor had possession of most of the latter class of property for only five years, or between his mother's death and his own. That he enjoyed these hundreds of paintings, porcelains, and art objects with a sense of tangible personal ownership is a debatable question. The internal evidence of the appraiser's report and Col. Astor's career indicate that he did not.

The distinction is emphasized by the appraisal. The art objects purchased by Col. Astor are segregated from those which passed to him from his mother, thus adding to the impression of Col. Astor's simple tastes. His bedroom furnishings were not more costly than would be those of a man whose entire fortune was represented by the ornaments of the adjoining apartments. Compared with the valuation of $3,000 placed on the contents of "Col. Astor's room," for example, are those of other rooms in the residence:

Entrance hall	$16,067
Library	69,589
Drawing room	69,275
Picture gallery	22,357
Morning room	120,005
Dining room	75,400
North reception room	16,790
South reception room	15,470

The contrast is also marked in the appraisal of the family jewels and of Col. Astor's personal ornaments. The jewels in the estate vaults were valued at $161,920. Of this sum $150,000 was represented by a diamond sunburst, a necklace, and earrings which are subjects of family dispute. Aside from Col. Astor's Santiago and society medals, the remaining articles, appraised at $11,920, seem to be family and personal accumulations. Among the watches, rings, lockets, and pins are a number bearing the initials of Col. Astor's father, William Astor.

His Jewelry.

Col. Astor's personal jewelry, on the other hand, was appraised at only $4,612. The inventory chiefly creates an impression of a man who went in very strongly for cuff links and waistcoat buttons. There are eight sets of sleeve buttons, ranging from simple gold links to squares of rubies and disks of platinum and diamonds. The cuff links represent an investment of $900. Six pairs of waistcoat buttons, some of them studded with sapphires, diamonds, rubies, and pearls, represent an investment of $6,500. Four watches and as many more jeweled stickpins, in addition to pencils, chains, and desk and toilet accessories, could be matched on the dressing tables of many American men with far less pretentions to wealth than Col. Astor. The same might be said of his wearing apparel at the Fifth Avenue house. Three fur coats, valued at $1,170, buck large, but $800 worth of other wearing apparel is matched by uniforms appraised at a similar amount.

Though the art collection of Col. Astor represents a fortune of no mean proportions, the appraiser's report shows that Col. Astor bought very few pictures or bronzes. The paintings of Millet, Corot, Schreyer, Meissonier and Van Marcke, the tapestries and similar treasures described in the newspapers a few days ago were not purchased by Col. Astor, but came to him from his father. When William Astor died in 1892, they were valued at $398,610. Now the entire collection is said to be worth $464,810. Of this sum, $99,500 represents Col. Astor's purchases; the paintings being appraised at $9,000 and the bronzes at $37,500. Even these were not numerous. The paintings consist of a portrait of Col. Astor, by Leon Bonnat, a decorative panel called "The Guitar Player," and F. S. Church's "Dancing Bears."

The most important of the bronzes is Houdon's "Head of Voltaire," valued at $13,000. The others comprise a "Flying Mercury" by Rinaldi, figures of Neptune, Apollo and Venus and Louis XIV, mounted on a charger and "Satyr and Bacchante," by Chodieu.

Let us penetrate these externals and seek John Jacob Astor alone in his sanctum. There hints may be obtained of what he really wished to be and might have been.

To do this, one must leave behind the showrooms of the Fifth Avenue residence and lay aside for the moment the portrait of Col. Astor in its conventional pose as he became more or less familiar to the reading public.

Seeking this more intimate man, attention must be directed to three rooms in the Fifth Avenue residence which have been ignored in the newspaper reports of the appraisal and the existence of which was possibly realized only vaguely by those who dined at Col. Astor's table and danced in his ballroom.

Two of these rooms are in the basement, the third on the third floor. One basement room is set down in the appraiser's report as the laboratory. Its contents are valued at $1,000, none of the details being given. Adjoining it is a bedroom with an enameled bed and oak furniture worth not more than $100.

The room on the third floor was Col. Astor's library; those who entered it would not be likely to find much to excite their wonder. A flat top oak desk, armchairs in leather and velours, a globe, an old self-playing piano, an inexpensive carpet, a carved Italian armchair and their accessories might be purchased for $2,000 or so. On the bookshelves were no first or early editions or bindings demanding special attention.

In this room and the laboratory in the basement Col. Astor spent much of his time. His friends regarded him as a man with a serious turn of mind in matters relating to science and invention.

As an Inventor.

He invented a pneumatic machine to remove material from worn-out roads and was awarded a prize for it at the Chicago World's Fair in 1893. Another of his contrivances was a "vibratory disintegrator" to manufacture gas fuel from peat. A bicycle brake based on the principle of reduced friction, and a variation of a turbine engine represented other experiments. In 1910 he came forward with a device for a steamship chair with vacuum cups to hold it securely to the floor of a deck or cabin, thus supplanting fixed chairs on steamships.

For more than twelve months a mysterious craft lay in the Harlem River several years ago. It seemed to embody some idea to combine an airship with a practical water craft. Nothing seemed to come of the enterprise, and finally the boat disappeared. Col. Astor was mentioned at the time as the man who was behind the enterprise. On another occasion his application for a patent for an elaborate raisemaking machine was not granted owing to an objection that it anticipated the use of natural forces that could not be called exclusive.

Hidden away, too, in the list of stocks and bonds of the appraiser's report is another indication of Mr. Astor's enthusiasms in matters scientific. The item enumerates 500 shares of stock in the Nikola Tesla Company, of "nominal" value. Commenting on this investment Nicholas Biddle, who was closely associated with Col. Astor in his business affairs, had this to say:

"Impossible to Sell."

"This stock was not carried on Col. Astor's books. It was purchased by Col. Astor under an agreement made with Mr. Tesla personally of which his office had no information. The stock has never paid any dividends, and it is my understanding that the proceeds from the sales of the stock were used in certain experimental work which has not developed into a paying industry, and in my judgment it would be impossible to sell this stock."

In Col. Astor's library is also a reminder of his adventure in authorship which led to his election as a member of the Authors' Club, but resulted otherwise in a newspaper sensation of the moment rather than a permanent addition to science or literature. In 1910 appeared his romance, "A Journey in Other Worlds." He coined the word "apergy" to describe a force counteracting gravitation, and described a fantastic journey to Jupiter and Saturn.

In the appraisal of Col. Astor's private library are 165 copies of his book. In the main library on the first floor are stored another 100 unsold volumes. They go into the appraiser's report at a valuation of $1.50 each.

Was Col. Astor a good business man? On the death of his father, William Astor, in 1890, the family fortune was generally estimated to be about $65,000,000, compared with the gross valuation of $87,218,794 at Col. Astor's death, twenty years later. Seeking a reply to the question, the published outlines of the appraiser's report are also found to be deceptive.

As a man of 20 years, Col. Astor assumed the responsibility of his property at the estate offices, in West Twenty-sixth Street, and managed it for nearly twenty years. Nor was he merely a figurehead, dependent on his co-trustees and expert advisers, according to the testimony of Mr. Biddle which accompanies the appraisal.

His Hotel Properties.

In his large building projects Col. Astor followed the example of his cousin, William Waldorf Astor, rather than assumed an aggressive initiative. Thus his portion of the great hostelry at Thirty-fourth Street and Fifth Avenue, the Astoria, was put up after the Waldorf, at Thirty-third Street. In Times Square his cousin built the Hotel Astor before Col. Astor erected the Knickerbocker Hotel. In upper Fifth Avenue the New Netherland of William Waldorf Astor long antedated his cousin's Hotel St. Regis.

Among Col. Astor's stocks and bonds the appraisal shows many of standard values. With others there is an impression that Col. Astor was "stung." In the eighty-nine separate items appear thirty-nine, or more than one-fourth, appraised as having a nominal value or doubtful value.

A careful analysis, however, shows that a number of these securities represent contributions which men in Col. Astor's position might be expected to make to social or public enterprises, that others were losing ventures of his father, and that a third class represent Col. Astor's personal losses.

Among the securities, for example, are those of the New Theatre, Col. Astor's holdings comprising a box-holder's certificate, 100 shares of stock of a par value of $10,000, and $25,000 in bonds. Their value is appraised as "nominal."

"That value was fixed," testified Mr. Biddle, "by Mr. Henry Rogers Winthrop, who was an officer of the New Theatre, and he advised me that the New Theatre, as what I might call a going concern, is out of business. The box owner's certificates would be valuable only as works of art, and, of course, they have no value, as the New Theatre is not conducted by the former management, and I understand that the property is leased at an amount sufficient only to cover the interest on the first mortgage bonds and cannot even pay the interest on the income bonds."

The other securities of Col. Astor's estate traceable to his social and public activities are the following:

One share of the Alumni House Association, $100. This was a benevolent association in connection with St. Paul's School, at Concord, N. H., which Col. Astor attended. His affection for the school is shown by his will, a $30,000 legacy being his sole bequest to an institution.

A 1-450th share of the net assets on final liquidation of the Country Club of Westchester County valued at $150.

Twenty-five shares of the Dutchess County Agricultural Society, of a par value of $250.

Five shares of the Livestock Society of America, of a par value of $250.

Forty-five shares of preferred and twenty-two shares of common stock in the Long Island Motor Parkway, valued at $6,700.

Five thousand dollars of gold income bonds in the Colony Club.

In addition to these are stocks and bonds of a similar class of appraised values as follows:

The 300 shares of the Metropolitan Opera and Real Estate Company of a par value of $15,000 are appraised at $100,000.

Four shares in the Newport Casino of a par value $2,000 are said to be worth $1,200.

The 108 shares of the Newport Country Club stock of a par value $10,800 are appraised at $2,700.

Two shares in the Newport Reading Room of a par value of $200 show a handsome premium in an appraised value of $700. Par value was allowed on four shares, of a par value of $2,000, in the Spouting Rock Beach Association, representing an interest in the bathing beach at Newport.

Five thousand dollars in first mortgage bonds of the Automobile Club of America are appraised at $4,000, and $12,000 second mortgage bonds of the same club are appraised at $7,700.

The $5,000 bonds of the Sleepy Hollow Club are appraised at par.

Col. Astor was apparently solely responsible for the following:

Certificates for 200 shares in the Amphere Electro Company of a par value of $20,000. "From information received a number of years ago," testified Mr. Biddle, "we have carried it on our books as worthless, and it appears in the records of obsolete securities that the charter of this company was forfeited for unpaid taxes in 1907."

Two hundred shares in the Atmospheric Products Company of a par value of $20,000. "That company has also ceased to do business, and this stock has been carried on our books for a number of years as worthless."

A certificate for 35 shares of Chestnut Ridge Railroad Company stock of a par value of $1,500. "A mortgage was foreclosed and the stock rendered worthless about 1901."

A certificate for 20 shares of the College World Company, of a par value of $100. "The charter of this company was forfeited for unpaid taxes, I am informed, about 1906."

Two hundred and fifty shares of the Commercial Bank of Honduras, of a par value of $2,500. "The charter of that bank has been revoked by the Government of Honduras. They have no assets. It also has been carried on the books of Col. Astor as valueless for some years."

Two thousand shares of the Depew Improvement Company, of a par value of $200,000. "This company went into the hands of a receiver in 1904 and is now out of existence, as it was taken over by the Lands Company of Depew." Further down in the inventory 1981 shares in the Lands Company of Depew, of a par value of $198,100, which is appraised at $99,050. This was received in exchange for the bonds.

A certificate for 1,500 shares of the Honduras Railroad Company, of a par value of $150,000. "That company is out of existence. I understand their charter has been forfeited by the Government of Honduras."

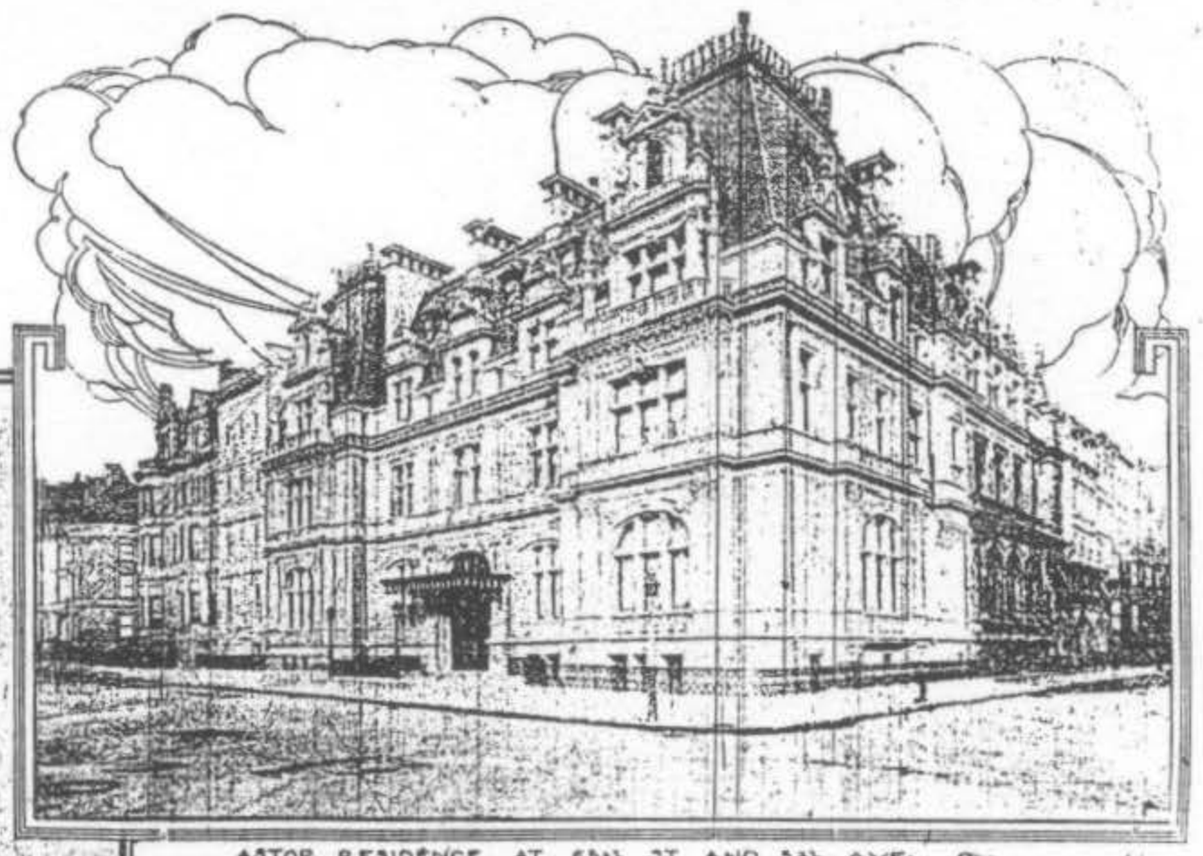
"That was the company that Col. Astor went into some fifteen years ago?" Mr. Biddle was asked.

Various Securities.

"About that," he replied. "I might add that in the New Jersey transfer tax upon this estate this stock was appraised as of nominal value and the New Jersey authorities acquiesced in such an appraisal."

A certificate for 25 shares of the Honduras Syndicate, 10 per cent paid, of a par value of $1,750. "The same condition exists as in regard to the Honduras Railroad," commented Mr. Biddle. "The charter of this company was forfeited for unpaid taxes about 1908."

A certificate for 500 shares of International Power Storage Company of a par value of $25,000. "The charter of this company was forfeited for unpaid taxes about 1909."

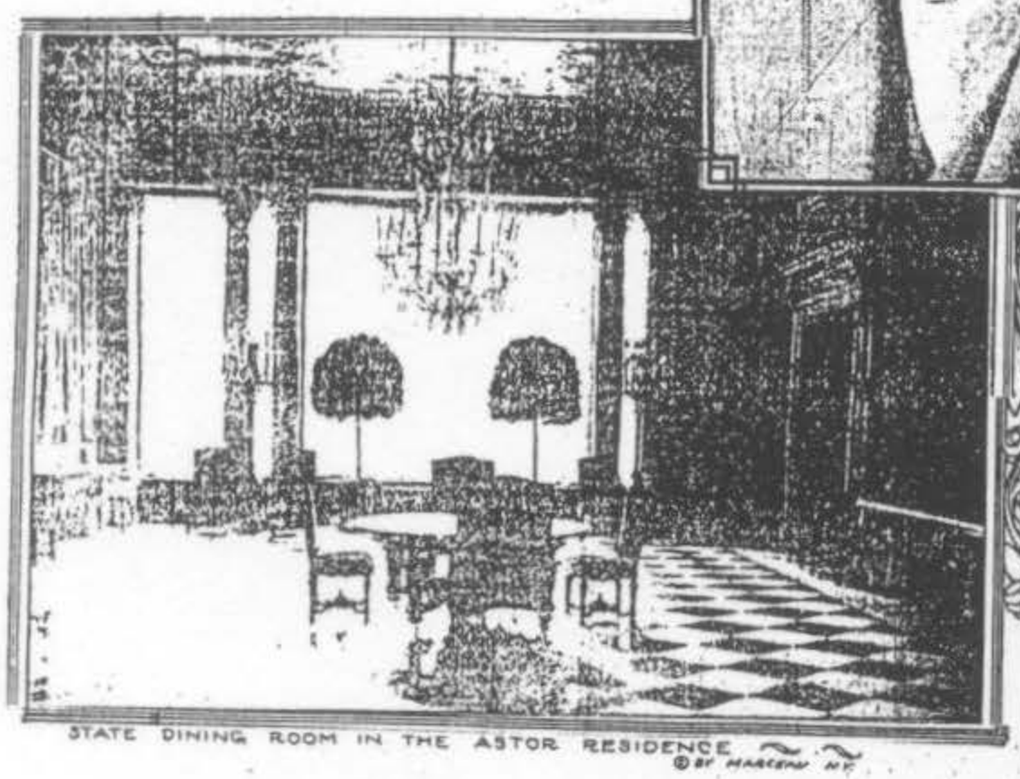


One hundred shares of Mutual Automatic Telephone Company stock, of a par value of $10,000. "This company is no longer doing business, as I am informed."

Seventy-five shares New York and Pennsylvania Brick, Tile and Terra Cotta Company, of a par value of $7,500. "I can find no record of that company," explained Mr. Biddle. "I have sent to an address in New York at which it formerly did business and it is not there any longer and I could find no record of where it has gone to."

Certificates for 600 shares in the Fair Chester Chemical Company. "I have been unable to obtain any information with regard to this company."

A certificate for 104 shares of Rider and Driver Publishing Company. Mr. Biddle said he had been unable to obtain definite information from the company regarding the value of the stock.



A certificate for 100 shares of the Union Car Company, of a par value of $10,000. "This company is out of existence," said Mr. Biddle. "I don't remember whether it was carried on Col. Astor's books or not."

APPRAISEMENT OF ESTATE REVEALS ASTOR'S

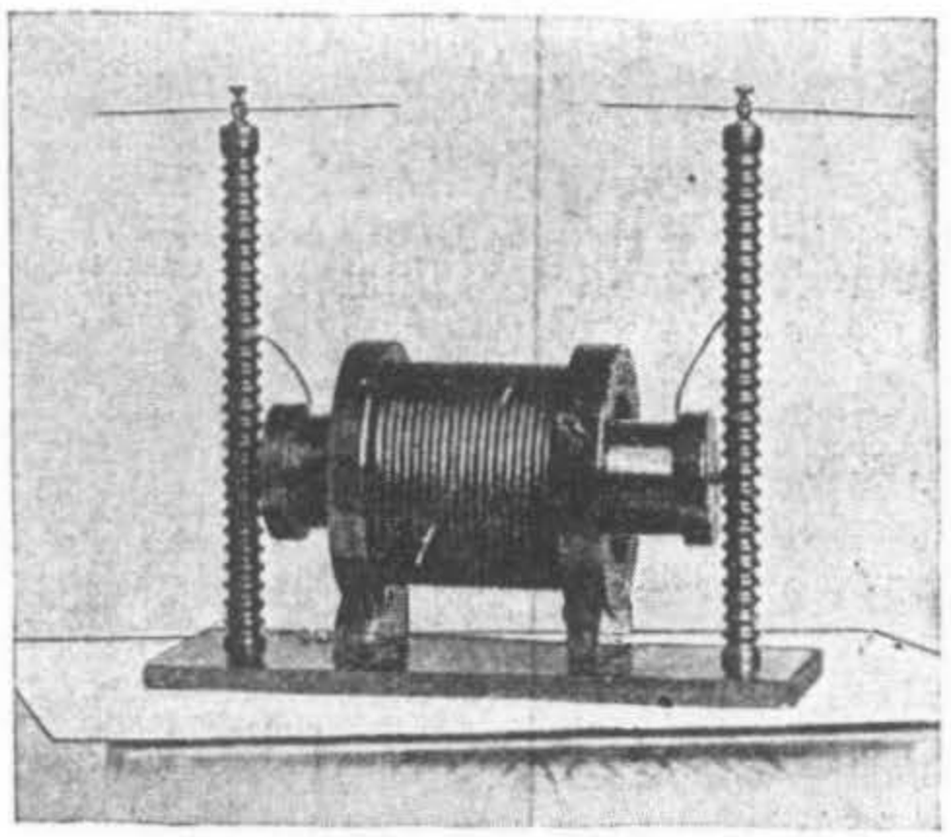
Interesting Sidelights Thrown on the Character of Victim of the Titanic Disaster by the Record of His Effects. Comparatively Modest in His Personal Luxuries, an Inventor and a Good Investor.

Hidden away, too, in the list of stocks and bonds of the appraiser's report is another indication of Mr. Astor's enthusiasm in matters scientific. The item enumerates 500 shares of stock in the Nikola Tesla Company, of "nominal" value. Commenting on this investment, Nicholas Biddle, who was closely associated with Col. Astor in his business affairs, had this to say:

"Impossible to Sell."

"This stock was not carried on Col. Astor's books. It was purchased by Col. Astor under an agreement made with Mr. Tesla personally, of which his office had no information. The stock has never paid any dividends, and it is my understanding that the proceeds from the sales of the stock were used in certain experimental work which has not developed into a paying industry, and in my judgment it would be impossible to sell this stock."

An Air Insulated Tesla Coil

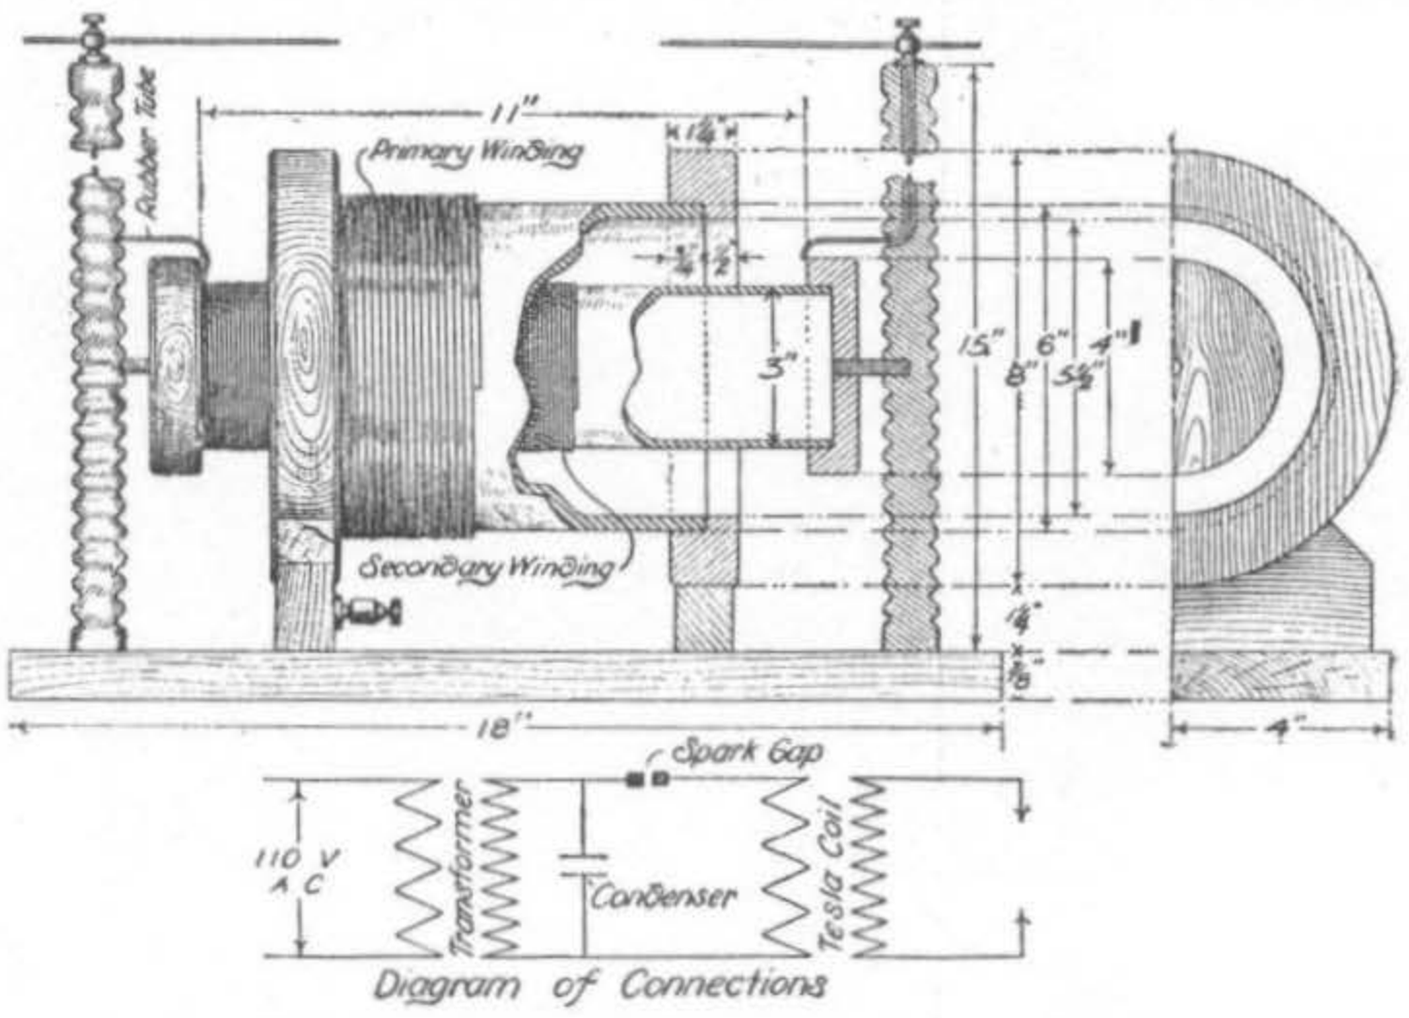


Experimenters who have wireless sending stations have all the apparatus necessary for the operation of an air insulated Tesla coil.

The coil here described is suitable for use with spark coils giving from a two to six inch spark or with a ¼ k. w. transformer. It is not advisable to make a larger coil unless oil is used for insulating. The coil shown in the photograph will give a seven inch spark when used in connection with a ¼ k. w. closed core transformer (magnetic leakage type), glass plate condenser and a rotary spark gap. When a stationary gap is used the sparking distance is about five inches.

The drawing gives the necessary dimensions. Part of the primary and secondary tubes are cut away in the drawing in order to make the construction clearer. The post in the end view is also cut away for the same reason. The primary consists of 20 turns of No. 14 B. & S. gauge rubber insulated wire wound on a paper or fiber tube six inches outside diameter. The length of the tube is not shown in the drawing because there is a great variation in the thickness of the insulation of different kinds of wire. There should be just space enough between the end pieces to accommodate 20 turns of the wire used. If stranded wire can be obtained it is preferable.

The secondary coil consists of one layer of No. 32 B. & S. gauge enameled wire wound on a tube three inches outside diameter. The winding should be eleven inches long. The other dimensions may be changed somewhat to suit the builder. The posts, however, must not be lower or the spark will jump into the primary winding.

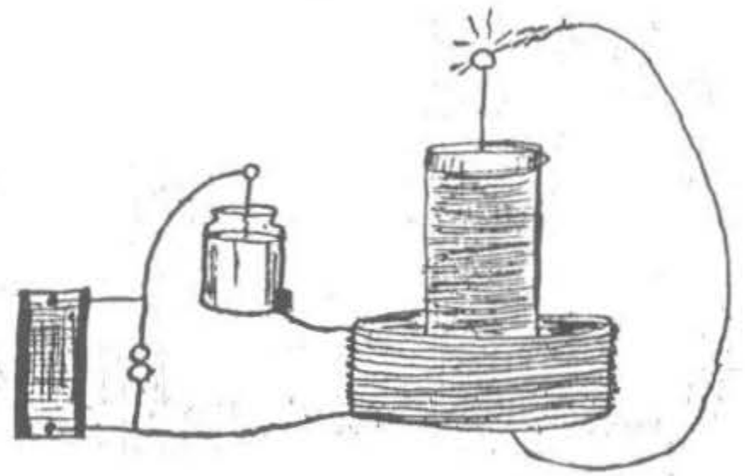


The framework may be made of any hard wood. It should be put together entirely with dowels, for if nails or screws are used the spark will jump into them. The tubes may be fastened to the end pieces with glue. The wood-

AN AIR INSULATED TESLA COIL

work may be finished with any substance which is a good insulator. A good imitation of hard rubber can be made by using maple and finishing with black shellac.

Very beautiful experiments may be performed with this coil in a dark room. The spark may be allowed to jump to



DETAILS AND CONNECTIONS OF TESLA COIL

a piece of metal held in the hand but no sensation of pain will be experienced. If the spark jumps directly into the body only a slight burning sensation will be felt. Lubricating oil may be placed on the end of the finger and lighted by means of the spark without burning the finger.—L. S. UPHOFF.

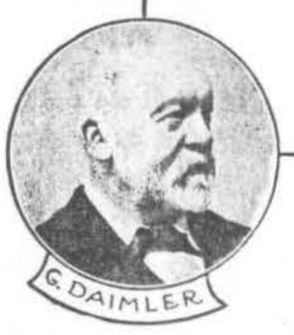
[1170.]—TESLA COIL.—Wireless amateurs generally use a "jigger" (which is really a Tesla coil) with small coils, but only a short spark, suitable, however, for wireless, is obtained. If wound with longer secondary it would probably give more, but with small coils we have been unable to get a longer spark from the Tesla than that of the ordinary induction coil alone. A primary of No. 12 and secondary of No. 22, about four turns of p. and 30 turns of s. might give good results; only a few ounces of wire are necessary, so it is easy to experiment. A 2in. coil is about the smallest to give good results.

Derby Wireless Club.

[153.]—TESLA COIL.—I have made several Tesla coils to work with a half-inch induction coil, and have found the following to be the best, a spark of about 2in. being obtained

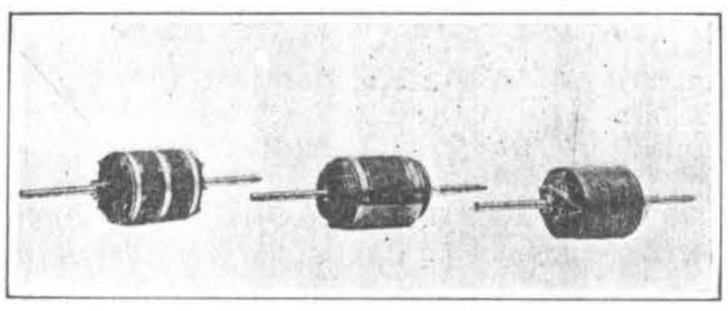
between the secondary terminals. (a) Primary twelve turns of lighting cable on cardboard tube, 6in. diameter; (b) Secondary: 150 turns 36 s.s.c. wound on paraffin waxed tube, 2in. diameter, 6in. long; (c) Primary should be outside secondary; (d) a suitable condenser can be made from a 3lb. glass jar coated to within an inch of the top with tinfoil inside and out.

G. W. Hale.

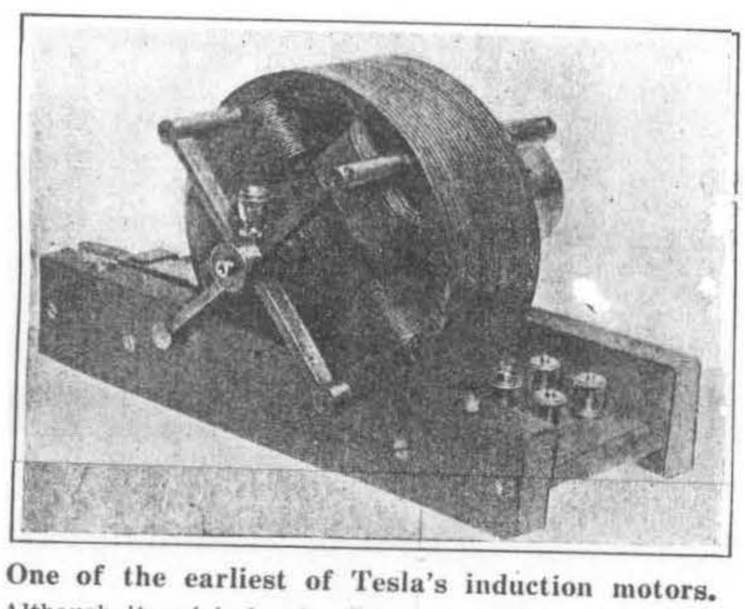


Invention Contest — First Prize Article

What Are the Ten Greatest Inventions of Our Time?



By "Esam" (William I. Wyman, Washington, D. C.)



"Five-and-twenty years ago is a hundred years off—so much has our social life changed in those five lusters."—Thackeray in "The Newcomes."

NO single invention of the last twenty-five years initiated an industrial epoch in the sense that the locomotive or Bessemer converter did, yet no former period has been so rich in developments of striking importance or so productive of improvements whose aggregate so vitally affected our economic and social life. In this short space of time the dreams of ages have come true—man has been able to fly, opaque bodies rendered transparent, and intelligence transmitted between distant points without material communicating means.

Three rotors used with the early Tesla induction motor shown below.

One of the earliest of Tesla's induction motors.

Although it weighed only a little over 20 pounds, it developed ¼ horse-power at a speed of 1,800 revolutions, a performance considered remarkable at the time.

This short quarter century has seen the world-wide acceptance of electrical transportation, the introduction of high-power generation and transmission of electricity, the radical changes in construction due to the use of steel and re-enforced concrete, and innumerable valuable improvements in chemical and allied arts. Perfected during this period were such epoch-making inventions as smokeless powder, high-speed steel, contact method of making sulphuric acid, electrolytic refining of copper, the quick-acting brake, automatic telephone exchange, centrifugal cream-separator, tungsten lamp, Diesel oil-motor, and Harveyized armor-plate, which changed existing practices so radically or induced economies of such vast degree as to make it difficult to exclude them from any list except by the adoption of a standard so high as to be unthought of at any other time.

In making a selection from the bewilderingly opulent array of creative activities of the period, only such inventions were included as were most revolutionary in character in the broadest fields, which affected most our mode of living, or which opened up the largest new sources of wealth. So weighing the merits of the different inventions, it is concluded that the ten greatest and their approximate date of successful commercial introduction are: (1) Electric furnace, 1889; (2) steam turbine, 1894; (3) gasoline automobile, 1890; (4) moving pictures, 1893; (5) wireless telegraphy, 1900; (6) aeroplane, 1906; (7) cyanide process, 1890; (8) linotype machine, 1890; (9) induction motor, 1890; (10) electric welding, 1889.

The Induction Motor of Nikola Tesla and How it Revolutionized Power Transmission.

Ninety per cent of electric current generated is alternating because larger generating units can be utilized and the current more easily transmitted. The induction motor, constructed by Tesla in 1888, and independently suggested in principle by Ferrari, was the first satisfactory medium to transform this current into power.

This epoch-making invention is mainly responsible for the present large and increasing use of electricity in the industries. It is working a revolution for economy and comfort in the mill, factory and workshop. In making the motor an individual power unit, it has made power arrangement elastic, drawing upon energy only when needed and applying it directly only where wanted, and has abolished line shafting and belting. It conserves thirty to sixty per cent of the energy formerly wasted in uselessly whirling line shafting. It saves overhead space and increases productivity by making the shop lighter, safer, cleaner and less noisy. And so well recognized are these advantages that establishments in every big industry are installing these motors as a measure of economic self-defense.

Nikola Tesla's Plan to Keep "Wireless Thumb" on Ships at Sea

Suggests Transmitters Powerful Enough to Cause the Earth to Vibrate at the Poles and Equator.

Nikola Tesla has come forward to refute the claims of men who recently excited the scientific world with announcements of discovery and invention calculated to crowd the bugbear of scientific warfare back into the primer class, and to safeguard the lives of seafarers. First he takes up and disposes of the announcement of an invention said to enable a receiving ship equipped with wireless to tell the longitude and latitude of a sending ship without the latter vessel offering its own calculations. "It hasn't been done, and it probably will be years before the means for so doing can be applied successfully," he says. As to the power of ultra-violet rays to explode the powder magazine of a warship from a distance, he insists it can't be done through that medium. If charges of powder have been so exploded, he contends, the detonation was accomplished with the familiar waves now utilized by the wireless. But Mr. Tesla admits that in all probability there will come a time when science has so harnessed and developed the means at hand that such results may be obtained. Mr. Tesla sets forth for readers of The Press his views on the two subjects as follows:

By NIKOLA TESLA.

THE first and incomplete announcements of technical advances should always be taken with a grain of salt. It is true that the newspapers are getting more and more accurate and reliable in putting forth such information, but, nevertheless, the news frequently is misleading.

For instance, not long ago reports were widely circulated that powder had been exploded at distance by infra-red or ultra-violet rays, and that a British battleship had been used in a test of this kind, which proved successful. The dispatches gave great opportunity to sensational speculation, but the truth is that there was no novelty whatever in what was done.

A mine or magazine may have been blown up, but this was accomplishd in a well-known manner through the application of a kind of electrical waves which are now generally adopted in the transmission of signals without wires. Similar experiments were performed in this country many years ago by myself and others, and quite recently John Hays Hammond, Jr., has done creditable work in this direction through the application of an art which has been named "Telautomatics," or wireless control of moving mechanism at a distance.

By means of such telautomatic vessels, surface, submarine or aerial, a perfect system of coast defense can be established. Torpedoes on this plan also can be controlled from battleships, and there is no doubt they sooner or later will be adopted and their introduction will have a revolutionary effect on the methods of warfare.

The results described are, however, not impossible. It is quite practicable to explode by rays of light a mine at a distance, as by acting on a mixture of chlorine and hydrogen. Certain dark rays also can be employed to produce destructive effects. As far back as 1897, I disclosed before the New York Academy of Sciences the discovery that Roentgen, or X-rays, projected from certain bulbs have the property of strongly charging an electrical condenser at a distance. The energy so accumulated readily can be discharged and cause the ignition of some explosive compound

Says They Can't Penetrate Steel..

But ultra-violet rays are of very short wave lengths and cannot penetrate steel shells, while the longer and more penetrative waves of the infra-red rays are chemically much less active. There is no doubt in my mind that we soon shall be able to project energy at a distance not only in small, but in large amounts, and what the effect of such an achievement will be on existing conditions words cannot express.

As regards the determination of latitude and longitude of a vessel at sea by wireless, there is nothing in use as yet which would make such direct observation possible. Some suggestions, however, which I have since many years advocated, have been adopted. They are the flashing of time signals over a wide area and the employment of an instrument known as a wireless compass.

Plan for Finding Locations.

These means enable an expert on a vessel to ascertain the exact hour at any sending station within reach, and also, in an imperfect manner, the direction in which it is situated, and from these data it is possible to get a rough idea of the position of the ship relative to the points of reference.

A perfect means for determining not only such and other data important to the navigator already is available, but it may require years to apply it. I refer to the use of the stationary waves, which were discovered by me fourteen years ago. The subject is too technical to be explained in detail, but the average reader can be made to understand the general principle.

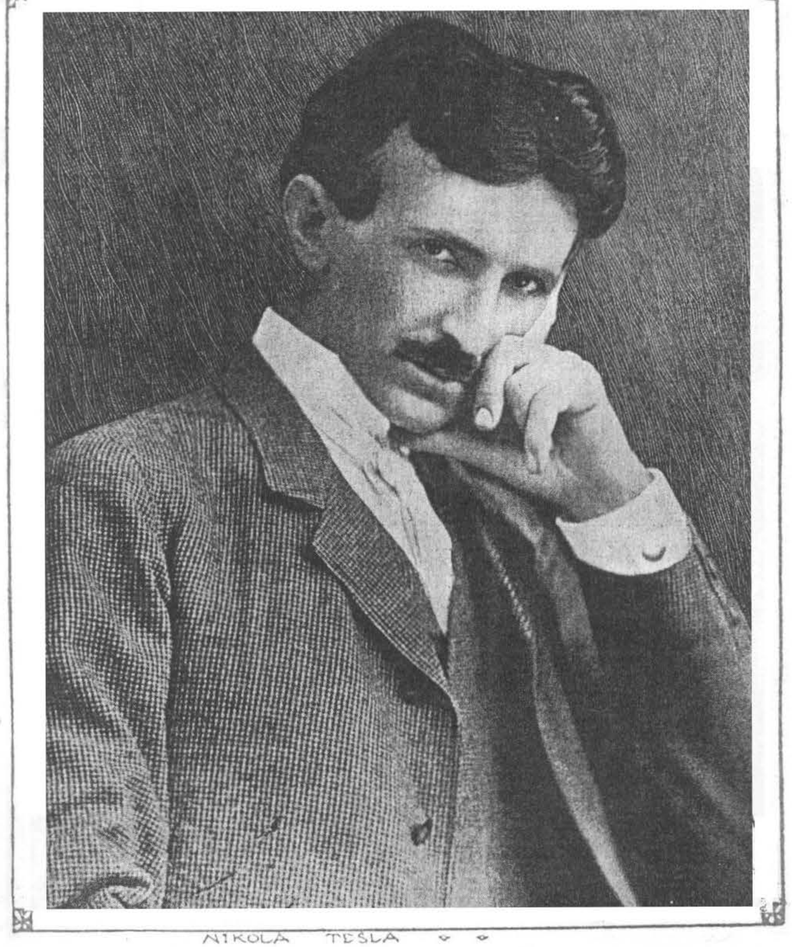
The earth is a conductor of electricity, and as such has its own electrical period of vibration. The time of one complete swing is about one-twelfth of one second. In order words, this is the interval the current requires in passing to, and returning from, the diametrically opposite point of the globe.

Now, the wonderful fact is, that notwithstanding its immense size, the earth responds to a great number of vibrations and can be resonantly excited just like a wire of limited dimensions. When this takes place there are formed on its surface stationary parallel circles of equal electrical activity, which can be revealed by properly attuned instruments.

Transmitter at One of the Poles.

Imagine that a transmitter capable of exciting the earth were placed at one of the Poles. Then the crests and hollows of the stationary waves would be in parallel circles with their planes at right angles to the axis of the earth, and from readings of a properly graduated instrument the distance of a vessel carrying the same from the Pole could be at once read, giving accurately the geographical latitude.

In like manner, if a transmitter were placed at a point on the Equator, the longitude could be precisely determined by the same means. But the best plan would be to place three transmitters at properly chosen points on the globe so as to establish three non-interferable systems of stationary waves at right angles to one another. If this were done, innumerable results of the greatest practical value could be realized.



Tesla's Plan to Learn Positions by Wireless

STATIONARY waves discovered by me fourteen years ago are the means for determining longitude and latitude by wireless. But it may be years before they will be successfully utilized.

Notwithstanding its immense size, the earth responds to a great number of vibrations. When thus excited there are formed on the surface stationary parallel circles, with their planes at right angles to the axis of the earth.

Imagine that a transmitter capable of exciting the earth were placed at one of the poles. Then the crests and hollows of the stationary waves would be in parallel circles, with their planes at right angles to the axis of the earth, and from readings of a properly graduated instrument the distance of the vessel carrying the same from the poles, could be read at once, giving accurately the geographical latitude.

In like manner, if a transmitter were placed at a point on the equator, the longitude could be precisely determined by the same means. The best plan would be to place three transmitters at properly chosen points on the globe, so as to establish three non-interferable systems of stationary waves at right angles to one another. If this were done innumerable results of the greatest practical value could be realized.

He Would Determine Vessel's Latitude and Longitude by Measuring the Length of Electric Waves.

Electric Journal January 1914

The Engineering Evolution of Electrical Apparatus—I

THE BEGINNINGS OF THE ALTERNATING-CURRENT SYSTEM

CHAS. F. SCOTT

One of the features of the JOURNAL *for the year 1914 is to be a group of articles outlining in reminiscent style, the history of the electrical industry. They will review the important steps in the development of various types of apparatus, indicating the important changes which have taken place and pointing out the engineering reasons why they were considered advisable. These articles, prepared by prominent engineers who have been in the fore-front in electrical progress, will naturally be, to a certain extent, of a personal nature and will thus have the feature of human interest as well as technical accuracy.—(Ed.)*

HISTORY may be abstract, or it may be concrete and personal; it may record events simply as facts, or it may show a continuous sequence of cause and effect. Electrical history is high-speed history. Men still live who were boys when Faraday discovered the principles of electromagnetic induction, the basis of nearly all that has followed. In the fifty years since the ring armatures of Gramme and Pacinnotti, and the drum armature of Siemens were invented, have come our dynamos and motors and our electric light and power systems. Nearly everything electrical that we have today has come from forms that were crude and elementary a generation ago or from inventions then unknown. It is a wonderful picture—this moving picture of some thirty years of electrical progress. The successive types of generators and motors, of transformers and meters and lamps, of circuit breakers and lightning arresters, of insulators and transmission lines have not come haphazard; they are forward steps to overcome difficulties or to meet new demands; there has been logical succession and true evolution. Nothing can be more impressive and instructive than to trace this development and to bring into a few pages the story of the development of a turbo-generator or a wattmeter, for example, from its prototype of a score of years ago.

Electricity was demonstrating its commercial usefulness in the early eighties; an electric car thirty years earlier, and arc and incandescent lighting, shown by Davy seventy years earlier, had been operated by costly batteries and had lain commercially dormant awaiting cheap electric power. The dynamo was brought to usefulness in the preceding decade. Edison's incandescent lamp with high resistance carbon filament came in 1879. A new problem was pressing for solution—how to get the current from the dynamo to the lamp and how to supply commercially a number of lamps from one dynamo in such a way that some of them could be turned off without affecting others.

Several lamps were at first connected in series and operated by current of constant strength, as are street arc lamps today. The method of multiple connection was then proposed, requiring constant potential mains—the system by which over 99 percent of the electric power now generated is distributed. Nothing shows more clearly how far from present practice were the electrical ideas of a generation ago than the following quotation from a lecture in 1878 by one of the most eminent electrical engineers in England. After describing certain experiments in which the candle-power of lamps connected in multiple decreased very greatly as each lamp was added, he said, "Hence, a subdivision of light is an absolute ignis fatuus."

To maintain constant potential requires dynamos which produce constant potential and circuits causing small loss. Lamps of five or ten volts can be operated only a few feet from the source of power without large line loss unless the conductors be very heavy; the Edison lamp for 100 volts increased the practical distance to five hundred or a thousand feet. This was increased by the three-wire system and the feeder-main system. But the permissible cost of conductors was reached well within a mile. Four-wire and five-wire systems and various series systems which would enable 100 volt lamps to be served by circuits carrying 300 or 400 volts or more were found to be unsafe or unsuccessful. Electrical distribution seemed limited to a mile or less, except by the series system. A large part of the early edition of Kapp's "Electrical Transmission of Energy" is devoted to the characteristics of constant current series motors, the only method in view by which the high pressures necessary for long distances could be secured. The central stations for incandescent lighting, therefore, seemed doomed to mere spot lighting—the maps of a large city would show spots a mile or so in diameter each with its own central station.

About 1885 the attention of Mr. George Westinghouse, was called to the alternating-current transformer as an instrument by which current transmitted at high voltage could then be transformed to low voltage for the operation of incandescent lamps. He sent an investigator to England and then acquired the Gaulard and Gibbs patents. These involved induction coils or "inductoriums," which were open magnetic circuit transformers.

They were connected with their primary windings in series, while their secondary windings had the same number of turns as the primary and supplied independent circuits. The system employed constant current, and the lamps on the secondary circuits were subject to serious changes in voltage when the number of lamps on a transformer secondary circuit was varied.

Mr. William Stanley, who was then engaged principally in the development of the incandescent lamp for Mr. Westinghouse in Pittsburgh, had been much interested in the alternating current. A contract arrangement was made by which Mr. Stanley should undertake the development and adoption of the alternating system for commercial service. In the fall of 1885 he set to work in an old rubber mill at his home in Great Barrington, Mass., and constructed a number of transformers, each wound to reduce the 500 volt main line potential to 100 volts in their secondary circuits. These transformers differed from the Gaulard "inductoriums" in having the primary wound for a relatively high potential and in having the primary terminals connected in parallel to a constant potential circuit. The coils were made with a closed magnetic circuit and the general proportions of the transformers were remarkably similar to those of the modern "shell type." The idea of connecting a primary coil having a resistance of only one ohm between the mains of a 500 volt circuit was so palpable a violation of Ohm's Law as to shock the convictions and the experience of those who were familiar only with direct-current phenomena. It was a bold idea of a daring inventor who first did that with which all are now so familiar. Regardless of popular ideas, however, the transformers gave good promise and a Siemens machine which had been imported from England for tests at Pittsburgh was employed as a generator. The transformers were erected in the spring of 1886 and properly connected, and supplied a number of stores in Great Barrington with current on a commercial basis. The plant continued in operation for several months until a screw driver was accidentally dropped into the dynamo and wrecked the coils. The success of the initial plant led to the commercial adoption of the alternating-current system by the Westinghouse Electric Company. The misgivings of experts, the apprehensions of the dangers of high voltage, the antagonism of opposing commercial interests did not prevail and the little "twenty-five light" transformers opened the way for a new era in electric development.

After the wrecking of the Siemens machine, a new alternator, originating in plans made by Mr. Stanley, and worked out in detail designs by Mr. Shallenberger and Mr. Schmid, was built in Pittsburgh. A full equipment of commercial apparatus was quickly designed and manufactured, and soon alternating-current central stations appeared, first at Greensburg, then at Buffalo and elsewhere. Two years after the starting of the Great Barrington plant there were about a hundred alternating-current installations.

THE ALTERNATING CURRENT IN 1888

Having been asked to write the first of a series of historical articles on "The Engineering Evolution of Electrical Apparatus," it is but natural for me to go back to my own early experiences as a starting point. I have already given a preliminary survey of the electrical situation, and I shall now make a sort of an inventory of the kinds of apparatus which were being made when I took up electrical work in Pittsburgh about twenty-five years ago, and shall comment upon various points.

In the early part of August, 1888, I went to Pittsburgh and happily found that a personal application was more effective than correspondence in securing a position with the Westinghouse Electric Company. I had a slight acquaintance with Mr. L. B. Stillwell, then assistant electrician, as I had met him nearly a year before when he came to the Baldwin Locomotive Works where an alternating-current lighting plant was being installed and where I was then employed as wireman. Mr. Stillwell showed me about the laboratory in Pittsburgh, pointing out particularly two new kinds of apparatus which had recently been invented. One of these was the Shallenberger meter, an induction meter for registering the current used by the consumers on alternating-current circuits. At that time the chemical meter was generally used on direct-current circuits, and there was no commercial alternating-current house meter. The Shallenberger meter (which was already in substantially the same form which it maintained for a dozen years, during which time enormous numbers of meters were made) was the outcome of the observation of the peculiar motion of a spring lying upon an alternating-current arc lamp about four months earlier. Mr. O. B. Shallenberger, who was working with the lamp, investigated the motion of the little spring. He substituted other things in place of the spring and determined that the motion was due to the joint action of the magnetic fields set up by two circuits, in one of which the current lagged slightly in time behind the current in the other. Close observation, careful analysis, intelligent experiment, remarkable ability in designing and proportioning the new apparatus, which was to embody in commercial and useful form the principle exhibited by the moving spring, resulted in a few months in a meter which was the forerunner of the many types of induction meters which are now in general use.

The other new invention was the Tesla motor. Nikola Tesla had secured his patents and had presented a paper before the American Institute of Electrical Engineers, in the preceding May, describing the

rotating magnetic field produced by polyphase currents and the means of employing this in induction motors. The patents had been acquired by the Westinhouse Company and Mr. Tesla was then employed

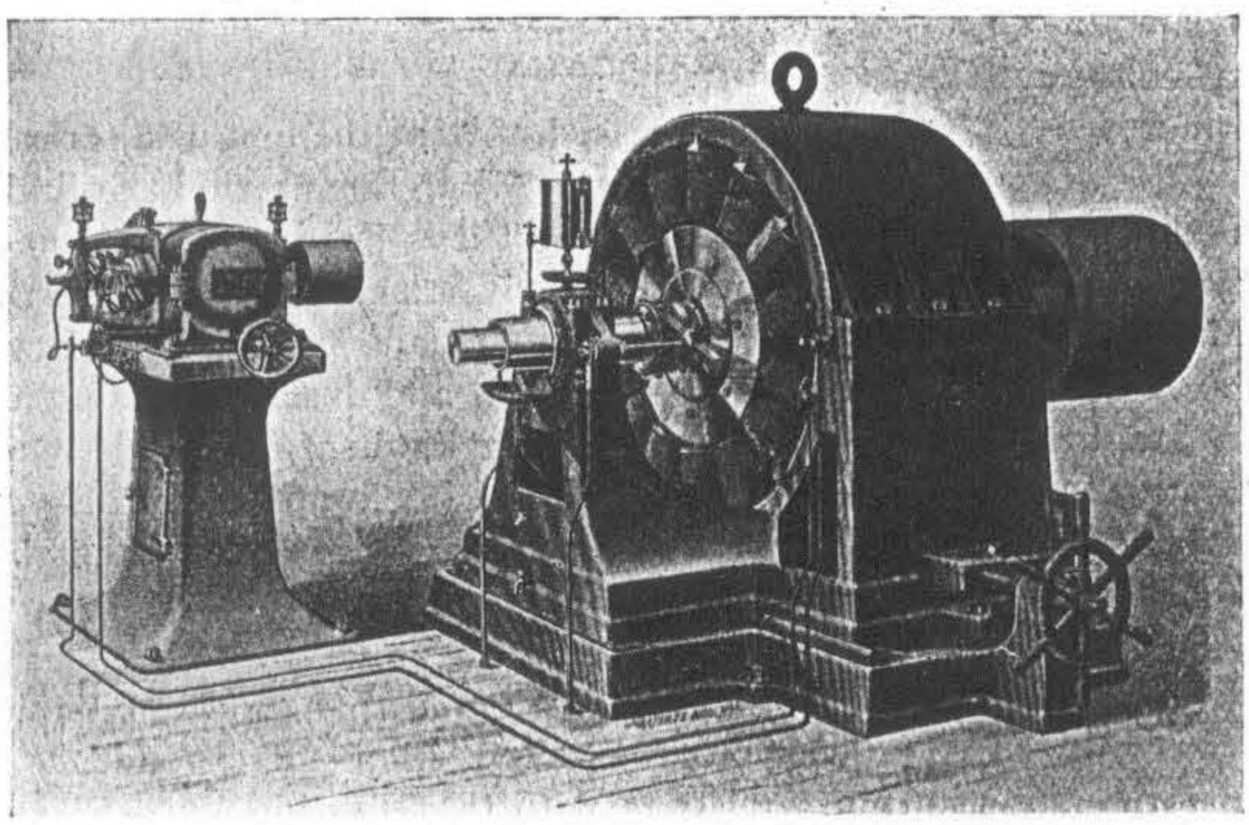

FIG. 1—1 500 LIGHT ALTERNATING-CURRENT DYNAMO WITH EXCITER—1888

in the development of the apparatus into commercial form. The previous year had been fertile in the study of alternating-current phenomena. Patent litigation has since shown that the development of motion by currents differing in phase was shared by Tesla and Ferraris and Shallenberger and Stanley, and the priority of Tesla to the motor and Shallenberger to the meter were matters involving differences of only a few months, or even less.

EARLY ALTERNATORS

In the summer of 1888 the Westinghouse Company was making three sizes of alternators. To these a fourth and smaller size was soon added. These machines were belt driven and operated nominally at 1 000 volts and 16 000 alternations per minute, corresponding to 133 cycles per second. Further particulars are as follows:—

No. 0— 400 lights, 8 poles, 2 000 r. p. m.
No. 1— 700 lights, 10 poles, 1 600 r. p. m.
No. 2—1 350 lights, 14 poles, 1 150 r. p. m.
No. 3—2 500 lights, 16 poles, 1 050 r. p. m.

The machines were driven by high-speed belts, in many cases from Westinghouse automatic engines. The noise and whir of the great belts in stations where there were a number of generators inspired a kind of awe in the visitor, which is entirely lacking in the modern beltless power house. These alternating-current dynamos had cast iron field magnets and rotating drum armatures, as shown in the accompanying illustrations. The construction was simple in general and in detail. It was simple electrically, as compared with the direct-current dynamo with its intricate armature winding and commutator. An argument then presented was that brushes for collecting the current for a 1 500 light alternating-current dynamo have a width of 7/8 inch, whereas, the brushes for a 1 500 light dynamo of the direct-current type would have an aggregate width of 20 inches. This ratio is fairly illustrative of the relative requirements of the two systems in all their transmitting parts. The direct-current brushes of that day were of copper and were vastly more delicate and liable to injury by sparking and flashing than the carbon brushes which are now used. The alternators were simple mechanically. To appreciate this fact one has to go back to some treatise on dynamos published twenty years ago and observe the multitude of forms of machines. Each system and each inventor seemed to require a peculiar form. Now there are few types, many parts are common to machines of different kinds and the name plate instead of the form of the machine must be consulted to discover the maker. But nowhere is found the general simplicity and rigidity and the grace of form of this early alternator of Albert Schmid. The little exciter near the alternator in Fig. 1 looks peculiar while the alternator does not. The first was of an ephemeral type, while the latter is the prototype of many machines of today. It is a wise man who can devise the types which will continue. The bearings were supported directly by parts of the great casting which formed the base; they were large and amply lubricated

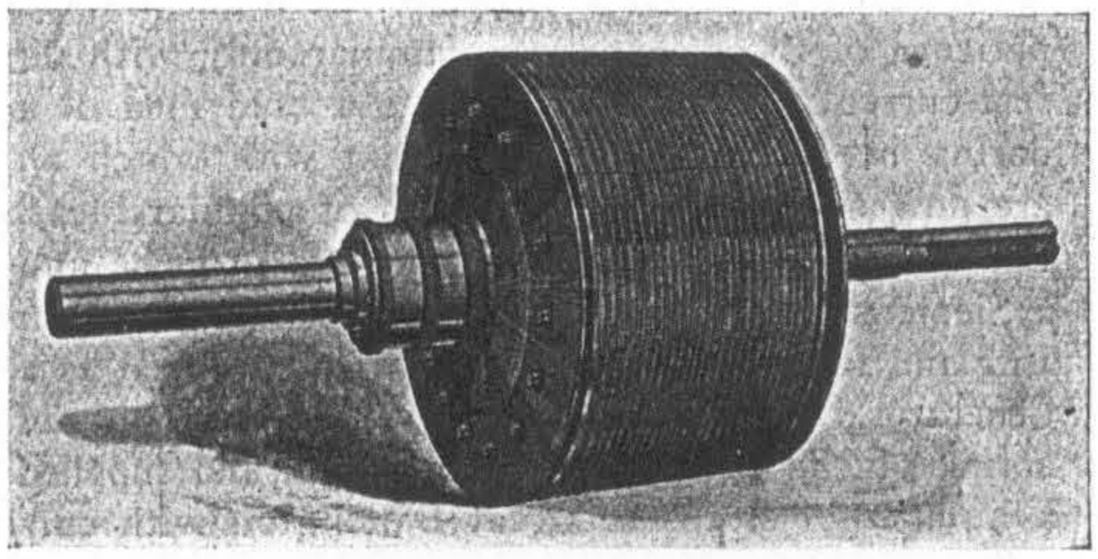

FIG. 2—ARMATURE OF ALTERNATING-CURRENT DYNAMO

"An alternating-current armature is a structure of great directness and simplicity. The body of the armature is of laminated iron plates freely perforated for ventilating purposes. A single layer of wire is wound in flat coils back and forth across the face of the armature in a direction parallel to the shaft, being retained by stops on the ends of the armature. Mica and other adequate insulation is provided and the whole is wrapped with binding wire. A ventilator is attached to each end of the armature and draws a strong current of air through it. The total weight of copper on a 750-light armature is 16 lbs., disposed in a single layer, which being on the surface is readily kept cool, and can be inspected for deterioration or flaws of any character. A direct-current armature of the type most generally in use, of 750 lights capacity on the other hand, carries more than 10 times this amount of wire.

"We would call particular attention to the absence of a commutator, the place of which is supplied by two plain collecting rings without breaks of any kind. Narrow collectors rest upon these rings and serve to take off the current as it is generated. No practical operator of an electric light plant need be told of the annoyance due to the maintenance of a commutator, the brushes of which require exact adjustment, any departure being followed by destructive sparking."—1889.

by the dripping of oil from large brass reservoirs. Excellent as this may be, if testimony be needed as to the superiority of self-oiling bearings over the kind which needed fairly constant inspection to see that the oil dripped properly, which had to be filled frequently

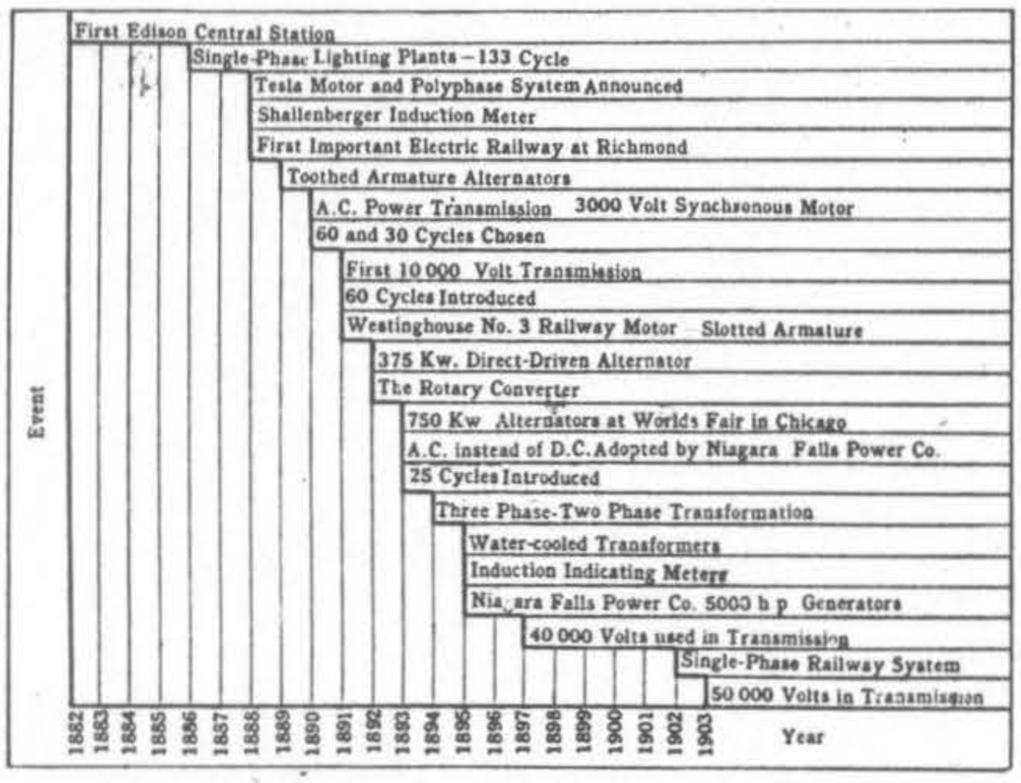

FIG. 3—CHRONOLOGICAL CHART OF SOME IMPORTANT EVENTS IN ELECTRICAL ENGINEERING HISTORY

and polished every night, the writer is prepared to testify from personal experience.

What were some of the limitations of the alternator which produced the current in hundreds of central stations for many years? It was heavy and expensive. Between the cylindrical surface of the iron core of the armature and the faces of the field poles must be space for insulation, for conductors, for insulation again and for band wires as well as free space between the band wires and the pole faces. Mechanically the space should be large; magnetically it should be small. If the armature got slightly out of center, it would strike the field poles, the band wires would give way and the "blowing up" of an armature was an exciting event. The life of the armature depended upon the integrity of a goodly fraction of a mile of steel band wire, wound under tension and subject to unknown stresses. The copper conductors could not be wound conveniently in more than a single layer, and the large conductors necessary for heavy currents in large alternators were heated by eddy currents generated in their motion through the magnetic field between the pole faces and the armature core. The band wires, being grouped together into bands in which the adjacent wires were soldered togther had heat producing currents induced in them in the same manner. Magnetic fields are apt to cause trouble when outside of their native element—iron. Winding in slots in modern armatures has replaced the old surface winding. Wires lying on a smooth cylindrical surface in a magnetic field have a "side force" on short-circuit which is hard to resist by any practical form of anchoring. Hence, a short-circuit used to cause mechanical damage followed by internal electrical distress and a season in the repair shop. In those days the skilled armature winder was the autocrat of the electrical industry. The slotted armature and the machine wound coil marked his doom.

The armature which immediately succeeded the first form was the toothed armature, which had a large tooth corresponding to each field pole, around which the armature coils were placed. The teeth had small projections at the circumference which served as a mechanical support for the coils. An armature of this kind was made for the field of the smallest alternator and was turned over to the writer to test. The air-gap was very small and the wire was large compared with that for the old drum armature; hence, a large output was anticipated. After obtaining the proper voltage and applying the load, the field current was increased as more and more lamps were added until presently there were a thousand lamps on what had been a 400 light machine. It was noted that the field current with the large load was three times what it had been with no load. The question came as to what would happen if all but a few lights were suddenly removed; would the voltage go to three times normal? This brought an appreciation for the first time of the significance of inherent regulation. Subsequently, the air-gap was made much larger and the regulation was very much improved. After a time the slotted armature con-

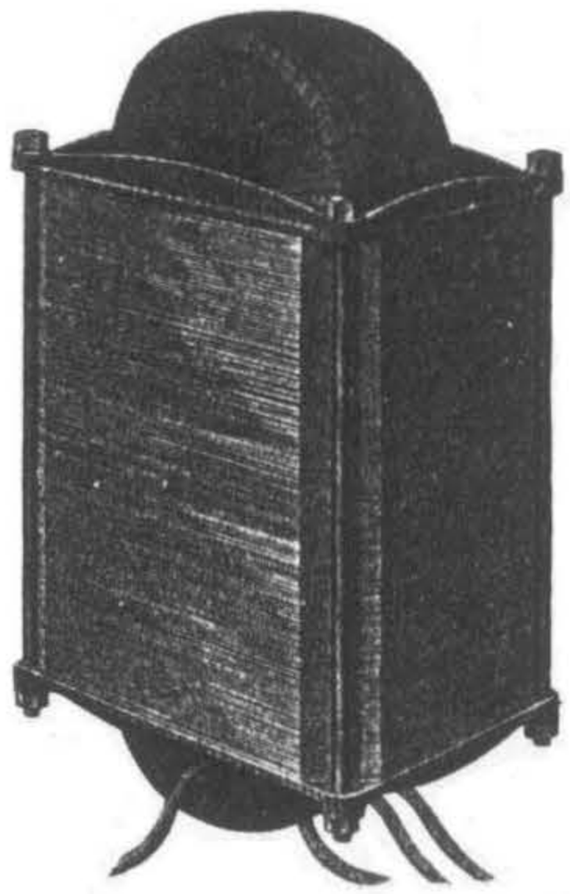

FIG. 4—THE CONVERTER OR TRANSFORMER

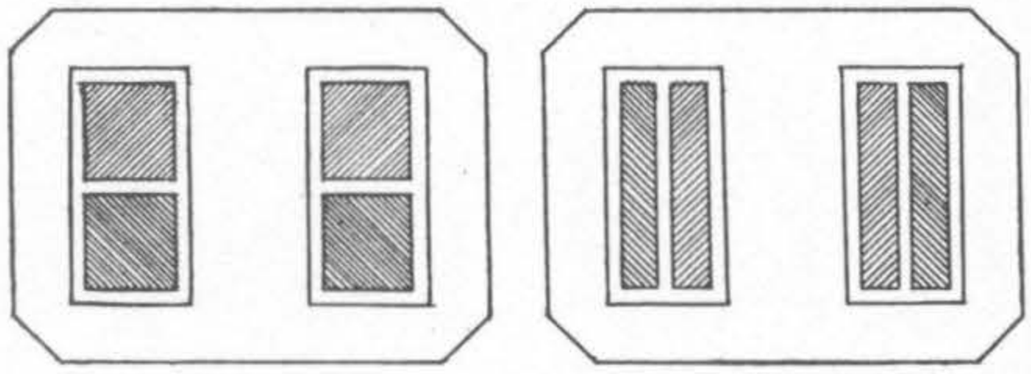

"It is a device of the simplest possible construction, having no moving parts whatever, its functions being purely electrical. It consists essentially of two coils, one of a great length of fine wire, called the 'primary coil' and receiving the current from the dynamo; the other of a short length of large wire, in which is induced the secondary current for lamp service."

struction, first finding favor in railway motors, was incorporated into generators and motors of all kinds.

TRANSFORMERS

The transformers (then called converters) which were made by the Westinghouse Company in

1888 were of five sizes, viz., of 5, 10, 20, 30 and 40 lamps the largest size being two kilowatts though the term kilowatts was not applied to them for several years. The transformers were wound for a primary e.m.f. of 1 000 volts and 50 volts secondary in most cases while a few were wound for 100 volts, usually with a tap at the middle point. The coils were separately wound and taped; they were approximately square in cross-section, so that the open-

PARALLEL COILS CONCENTRIC COILS

FIG. 5—FORMS OF COILS IN EARLY TRANSFORMERS

In parallel form the magnetic leakage between coils is considerable as there is a short wide path compared with that in the later concentric form, which therefore had much improved regulation.

ing in the iron was approximately a double square. The accompanying illustration shows such a transformer built up. Bare lead fuses, either wire or links, were placed between brass terminals on fibre bases in iron boxes on the case. Materials and construction of this sort would be wholly inadmissable today, though they were fairly satisfactory with the lesser currents, the lower e.m.f.s and the smaller generators which were then employed.

One of the difficulties with these transformers was the large drop in secondary voltage between no load and full load. This drop was partly caused by the resistance of the windings and partly by something else which was termed "drop due to iron." The latter was hard to measure accurately, as it seemed to vary from time to time. This factor was of serious importance when incandescent lamps constituted the only load, and it rose to very disagreeable proportions when there was a lagging current or, in modern terms, when the power-factor was low. The fact that the square coils were placed side by side in parallel form permitted a considerable magnetic leakage between the coils, the effect of which was very pronounced with the frequency of 133 cycles. The first modification in the transformer was to change the form of the coils, making them concentric by winding each coil with approximately twice the number of turns per layer and half the number of layers. This changed the path for the magnetic leakage, making it about twice as long and of one-half the cross-section that it was in the former arrangement, thereby improving the regulation.

The testing of transformers consisted of an insulation or a ground test and a running test. If the insulation was sufficient to prevent enough current from flowing through the primary of another transformer to light a lamp on its secondary, it was considered adequate. In other words, the insulation test was really made at an e.m.f. of 1 000 volts or less. The running test was made by coupling transformers in parallel to a large bank of lamps and running them for several hours.

AUXILIARY APPARATUS

While the generator and the transformer were the essential apparatus in the alternating system, various auxiliaries were necessary to make the system operative, such as switches, fuses, measuring instruments and the like. Past experience was limited to low voltage, direct-current service and to arc light circuits. Auxiliaries for alternating current and for 1 000 volt use had to be devised quickly. In the light of present knowledge they were simple and almost rudimentary. On the other hand, when one considers the limited experience there was to guide and the necessity for producing these instruments quickly, one cannot but admire the results. To Mr. Shallenberger and to Mr. Philip Lange, who was in charge of the construction of detail apparatus, belongs this credit in large measure. A number of points relating to this detail apparatus are of interest.

The rheostats had wooden face plates back of which were mounted wooden frames holding spirals of German silver wire.

The switches for the switchboards employed wooden bases and the contacts were open and exposed. Double-pole, double-throw switches were ordinarily employed for connecting a dynamo or an outgoing feeder to either of two sets of bus-bars. The transfer was made by throwing the switch quickly, resulting in only a momentary interruption of the circuit.

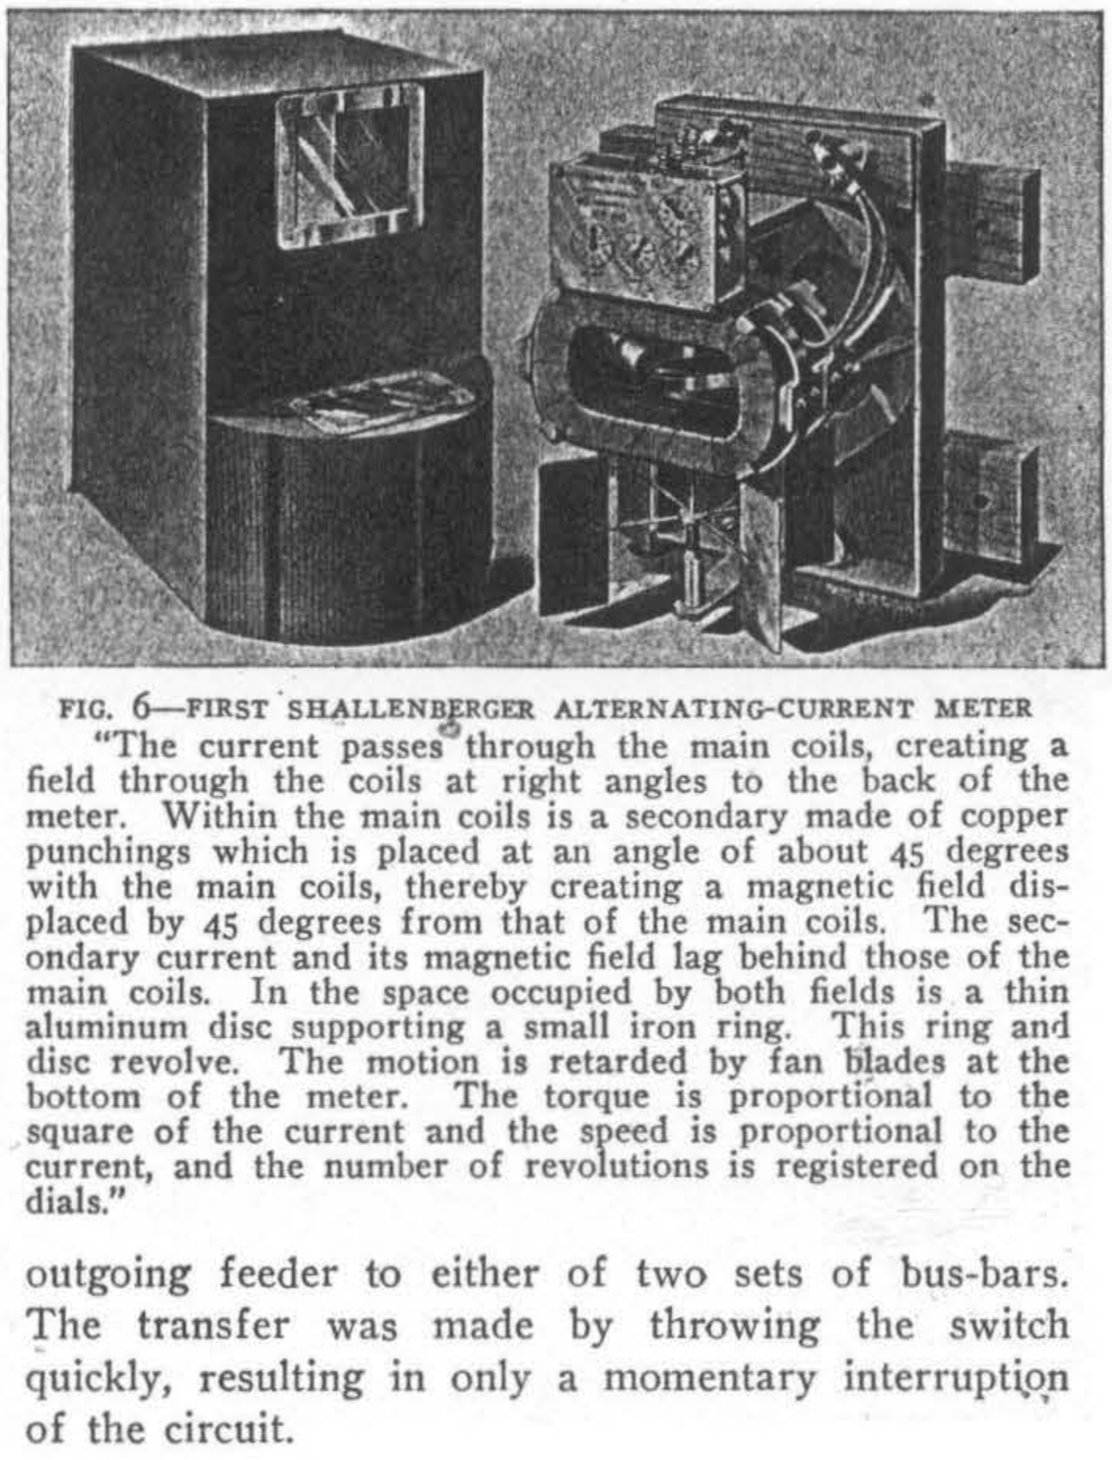

FIG. 6—FIRST SHALLENBERGER ALTERNATING-CURRENT METER

"The current passes through the main coils, creating a field through the coils at right angles to the back of the meter. Within the main coils is a secondary made of copper punchings which is placed at an angle of about 45 degrees with the main coils, thereby creating a magnetic field displaced by 45 degrees from that of the main coils. The secondary current and its magnetic field lag behind those of the main coils. In the space occupied by both fields is a thin aluminum disc supporting a small iron ring. This ring and disc revolve. The motion is retarded by fan blades at the bottom of the meter. The torque is proportional to the square of the current and the speed is proportional to the current, and the number of revolutions is registered on the dials."

The bus-bars for 1 000 volts were usually bare copper rods held by wooden supports on the front of the board. On one occasion a young electrician whose experience had been with batteries, joined the bars by a wire to see if he could get a spark. He did, but fortunately was not seriously burned. The

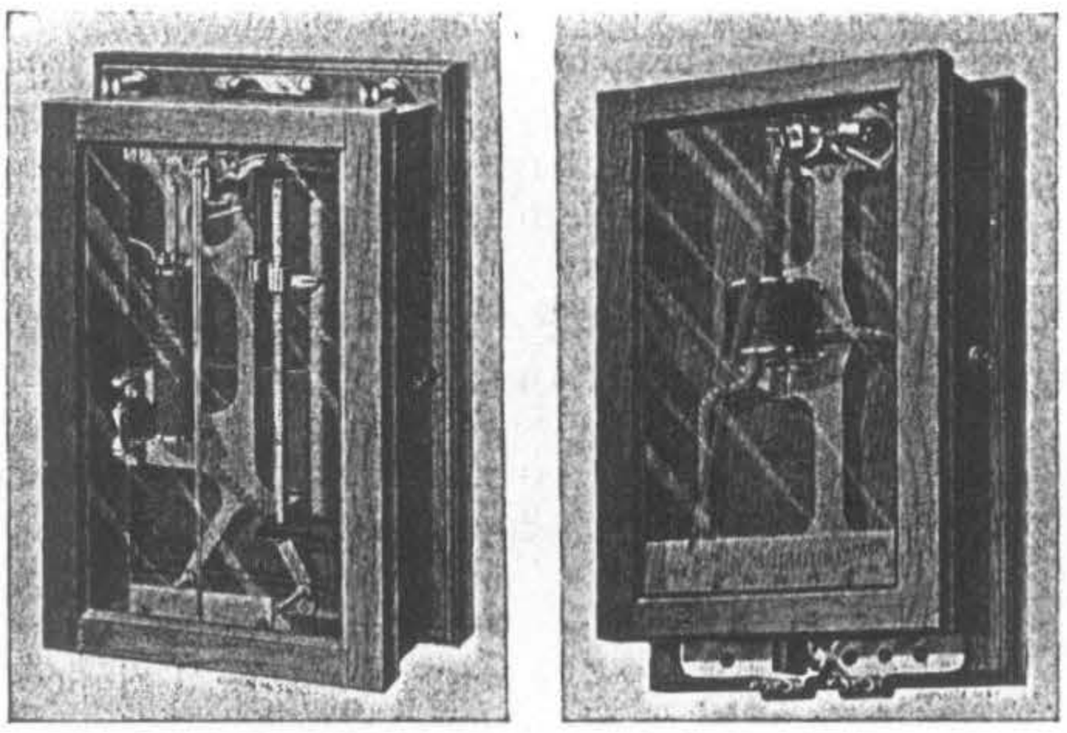

FIG. 7—STATION VOLTMETER AND AMMETER

"A solenoid pulls a soft iron wire plunger which is attached to one end of a lever which carries a weight at its other end. The e.m.f. necessary for causing the voltmeter pointer to come to the arrow is determined by the setting on the fixed resistance in the right hand side of the case."

safety catch or fuse was a wooden block about four inches square on which were mounted two lead fuses, one or both of which could be used, depending on the arrangement of the plugs which completed the circuit. The switchboard transformers were placed in wooden boxes and were mounted at the top of the

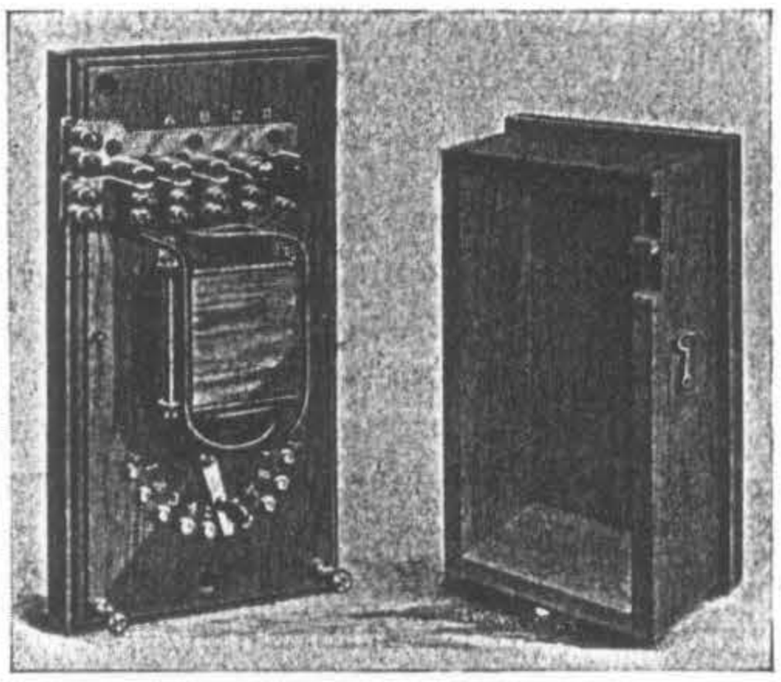

FIG. 8—VOLTMETER COMPENSATOR

"The number of turns through which the primary current passes is determined by the position of the plug near the top. The number of turns in the secondary winding which is in series with the voltmeter is adjusted by the switch near the bottom. In this manner the instrument can be adjusted to reduce the voltmeter reading by the same percentage as the line drop reduces the pressure at the lamps."

board. The board on which the apparatus was mounted was either of matched flooring or was an open wood framework.

The early voltmeter had a lever on one end of which was a weight (adjustable by the number of shot in a brass cylinder), and on the other an iron wire plunger which extended into a solenoid. Incandescent lamps were used as a resistance in series with the solenoid. When the applied e.m.f. was at normal value, the pull by the solenoid was just sufficient to cause the pointer attached to the lever to point vertically. There was no graduation on the scale. This voltmeter was soon superseded by another in which German silver resistance replaced the lamps.

The ammeter needle traversed a circular dial under the action of a plunger in a solenoid which carried the main current. In a later form the mechanism was simpler, the deflection being indicated on a scale near the bottom of the instrument.

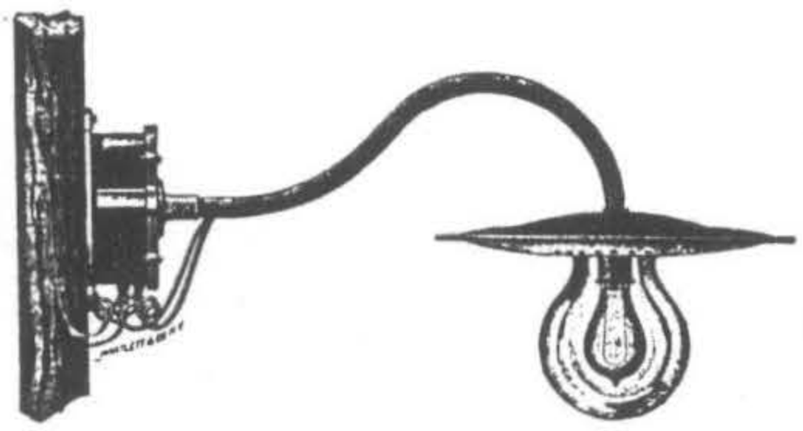

FIG. 9—STREET LAMP COIL, 1888

"These coils are so wound that twenty of them are placed in series when 1 000 volts are used. A 50 volt incandescent lamp is connected in shunt across each coil. When the lamp is burning the coil is 'not in action'; when it is broken the total current passes through the coil, which practically replaces the lamp. The brilliancy of the remaining lamps is not appreciably affected until five or six lamps are broken and then it is dimmed. This result is accomplished without any of the magnets or fusible connections or any of the moving parts or contacts which are annoying and crude accompaniments of many so-called series systems."

On the feeders were voltmeter compensators. These were series transformers, the primary circuit being in series with the feeder, and the secondary in series with the voltmeter. Outgoing current caused the voltmeter to read low, and it was necessary to

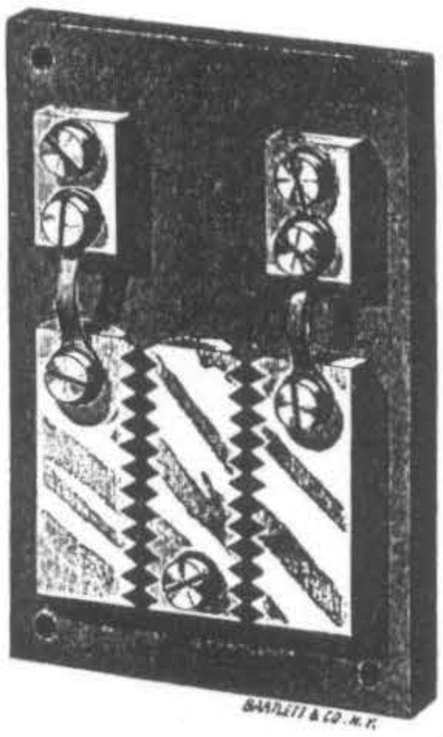

FIG. 10—LIGHTNING ARRESTER, 1888

This arrester was installed on 1 000 volt circuits. The middle section was grounded and the other two were connected to the dynamo terminals. It worked well if there was no lightning; but a spark was apt to be followed by dynamo current which volatilized the spark points and short-circuited the dynamo.

raise the bus-bar e.m.f. in order that the voltmeter might give normal indication. The compensator caused a drop in the voltmeter circuit proportional to that in the feeder, so that when the voltmeter reading

was normal the e.m.f. at the end of the feeder was normal also. When several feeders ran from the same bus-bars it was impossible to get the proper voltage for each one when the line losses were different, but a mean value could be selected. Recognizing this limitation, Mr. Stillwell devised, in the fall of 1888, the regulator which bore his name. A transformer had its primary coil connected between the two wires of the outgoing circuit and its secondary coil in series with the circuit, thereby increasing (or decreasing) the e.m.f. delivered to the circuit by the

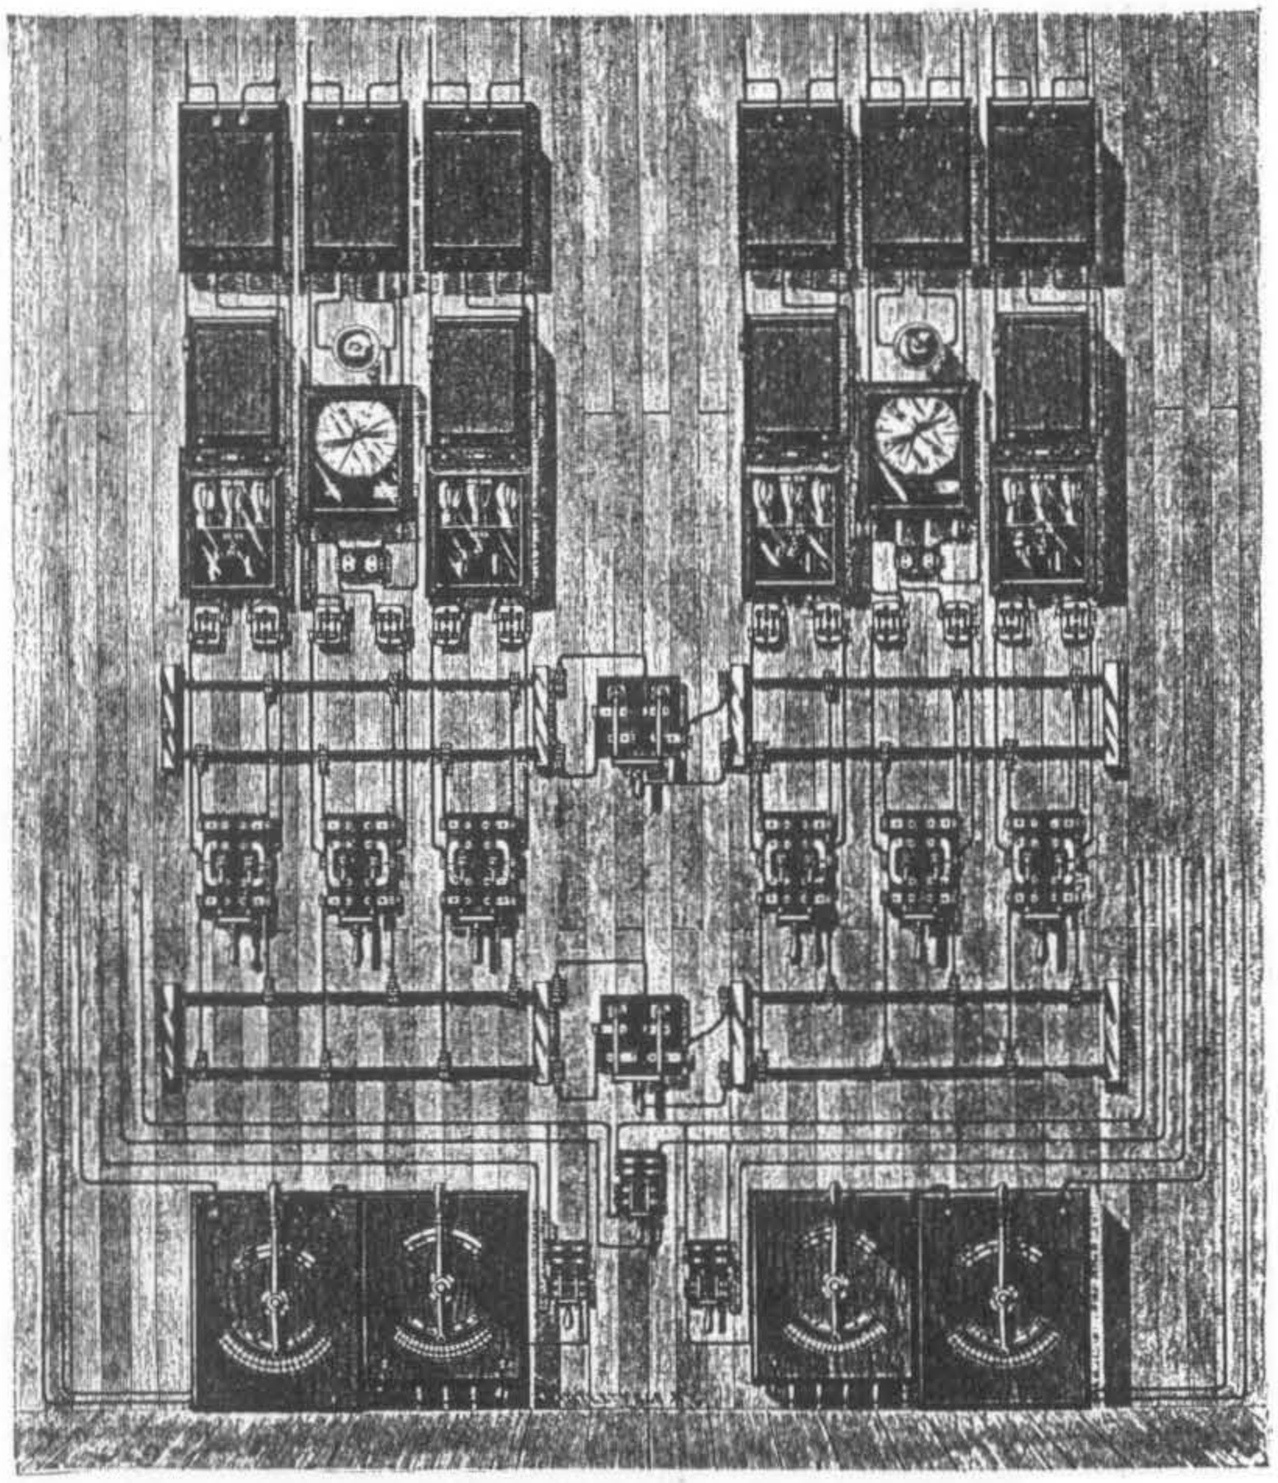

FIG. 11— TYPICAL SWITCHBOARD OF 1888

"This switchboard accommodates two exciters, two 1 000 volt alternators and four feeders. The exciter control circuits are at the bottom of the board. The alternators are connected to the middle point of the middle switches of the right hand and left hand side of the board, and may be connected to the upper or the lower pairs of bus-bars. The right hand and left hand sections of each pair of bus-bars may be separate or connected in parallel by multiple arcing switches. The generator circuit is provided with a transformer, supplying a pilot lamp, and an ammeter with short circuiting plugs and fuse. Each feeder may be connected to the upper or lower bus-bars by a double throw switch and is provided with fuses, a voltmeter, a compensator and a transformer. Wood is the only insulating material used, except in the internal parts of transformers and instruments."

amount of the secondary e.m.f. The latter was adjustable by a change in the number of turns; hence the e.m.f. on an individual feeder could be adjusted to such a value that when reduced by the line drop the desired e.m.f. would be delivered to the load.

The early lightning arrester was a number of spark gaps in parallel between brass plates on a rubber base. This form was useful for the protection of telegraph circuits, but was utterly inadequate when current from a dynamo was ready to follow a spark. The researches and notable inventions of Wurts were the early chapters in the story of modern lightning protection. He began his work on the improvement of fuses and lightning arresters about 1888.

The change which has come about in measuring instruments is best indicated by a question which was recently asked by a young man who had spent a year or more in a large commercial testing room. He saw a Siemens electro-dynamometer in a college laboratory and inquired whether they were put to any practical use. He was told that in early testing room and laboratory work the dynamometer was the only instrument for measuring current with the exception of station instruments and a few small imported direct-current ammeters of doubtful quality. Even after the Weston direct-current ammeters came into general use in the early nineties, it was some time before there was a substitute for the dynamometer for the measurement of alternating current. During this early period practically the only voltmeter was the Cardew voltmeter, a hot wire instrument in which the fine wire was protected by a brass tube three or four feet long, the expansion of the wire being indicated by a pointer on a circular dial. This voltmeter was made for 60 volts and 120 volts, the former requiring about one-third of an ampere and the latter a somewhat less current at full deflection. For alternating-current power measurements, a dynamometer was used in which the series current passed through one coil and the shunt current passed through the other coil and a suitable non-inductive resistance. These were the best measuring appliances available. Sometimes the brilliancy of an incandescent lamp was used for indicating voltage, and Mr. Telsa insisted that he could determine the number of amperes taken by a fan motor by breaking the circuit and noting the size of the arc.

TESLA MOTORS

The first Tesla motors were made with definite iron field poles, similar in general form to a multipolar direct-current machine of the present day. The magnetic circuits were laminated; coils were placed around the individual poles. In a two-phase motor, alternate poles were connected as one circuit and the remaining poles as the second circuit. In each circuit

the coils were first positive and then negative. When current was passed through one circuit alone, alternate coils were energized, producing positive and negative poles. When the current through the first circuit decreased and that in the second increased, there was produced a succession of positive and negative poles, shifting from the angular position of the first circuit to that of the second. This shifting magnetic field acted upon an internal secondary member or armature. In the early motors this consisted of a smooth cylindrical core with wires wound in coils on

FIG. 12—SAFETY CATCH HOLDER OF SWITCHBOARD FUSE BLOCK

"This is used on 1 000 volt circuits. If the upper plug be removed, the right hand fuse alone is in circuit. If this fuse melts due to excessive current, a plug may be inserted in the upper position, thereby immediately placing the left hand fuse in service." In case of short-circuit, however, the whole block was apt to be enveloped in an arc which destroyed the metal terminals, as well as the wood base.

the surface, these coils being short-circuited. There were usually as many windings as there were total field poles in the two primary circuits. Motors of this type would usually start fairly well and were able to carry a fair load. They took, however, a large magnetizing current due to the limited pole surface and to the relatively large air-gap between the iron of the stationary poles and the iron surface of the rotating core.

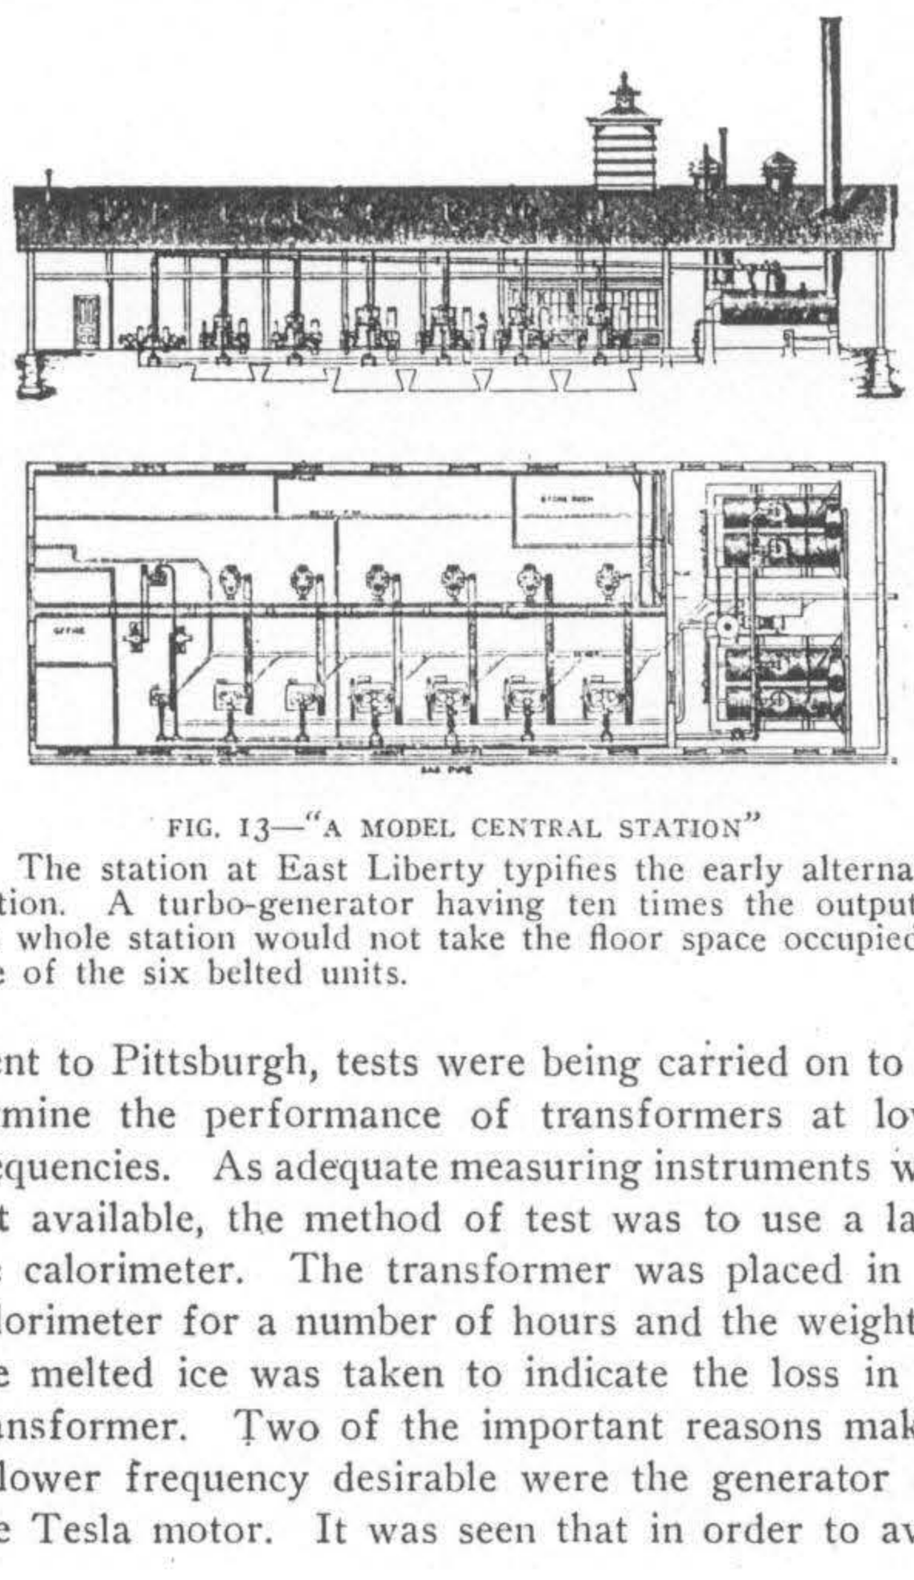
Furthermore, as the magnetic fields from the two primary circuits enter the secondary at definite independent positions, a coil on the rotating member in certain positions would confront one field pole only and in other positions might confront one field pole of each circuit and receive induction from both. Hence there was lack of uniformity of action and dead points sometimes resulted. Furthermore, if the rotating member were made with definite poles, so that the air-gap might be reduced, the excellence of the magnetic circuit varied for different angular positions of the secondary. These difficulties were in large measure overcome by making the secondary core with a large number of small slots and small teeth. In the slots were placed the coils with windings so distributed that the resultant action in the secondary was practically the same, whatever the angular position of the secondary. Later on the primary was also provided with a large number of small slots in which the windings were so distributed that several primary circuits produced a practically uniform rotating magnetic field. In such a field the secondary winding does not need to be specially distributed and the squirrel cage type can be employed in which each conductor is connected to a ring at each end of the secondary.

The method of winding in small slots, instead of placing the windings on the surface of an armature or around large poles made a radical change in the design of alternators, induction motors and direct-current generators. The first important machine of this type which was made in Pittsburgh was the No. 3 railway motor which combined a large number of characteristic features, making it the prototype of the modern railway motor. This new type of winding apparently sacrificed some of the best features of the induction motor. The simplicity of the early machine was unique. The primary windings were in a few coils as simple as ordinary field coils, readily wound, easily put in place and replaced. To separate this winding into many small coils to be placed in small slots was unfortunate from the standpoint of simplicity and insulation.

The early endeavor was to adapt the induction motor to 133 cycles and by "split phase" or other methods to operate it on the existing single-phase circuits. It is no wonder that little headway was made in solving a problem which scarcely any one would attempt today. The motor could not be adapted to the frequency, and so the frequency was adapted to the motor.

FREQUENCY

The frequency of the early apparatus was 133 cycles, or 16 000 alternations per minute as it was then ordinarily designated. About the time the writer



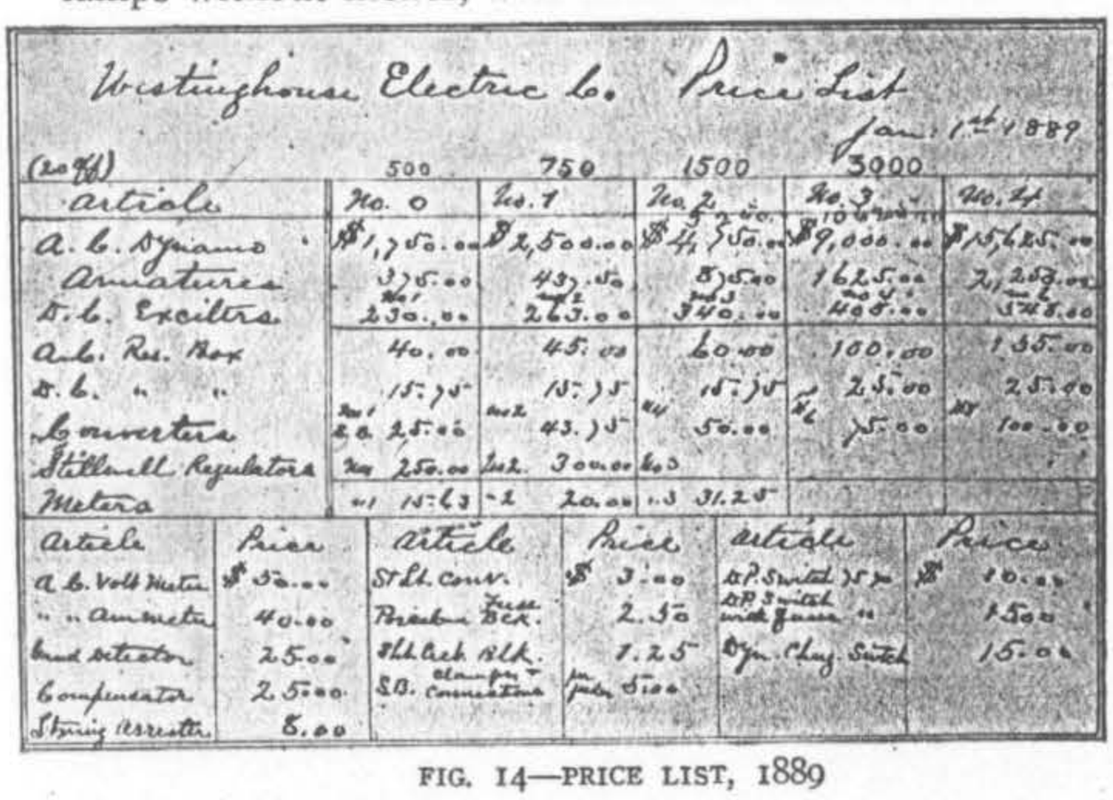


FIG. 13—"A MODEL CENTRAL STATION"

The station at East Liberty typifies the early alternating station. A turbo-generator having ten times the output of the whole station would not take the floor space occupied by one of the six belted units.

went to Pittsburgh, tests were being carried on to determine the performance of transformers at lower frequencies. As adequate measuring instruments were not available, the method of test was to use a large ice calorimeter. The transformer was placed in the calorimeter for a number of hours and the weight of the melted ice was taken to indicate the loss in the transformer. Two of the important reasons making a lower frequency desirable were the generator and the Tesla motor. It was seen that in order to avoid

belts, it would be necessary to run alternators at a low speed for direct connection to engines. This made desirable a less number of poles than would be necessary for the high frequency, for instance, at 100 r.p.m. 160 poles would be necessary. Furthermore, the induction motor operated much more satisfactorily at a low frequency.

In the fall of 1890 Mr. Stillwell returned from a visit to Europe. He had seen alternators direct connected to slow-speed engines. After carefully studying the American situation he prepared a report on which the subsequent engineering policy of the company was based, in which a frequency of 60 cycles was proposed as a general standard for lighting service and 30 cycles for power service. The higher frequency met the requirements of engine speed; it permitted transformers to be made at reasonable cost (the cost increased as the frequency was lowered) and it was high enough to permit the operation of arc lamps without flicker, with American carbons. soft carbons permitted a slightly lower frequency. The lower frequency of 30 cycles seem a desirable one from the standpoint of the induction motor and power work generally. In 1892 an exhibition of alternating apparatus was made at Pittsburgh which was viewed by Prof. George Forbes of England, Prof. Henry A. Rowland and Dr. Coleman Sellers members of the commission for determining the system to be adopted by the Niagara Falls Power Company. They were shown rotary converters operating at 30 cycles. The matter of frequency was discussed. The effect on incandescent lamps was determined to be unobservable at 30 cycles, very pronounced at 20 cycles and somewhat in question at 25. Prof. Rowland remarked that the way to make a test was to have some old woman read by the light and note whether or not her eyes became tired. This seemed a remarkable statement from the leading physicist of America with regard to what seemed to be a physical phenomenon, but after all it is not physical condition but physiological effect that is of importance. The commission of American and foreign engineers which determined the system to be used at Niagara was at first in favor of direct current by a considerable majority. The final decision in favor of alternating current was not made until the summer of 1893 when polyphase alternating current was choosen and a little later 25 cycle alternators of 5 000 horse-power, delivering two phase current were purchased from the Westinghouse Company. The design of the alternators favored either a 12 pole or a 16 pole alternator. The water turbines had been purchased; they ran at 250 r.p.m. Hence the choice lay between 25 and 33 1/3 cycles and it was impossible to secure 30 cycles. The 12 pole machine giving 25 cycles was chosen. This was a notable event. The adoption of polyphase alternating current and the use of 25 cycles by the largest power undertaking of the time set a precedent which is now almost universally followed. Frequencies of 40 and 50 and 66 cycles have been advocated and used, but (with few exceptions) are now obsolete.

THE IMPORTANCE OF TRANSFORMER AND POLYPHASE SYSTEM

In the early days, say from 1880 to 1895, there were many systems and many types of apparatus. This is well illustrated by one station which had machines for arc lighting at 6.6 amperes, for arc lighting at 10 amperes, for incandscent lighting by the three-wire system, for power by 500 volts direct current, and for incandescent lighting by alternating current. Each kind of service required its own individual circuits and the arc lighting required individual circuits from each machine. Subsequently current for all kinds of service was derived from alternators far greater in capacity than a score of the former machines.

If we were to trace the electric development of the past twenty-five years, we should find the transformer as the simple factor which has determined the whole course of that development. With few exceptions in which direct current from relatively small plants is used locally, practically all of the electric energy now used for lighting and for power purposes passes through one or more transformers.

A second factor in shaping the course of electrical development was the Tesla motor and the polyphase system. To accommodate the motor with a proper supply of current, single-phase generators gave way to polyphase alternators, and high frequency was followed by low. The Tesla invention proved to be not merely a motor, as was first assumed, but a system. Polyphase apparatus is now practically universal. All of the long distance systems of power transmission and practically all of the great central stations for street railway and lighting and power service produce polyphase alternating current, even when the consumption circuits require direct current. When the polyphase system was first introduced, the parallel operation of alternators was unusual, but it is now universal.

Without the transformer and the polyphase system there is no means at present known by which the extension of the use of electricity could have made one-tenth of the progress that it has made. It is easy to recognize this now, but it was not so easy to foresee. In fact, there was criticism and condemnation of the alternating current by experts, and there was antagonism and opposition by commercial interests. The foresight, the courage and the wonderful constructive ability, persistence and power of Mr. Westinghouse made him the great human factor in the recognition, introduction and development of the alternating system, and, therefore, in the electrical development of the past twenty-five years.

Those only who were associated with the company before the writer went to Pittsburgh have been mentioned. Among the first of those who followed and who have had a great deal to do with the subsequent development of apparatus, including some of the types to which reference has already been made, were Messrs, Lamme and Storer and Skinner and Davis. It is anticipated that further articles by various men will trace the engineering steps which have led up to the efficient apparatus of to-day. Present practice is the outcome of the efforts of many workers in many places. The particular thing which may bear the impress of a particular inventor or may be put forward with energy by one company or another may flourish for a time, but merit determines its final disposition. Among the types of apparatus which are now in common use and in many cases are manufactured by several companies it will be interesting to note that a considerable number had their origin Pittsburgh. In many cases the idea originated with a Pittsburgh inventor. In other cases an acute engineering instinct has selected, combined and put into operating form apparatus or methods which were previously undeveloped or experimental.

Electric Journal February 1914

The Engineering Evolution of Electrical Apparatus—II

THE ALTERNATING-CURRENT GENERATOR IN AMERICA

B. G. LAMME
Chief Engineer
Westinghouse Electric & Mfg. Company

FOREWORD—The following article contains a fairly complete brief history of the evolution of the alternating-current generator in so far as the Company with which the writer is connected is concerned, as drawn from the writer's memory principally. Reference is made incidentally to the work of other manufacturing companies, but this cannot be very complete, as the writer naturally does not have the necessary material available for describing such developments, except in a very general way. Therefore, the inadequacy of this history, outside of the Westinghouse part, should be charged to the lack of data rather than to lack of respect for the work of others.

IN the early days of the alternating-current generator, it was constructed in almost as many types as there were designers. The principal endeavor of each designer appeared to be toward the development of a new alternator which would bear his name. A few of these early types were of the rotating field construction, while a much greater number were of the rotating armature type. Some had iron core armatures, while others had coreless armatures, and there were many discussions as to whether the core or the coreless type was superior and would survive. Many of the early predictions would now form quite interesting reading, in view of the fact that present practice is so far removed from the early anticipations. Here and there among the early machines was one which contained some of the important elements of recent apparatus, but in many cases such machines disappeared in the general course of development, the meritorious features being insufficient to save the type.

SURFACE WOUND ARMATURES

In America, the principal early type of alternator had a rotating armature with surface windings and an external cast iron multipolar field. This type was used very considerably or, in fact, almost exclusively, from 1886 to 1890. This was the type built by the Westinghouse and the Thomson-Houston Companies. There were only minor differences in the construction of the machines built by these two companies which, however, at that time, appeared to be very great. These differences consisted principally in the way the end windings of the armature coils were supported, in the construction of the end bells and ventilating openings in the armature core, in the method of attaching the armature core to the shaft, in the winding of the field coils in metal bobbins, etc. Both machines had surface windings with concentric coils, one layer deep in the radial direction. In the Westinghouse construction, the end windings were turned down toward the shaft and were supported by radial wooden clamps, as indicated in Fig. 1. In the Thomson-Houston armature, the end windings were arranged in an axial instead of a radial direction, and were supported by bands or external clamps. This construction is also indicated in Fig. 1. The Slattery machine, which was also on the market at that time, was of the same general type as the above machines. Presumably these two different methods of end winding were used on account of the patent situation. At that time there was much discussion of the respective merits of the two constructions.

These early machines were built principally for frequencies of 15 000 and 16 000 alternations per minute (125 and 133 cycles per second). In those days, everything was rated in alternations per minute, as this represented the product of the number of poles by the number of revolutions. Such high frequencies were selected, mainly, on account of transformer conditions, and not alternator design. Practically all alternating service consisted of house to house lighting, and in relatively small units, and the higher frequency was supposed to be of great advantage in transformer design and operation, which presumably was the case with the very small amount of data and experience available at that time.

About the only commercial voltage for alternating work at that time was 1 000 or 1 100 volts. This was supposed to be excessively high and dangerous, and there was much question whether such an excessive voltage should be permitted. This matter was actually taken before a number of the state legislatures for the purpose of obtaining laws prohibiting or limiting the use of such voltage. Another reason why no higher voltage was used was in the construction of the alternators and transformers. With the experience and materials available at that time, together with the high speed rotating armature construction and the surface windings, even 1 100 volts was a very serious problem in the generator. About 1889 or 1890, there appeared some slight demand for higher voltages, and a few 2 000 or 2 200 volt surface-wound alternators, of the then standard type, were built. However, even then it was recognized that the surface-wound type of alternator was not well adapted for higher voltages, and there was much question whether a different type winding should not be developed for 1 100 volts. This gradually led to the next big step, namely, the development of the "toothed" type of alternator with one big tooth per pole, in distinction

from the slotted type of armature with a number of slots per pole, which was a considerably later development.

TOOTHED ARMATURES

The first commercial toothed type of armature appears to have been gotten out by the Westinghouse

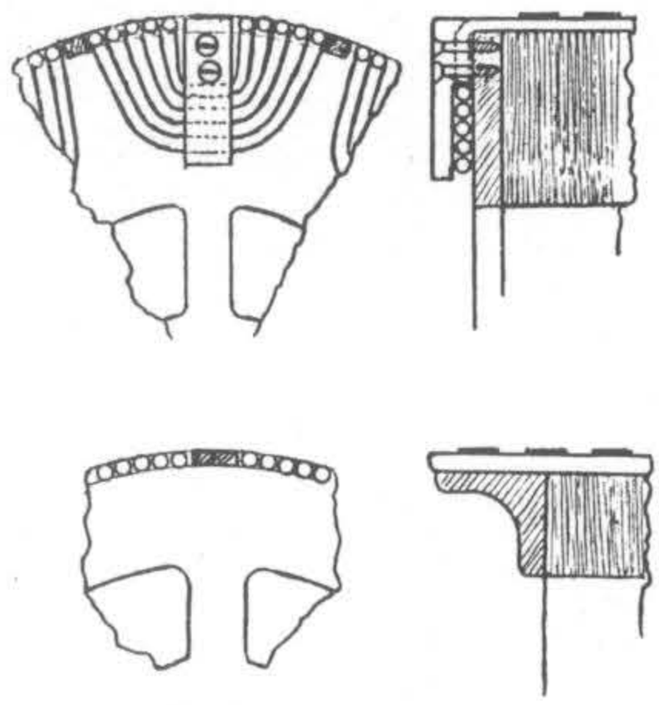

FIG. 1—SURFACE WOUND ARMATURE WITH RADIAL CLAMPS (UPPER) AND WITH AXIAL CLAMPS (LOWER)

Company. These first machines were radically different, in details of construction, from the later toothed armature types of machines which came into general use. The first toothed armatures were small air-gap machines. In the surface-wound armatures, the clearance between the armature surface and the field poles was comparatively small, although the total air-gap (iron to iron) was large on account of the surface winding. In constructing the new toothed armature, the actual clearance (iron to iron) between armature and field was kept about the same as in the surface-wound alternators (bands to iron), but this clearance actually represented the total air-gap in the toothed type. Moreover, in sinking the windings below the

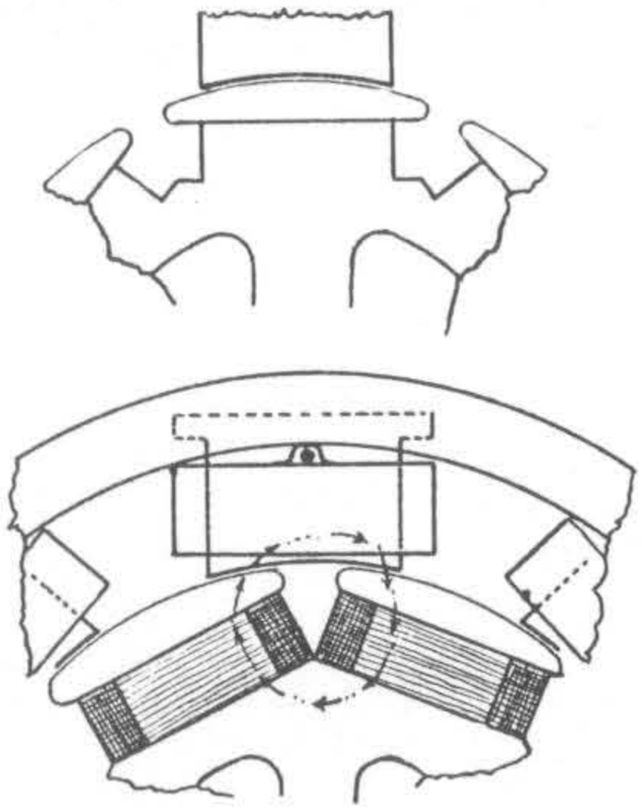

FIG. 2

surface, it was endeavored to maintain a practically uniform outside surface, so that overhanging tooth tips were used with relatively narrow slots for putting in the windings. The general construction was similar to Fig. 2. On account of the small clearance, and consequent higher magnetic conditions, it was found necessary to use laminated poles with these machines in order to avoid excessive field heating.

The self-induction of the armature windings on these machines was very high compared with the old surface-wound armatures and, therefore, in order to obtain passably good regulation, fewer armature turns had to be used, with correspondingly higher inductions, and this made the use of solid poles impracticable on account of heating. Furthermore, on account of the overhanging tooth tips, the small air-gap and the high induction per pole, this early type of toothed armature was very noisy. In one instance, it was credibly reported that one of these machines could be heard two miles away on a quiet night. However, several machines of this construction were put out by the Westinghouse Company, and operated for many years.

Meanwhile, the possibilities of the toothed armature construction in the old cast iron field were being given consideration. The writer made a special study of this matter, and finally decided that, in order to make this construction possible with solid cast iron poles, it would be necessary to work at relatively low

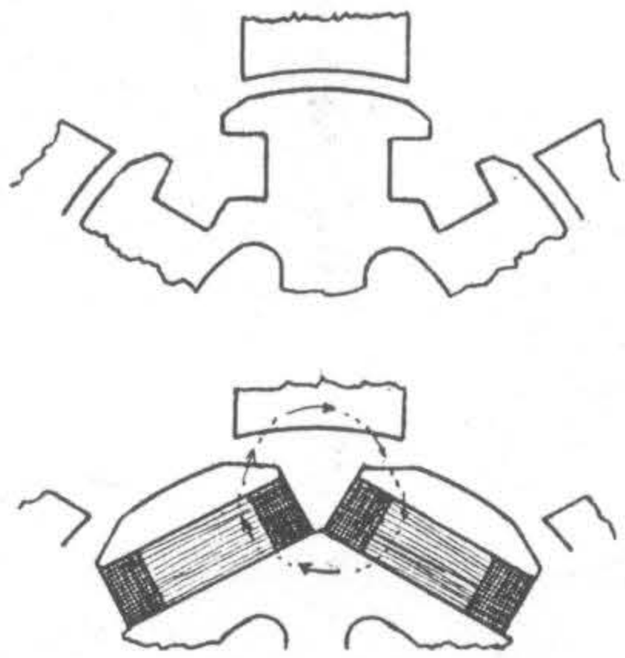

FIG. 3

inductions per pole, and with a very large air-gap, (fully as large as on the old surface-wound machines) and with a shape of tooth tip which did not have such great width compared with the pole tip as shown in Fig. 2. This meant that a pole tip and air-gap as shown in Fig. 3, should be used. With this arrangement, the armature self-induction would still be relatively high, and the regulation correspondingly bad, necessitating some form of compounding for regulating the voltage, similar to the compounding of a direct-current generator. This armature construction was worked out in detail for a 37.5 kilowatt field (that is, for the standard field of the 37.5 kw surface-wound type of machine). The armature teeth were similar to those in Fig. 3, in shape, and the air-gap or clearance from iron to iron, was made 3/8 inch on each side of the machine. The field was also compounded. When this machine was put on test, it was found at once that it could be loaded to 60 kilowatts without undue heating of the armature and field iron, and the problem of perfecting this machine then became one merely of increasing the amount of arma-

ture copper to carry the current at the 60 kilowatt rating. This, therefore, represented a big step in the development of the American type alternator. It was found that all the other Westinghouse standard cast iron machines of the rotating armature type could readily be changed in line with the above improvement.

COMPOUNDING ALTERNATORS

The compounding of the 60 kilowatt machine was not a new feature, for already some of the laminated field toothed-armature type of machines had been compounded, in order to improve their regulation. Two different methods of compounding alternators had been developed by the Westinghouse and Thomson-Houston Companies, respectively. In the Westinghouse armature construction, the armature discs were punched in single pieces, with spokes, and were threaded directly on the armature shaft, no spider being used. This construction is illustrated in Fig. 4. In the assembled armature, the spokes were therefore of laminated material. These laminated spokes were utilized as the core of a compounding transformer. One lead from the armature winding was carried around the spokes of the armature before passing to the collector ring. This winding formed the primary of a series transformer. The secondary was also wound on the spokes, and the two ends were carried to the bars of a rectifying commutator on the shaft. The number of commutator bars was equal to the number of poles. The alternating current from the secandary winding was by this means changed to a pulsating direct current.

In the Thomson-Houston method of compounding, the main armature current was carried directly to a rectifying commutator, and, after being commutated, was passed to the field-compound winding, and back to

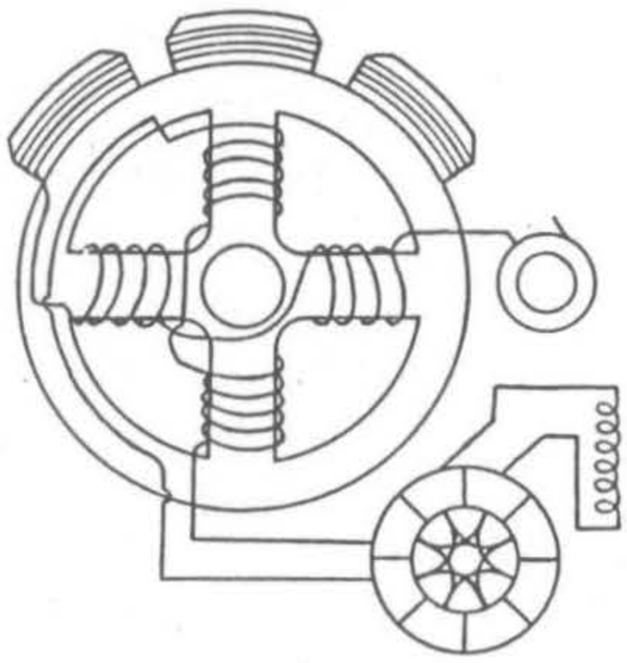

FIG. 4—SKETCH OF COMPENSATED TYPE OF WINDING

the commutator, and then to a collector ring. The main armature current therefore passed directly through the field, while in the Westinghouse method the secondary current from a series transformer was passed through the field. Both methods represented series compounding, and gave practically equal results, but there was much discussion as to the merits of the two methods. Both of these methods delivered pulsating direct current to the field winding. There was considerable inductive e.m.f. set up in the field windings by this pulsation, and this tended to cause inductive discharges across the rectifying commutators. In the Thomson-Houston method this trouble was overcome to a considerable extent by the use of a non-inductive shunt in parallel with the rectifying commutator, i.e.,

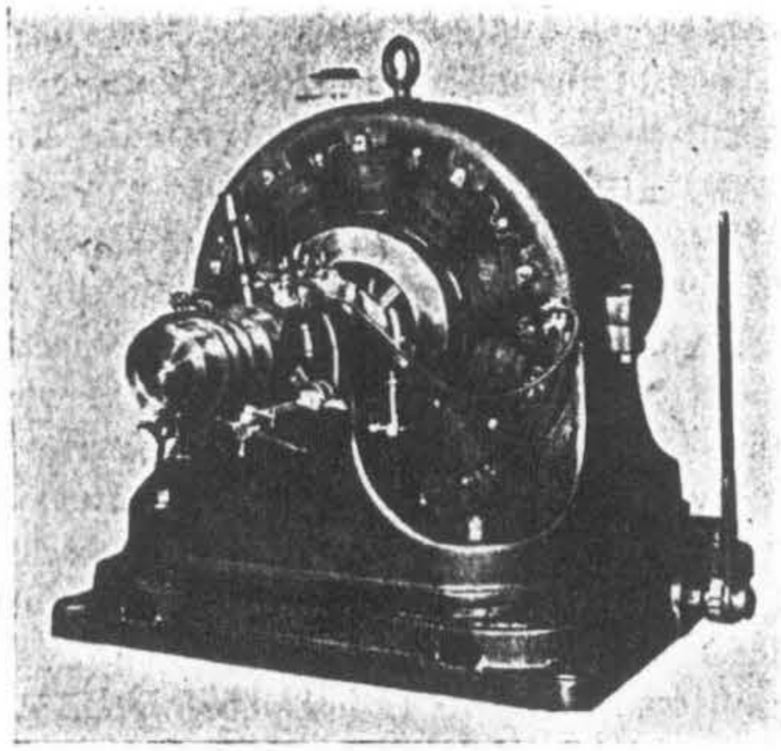

FIG. 5—EARLY WESTINGHOUSE 60 KILOWATT ALTERNATOR WITH COMPENSATING WINDING

across the compound winding. In the Westinghouse method a similar result was accomplished by saturating the series transformer (or armature spokes) to such a high point that the inductive kick from the field could readily discharge through the secondary winding of the transformer without giving high enough voltage to flash across the commutator.

The details of this method of compounding have been gone into rather fully, as this compounding was, at that time, an important step in our progress. The fact that of all these machines were built for single phase, allowed us to use such compounding. With the advent of polyphase generators, such methods of compounding soon disappeared, principally for the reason that a great majority of the early polyphase machines handled separate single-phase loads on the different phases, and it was not practicable to compound for these independently.

The above toothed type generator came into use about 1890 and lasted for several years, or practically until polyphase generators actually came into fairly general use before true polyphase loads became common. These toothed type generators allowed the use of relatively high voltages, as far as the armature winding was concerned, so that 2 200 volts became comparatively common, and even 3 300 volts or higher was used in some cases. In fact, the limit in such machines appeared to be at the collector rings, rather than in the armature winding.

Something may be said regarding the type of winding used on the armatures of these machines. In the Westinghouse construction the armature coils were machine-wound and taped before placing on the armature core. Each coil was made wide enough to slip

over the top of the armature tooth, as shown in Figs. 6 and 7. This made the coil considerably wider than the body of the armature tooth, so that, after slipping over the tooth top the coil had to be reduced in width by special clamping tools. Supporting wedges were then driven in between adjacent coils.

Something may be said regarding the temperatures of these early alternators, both of the surface-wound and of the toothed types. In those days temperature measurements were very crude compared with present practice, which is admittedly still only approximate. In some of the surface-wound armatures excessively high temperatures must have been encountered in many instances, judging from the appearance of the insulation on the individual wires, after a year's service, for instance. However, it was difficult to obtain reasonably correct temperature of the armature windings, for the actual temperature of the conductors was undoubtedly reduced very greatly before the armature could be brought to a standstill. Even after this, temperature rises of 50 or 60 degrees C. were not considered as excessively high. Without doubt, some of these early machines, at times, attained actual internal temperatures of 120 to 130 degrees C., or even higher, with insulation on the conductors consisting of untreaded cotton fibre. No overloads were possible, for each size of machine was rated in as many "lights" as it could carry on a shop test without breaking down. The first few minutes, while starting up a new alternator in the testing room, were always anxious ones for the operators, especially so if any "improvements" had been made on the armature winding. Any defect in winding, or wrong connection usually resulted in a stripped armature and much flying copper. If nothing happened within the first few minutes after the machine was put on load, the attendants all came out from behind posts and other protections and went on with their work.

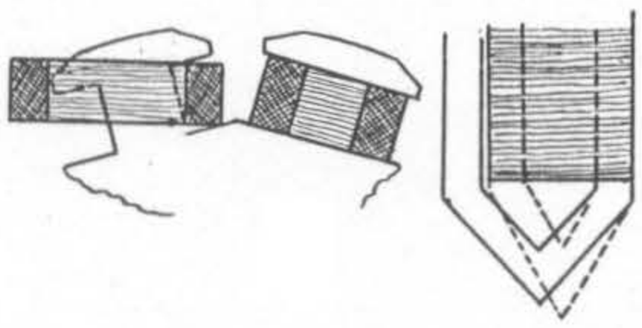

FIG. 6—SKETCH SHOWING METHOD OF PUTTING MACHINE WOUND COILS ON THE POLES

When the toothed armature came into use the above conditions were much alleviated. Defects in construction, or short-circuits, could not strip such armatures, and thus the danger and excitement were removed. However, it was found that the first short run did not tell the story of excessive heating as promptly as in the case of the surface-wound type. Experience showed that the toothed construction apparently could stand a severe shop test and still go wrong under similar loading within a short time after being installed. It was found that a given size of conductor would not carry as much current in the concentrated coils of the toothed construction as was the case in surface-wound coils. However, the method of testing the temperature did not show this, as the main part of the toothed armature coil was so embedded and so covered with insulation that the thermometer readings did not indicate nearly the true temperatures. The size of wire and the amount of copper in the coils then had to be increased until the machines did stand up in service. The true explanation of the discrepancies was not well understood at that time. In these toothed alternators, as in the surface-wound machines, the first machines were rated in "lights," but gradually the kilowatt rating came into use and became standard practice.

INTRODUCTION OF POLYPHASE ALTERNATORS

In 1892 and 1893, polyphase alternators began to be considered seriously. In 1889 and 1890, a few such alternators had been built for the operation of Telsa induction motors. These early polyphase alternators were of the surface-wound, rotating armature type. These machines were very special in construction, and, like the Telsa motors, did not find much of a market. However, in 1892 and 1893, it began to be recognized that the best way to encourage the development of the induction motor would be by creating a demand for it, and it was decided that a good way to create a demand would be by encouraging the general adoption of polyphase alternators and supply circuits, with the idea that, when a suitable supply circuit was available, there was eventually bound to be a demand for motors to operate upon such circuits. With this general policy in view, there was great activity in the development of polyphase generators. This very quicky led to a very considerable departure in armature construction from the usual toothed armature as used in single-phase machines. The polyphase winding, requiring two or more coils per pole, naturally tended toward the slotted armature construction with two or more slots per pole. It was soon recognized that, in general, the larger the number of slots per pole and the smaller the number of conductors per slot, the better would be the general characteristics of the machine, so that the construction naturally tended toward the modern slotted type. Moreover, practically all the development in polyphase alternators was at relatively low frequency, compared with former practice. It so happened that there had been a well-defined tendency toward lower frequency in the period from 1890 to 1892. This tendency was largely independent

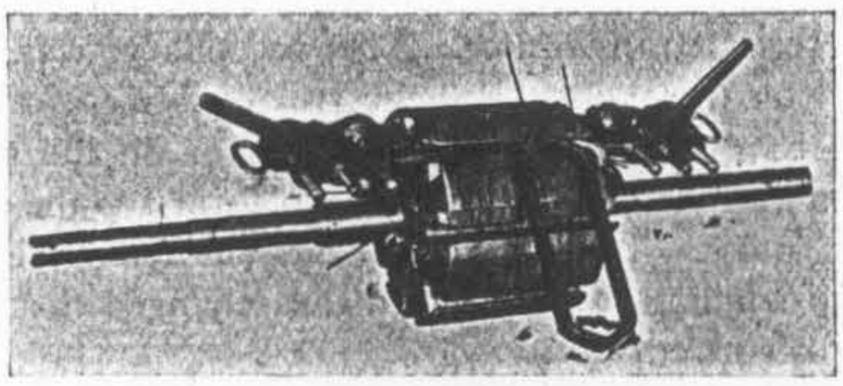

FIG. 7—VIEW OF ARMATURE IN PROCESS OF PLACING COILS AND CLAMPING THEM INTO SHAPE IN THE SLOTS

of the induction motor problem for, at the time it became most pronounced, there was no true induction motor problem. It was becoming recognized that 125 to 133 cycles per second was too high for certain classes of work and for engine type generators, and that, in general, a very considerably lower frequency must eventually be adopted. A great many lower frequencies were tried by the different manufacturing companies, ranging from 50 to 85 cycles. However, 60 cycles seemed to have the preference at the time polyphase alternators began to come in.

The early polyphase generators were mostly of the rotating armature type, and usually with a fairly large number of slots per pole. One notable exception was the "monocycle" machine which usually had only two slots per pole, one large slot for the main armature winding, and one smaller slot for the so-called "teaser" winding. Also, the early two-phase alternators of the "inductor" type, built by the Stanley-Kelly Company, frequently had only two slots per pole. However, it may be said that, from 1893 to about 1898, the great majority of the American built alternators were of the rotating armature type with distributed armature windings. The principal exceptions were the Stanley inductor type of machines and a few special "rotating field" machines, as distinguished from the inductor type.

The rotating armature machines were usually of 1 100 or 2 200 volts, although a few of considerably higher voltage were constructed. A few cases may be cited where special constructions were used. For instance, the principal lighting plant at the Chicago World's Fair in 1893, consisted of a large number of Westinghouse "twin" type generators. Each unit had two single-phase, standard toothed type armatures side by side on the same shaft. The teeth of the two armatures were staggered 90 electrical degrees with respect to each other, so that the two together could deliver currents having 90 degrees relation to each other. The object of this construction was to obtain polyphase current with standard single-phase types of machines without any radically new development. This type of unit did not persist and, in fact, was simply an expedient for this particular occasion.

THE FIRST NIAGARA GENERATORS

Also, in 1892 and 1893, the first large Niagara electrical development was worked out. The advisory engineers of this plant proposed 5 000 horse-power generators, having stationary internal armatures and rotating external fields to obtain large flywheel capacity. In fact, the construction was not unlike the usual rotating armature machine of that period, as far as general appearance of the armature and field cores and windings were concerned. However, the method of supporting and rotating the heavy external field at a speed which, at that time, was considered excessively high, required an "umbrella" type of field support, which gave these machines a distinctive appearance. This type of construction did not persist, although these early machines are still in operation.

A further distinctive feature in these first Niagara machines was in the frequency employed. A speed of 250 revolutions per minute was decided upon. The engineers of the power company proposed eight pole machines, giving 2 000 alternations per minute or 16 2/3 cycles per second. The Westinghouse Company proposed, as an alternative, 16 poles, giving 33 1/3 cycles, the advantages claimed for this frequency being that it was better suited for motors and rotary converters, which were then promising to become of importance. One advantage claimed for the 16 2/3 cycle machine was that it would permit the use of commutator type alternating-current motors. After much discussion, and weighing and balancing of all the various arguments for and against these two frequencies, it was finally decided to use 12 poles, giving 3 000 alternations per minute, or 25 cycle polyphase current and, as far as the writer knows, this was the origin of the present 25 cycle standard.

Considering what a radical departure from ordinary construction was made in these first Niagara generators, it is self-evident that many curious and interesting conditions developed during their design, construction and tests. As far as the writer knows, these were the first large alternators which were deliberately short-circuited at their terminals when running at full speed and at normal field charge. There were no instruments available to measure the first current rush, but it was obvious that this current was far greater than the steady short-circuit current of the machine under similar field charge, for there were ample evidences of a terrible shock at the moment of short-circuit. It was suspected at that time that the first rush of current was only limited by the armature impedance, and not by the so-called synchronous impedance which fixes the value of the steady short-circuit current.

This also was the earliest machine of which the writer predetermined the field form and wave form by analysis of the flux distribution. Later, when making shop tests on one of these machines, the e.m.f. wave form was measured directly by rotating the field at normal field charge at such an extremely low speed that a voltmeter connected across the armature terminals showed such gradual variations in e.m.f. that readings taken at regular intervals could be plotted to form the voltage wave. Slow rotation was obtained by means of a steel cable wrapped about the outside of the external field and with one end of the cable attached to a small diameter spindle around which it was wrapped at a very slow rate. This was a very crude method, but the wave form thus abtained checked very accurately with tests made some years later.

Also, the early Niagara machines embodied one of the first distinct attempts to ventilate alternators artificially. Early belted machines had had small ven-

tilating bells on each end. But these Niagara machines were designed primarily with a view to setting up an abnormal air circulation by means of special "scoops" or ventilators on the umbrella supports. Very much thought and discussion were given to this subject of artificial ventilation. The results of our tests led to the arrangement of thte scoops so that they acted as exhaust pipes.

Also, water cooling of the armature spider was tried on some of these early machines, but proved ineffective, due to the fact that the cooling medium was applied too far away from the point of development of the larger part of the armature iron and copper losses.

INFLUENCE OF DIRECT-CURRENT DESIGN

It must be kept in mind that the general trend of direct-current development had a certain influence on alternating-current generator work. For example, there had been a slow, but positive tendency in direct-current generators, toward the engine type construction. Also, from 1890 to 1893, direct-current generator armature construction had changed from the surface wound to the slotted type. This doubtless had some influence in changing alternator design toward the slotted type, especially when the polyphase type of windings came into use. Also, there was a pronounced tendency toward the engine type, slow speed alternator, accompanying direct-current practice. Practically all of these early engine type alternators, except the induotor type, had rotating armatures. Meanwhile, an interesting development took place in the armature construction of some of these machines. In most of the smaller belted machines, open armature slots were used with machine-wound armature coils. However, many of the early larger machines, especially of the engine type, were built for relatively low voltage, such as 440 volts, two or three phase. This admitted in many cases of simple bar windings with one or two conductors per slot. This allowed partially closed armature slots with shoved-through straight conductors, and bolted-on end windings, giving a very strong substantial type of winding for resisting the rotational stresses. The partially closed slot became a sort of standard in Westinghouse machines, and endured for a number of years, and was even carried into the stationary armature type of machine when rotating fields came into general use. This partially closed slot arrangement was a very good one as long as the generator voltages were relatively low. The same may be said of the rotating type of armature as a whole. However, when high voltages came into more general use, a different construction was preferable.

In reviewing the period of the rotating armature, slotted types of machines, the monocyclic system should be briefly described. Apparently this was gotten out with the idea that it avoided the patented features of the Tesla polyphase system. The armature circuits on this monocyclic system were so arranged that, when carrying load, one phase carried nearly all of the energy load, while both phases supplied magnetizing current for the operation of induction motors. During the period when this machine was in vogue, single-phase lighting work represented the principal service, while induction motor loads were relatively small. With increased use of polyphase loads, and with the elimination of the patent situation, the monocyclic system gradually dropped out.

It was early recognized that a stationary armature winding would be an ideal one in some respects, but it was thought that any rotating field construction was bound to be a difficult and expensive one. The inductor type construction was supposed by some engineers to overcome the objections to the rotating field, but many others considered that this type was not a final one, as it did not use the magnetic material in the machine to the best advantage. In the earlier alternators, with insufficient ventilation through the armature core, relatively low magnetic densities were necessary to avoid excessive iron heating, and the inductor alternator, with its non-reversal of armature flux, was worked at almost double the induction of the rotating armature type of machine, and thus the disadvantages of the non-reversal of flux of the inductor type were masked. In other words, the inductor alternator was worked well up toward saturation, while the other types were worked at only about half saturation. However, with improvements in ventilation due to radial ventilating ducts, improvements in iron by better annealing and painting of the laminations, etc., the flux densities in the rotating armature machines were gradually increased until high densities, approaching saturation, were reached. A corresponding increase in flux densities in the inductor type was not possible, on account of saturation. Therefore the rotating armature type of machine, in the later designs, was much more economical than the inductor type, although the latter had a very considerable advantage, especially at high voltages, in its stationary armature construction. Due to the merits of the stationary armature construction, the present rotating field type of machine was gradually evolved, which possesses the advantages of the stationary armature of the inductor type machine and the reversing flux of the rotating armature alternator. It was the development of this type of machine which sounded the death-knell of the inductor type. However, the Westinghouse Company, about 1897, decided to bring out a line of inductor type alternators to meet market conditions, although such decision was contrary to the recommendations of the designing engineers of the company, whose recommendation in particular was in favor of the rotating field construction as a more permanent type. However, as the rotating field type was not yet established, except in a very minor way, and as the inductor type had been on the market for years, it was decided to build the inductor type, although the design adopted was somewhat different from the Stanley type. Three sizes of these machines were built, two belted and one engine

type, but the inductor type, as a commercial proposition, soon died out.

One of the interesting peculiarities of the inductor type alternator, as usually built, was in the enormous stray field appearing in the shaft, bearings, bedplate, and sometimes in the engine-governing mechanism in engine type units, necessitating in at least one case, the use of brass governor balls. In the usual construction of inductor alternator, there was but one exciting winding. The magnetic circuit and the field winding were arranged as in Fig. 8, which show both the Stanley and the Westinghouse constructions. The normal or useful path of the magnetic flux is indicated by the dotted lines *a, a.* Obviously, the field coil which set up flux through these paths could also send magnetic fluxes through the shaft, bearings and bedplate along the dotted lines *b, b.* Moreover, if the two bearings were not connected by a magnetic bedplate, as might be the case in engine type machines, then, in two-crank engines the engine cylinders and other parts became opposite poles of a very powerful electro-magnet, when the field coil was excited. The

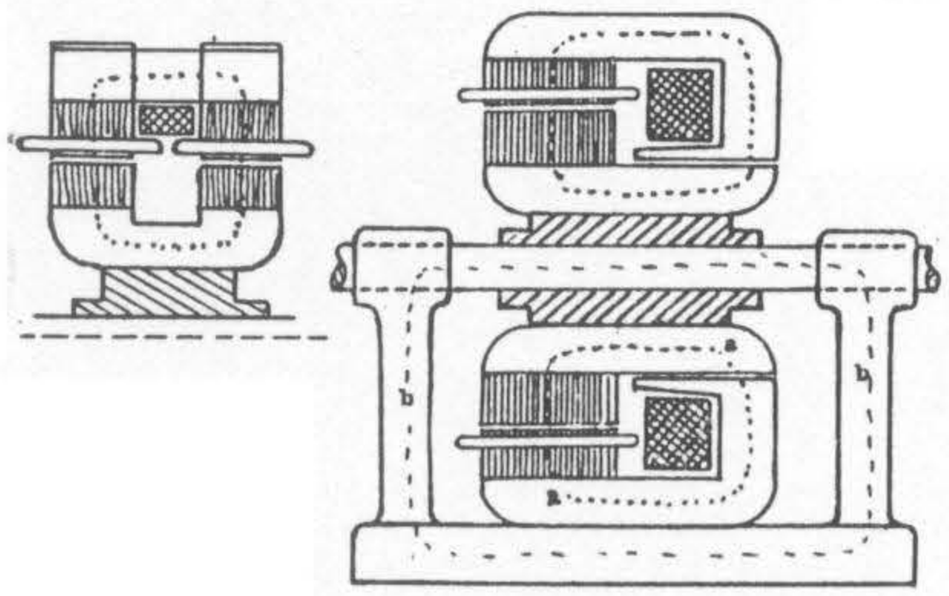

FIG. 8—SKETCH OF MAGNETIC CIRCUIT OF AN INDUCTOR ALTERNATOR

stray magnetic field set up in engine type units was sometimes so strong as to interfere with the governing mechanism. Also, with a strong undirectional flux between the bearings and shaft, each bearing became part of a small unipolar generator, of which the bearing surfaces formed the brushes. In some machines, quite heavy currents were generated in the bearings, sufficient to "eat away" the bearing surfaces or to pit them so that bad bearing operation resulted. As this was primarily a magnetic trouble, insulating the bearings from their pedestals would not stop the action. To overcome this trouble, the Stanley Company added a "bucking" coil placed around the shaft at one side of the generator, this coil being in series with the main field winding and magnetizing in the opposite direction. The ampere-turns of this bucking coil being made equal to those of the field coil, the resultant ampere-turns between the two bearings would be zero. Obviously, in an alternator with a bedplate and two bearings in which the armature frame rested directly on the bedplate, a single bucking coil at one side of the machine would not neutralize the stray field through both bearings.

ROTATING FIELD GENERATORS

Considering next the rotating field type of machines, possibly the earliest example was the Niagara type, mentioned before. This had an internal stationary armature, with windings on its outer periphery like the ordinary rotating armature. Outside this was the rotating field, consisting of a heavy forged steel ring with inwardly projecting poles. However, this type of construction was relatively expensive, and was never adopted generally. The more modern rotating field type of alternator, with external stationary armature, was a rather gradual development and, during this period, there was much heated discussion as to the relative advantages of the rotating field and rotating armature types. The rotating field gradually superseded the rotating armature construction for a number of reasons, the principal one having to do with the armature windings and voltages. In the rotating armature, the end windings were more difficult to support than in the stationary armature. Also, with the gradual advent of higher voltages, the stationary winding proved to be far superior. However, as a goodly proportion of the alternators built during this transition period were of the engine type and for low voltage, in which heavy bar windings could be used, (such being conditions under which the rotating armature made its best showing,) this type persisted for several years after the rotating field type became commercial. Gradually increasing voltages, however, necessitated the use of stationary armature machines, for at least part of the business. The manufacture of two types of apparatus for the same general purpose could not persist, and eventually that type was adopted exclusively, which allowed both high and low voltages. By 1900, the rotating field alternator had come into very general use, and the rotating armature type was disappearing. This rotating field type has persisted until the present time, although many minor modifications have been brought out from time to time, due largely to change in speed conditions, etc.

In the rotating field development, the tendency for a number of years was strongly toward the engine type construction and relatively low speeds in many cases. The construction was carried to the extreme, in some cases, where the usual flywheel capacity required for the slow speed engines was incorporated in the field structure of the alternator itself. In some cases, this meant enormously large machines for the output. A prominent example of this is found in the seventeen 6 000 kilowatt engine-type machines designed in 1899 and 1901 respectively, and installed in the Fifty-ninth and Seventy-fourth street power stations of the Interboro Rapid Transit Company of New York City. As an indication of the changes taking place in the electrical field, it may be stated here that arrangements have been made recently to take out a number of these machines and install in their place 30 000 kw turbo-generator units. The exist-

ing engine type machines are probably in as good condition now as when first installed, and are being replaced simply because they occupy too much space in proportion to their output.

The rotating field alternator of the early days was not radically different from the rotating field alternator of today, the principal differences being in the type of armature windings, methods of ventilation, etc.

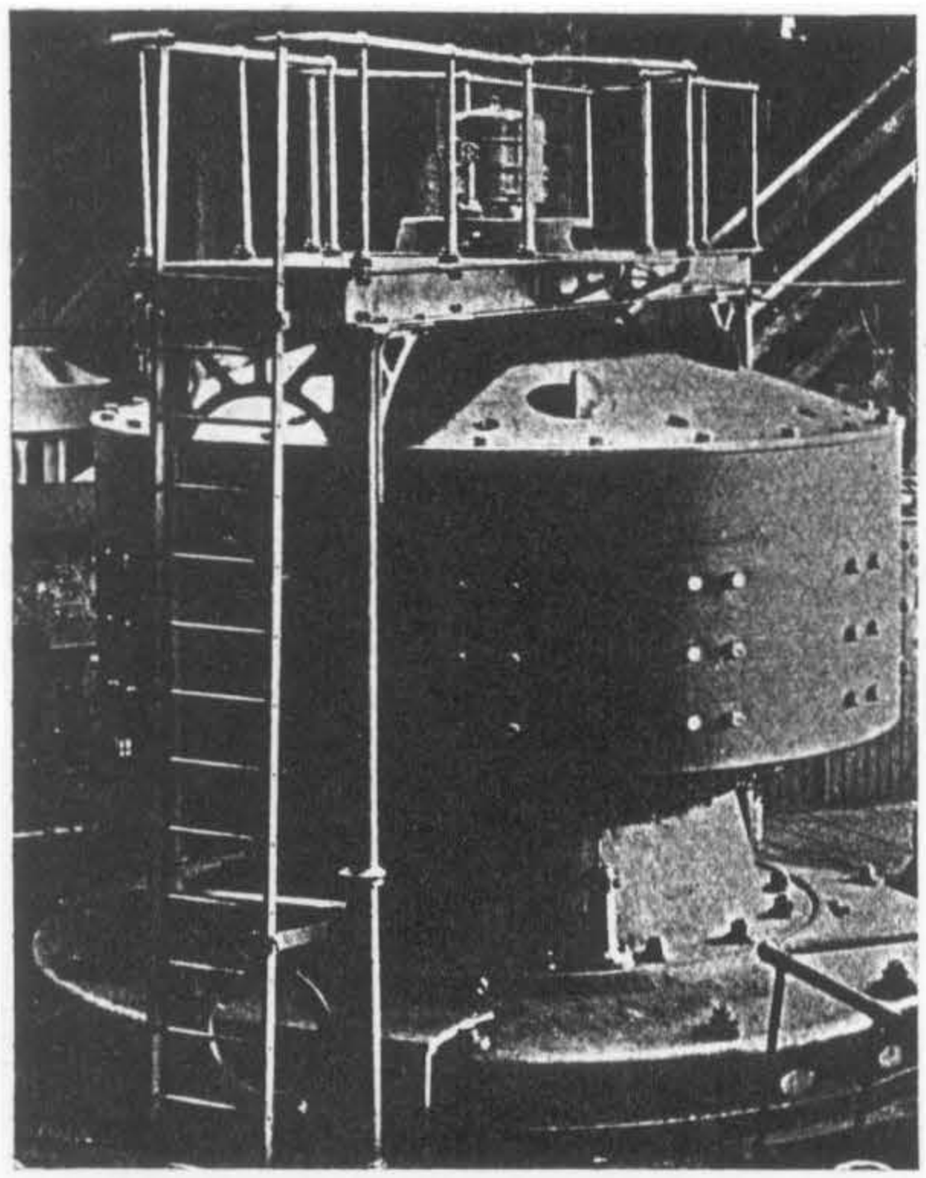

FIG. 9—SHOP VIEW OF 5 000 HORSE-POWER TWO-PHASE NIAGARA ALTERNATOR

FIELD CONSTRUCTION

In the types of field windings there has been but little change. In many of the old stationary field machines of large capacity, the field windings consisted of strap wound on edge, one layer deep. For smaller machines, either square or round wire was commonly used In the later rotating field machines, similar constructions are used. In the construction of the field itself, there have been some variations and modifications. In many of the older machines the poles were laminated as at present. The method of attaching the poles varied in different constructions. In many of the earlier Westinghouse rotating fields the laminations were punched with two or more poles in one piece, the poles having no overhanging tips, and the field coils being held in place by metal wedges between pole tips, fitted into notches or grooves at the pole tips, each pole being attached to the field ring or yoke by means of bolts or dove-tails. This latter construction possesses numerous advantages, in that cheap dies can be used, and the same pole punchings can be used for a number of different designs, in which either the diameter or the number of poles is varied.

WATER WHEEL TYPE GENERATORS

With the advent of the turbo-generator on a large scale, the engine type rotating field alternator almost disappeared from the manufacturing field, except in the smaller size units. However, during this period there has been a gradual development in the use of water powers, and water-wheel driven generators have come into much greater prominence in the past few years. In this line of development, speeds and capacities, unheard of in the earlier days, have become accepted practice with the development of both high-head and low-head water powers. In the former the tendency has been toward very high speeds for a given capacity such as the 17 000 k.v.a., 375 r.p.m., Westinghouse machines, built for the Pacific Light & Power Company, and the 10 000 k.v.a., 600 r.p.m., Westinghouse generators, built for the Sao Paulo plant in Brazil. Typical examples of low-head, slow-speed practice are found in the 60 cycle, 75 r.p.m., 96 pole, 2 700 k.v.a. Westinghouse generators for the Stevens Creek development, and the 25 cycle, 58 r.p.m., 52 pole, 9 000 k.v.a. General Electric generators for the Keokuk plant. The former are abnormal in the very large number of poles required for moderate output, while the latter are abnormal in the very low speed. Both of the above machines are of the vertical type, and are examples of a very pronounced tendency toward vertical machines, which has been apparent in the later water wheel practice.

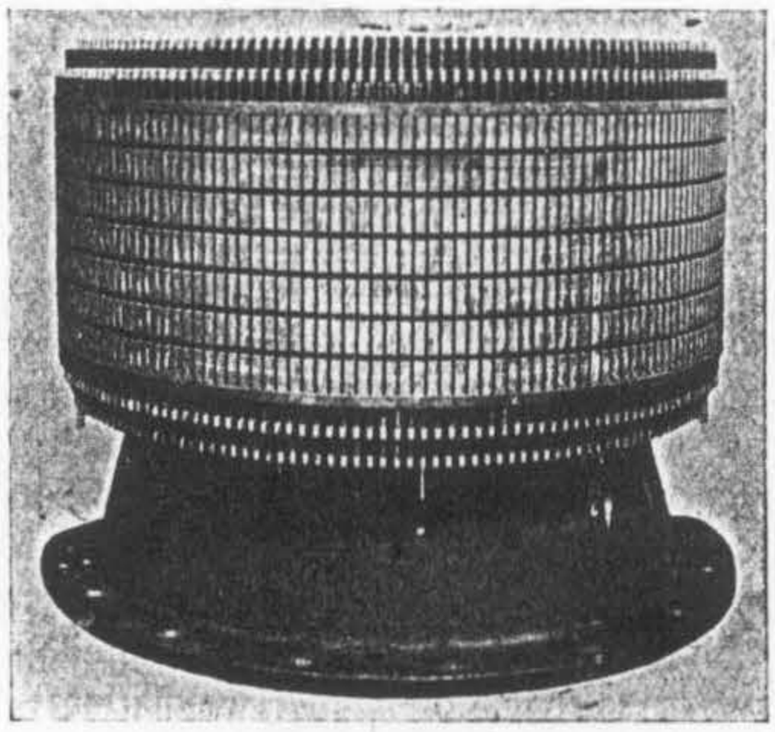

FIG. 10—STATOR OR ARMATURE OF NIAGARA ALTERNATOR

On account of the high speeds of some of the modern rotating field alternators, mechanically stronger spiders have come into general use. Even in moderate speed units the usual high runaway overspeed of 100 percent has necessitated the use of very substantial spiders.

(*To be continued*)

Electrical Journal March 1914

The Engineering Evolution of Electrical Apparatus—III

THE ALTERNATING-CURRENT GENERATOR IN AMERICA (Cont.)

B. G. LAMME

DURING the past few years, some very interesting spider constructions for the rotating fields of large high speed alternators have been built to meet the severe speed requirements. Some of these have been made up of cast steel centers or spiders with cylindrical rims built up of overlapping laminated punchings, thoroughly bolted together and attached to the spider by dove tails. The outer periphery of the laminated ring carries dove-tail grooves for poles. In another construction, the entire spider consists of thick rolled iron plates, bolted together, and with dove-tail grooves on the outside for the poles. In still other constructions, the rim of the spider consists of a heavy steel ring in one or more sections to which the cast spider is bolted. Usually with this cast rim the poles are bolted to the spider. In some cases the rim forms an integral part of the spider itself, being cast with the spokes and hub. The type of construction adopted in each case is, to a large extent, dependent upon the stresses to be taken care of, so that no one type seems to fit all cases to best advantage.

THE PROBLEM OF VENTILATION

In the later rotating field alternators the problem of ventilation has received much consideration, especially in the case of machines operating at abnormal speeds. In very high speed machines of very large output the armature and field cores have a ratio of width to diameter which is relatively much greater than in ordinary machines, and this has necessitated abnormal conditions of ventilation. Something may be said here regarding the general problem of ventilation of alternators and its influence on the evolution. Back in 1891 or 1892, radial ventilating ducts or passages came into use commercially on certain direct-current machines. The results being quite satisfactory, it was natural that alternators should have the same method of ventilation. The use of such ducts was in reality one of the great steps forward in the evolution of dynamo-electric machinery, although but little recognition has been given to this fact in electrical literature. The use of radial ventilating ducts has continued to the present time with little change except in the construction of the spacers themselves, which have been many and varied in design and materials. With the change from the rotating armature to the rotating field construction of alternators this feature was retained in full. In some of the earlier Westinghouse rotating field machines the field structure also had numerous ventilating ducts, principally for the purpose of supplying ample air to the armature ducts. Also, about ten years ago, special ventilating end bells and vanes began to be used on rotating fields, in order to set up an extra air circulation through the armature end windings, etc., due largely to the fact that the slow-speed engine-type machines of that period did not have much natural blowing action. Following this, and partly as an outgrowth of turbo-generator enclosing, came the semi-enclosed alternators, mostly for high-speed water-wheel driven units, and this practice is not uncommon at present.

The proper ventilation of an alternator or, for that matter, of any dynamo-electric machine, is very much of a problem, for no two cases, in different sizes or types of machines, are quite alike. The problem lies first, in furnishing the proper quantity of air to carry away the heat developed, and in then distributing such air in proper proportion through the complex multiple paths in the machine. The proper distribution of the ventilating air is usually the most serious part of the problem. The present solutions of the problem are based largely upon past experience, and no really workable rules have yet been developed. In arriving at the present practice many disheartening experiences have been undergone by all designing engineers. The writer has known many cases where totally unexpected results, both good and bad, have been developed and, in some of these cases, no logical explanation was forthcoming, so that the results could not be taken advantage of, with any assurance, in future work. This has been one of the most discouraging features in the general problem of ventilation.

ARMATURE WINDINGS

Something might be added here on the subject of armature windings. There have been probably as many types of armature windings developed as there have been types of alternators. The windings for the earliest smooth body and the toothed armature constructions have already been described. In the early Westinghouse polyphase alternators, two-phase was used mostly, due principally to the fact that single-phase lighting circuits formed the principal load, and, with two-phase machines, there were only two circuits from a machine instead of three circuits with the three-phase winding. Moreover, many of these very early polyphase alternators were used in reality as straight single-phase machines, taking current off one phase only. For this purpose a closed coil armature winding, like that of a direct-current generator or rotary converter, with four taps for taking off the two phases, gave about the most economical type of winding, as far as armature copper losses were concerned. When such an armature is used for single phase it

can deliver seven-tenths as much output as a single-phase machine as it can give two-phase with the same total copper loss per coil. It was partly for this reason that many of the early Westinghouse polyphase

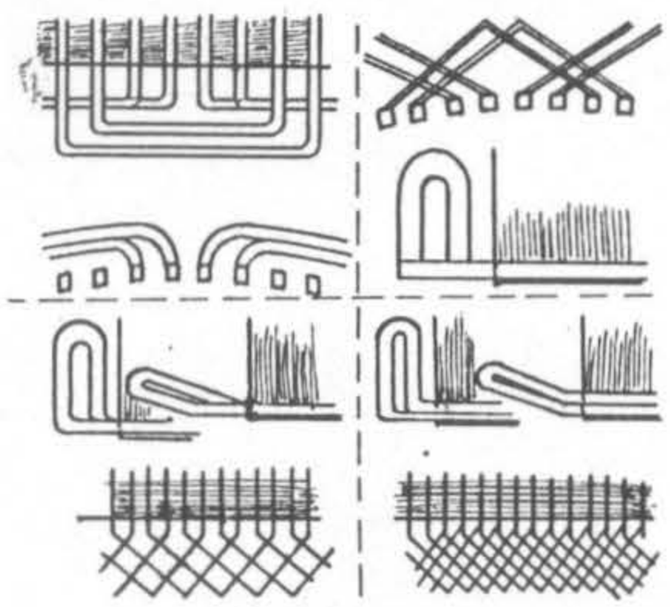

FIG. 11—VARIOUS TYPES OF EARLY STATIONARY ARMATURE WINDINGS

machines had a single closed coil winding. Another reason for such winding was that there were no definite phase groups and no high potential between phases. Furthermore, the arrangement of the end windings was such that the coils tended to interlock and support each other, thus assisting in resisting centrifugal forces. This winding was used mostly for two-phase machines, but was also used to a considerable extent on three-phase armatures.

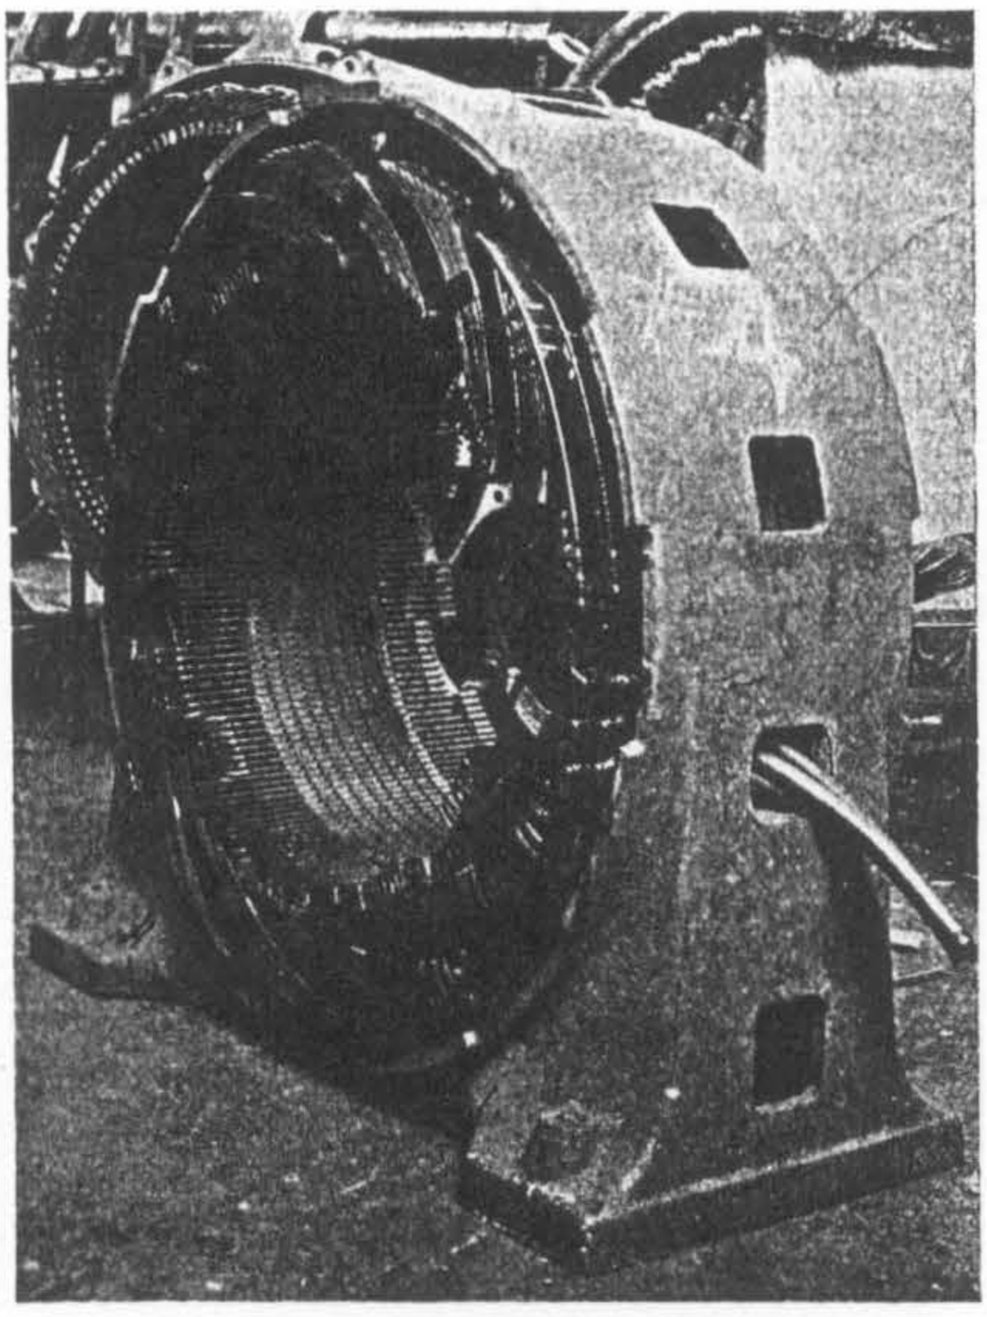
With the advent of the rotating field type of machine, this closed coil type of armature winding was not used to any great extent, open-coil two-phase and star-connected three-phase taking its place. Delta-connected three-phase was used in very rare cases, as there was danger of circulating current with such windings.

In the construction of armature windings possibly more radical changes have taken place than in the types of windings. Many of the larger low speed rotating armature alternators had bar windings with separate end connectors, soldered or bolted on. Many of the earlier stationary type armatures had either built-up bar or strap windings, or concentric type windings in which each phase winding was arranged in a concentric group, and the groups of the different phases overlapped each other. Some of these were made with partially closed slots and others with open slots. The built-up bar or strap windings were frequently of the partially closed slot type, while the concentric windings were more usually of the open slot type. Gradually, however, both these types of windings were superseded by the "duplicate coil" type of winding, similar in appearance to the usual direct-current armature and induction motor primary windings. This later type of alternator winding was arranged in two layers of coils at the ends, in either one or two layers in the slots. The two-layer, two-coil per slot arrangement is now practically the standard. These types are illustrated in Fig. 11.

In the rotating field machines, partially closed slot construction was carried to comparatively high voltages. For instance, the 6 000 kilowatt, 75 r.p.m., 11 000 volt, three-phase generators built for the Manhattan Elevated Railway in 1900 had three bars side by side, in each slot, with soldered-on end connectors.

As the partially closed slot and the open slot constructions are radically different from each other, something should be said regarding the reasons which prompted the use of either type. As already indicated, the partially closed slot type came in with the larger rotating-armature low-voltage alternators in which bar windings could be used. This construction gave good mechanical support for the bars in the slots, thus avoiding the use of bands. Moreover, with the very narrow slot openings at the top of the slots, there was very little "bunching" of the magnetic flux at the armature tooth tips with the consequent low pole face losses, even with very small air-gaps, and high gap flux densities. The disadvantages of the partially closed slot is found largely in the type of windings required.

In these early machines, it was not found practicable, in general, to use completely formed and insulated coils with such slots, and therefore, either hand windings or built-up types of windings were used. While these were possible and practicable in a manufacturing establishment, yet such types of



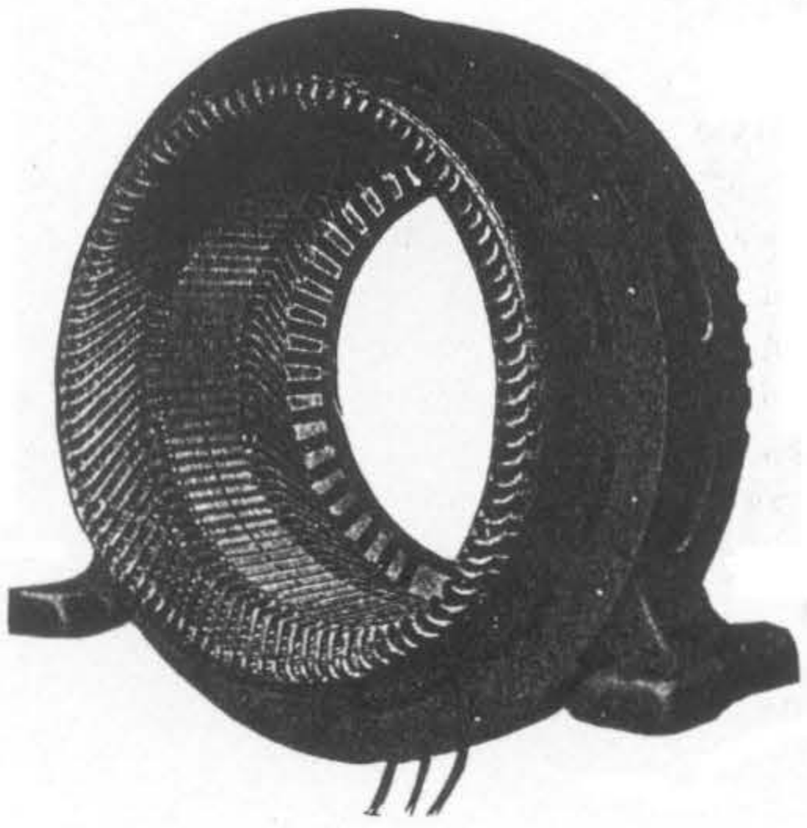


FIG. 12—BAR AND END CONNECTOR TYPE OF WINDING WITH PARTIALLY CLOSED SLOTS

windings are usually difficult to repair by the ordinary operator inexperienced in the refinements of armature winding. When it comes to repairs, the usual machine-wound coil, which is completely insulated before being placed on the armature core, is very superior

but, in general, this type of winding requires an open slot construction. However, when the stationary armature construction came into general use, the advantages of the overhanging tooth tips in supporting the coils largely disappeared. There remained there-

FIGS 13—DUPLICATE COIL TYPE OF WINDING, TWO COILS PER SLOT

fore the disadvantages of the flux bunching, against the advantage of coil construction, if open slots were used. However, the use of laminated poles, and the judicious proportioning of the air-gaps and flux densities, to a great extent eliminated the losses due to open slots. In consequence, the open slot construction and the duplicate type of armature coil, have apparently come to stay, in this country.

Various attempts have been made to obtain the advantages of both the open and the partially closed slot arrangements. Probably all large manufacturers of alternators have tried some form of magnetic wedge, instead of the usual fibre or wood wedges which serve to retain the coils in the slots. Another arrangement is the equivalent of combining two or more open slots in one, with an over-hanging tooth tip, which covers the slot with the exception of the width of one coil. Two or more completely insulated coils are fed successively into the slot opening and arranged side by side. This does not give any narrower slot opening than with the open slot construction, but the number of openings is reduced to one-half, or one-third. This construction is used rather extensively in the rotors of large induction motors, but apparenty is but little used in generators.

Bracing of the end windings against short-circuit shocks has been a comparatively recent practice. The necessity for such bracing has been dependent to a considerable extent upon the output per pole, and the old time machine seldom had such a large output per pole that the short-circuit current-rushes were sufficient to cause dangerous distortions of the end windings. However, such bracing was used on the Niagara machines, previously described, and also on the Manhattan generators above referred to. These, however, were very rare instances. However, with the recent high-speed, high-output water-wheel generators, the outputs per pole have become such that some form of end bracing has become rather common.

Modern Westinghouse machines of this kind are braced to stand a dead short-circuit across the terminals without damage to the windings. Under this condition, these large machines may give a momentary current rush of from ten to twenty times the rated full-load current. However, the bracing required on the end windings of such machines is of relatively much less importance than on turbo-generators of corresponding capacity, due to the fact that, in the former class of machines, the end windings are relatively short compared with those of turbo-generators.

The above description brings us practically up to date, as far as the ordinary synchronous alternator is concerned. No description of the development of the turbo-alternator has yet been given. This forms a rather distinct development which should follow at this point presumably, but it is thought advisable to interpolate here some description of the problems of parallel operation, e.m.f. wave form, regulation, etc., which came into prominence and were practically taken care of previous to the advent of the turbo-generator on a large scale.

PARALLEL OPERATION OF ALTERNATORS

One of the great problems which developed in the operation of alternators was that of the parallel running of two or more units. At one time this was a very serious question, but in recent years, it is very

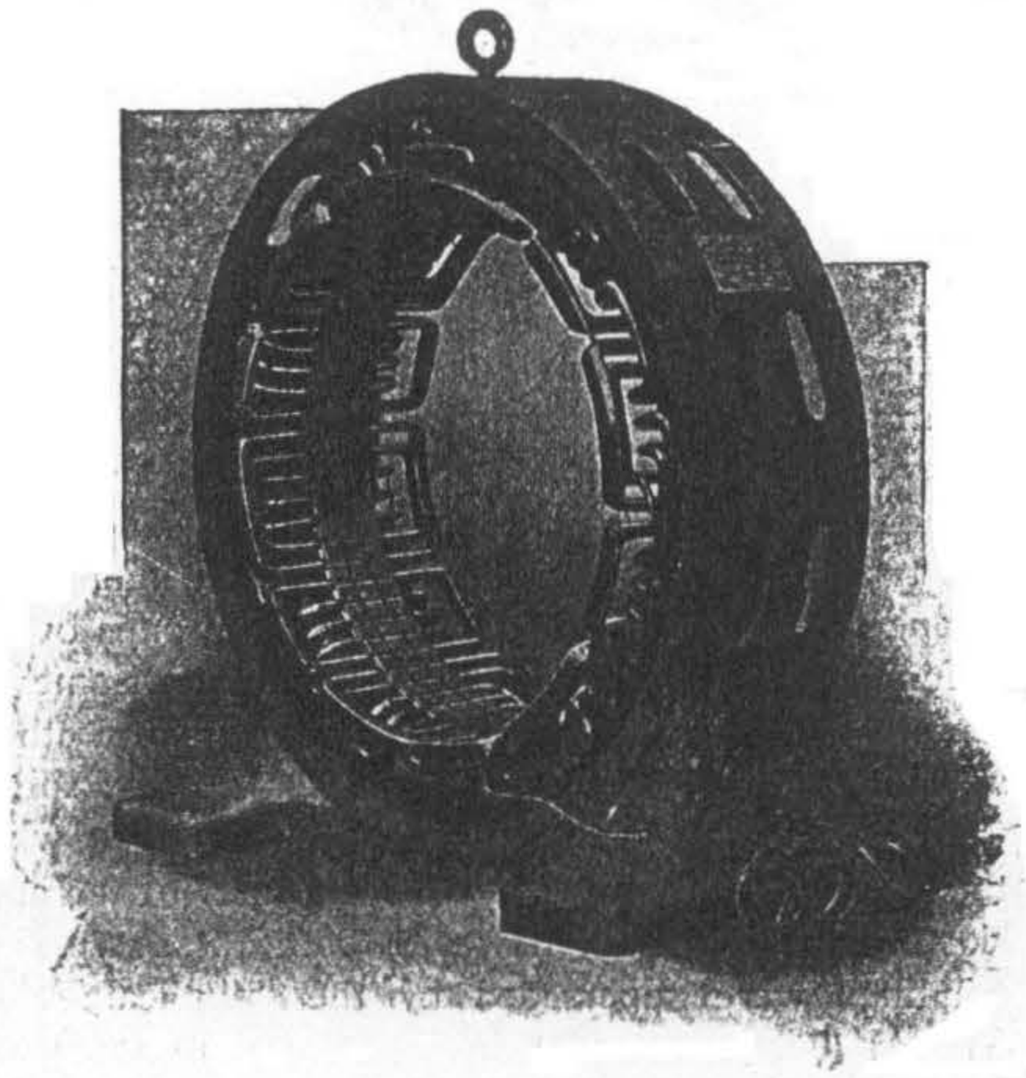

FIG. 14—DETAIL VIEW OF THREE-PHASE CONCENTRIC WINDING

seldom heard of. Considering the almost universal practice of paralleling alternators, which holds at the present time, one might be led to wonder why there ever was any trouble. Far back, in the days of the high-frequency surface-wound alternators, paralleling was attempted in many cases and, not infrequently,

with considerable success. However, a failure in an attempt to parallel, in those days, usually meant the destruction of the apparatus. Those old time surface-wound alternators usually had very low self-induction,

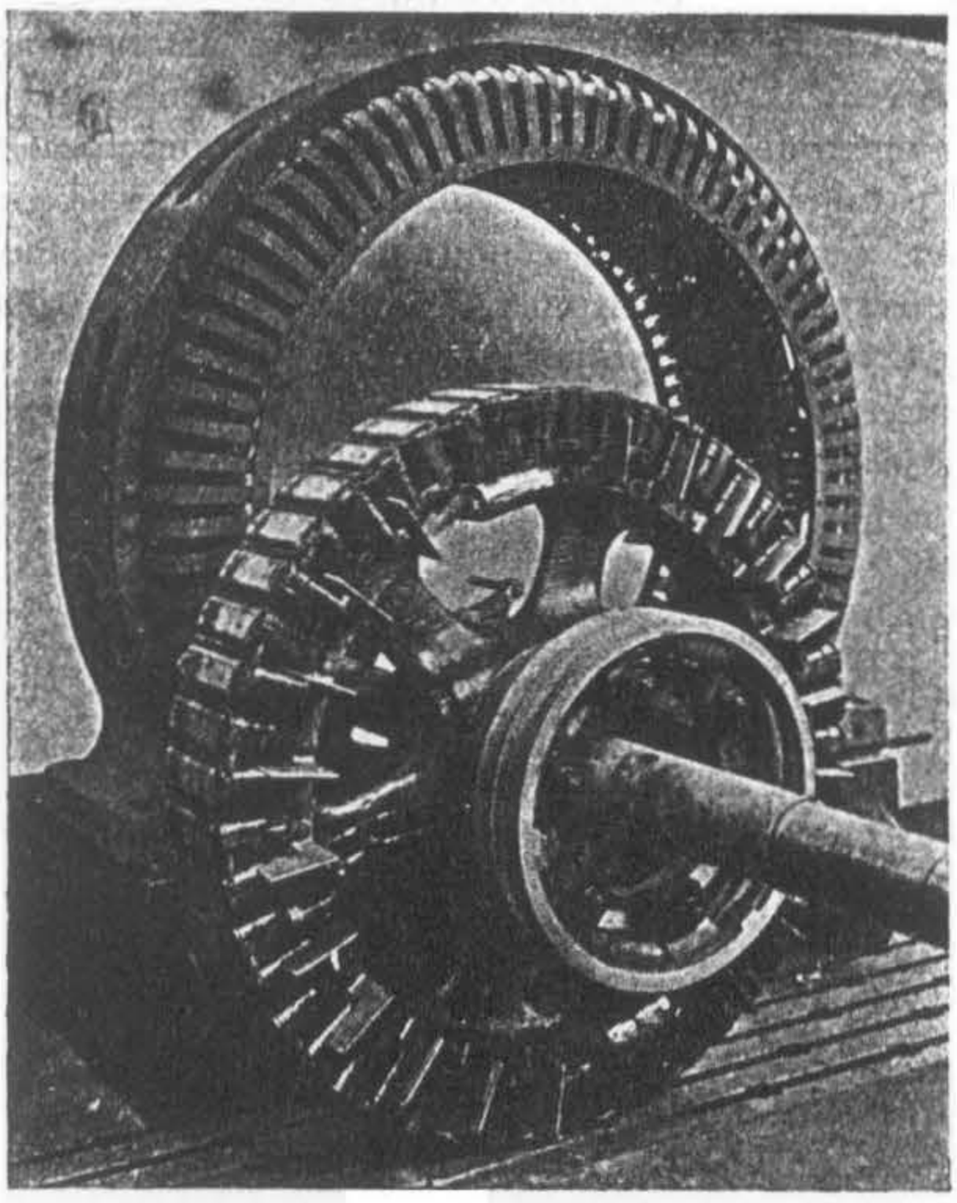

FIG. 15—75 K.V.A., THREE-PHASE, 60 CYCLE, 2 300 VOLT, 150 R.P.M. ROTATING FIELD ENGINE TYPE ALTERNATOR

so that, in case of sudden short-circuit, an enormous current could flow, sufficient usually to strip the armature winding from the core, by bursting the bands, or otherwise. A failure in an attempt to parallel two machines was practically equivalent to a short-circuit, and this usually meant destruction of the apparatus. However, if once paralleled successfully, the machines usually did not act badly. One favorable condition, not then appreciated, was that all these early machines were belt-driven. It may be said, however, that in those days parallel operation, while considered possible, was also considered more or less risky. In the period immediately following the surface-wound alternator, parallel operation was very much the exception, rather than the rule and, when engine-type alternators came into use, paralleling was considered for several years as very questionable. At this time the situation was as follows:—Belted alternators could be paralleled in many cases. Direct-coupled alternators, if flexibly driven, could be paralleled almost as well as belted machines, while direct-coupled or engine type generators, without flexible coupling or drive, could not be relied on to parallel without hunting. It thus became recognized that some flexibility between the generator and its prime mover was an important adjunct to parallel operation. This led to the consideration that the engine might be back of the difficulty in many instances, and it was then assumed that inequalities in the regular rotation resulting from insufficient flywheel or from hunting governors, tended to cause hunting in the generators. Investigation showed that such conditions did tend to produce hunting, but that the magnetic conditions in the machine itself would oftentimes maintain, or even accentuate, the hunting. Obviously, therefore, the trouble was both in the prime mover and in the generator. It was noted further that if the angular fluctuations in the driving power were relatively small, hunting usually would be very small, or would not be apparent at all. It was further recognized that, with belt or flexible drive, which tended to smooth out the speed fluctuations due to the prime mover, the hunting tendency tended to disappear. Attention was then turned toward improvement of the prime movers, especially in engine-type machines, in order to reduce fluctuations in angular velocity by means of heavy flywheels, and by means of dampers of some sort, such as dashpots, on the governing mechanism of the engine. Much improvement was accomplished in this way.

The Introduction of Dampers—During this period many attempts were made to lessen the tendency of the alternator to maintain hunting. Investigation showed that, during hunting, the magnetic flux in the field poles shifted back and forth across the pole faces in time with the hunting, while such action did not occur when there was no hunting. This at once led to the theory that a low resistance winding on the pole face , or imbedded in the poles, would prevent or oppose this flux shift, and thus assist in overcoming hunting. However, about this time, rotary converters were coming into use, and it was found that, in such machines, hunting was usually more severe than in alternators, so that, in this country, the first true application of damping windings or devices to stop hunting were applied on rotary converters. It was also noted at this time that solid pole generators and rotary converters did not hunt to the same extent as did laminated pole machines, and it was correctly assumed that the solid pole faces gave an effect similar to that of low resistance damping windings. However, as it was desirable to use laminated pole tips, copper dampers on the poles gradually came into use. Some of these early dampers were very crude in form and type compared with present constructions. However, imperfections in the construction of the dampers were balanced to some extent by the large section of copper used

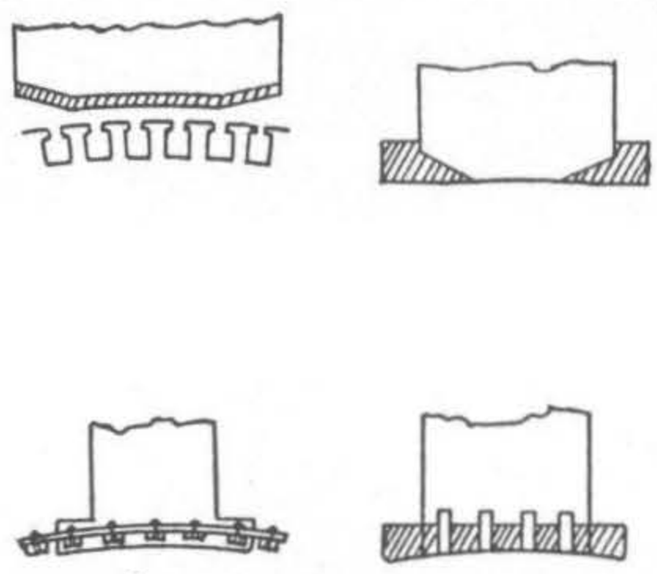

FIG. 16—VARIOUS FORMS OF DAMPERS

and consequent low resistance. The earliest form of damper used in this country consisted of copper rings surrounding the poles and copper tips overhanging the beveled pole edges. This was the form most commonly used on converters. On alternators, in some cases, the damper consisted simply of a low resistance ring around each pole. In still other cases the damper consisted of a heavy copper plate covering the pole face. This latter construction was only possible in machines with large air-gaps and very narrow or partially closed armature slots. These crude forms of dampers were gradually superseded by the so-called "grid" damper which consisted of a copper grid surrounding the pole and with ribs which lay in slots in the pole face. These various types of dampers are shown in Fig. 16. In very few cases were these old types of dampers so interconnected as to form a complete cage winding around the field.

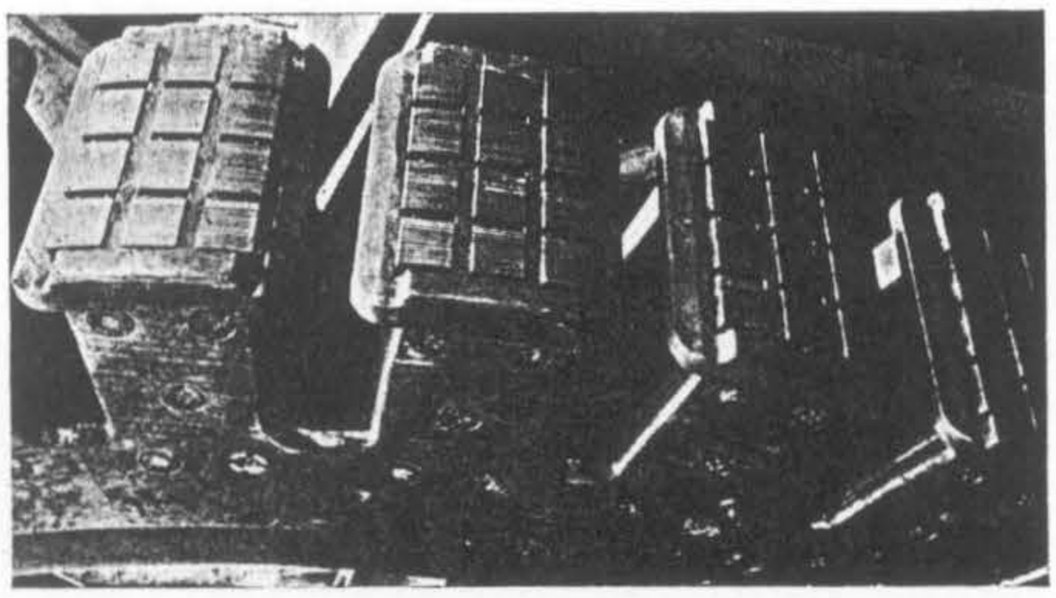

FIG. 17—GRID DAMPERS ON FIELD POLES

Many tests were made at various times to determine the effect of interconnecting the grids on the different poles to form one complete cage. As a rule, there was no appreciable gain, and it was then assumed that such interconnection had no material advantages. However, it later developed that the reason why interconnection of the dampers did not improve the damping action very materially, was due largely to the very great amount of copper in those parts of the grid dampers lying between the poles.

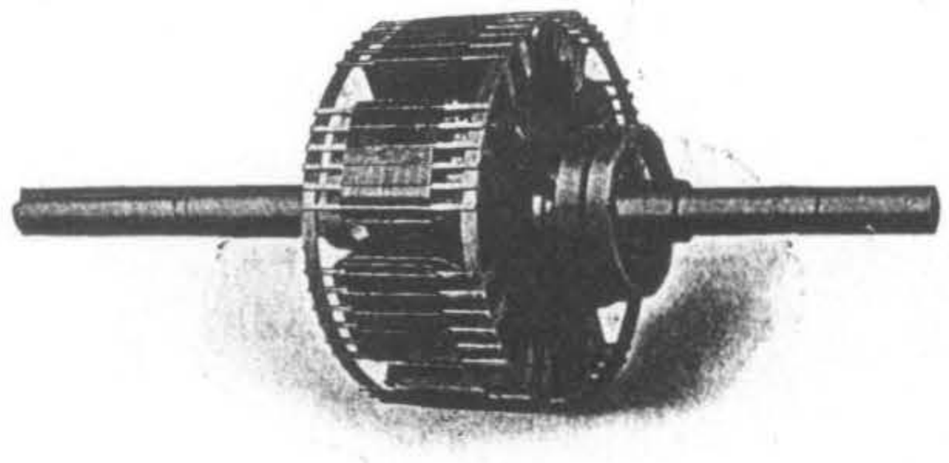

FIG. 18—CAGE WINDING TYPE OF DAMPER

The grid damper was very effective, but was expensive in material, and was not easily applied on poles with overhanging pole tips. This type of damper was gradually superseded by one smilar to the usual cage winding on the secondaries of induction motors, and this is the type which is in most general use at the present time. This construction has practically the same effectiveness as the old grid type, but is much more economical in material and, being placed in partially closed slots, it does not as greatly affect the iron losses in the machine, as was liable to be the case with the open slots, generally used with the grid damper.

With the gradual introduction of dampers and improvements in angular rotation of the prime movers, hunting troubles in alternators practically disappeared, and parallel operation presented no difficulties, except under very abnormal conditions. Apparently these dampers or "amortisseurs," as they are sometimes called, were first proposed by the French engineer, Maurice LeBlanc, about 1891. However, they were "rediscovered" in this country by engineers who were not familiar with the above engineer's work.

VOLTAGE WAVE FORM

The e.m.f. wave form of alternating-current generators has been a matter of much discussion since the early days of alternator design. The old surface-wound machines gave a very close approximation to a perfect sine shape, due to the arrangement of the winding and to the very large air-gap. The first toothed armatures, with their very small air-gaps, gave e.m.f. waves which departed very widely from a

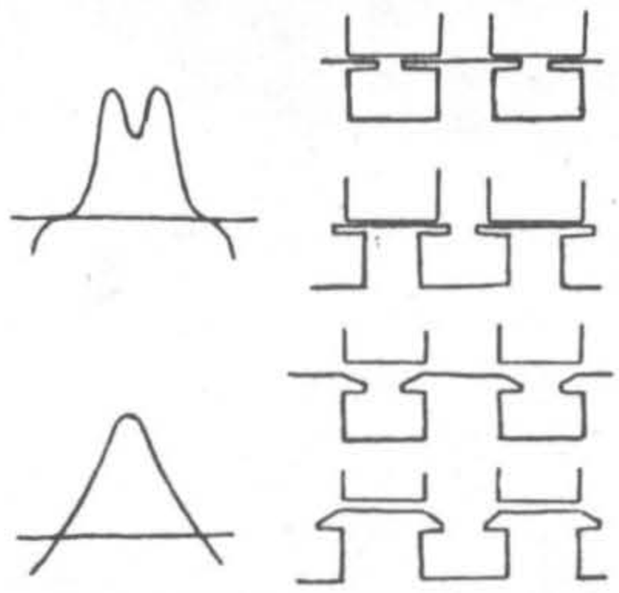

FIG. 19—VOLTAGE WAVE FORMS
Of early toothed armature machines and of later toothed armatures with larger air gaps and beveled poles.

true sine. In fact, this had about the worst wave form of any of the alternators which have been put out by the Westinghouse Company. Its shape was somewhat like that shown in Fig. 19, as would now be expected when the configuration of the armature tooth tips is taken into account. The later toothed armatures with large air-gaps and beveled tooth tips gave much better wave shapes.

With the advent of the true polyphase windings and the slotted armatures with several slots per phase per pole, fairly close approximation to sine shaped e.m.f. waves became common. In the first Niagara Falls 5 000 horse-power, two-phase alternators, the voltage wave was slightly flattened on the top due to the fact that the pole face width was somewhat greater than the width of each phase group in the armature. . When very high voltages came into general use, and especially in machines with small pole pitch, the number of armature slots per phase per pole was reduced to a minimum in order to lessen the total insulation space. In extreme cases, but one slot per

phase was used, giving but two slots per pole for two-phase and three slots per pole for three-phase. Such windings required special shaping of the field pole tips in order to approximate even roughly a smooth wave form of the sine shape. Later practice, however, has tended toward the equivalent of at least two slots per phase per pole, in order to obtain better results. Sometimes the desired result is obtained by the use of one extra idle or "hunting" tooth per phase.

In the early days of parallel operation of engine type alternators which, as described before, represented the most difficult conditions, great stress was laid upon the question of wave form in some of the discussions of parallel operation, and particularly, in the operation of rotary converters without hunting. Gradually, however, this question disappeared and it became recognized that all the cases of hunting encountered could be explained in some other way than by the e.m.f. wave forms, and it is now generally accepted that about the only effect on parallel operation due to wave form lies in possible circulating currents of higher frequency than the fundamental.

At the present time, a very close approximation to the sine shaped wave is considered preferable for general purposes, especially in transformation and transmission work. There have been some instances of telephone disturbances due to wave form but, as a rule, some local peculiarities of the distribution circuits have been involved in this trouble, for, in other cases, similar or even worse shaped waves have given absolutely no telephone disturbances.

REGULATION AND COMPOUNDING

Something should be said on the subject of regulation of alternators, for this is a very important characteristic, and has had considerable influence on types and designs. The old surface-wound alternators had extremely good regulating characteristics due to their low armature self-induction and low armature reaction consequent upon their large air-gaps. The writer does not know what value the current rose to, on steady short-circuit, compared with the normal rated current, but it was probably four or five times full load. The current rush on short-circuit was probably five times as great as the steady value. It is not to be wondered at that such armatures not infrequently wrecked themselves in case of a dead short-circuit. In the later toothed armature types, the armature self-induction and reaction on the field were very much larger, proportionately, than in the surface-wound machines. This, however, spoiled the regulation and some method of compounding was used, as already described. This compounding was common practice until larger capacity machines, especially the engine type, came into use. Even some of these latter were compounded by commutating the armature current (either directly or from a series transformer) and compounding the exciter field by means of the commutated current. A few of the smaller size alternators were both self-excited and compounded by commutating derived alternating-current circuits from the armature. This, however, was found to be very delicate, as the excitation and compounding were greatly affected by changes in the power-factor of the load, and by changes in speed.

One early attempt was made to compound single-phase alternators to correct for power-factor. In this case the commutated armature current was sent through the series or compound winding of the exciter. The brushes on the alternating-current commutator were so set that at 100 percent power-factor they were commutating about the middle of each voltage wave. In consequence, the current delivered to the brushes was not a true direct current but consisted of a double number of half waves, half of which were inverted, and the direct-current component of this commutated current was small and had but little compounding effect. However, with change in power-factor of the load, the phase of the current shifted, so that at some reduced power-factor, commutation occurred at the zero point of the current waves and the resultant current was all effective for magnetizing the exciter field. The total commutated voltage was very low and the commutator bars were shunted by a resistance so that there was no bad sparking, even when commutating at the middle of the current wave. This method did actually compound fairly well for change in power-factor, but the field for such method proved to be very limited, for compounding of alternators fell into disuse shortly after this.

The usual method of compounding on the early alternators was simple series current compounding, just as in direct-current apparatus. Where the commutated current was supplied directly to the field compound winding, voltages of about 30 to 60 volts were most common at rated full load. With much higher than 60 volts, there was a liability of short-circuiting the compounding by arcing between bars on the commutator. There was also a liability of arcing or flashing when the phase of the current shifted due to change in power-factor.

When polyphase rotating armatures came into use, similar methods of compounding were resorted to. However, the secondary current was a resultant of the two, or three primary currents, for each of the primary phases was carried around the compensating transformer (or spokes of the armature) and the secondary winding carried a current in phase with the resultant of the primary ampere-turns. In the case of three-phase windings, the direction of one lead was reversed around the compensating transformer. Some curious conditions arose from the phase relations of the secondary current when parallel operation was practiced. It was necessary, when parallelling the main winding, to parallel also the compound winding. As the compounding current from each machine pulsated from zero to maximum value in each alternation, it was necessary to so parallel the terminals that all the commutated currents had zero value at the

same instant, otherwise, the brushes on one commutator would, at times, short-circuit the current from the other commutator.

With the advent of larger belted machines, and of engine-type machines in particular, the compounding of polyphase machines was more or less unsatisfactory and was practically abandoned. To compensate for the lack of compounding, better inherent regulations were aimed at in the designs. This meant, primarily, machines which would give comparatively large currents on steady short-circuit, three to four times full load being rather common, and even six times full load being attained in some machines. The momentary current rush at the instant of short-circuit must have been excessive on some of these machines, due to their very low armature self-induction. However, due to the relatively small ampere-turns per pole, no very destructive distortions were found in practice. This characteristic of the short-circuit currents was carried into the rotating field construction, and even into the early turbo-generator work.

This practice of giving the alternators good inherent regulation was expensive in a number of ways, as it usually meant higher iron losses and less output than was possible otherwise, with a given size machine, or a given amount of material. Even at this early date, it was recognized that some form of automatic field current regulator which would maintain the terminal voltage constant, regardless of the inherent regulation, would be a very useful piece of apparatus. Some form of regulation which would take care of change in power-factor, as well as load, was the aim of many designers. Among the different schemes brought out, the Rice method of compounding, brought out by the General Electric Company, is of interest. This was used principally with rotating field alternators. In this scheme, the exciter was usually placed on the same shaft as the alternator field, and, in such case, had the same number of poles as the alternator. The leads from the alternator armature were carried through the exciter winding in such a way that a lagging current, carried by the alternator, tended to strengthen the field of the exciter by shifting the armature reaction with respect to the exciter field poles. In this way a compounding action on the exciter was obtained which was practically in proportion to the demands of the alternator field with varying power-factor. In the case of engine-type machines of comparatively low speed, the exciter was geared to the alternator shaft, so that it ran at a considerably higher speed and the number of poles in the exciter was correspondingly reduced.

This method of compounding was effective, but the whole combination was apparently unduly complicated and expensive. Furthermore, it did not give the desired compensation under all conditions of operation, as it would not correct for changes in speed.

A later method of compensation for power-factor was devised by Alexanderson, and was used on a limited number of General Electric machines. In this scheme a derived current from the alternator itself was commutated in such a manner that compensation, proportional to the power-factor, was obtained. This was a purely self-excited alternator scheme and, like all self-exciting schemes in such apparatus, it was sensitive to speed changes, probably to a much greater extent than the Rice arrangement above described. A fundamental defect in all self-exciting compensated alternator schemes lies in the fact that stability of excitation is dependent upon having considerable saturation in the alternator magnetic current and, coincidently, if there is such saturation, the compound current has no direct relation to the load or power-factor. Thus such machines are either sensitive to speed changes, or their compounding is only approximate.

Following these scheme came the use of automatic regulators of which the Tirrill is best known. This regulator acts directly on the exciter field by short-circuiting a resistance in series with the field winding, the range of exciter voltage being controlled by the length of time the rheostat is short-circuited. Instead of cutting the resistance out in steps, which tends to give sluggish action in the fields, the Tirrill regulator cuts the whole resistance out each time, and the length of time is varied. This results in quick action. As the regulator tends to hold constant voltage at the alternator terminals, or on the line, change in power-factor or in speed does not modify the action. This type of regulator has proven very effective, especially in the case of alternators subjected to sudden and violent changes in load, power-factor and speed.

With the advent of larger alternator units, in proportion to the changes in load, the inherent regulation has been made relatively poorer, primarily because better machines otherwise are thus obtained. The short-circuit currents are reduced, and relatively lower iron losses, and lower temperatures or, higher outputs with a given temperature, are obtained. This has been carried further in turbo-generator design than in any other class of alternators, due partly to fundamental limitations in design. However, this poorer inherent regulation has proven to be of no practical importance, where suitable automatic regulators have been used with the machines.

One fallacy which was frequently found in the past, and which still persists to some extent, is that alternators should have equal inherent regulation to parallel properly. This is based partly on the feeling that the field currents of the alternators should vary over equal range when carrying their proper proportion of load, together with the knowledge that the variations in field current are dependent, to some extent, upon the inherent regulation. However, the fact that the shape of the saturation curve, in a given alternator, may have much more influence on the excitation, especially at high saturations, is usually overlooked.

The Engineering Evolution of Electrical Apparatus—IV

THE ALTERNATING-CURRENT GENERATOR IN AMERICA (Concl.)

B. G. LAMME

TURBO-GENERATORS

THE ADVENT of the turbo-generator has had a predominant influence on alternator design. After the turbo-alternator once became established commercially in this country, it quickly revolutionized conditions by driving the large engine-type alternators out of the field. The evolution of all electrical apparatus has been comparatively rapid, but that of the turbo-alternator has possibly exceeded anything else in the electrical field. This evolution therefore merits a fairly complete description.

The first turbo-alternators, built by the Westinghouse Company, were installed in the power plant of the Westinghouse Air Brake Company about 1898. There were three rotating armature machines of 300 kilowatts capacity, which ran at a speed of 3 600 r.p.m.,

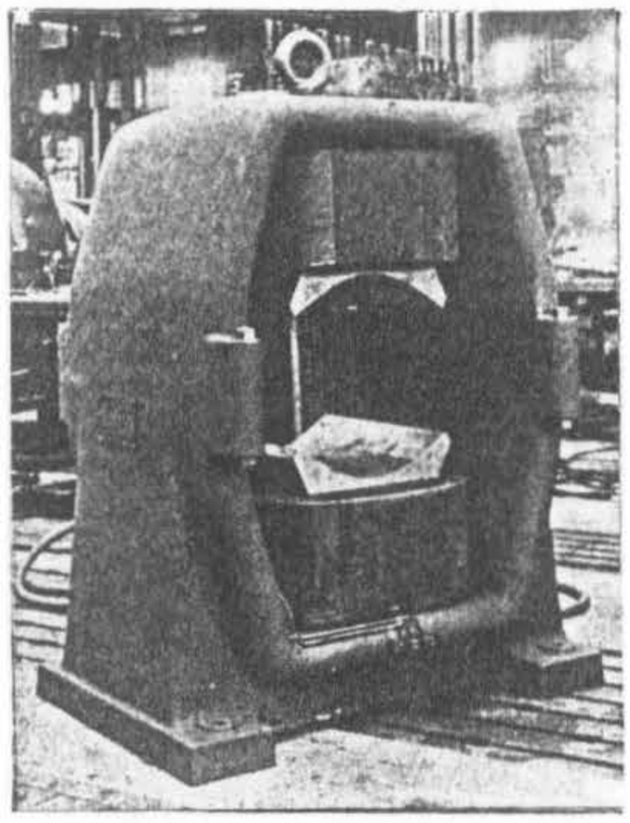

FIG. 20—FIELD OF EARLY ROTATING ARMATURE TURBO-GENERATOR

giving 7 200 alternations per minute, or 60 cycles per second. They were coupled to Parsons turbines, built by The Westinghouse Machine Company. The Parsons Company in England had been building rotating armature alternators for a number of years, and the Westinghouse Company simply followed the Parsons' precedent. These first machines were operated for several years, but it was obvious, soon after their installation, that the rotating armature type of machine would not serve for general turbo-alternator purposes. It was evident that, for voltages even no higher than 2 200, the rotating armature construction, at the necessary turbo-generator peripheral speeds, would become almost impracticable. Attention therefore was soon turned toward a 3 600 revolution, two-pole, rotating field type, and a very large number of possible constructions were considered. Finally one like that shown in Fig. 23 was worked out and built in 1899. This had the field windings completely embedded in a number of parallel slots, with supporting metal wedges at the tops of the grooves or slots. One machine of this type was built and tested. It operated in a satisfactory manner, except as regards windage and noise. The machine was not closed at the ends, like modern turbo-alternators, and thus any noise generated in the ma-

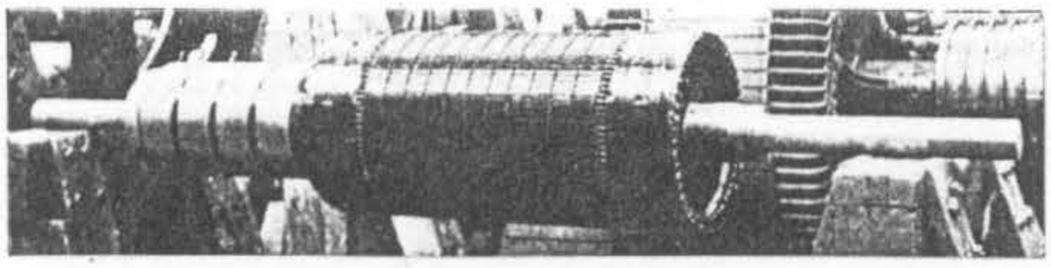

FIG. 21—ARMATURE FOR TURBO-GENERATOR OF TYPE SHOWN IN FIG. 20

chine could be readily transmitted to the outside. The noise was caused largely by the two flat sides of the rotor. It was so shrill and penetrating that it was very disagreeable to be around the machine, and was even painful to the ears after a short time. This construction was therefore abandoned temporarily, but after a few months it was taken up again and a new rotor was built which was entirely round, as shown In Fig. 24, but was otherwise very similar to that shown in Fig. 23. This new rotor, although noisy compared with modern machines, was so quiet, compared with the first construction, that it was immediately adopted as a standard construction. This is the now well-known parallel slot construction which has been used very extensively by the Westinghouse Company, although many very radical changes have been made in the constructive features of the rotor itself. This type of rotor was used originally only for

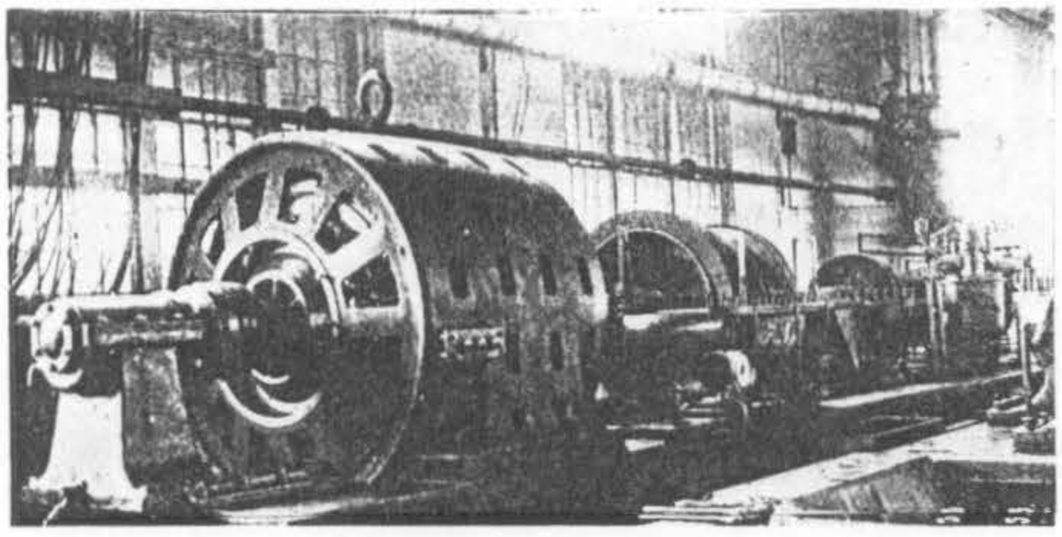

FIG. 22—1 000 KW OPEN TYPE TURBO-GENERATOR

the 400 kilowatt size at 60 cycles.

In the earlier machines of this type a number of very curious conditions developed. In the first machines the rotors were built of a number of thick discs or "cheeses" side by side, which were put on the shaft at high pressure. The two end discs were thicker

than the others in order to accommodate the grooves in which the rotor end windings lay. The discs were made of high grade forgings. After some of these machines had been in operation for a considerable period it was found that some of the discs in the field core were traveling axially, i.e., quite appreciable gaps

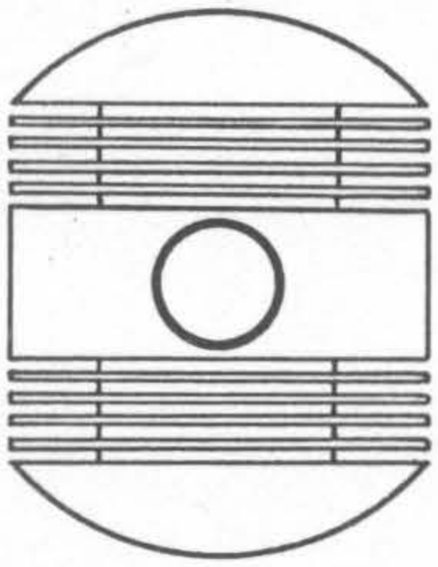

FIG. 23—EARLY TWO-POLE ROTATING FIELD

or spaces were showing between adjacent discs. In one instance they traveled to such an extent that the field windings were stretched longitudinally at the openings between the discs, until the conductors were actually attenuated to an extent visible to the eye. Obviously, the stretching force must have been enormous.

Eventually, the construction was changed on these two-pole rotors to a single disc of forged steel. Still later, steel castings were used quite extensively instead of forgings although, later still, the castings were abandoned in favor of forgings. There was much adverse opinion regarding the advisability of using castings for the 3 600 revolution machines, as some engineers held that they were more liable to contain flaws than would be the case with forgings. An interesting fact in connection with this is that, while a number of these early high speed machines "exploded," generally during runaways, yet in no instance was a cast steel field wrecked from this cause. This, however, does not constitute a proof of the superiority of cast steel, for it so happened that all the serious runaways were on machines with forged rotors. However, the record is a clear one as far as cast steel fields

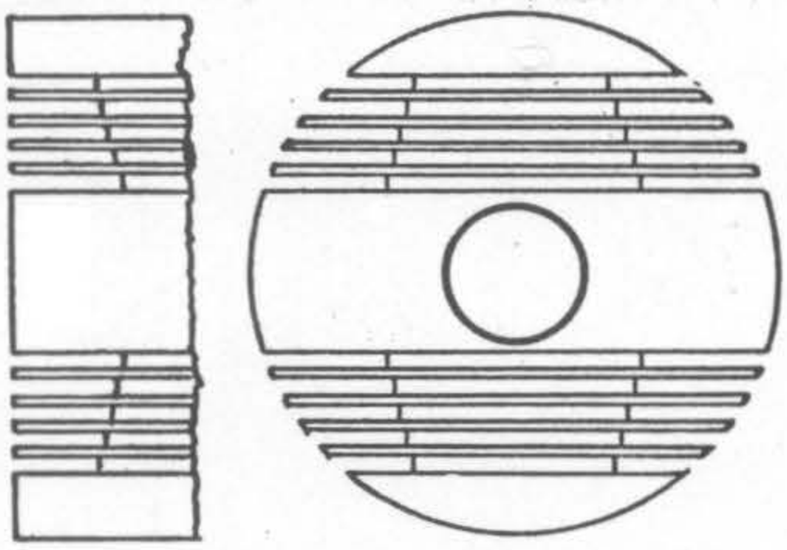

FIG. 24—ROUND TYPE TWO-POLE ROTOR

are concerned, for, of all the sizes and speeds of steel rotors which the Westinghouse Company has put out, not a single cast steel disc has burst. Present speed and output requirements have now carried the construction up to a point where special forged materials are the accepted practice.

Soon after the two-pole, 400 kilowatt rotating field machine was put on the market, a four-pole, 750 kilowatt, 1 800 revolution machine was built. The rotor of this machine had four salient poles bolted on. These poles were provided with overhanging pole tips, and the field winding consisted of four coils wound with strap-on-edge. In fact, this first construction was very similar to the present type of rotor fields now used for other than turbo work. This construction proved difficult and expensive, but was applied to a number of six-pole, 1 200 revolution machines. However, the parallel slot construction used in the two-pole machines was so satisfactory that it was soon adopted for the four and six-pole machines, as shown in Fig. 25. In the six-pole machine it was not possible to make the poles integral with the central core, on account of the inability to machine the parallel slots in the sides of the poles, or put in the windings. Therefore, separate poles were constructed, with parallel slots, and these

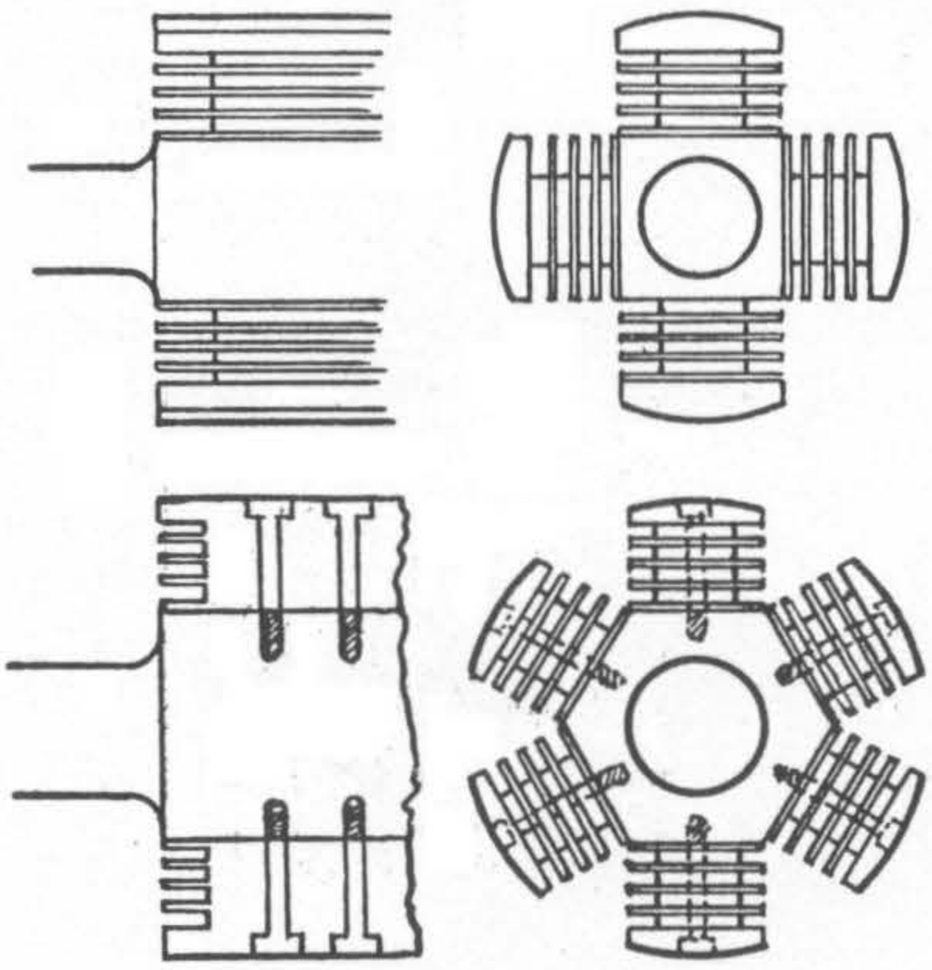

FIG. 25—PARALLEL SLOT FOUR-POLE AND SIX-POLE FIELD CONSTRUCTION

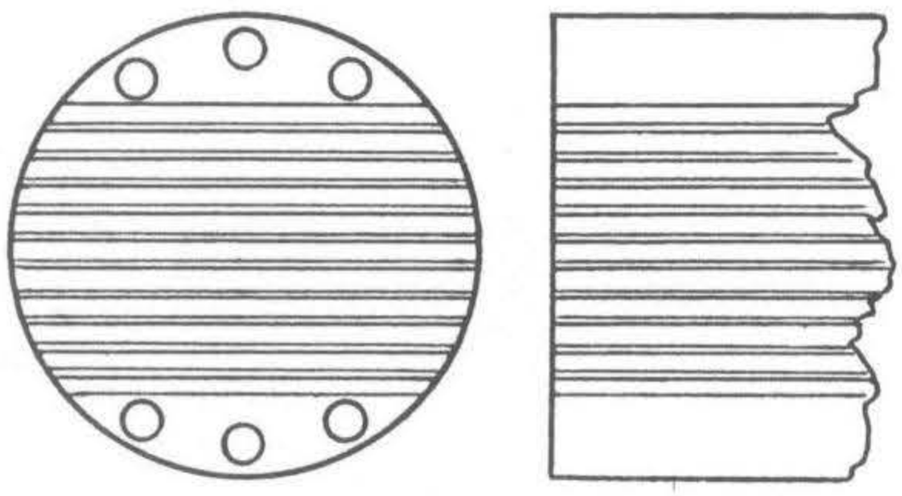

were first wound and then bolted into place on the central core which, in this case, was made integral with the shaft. The four-pole machine was constructed for 750 and 1 000 kilowatts capacity, and the six-pole construction was made for 1 500 to 3 000 kilowatts.

Meanwhile, there had grown up some demand for moderate capacity 25 cycle machines at 1 500 revolutons. These were constructed along exactly the same lines as the two-pole, 3 600 revolution machines above described.

In this early work one order for four 5 500 kw, four-pole, 1 000 revolution machines was taken. This was entirely beyond the constructions undertaken before by the Westinghouse Company. The parallel slot type of rotor was adopted. An attempt was made to get forgings in a single piece large enough for these rotors, but they were found to be glass hard and brittle, except at the outer surface. As very large steel castings were frowned upon, it was decided to make

these rotors of discs turned out of very thick steel plates, somewhat like the early 400 kw machines already described. Parallel slots were used as in the smaller four-pole machines. This construction proved to be feasible but was very expensive, and shortly after this large cast steel discs were used, two discs side by side being used to form one rotor. This construction was satisfactory, and was used for many years.

Shortly after turbo-generators came into general use, there was considerable complaint regarding the noise due to windage. All these machines were equipped with some form of ventilating device, which formed either part of the normal construction of the rotor or consisted of some special blowing device at the ends of the rotor. Both the high speed and the large quantity of cooling air required, tended to make a noise which was very objectionable. A series of

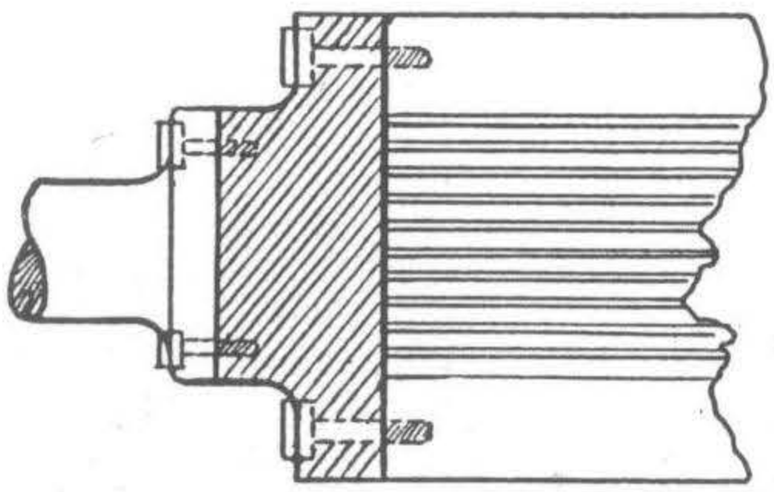

FIG. 26—TWO-POLE FIELD OF THE BOLTED ON CONSTRUCTION

experiments with covers over various parts of the machines, showed that, by completely enclosing the two ends of the machine and by enclosing the field frame except at the top and bottom, (in a horizontal machine) the windage noise could be so deadened as to be practically unobjectionable. However, the tests also showed that artificial ventilation was necessary under this condition. This very quickly led to the practice of enclosing and artificially cooling turbo-generators, which practice has been maintained to this day. The first Westinghouse enclosed machines were built about 1903.

The use of artificial cooling marked a great step in advance in turbo-generator work, for the results indicated that, by supplying a sufficient quantity of air and properly distributing it through the machine, very marked increase in capacity was possible, and a point was soon reached where the possible capacities were beyond the mechanical limitations of the construction. This led to radical modifications in the type of rotor, with a view to taking advantage of the increased capacity. Apparently all manufacturers did more or less development work along such lines. In the Westinghouse constructions, the use of a through shaft was found to be one of the serious limitations, and this led to types of rotors without any through shaft. In the two-pole machines, this was particularly important, and the problem was especially difficult with the parallel-slot construction, provided ample space was allowed for the field winding. The old through shaft two-pole construction lost considerable winding space, due to the shaft space, as shown before in Fig. 24. Attempts to construct such a machine with the shaft forming part of the core, resulted in still less efficient use of the possible winding space. It was obvious that if the whole possible winding space were taken up with slots, then the capacity of the field winding would be greatly increased. In consequence, a rotor construction, such as shown in Fig. 26, was designed and constructed. In this, bronze end supports or "heads" were bolted to each end of the field core, and the shaft proper was attached to these bronze heads. Bronze, or a similar non-magnetic material, was necessary to prevent magnetic short-circuiting of the field flux. This design was constructed and tested on a 1 000 k.v.a., 3 600 revolution machine, and then was built successively for 1 500, 2 000, 3 000. 4 000 and 5 000 k.v.a. machines, all at 3 600 r.p.m. The same construction was also applied to two-pole machines of 25 cycles, up to 12 000 k.v.a. capacities. This construction of rotor has given an extremely good account of itself. However, it proved to be expensive on small capacity machines, as the bronze heads formed an undue proportion of the cost of material. For higher capacities of 3 600 r.p.m. machines, increase in capacity is obtained largely by increasing the length of the rotor core, and thus the bronze heads form a relatively lower percentage, and the construction becomes more reasonable in cost.

From the preceding, it may be seen that only two types of turbo-generators have been used very extensively, namely, the parallel-slot type and the radial slot. Each of these types has some very pronounced advantages. The principal advantage of the parallel-slot type is in the arrangement and support of the field coils. Each coil can be wound directly in place, with the conductor under tension, and the finished winding is completely encased, and is thoroughly protected against dirt, movement of the conductors, etc. Against this, the radial slot machine allows more room for copper, and is magnetically more economical in material. However, the field windings are more difficult to apply and must be supported at the ends by auxiliary means, such as separate external steel rings.

The enormous increase in output of turbo-generators, within very recent years, has made the electric

and magnetic proportions of the rotors a feature of first importance in the design, so that the radial slot type for two-pole machines has become the standard construction, almost universally. This will be referred to again under the four-pole construction.

While the two-pole parallel slot construction was being developed for larger capacities, the four-pole construction for 60 cycle machines has been

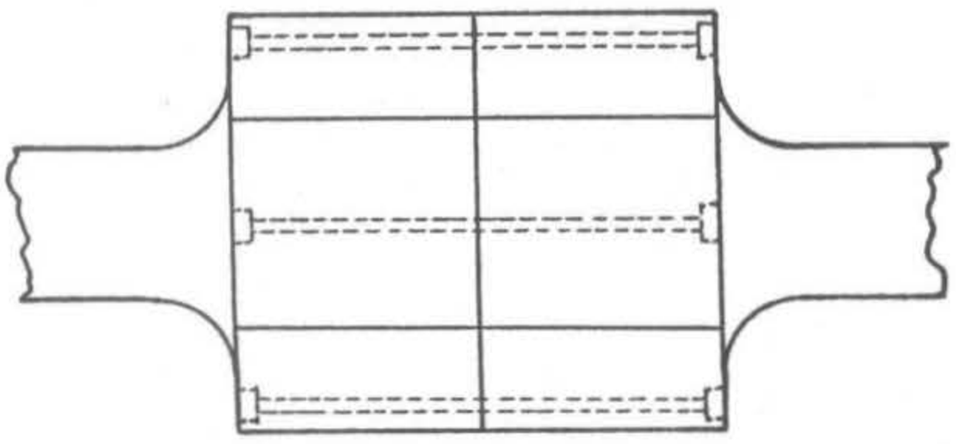

FIG. 27—FIELD CONSTRUCTION WITH TWO HALVES HELD TOGETHER BY HEAVY BOLTS

pushed up to capacities of about 12 000 k.v.a. with the parallel slot, cast steel rotors. In order to do away with the through shaft construction, the rotor was made of two castings or discs, each of which was cast solid with the shaft, as shown in Fig. 27. The two discs, after machining, were bolted together by a number of very heavy bolts located near the pole tips and, in some cases, shrink links were placed in the pole face, connecting the two halves together. The parallel grooves were then machined in the steel core, just as in the through-shaft type. In this four-pole construction, the problem of armature ventilation was comparatively simple. Air-gap ventilation (that is, all air through the armature core supplied from air-gap) was easily accomplished, due to the open spaces between the poles, which could admit an ample air supply. However, the same construction tended toward high windage losses due to air "churning."

This problem of ventilation has had much to do with the evolution of turbo-generator design.* In the two-pole, parallel slot machine for 3 600 r.p.m., in which the diameter of the rotor is relatively small, the amount of air which can be forced into the air-gap from each end is rather limited. Assuming, for example, a rotor diameter of 24 inches, which is almost as large as we can go for a 3 600 r.p.m. machine, then, with an air-gap (iron to iron) of ¾-inch, which is also a fairly large gap, the total cross-section of the air inlet at the air-gap at both ends of the rotor will be 112 sq. in. With the very high air velocity of 10 000 ft. per minute, this means a total air supply of less than 8 000 cu. ft. per minute. This may be sufficient for a moderate capacity turbo-generator, but for machines of high capacities, such as 3 000 to 5 000 k.v.a., this is not nearly enough cooling air. Obviously, either much larger inlets through the air-gap are required, or some additional method of cooling is necessary. Larger air-gaps usually mean either more expensive machines, or reduced output with a given machine, due to lower flux densities. Therefore, the tendency, in machines of the very high capacities, and very high speeds, has been toward a combination of air-gap with other methods of ventilation. In the 25 cycle, two-pole machine with a maximum speed of 1 500 r.p.m., rotors of larger diameter are possible and, as a rule, much larger air-gaps are practicable than in 60 cycle machines. In consequence, air-gap ventilation comes nearer being practicable but, in the larger capacities, even this is insufficient and auxiliary methods have been necessary in some cases.

This need for auxiliary methods of ventilation led to the axial method of ventilating armature cores in distinction from the radial method, in which the air was carried out through numerous radial air ducts or passages. In the axial method, a large number of ventilating holes are arranged in the armature core parallel to the axis of the machine. These form ventilating paths in parallel with the air-gap path With the small diameter long cores necessary for 3 600 r.p.m., high capacity machines, the development of this method of ventilation was contemporaneous with the development of the higher capacities. The same has proven to be the case for the later types of Westinghouse four-pole, 60 cycle, 1 800 r.p.m. machines, which departed very considerably in rotor construction from the four-pole cast steel type already described.

As the capacities of the 3 600 r.p.m., 60 cycle machines were gradually pushed up, a corresponding development occurred in the 1 800 r.p.m. machines. At 10 000 to 12 000 k.v.a., the four-pole cast steel construction was apparently approaching its limits. For larger sizes, therefore, a different construction was adopted which allowed more suitable material to be obtained. For the largest diameters and highest

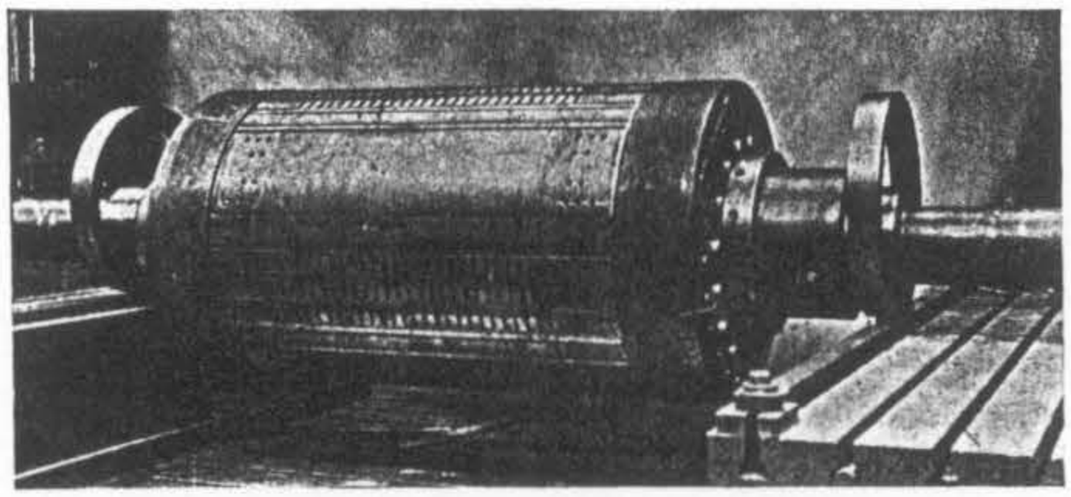

FIG. 28—MODERN ROTATING FIELD ON BALANCING WAYS

speeds, a plate construction was adopted by the Westinghouse Company, in which the end discs and the shaft ends were forged as units, and the intermediate discs were made of rolled plate material, the whole construction being bolted together permanently to form a solid core. This core was then slotted with radial slots, and the usual radial slot type of field winding is used. A similar construction was adopted on the

*A more complete exposition of the subject of "Turbo-Alternator Ventilation," etc., is contained in a paper by the author, read before American Institute of Electrical Engineers, January, 1913.

larger 25 cycle machines. For intermediate capacities, both 60 and 25 cycles, solid discs are used in some cases instead of the plate construction. This brings the larger turbo development up to the present date.

In the comparatively small 60 cycle turbo-generators, where the parallel slot construction with the bronze driving heads was relatively expensive, as already described, the later development has been to-

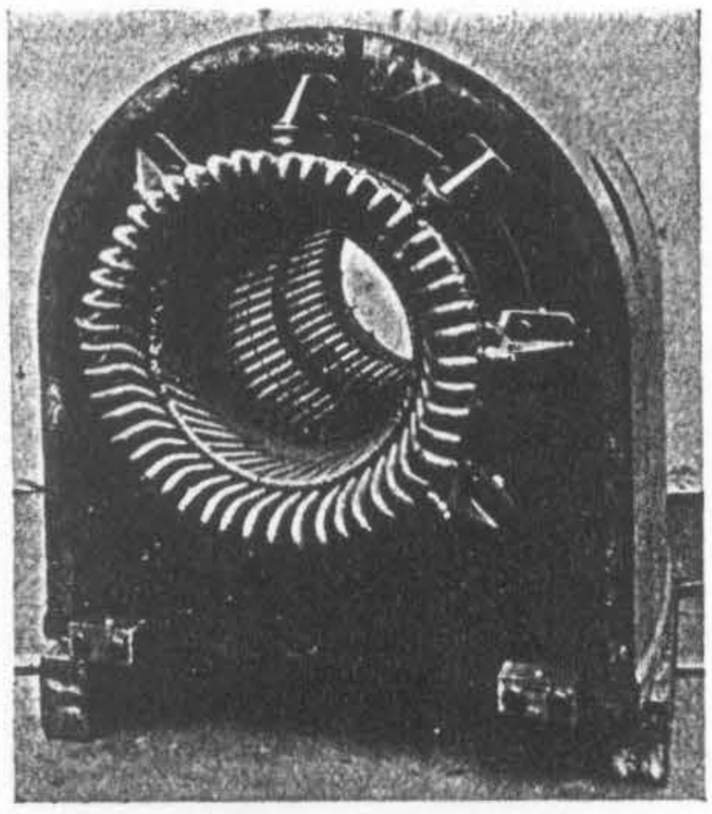

FIG. 29—STATOR OF 625 K.V.A., 2 300 VOLT, 3 600 R.P.M. TURBO-GENERATOR

With axial ventilation and central duct. Supporting ring both inside and outside the end windings. Typical method of bracing smaller machines.

wards core and shaft forged in one piece, and with radial slots, and eventually this construction may be carried up to the largest practicable size of 3 600 r.p.m. machines. It is difficult to predict the limit in capacity which may be reached eventually in 3 600 r.p.m. generators but 6 250 k.v.a. appears to be practicable.

Some special radial slot machines had been developed for the New Haven Railroad about 1907. As these machines were designed to deliver 25 cycle single-phase current, and as the pulsating armature reaction of such machines would be relatively high, the rotors were designed with laminated cores, with a view to lessening core losses. The rotors were made of single disc lamminations shrunk on the shaft. The discs were provided with radial slots. The construction was very similar to the later radial slot rotors, except that the rotor end windings were also embedded in slots, and supported by wedges embedded in the periphery of the core, whereas, in the later radial slot rotors, the end windings are supported by external rings. These early radial slot rotors showed very considerable overheating in single-phase operation, and it was found necessary to apply a very complete cage damper embedded in the periphery of the rotor. Later experience showed that the solid core parallel slot rotor with an equal damper applied to its surface was just as effective, and many of the later single-phase machines were built in this manner. However, some recent 11 250 k.v.a. single-phase generators are being built of the plate construction already described.

REGULATION AND SHORT-CIRCUIT CURRENTS OF TURBO-ALTERNATORS

Like the ordinary synchronous generator, the modern turbo-alternator is designed with a comparatively high inherent regulation. In fact, in order to avoid excesive short-circuit currents, the inherent regulation must be made comparatively poor by making the armature self-induction as high as practicable. Even under the best condition, such machines are liable to give 12 to 15 times rated current during the first current rush. Furthermore, the solid plates or discs, of which most turbo-rotors are now made, tend to prolong the period of maximum short-circuit current. The consequence of these conditions is a tremendous racking force acting on the end windings during a short-circuit current rush, which tends to distort the winding badly unless it is very strongly braced. The Westinghouse Company encountered such a difficulty on some of their earliest turbo- alternators and there has been a practically continuous development along the lines of more substantial bracing which has kept pace with the increased requirements of the higher speeds and the higher capacities. The bracing used on the modern machines is designed to resist distortion of the end windings, under dead short-circuit, without reactances interposed, and each new size as it is developed is given such a short-circuit test. A 20 000 k.v.a. 60 cycle, 1 800 r.p.m. high voltage alternator was recently subjected to such short-circuit tests at full voltage without injury.

The preceding gives a brief history of the development of the turbo-generator, insofar as carried out by the Westinghouse Company. The General Electric Company went through a corresponding course of development, in general, although not in

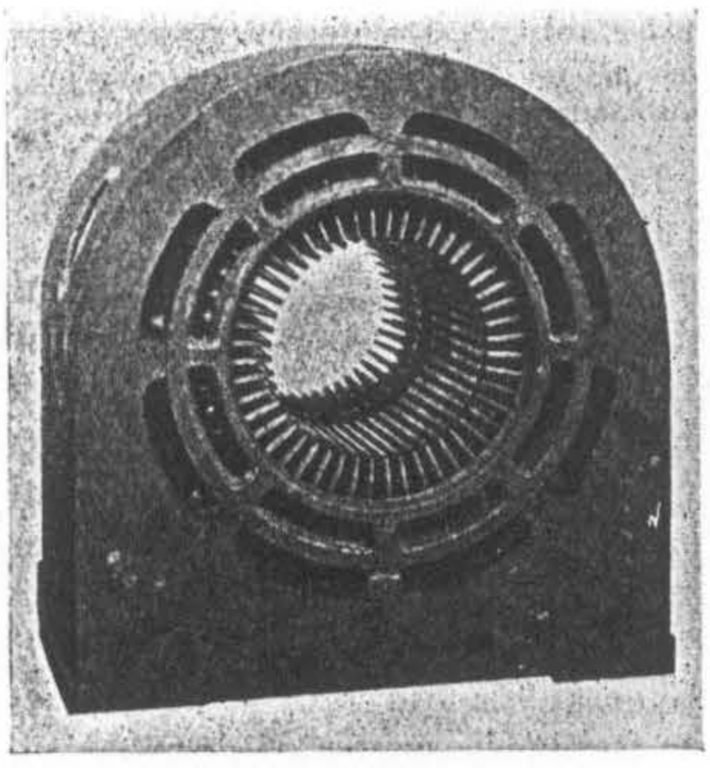

FIG. 30—SAME MACHINE AS SHOWN IN FIG. 29 BEFORE WINDING

the specific constructions described, and a number of interesting types or constructions have been brought out. The gradual increase in speed has undoubtedly had much to do with the evolution of their various types, just as in the case of the Westinghouse evolution. One of the most radical steps which the General Electric Company has made in the past few years is in the change from the vertical to the hori-

zontal type of machines. Presumably the very high speeds which later came into use have had much to do with this change. In the earlier turbo-generator practice, the speeds of the General Electric Company's machines were relatively lower than the Westinghouse, presumably on account of the type of steam turbine used. Many of the early rotor constructions were of the salient pole type for four poles and higher. Gradually these were superseded by constructions leading up to a radial slot type in which the slots were formed by teeth inserted in dovetail grooves in the rim of the spider. This type was very similar in appearance to the later types, except that the slots had overhanging tooth tips, thus giving a partially closed slot construction. More recently, with greatly increased speeds, this construction has been superseded by solid forged cores with shaft forged on, and with radial grooves milled in the surface for the field

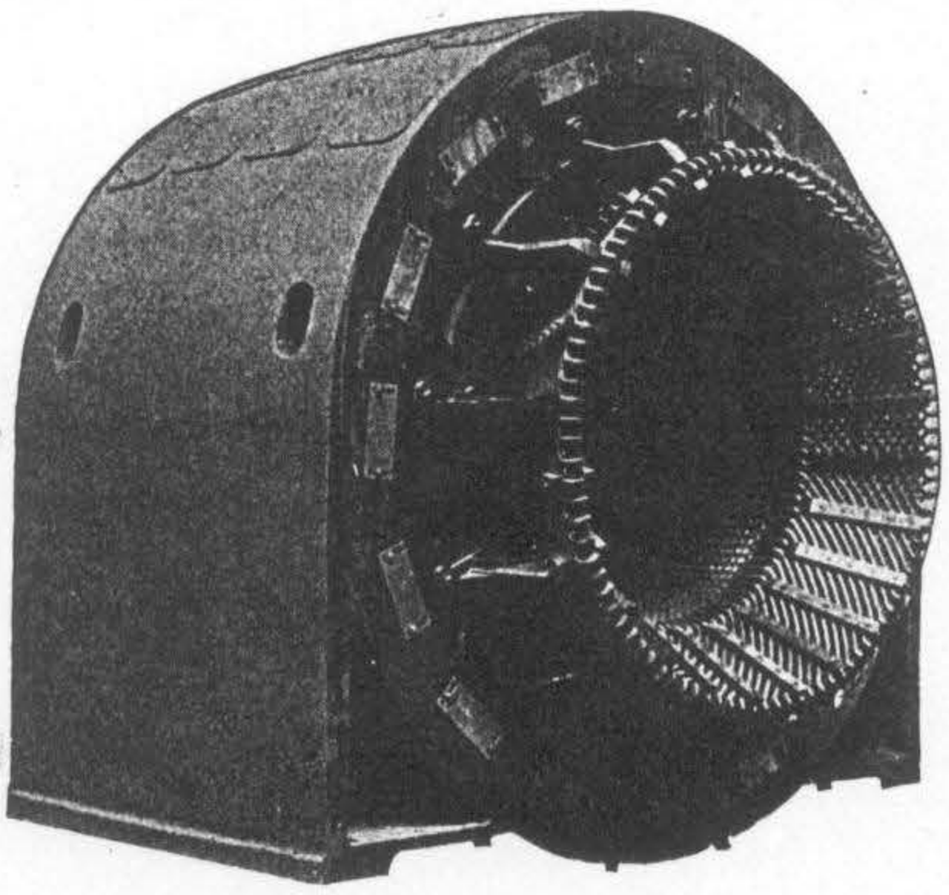

FIG. 31—STATOR OF LARGE MODERN TURBO-ALTERNATOR
Showing end winding and method of bracing large machines to withstand short circuits.

winding. These latter rotors are used largely in the horizontal type high speed machines.

In the Allis-Chalmers construction, in the larger machines having four or more poles, the earlier construction of the rotor consisted of forged discs with through shafts. These discs had radial slots for the windings very similar to the present construction of all manufacturers. The smaller machines generally had cores forged in a single piece with the shaft, and with radial windings. As regards methods of ventilation, both the General Electric and Allis-Chalmers Companies went through a course of development leading up to their present practices.

As regards parallel operation, turbo-generators have been particularly free from this old time difficulty, due largely to the uniform rotative effort of the steam turbine, and partly to the high flywheel capacity of the turbo-generator and turbine rotors, which tends to limit any speed oscillations, due to the governors, to a relatively low period, such as would not tend to accentuate the hunting action in the generators themselves. Moreover, in those rotors which have been built with solid cores or of thick plates, the solid material tends to act as a damper circuit. As a consequence, hunting in turbo-generators, or difficulties in parallel running, have been extremely rare.

INDUCTION TURBO-GENERATORS

This type of turbo-generator has been proposed commercially a number of times during the past ten years, and a few installations have been built. The first of any importance, consisting of a 1 250 kilowatt generator of 30 cycles, 1 800 r.p.m., two poles, was installed in the plant of the Baltimore Copper Smelting & Rolling Company. This generator was a true polyphase induction motor, direct connected to a steam turbine. The construction of the generator was exactly the same as would have been used at that time in a two-pole, 1 800 r.p.m. induction motor of the same capacity. The entire load of this machine consisted of a 1 200 kilowatt rotary converter connected directly to the terminals of the generator. The generator and converter were brought up to speed separately and the rotary converter, with its field excited, was connected directly to the generator and furnished the excitation for the generator. There was no other synchronous apparatus in circuit except the converter.

Several years ago, a number of much larger induction generators were built by the General Electric Company for the Interborough Rapid Transit Company of New York City. These machines are of 6 000 k.v.a. nominal capacity and operate in parallel with the 11 000 volt, three-phase, engine-type generators previously installed in the same power house. The engine-type generators furnish the excitation for the induction generators. The entire load of this station is represented by rotary converters. There have been no prominent instances of the use of induction generators for other than steam turbine drive. Apparently this type of generator has no very wide field.

CONCLUSION

This history is admittedly far from complete, in that it has not mentioned the work of some of the earlier, and also some of the later manufacturing companies. The field is far too large to permit everything to be covered. Moreover, no attempt has been made to describe European constructions and developments in alternating-current generators. It may be stated, however, that in some very important features, European engineers antedated the Americans, while in other equally important constructions American designers were first in the field. As a rule, the representatives of the electrical manufacturing companies have been so wide awake and ready to adopt new principles when they contained any promise, that it is sometimes very difficult to give any company or individual proper and deserved credit for being first in any given development. Furthermore, no attempt has been made to give credit to the various engineers who have been closely identified with alternator development, for it would be impossible to do justice, or give deserved credit to all of them.

THE CONSTRUCTOR

Currents of Ultra-High Frequency and Potential

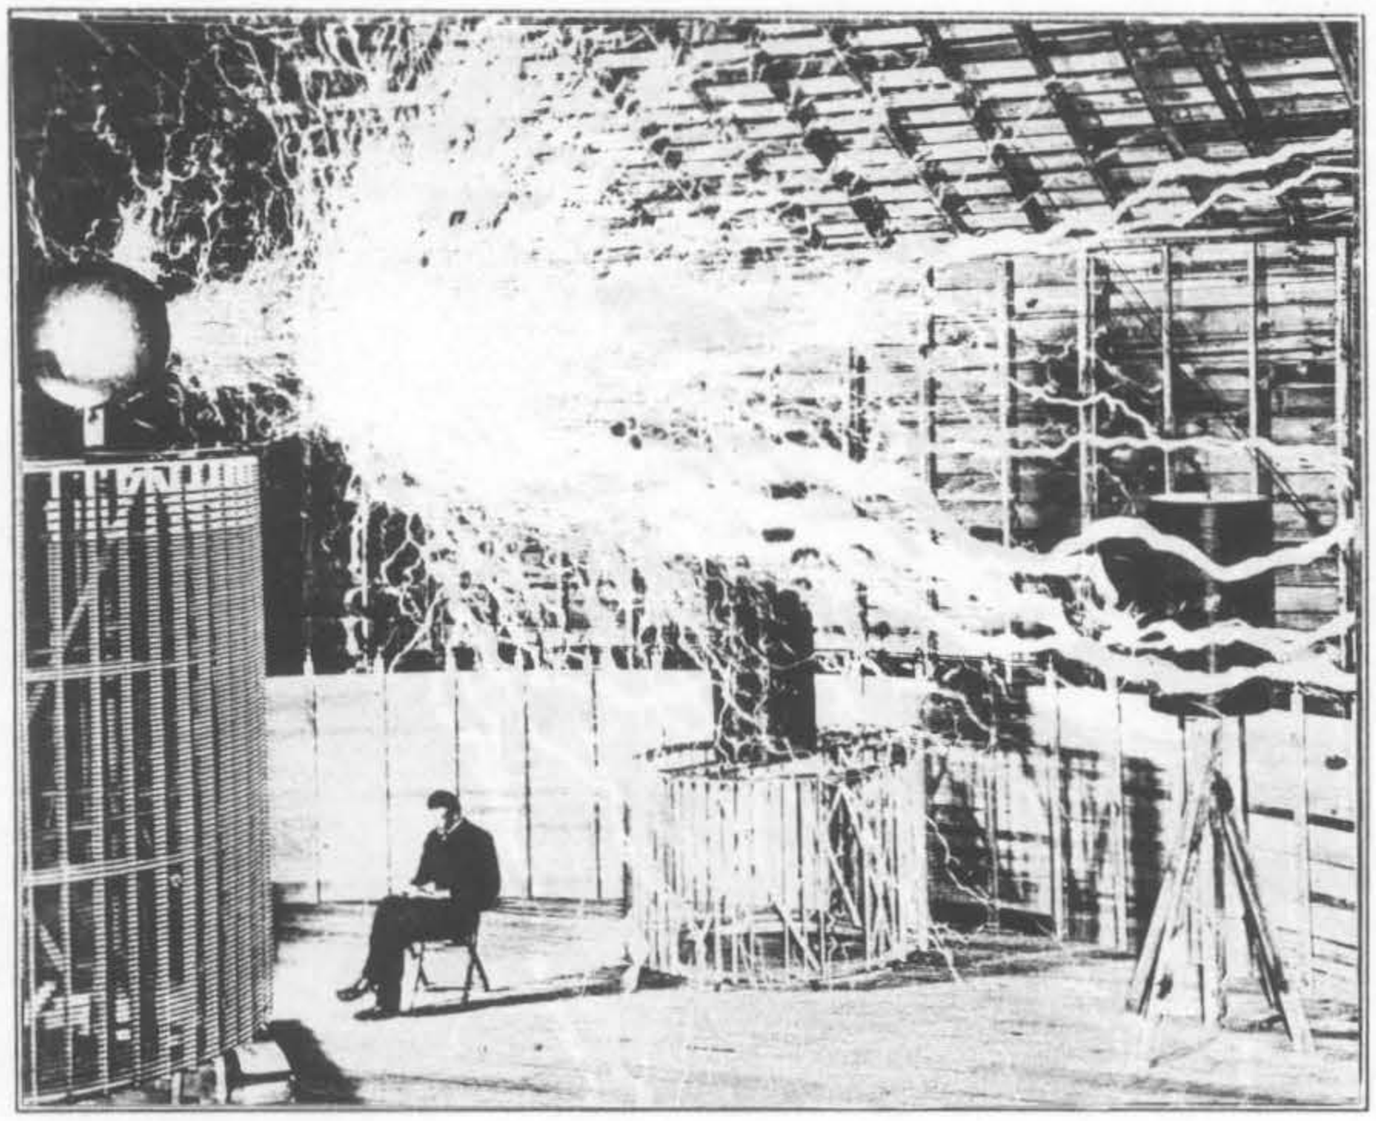
With a Description of the Usual Apparatus Involved In Their Production.

H. Winfield Secor.

EXPERIMENTS with electric currents of ultra-high frequency and potential, form probably the most interesting phase of electrical science, both for the layman and experienced electrician as well . The apparatus for producing these interesting currents is fortunately of low first cost, and thus it is well within the reach of every electrical student.

Our first photograph, Fig. 1, illustrates a large size Tesla high frequency apparatus, recently built by the E. I. Co. for theatrical purposes. Of course, most of our readers have possibly seen one or more of the so-called "Electrical Conquerors," touring the country, who style themselves variously as "Masters of the Electric Current," or "The Man Who Cheated the Electric Chair," etc., etc. Anyone can cheat the electric chair, if the Electrocution authorities would only be so kind as to charge the chair with half a million volts, at a "frequency of 500,000 cycles per second, or so." In other words, when we deal with such electrical currents as this, they may be readily taken through the body, without feeling them to any appreciable extent.

In the usually accepted meaning of the term, "high frequency," the number of cycles occurring per second is not



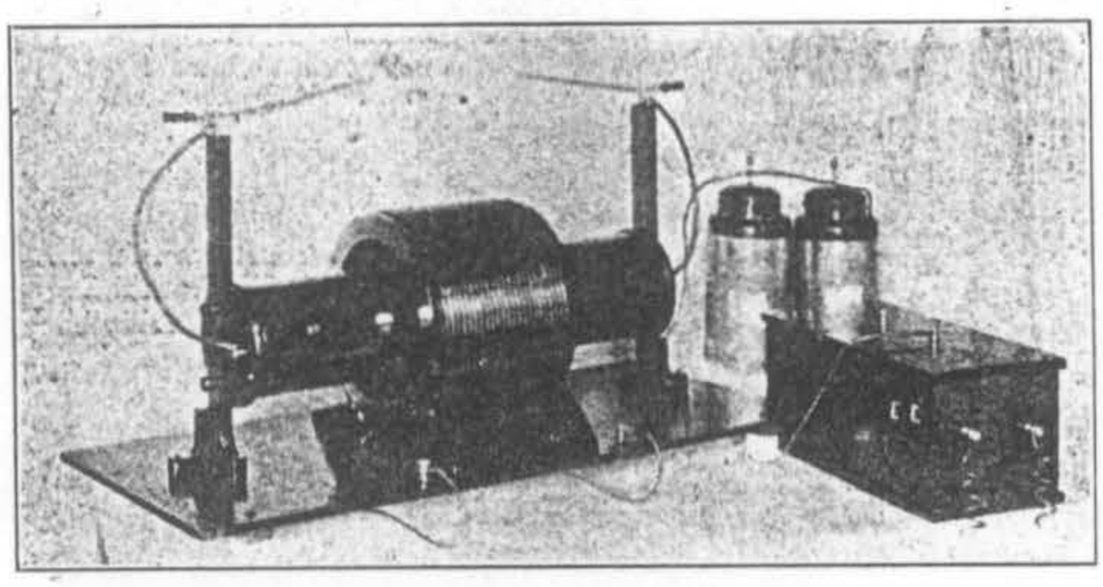


Fig. 4.

A Large Tesla Coil.

any such low figure as found on lighting circuits, viz., 60 cycles, but in the order of 100,000 to 1,000,000 cycles per second.

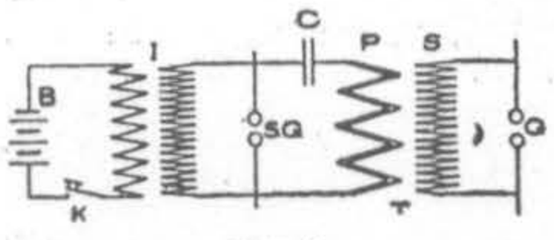

Fig. 2.

When such high frequency currents as these are employed, many wonderful and unlooked for phenomena take place; among other things the currents of such a frequency can be handled with impunity, and even passed through the body, notwithstanding that the voltage may be several million, and the amperage several amperes (½ ampere through the body at 2,000 volts D. C., or low frequency, A. C. means death).

High frequency currents of this order no longer obey the rules governing the ordinary low frequency oscillating currents. For one thing, they travel only on the surface of conductors, not through them, penetrating only a few thousandths of an inch below the surface, this phenomena being known in electrical parlance as the "skin effect" which accounts for the reason that these currents do not hurt the body when handled, i. e., they possibly do not reach far enough below the skin of the body, to shock or destroy the nerves and muscles. This is the theory in general acceptance to-day.

A great part of our knowledge of these high frequency currents is due to the untiring and exhaustive researches of Nikola Tesla, a well-known Electrical Engineer and Scientist, after whom the Tesla coil, which is used to produce high frequency currents with, is named. To the student interested in this little known field of electrical science, it is recommended that he procure a copy of Mr. Tesla's book, "Experiments with Currents of High Potential and High Frequency."

High frequency alternating currents may be produced by a special dynamo, such as Prof. Fessenden's, or by a regular high frequency disruptive discharge set, as shown at Fig. 1, employing a step-up transformer excited by another high voltage transformer or induction coil, coupled with a spark gap and condenser in the exciting circuit, after the manner depicted in Fig. 2, which is the commonest arrangement.

In the diagram shown, I is the induction coil of not less than 2 inch spark capacity. T is the air core, Tesla or high frequency transformer, serving to step-up the voltage delivered by the induction coil secondary to many times its original value. C is a condenser composed of glass plates, coated with tin foil on both sides, or regular Leyden jars. S G is the spark gap, in which the disruptive discharge of the condenser takes place. G is the discharge gap of the Tesla

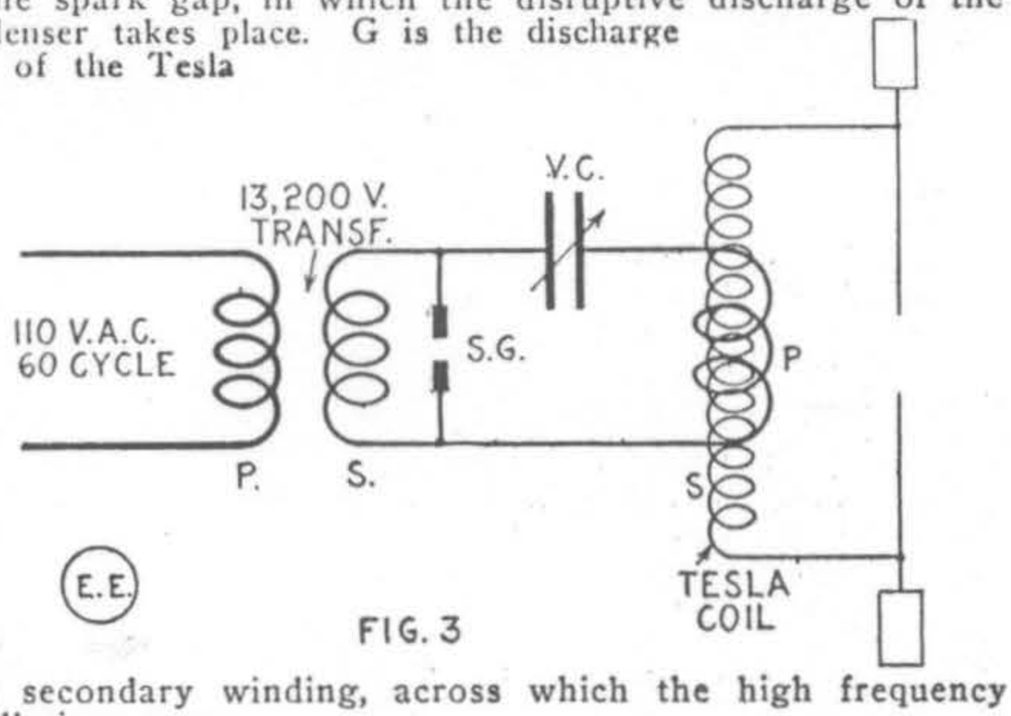

FIG. 3

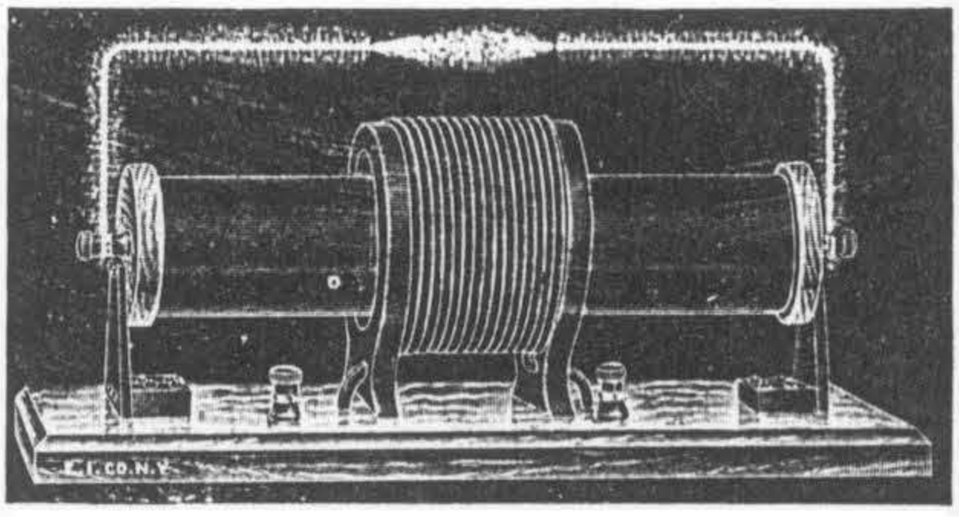
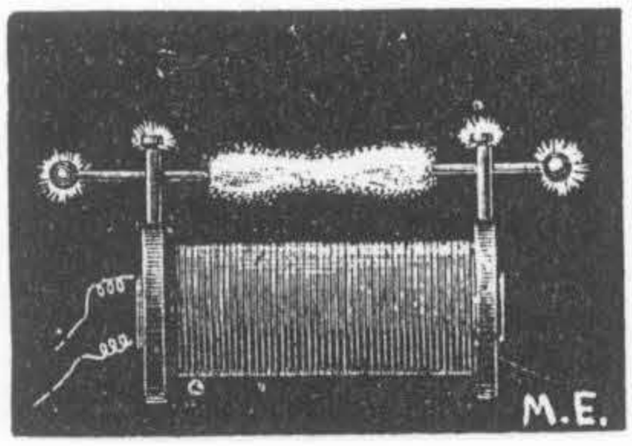
coil secondary winding, across which the high frequency oscillations surge.

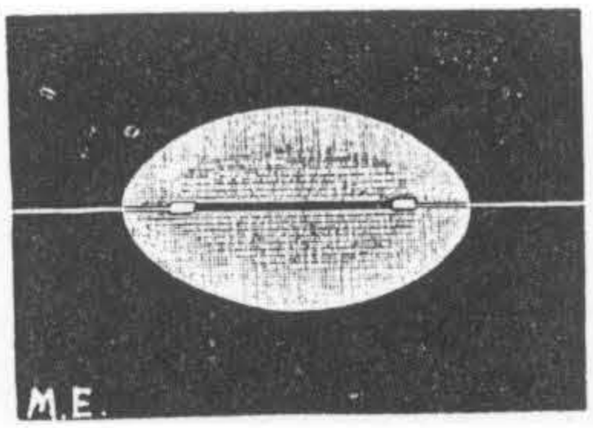
The action of the apparatus is as follows:—The induction coil or transformer I, is excited from the battery shown at B or the regular line wires, and its secondary current at

10,000 volts pressure or more, is caused to charge the condenser C, which immediately discharges itself through the primary coil of the Tesla transformer P, and the spark gap S G; and due to the conditions imposed by such a circuit, the condenser discharge becomes not a single oscillation for each cycle of induction coil current, but many thousand, so that with certain proportions to the circuits as regards their inductance and capacity, the frequency of the current passing through the Tesla coil primary, may reach a million or more cycles per second, rendering the current harmless owing to the "skin effect" already mentioned. The currents thus produced are, of course, highly damped, i. e., the series of oscillation corresponding to each cycle of primary transformer current, dies down to zero before the next series of oscillations start.

Referring again to the cut, Fig. 1, the large Tesla coil here pictured is capable of delivering 10 to 15 inch high frequency sparks at its secondary terminals, when excited by a ¼ to ½ K.W. set-up transformer or a large induction coil of 8 to 12 inch spark capacity. In this particular set of apparatus, the exciting transformer is of special design, and of the open core type, so that it may be operated on 110-volt direct current circuits by means of a "Gernsback" Electrolytic Interrupter, or on 110-volt, 60 to 120-cycle, alternating current circuits directly. This is necessary for stage equipment, as the service available is sometimes *Direct,* and sometimes *Alternating Current.* This is the cheapest manner of arranging a universal Tesla Coil outfit. The better way is to employ one of the Electro ¼ K.W. step-up wireless transformers, wound 110 volts primary, to 13,200 volts secondary, and of the closed-core type. On A. C. circuits the transformer just mentioned is simply connected as in the manner indicated at Fig. 3. In the outfit shown at Fig. 1, two 2-qt. Leyden jars are used for the oscillation condenser. In the set just being outlined and utilizing the closed-core transformer, a special adjustable $10.00 E. I. Co. No. 531A, type H. F., glass plate condenser, is preferably used. The spark gap in these particular sets is an ordinary fixed one. A rotary gap is in every way superior, however, and the "Electro" $15.00 rotary type, fitted with 110-volt universal D. C. or A. C. motor is highly recommended. With the fixed gap, the discharge often tends to arc and this destroys the proper discharging of the condensers. Lowering of the frequency is then most liable to occur, and so a rotary gap should always be used. The connections of the high frequency generating circuit, including the spark gap, condenser, and Tesla coil primary circuit, should all be made with a large *low-resistance high frequency* electrical conductor, such as 1/32 in. x ⅞ in. copper strip; or also stranded copper cable, about No. 4 B. & S. gauge capacity or larger, as the high frequency current only traverses the outer skin of any conductor. Hence the greater the skin surface, the better. The penetration at radio frequency is but a few hundredths of an inch.







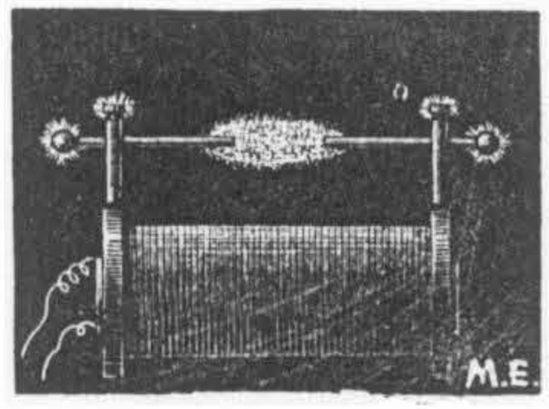


Fig. 5.

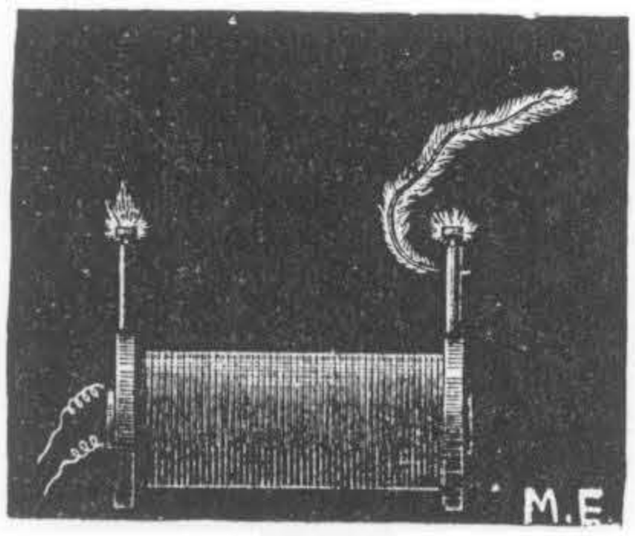
The large Tesla coil here portrayed has an inner secondary coil, about 2 feet long and 5¼ inches in diameter. It is wound with comparatively fine magnet wire in a special manner, to give the highest possible dielectric strength; as this winding has generated in its potentials approximating 700,000 to 1,000,000 volts. The primary coil on this particular coil is formed of several turns of finely stranded copper cable, insulated with pure para rubber. Its turns, of course, do not have the potential stress imposed on them that the secondary coil has. The frequency and character of the Tesla secondary discharge, is made variable by charging the number of primary turns, and also the amount of condenser capacity in circuit. The mathematical expression for computing this frequency is as follows:



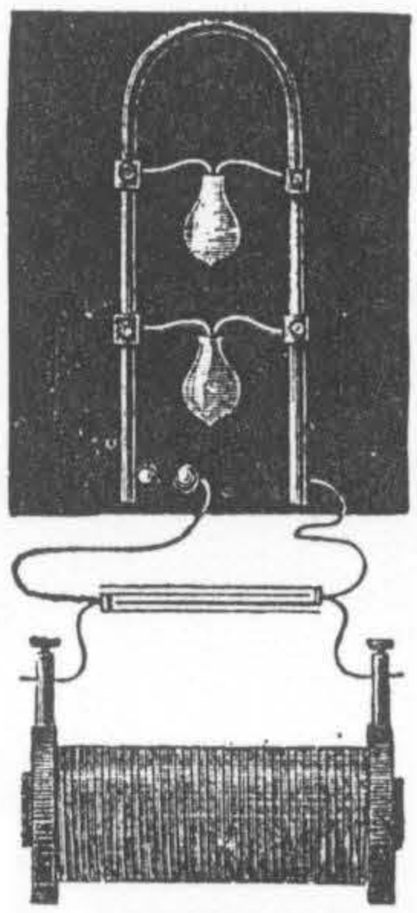


Fig. 6.

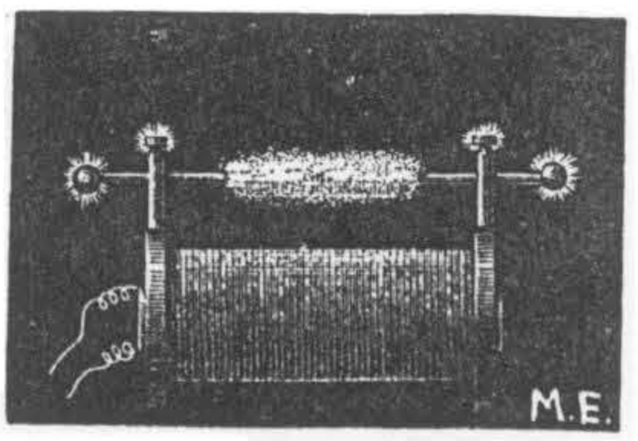

Fig. 7.

$$F = \frac{5{,}033{,}000}{\sqrt{L \times C}};$$

Where F is the frequency in cycles per second, L is the inductance of the exciting circuit in Cm. and C is the capacity of the circuit in M.F.

Decreasing the number of Tesla Primary turns or the condenser capacity thus increases the frequency; which also is an inverse function of the wave length. If the wave length of the circuit is ascertained by means of a wave meter, then the corresponding frequency is found by dividing the wave velocity through ether, viz., 300,000,000 meters, by the wave length in meters, and the result is "frequency in cycles per second."

For the open core transformer shown at Fig. 1, it is necessary to also connect in the primary 110 volt A. C. or D. C. circuit and adjustable impedance coil.

For operating the second mentioned set with 13,200 volt closed-core transformer, on direct current service, a dynamotor delivering 110 volts A. C. 60 cycles, is most adaptable. This would cost $51.00 from the E. I. Co. The Tesla coil alone sells for $15.00 and is finely finished. This set is very

(Continued on Page 154.)

away. The voltage of this discharge was up in the billions, and the amperage 800.*

The object of all these experiments by Nikola Tesla, was along his line of work regarding the wireless transmission of electrical energy, for useful purposes. It may seem like a dream to-day, but then it is only a little over fourteen years ago that man only dreamed about the wireless telegraph, and at the end of this short space of time, there are laws passed which compel its use on all ships that travel the high sea.

Tesla, in his first book, published over twenty years ago, advocated the cause of the wireless transmission of energy, for the lighting of lamps and running of motors, and at that time, in a lecture before the Institute of Electrical Engineers, at London, England, he demonstrated wireless lights and a "no-wire" motor operating over short distances.

The form of the energy was to be in high frequency oscillations stepped up to many million volts, and radiated from extra high aerial wires, extending into the upper strata of rarefied air, through which the high voltage currents travel easily.

The aerial wire would of necessity be quite high, probably more than 50 miles.

A very neat and efficient Tesla transformer designed especially for experimental research, is built by the Electro Importing Company, of New York City.

A cut showing their instrument in full activity is portrayed at fig. 5, which shows the wonderful display it gives when excited from a two inch spark coil run on batteries. A larger exciting spark coil will of course increase the activity of the Tesla coil considerably. The same company also build large size Tesla transformers, complete with condensers, rotary spark gaps, and exciting transformers, upon request, from six to thirty-six inch Tesla spark. In fig. 2, is shown the wiring connections from the Tesla transformer mentioned above. The transformer itself sells for an extremely low price and should certainly commend itself to experimenters, school laboratories, and demonstrators.

Some of the marvelous and mysterious experiments that can be performed with this Tesla coil are reproduced in the cuts figs. 6 and 7. These experiments and numerous others, together with the manner of making them are fully explained in a brochure supplied with the Tesla coil.

This size of high frequency coil, which is capable of delivering three to four inch sparks at its secondary terminals when excited by a two inch spark coil, employs a simple fixed spark gap, fitted with ball or pointed electrodes, flat faced one having not been found suitable in the small sets. This Tesla high frequency set will produce an oscillatory high potential current of several hundred thousand volts, at a periodicity of half a million cycles per second or more.

The application of high frequency currents to the body in various ways was first developed by Prof. d'Arsonval of Paris, and he made a number of different tests, to ascertain the effects of various currents applied to the body, and having different frequencies. When the current applied did not have a frequency greater than 15 cycles per second it was found that a succession of separate on "Clonic" Muscular Contractions were produced. With a frequency of 20 to 30 cycles per second a series of continuous contractions or in other words, a "Tetanus," or "Tonic Spasm," occurred. When the frequency of the oscillations or currents were increased beyond this point, the Tetanus effect was also increased. When a Periodicity of alternation approximating 3000 cycles per second, was employed, the maximum intensity in the muscular contractions took place; and a further increase of frequency caused a decrease in the strength of the contractions, until at a frequency of 10,000 cycles per second absolutely no effect was produced upon either the Motor or Sensory Nerves. Therefore an alternating or oscillating current, which alternates at 10,000 or more cycles per second, is termed a "High Frequency Current" from a therapeutical point of view, and sensibly also, from an electrical point of view.

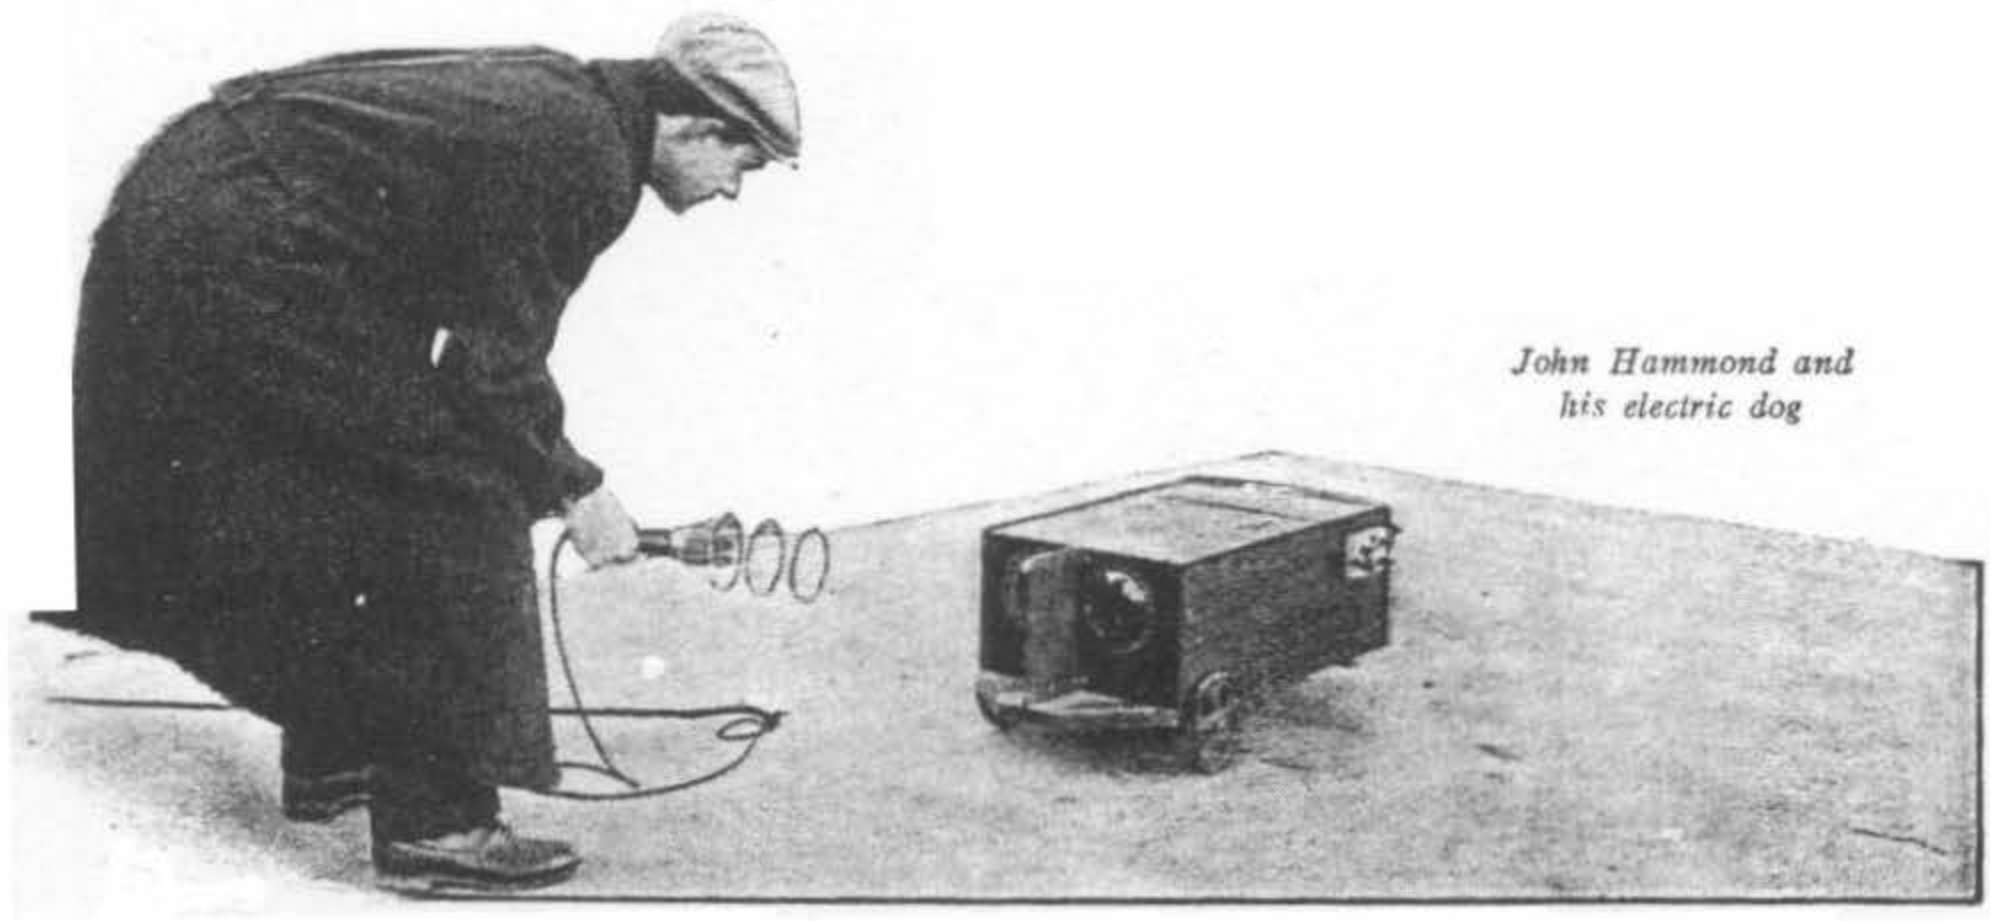
CURRENTS OF ULTRA-HIGH FREQUENCY AND POTENTIAL.



(Continued from Page 152.)

well suited to Physician's Electrotherapeutical requirements also, as well as stage or Experimental work.

While on the subject of large Tesla disruptive discharges, it may be of interest to refer to Fig. 4, which shows some of the stupendous sparks obtained by Nikola Tesla, some years ago, in experiments carried out by him.

Tesla, in some of his researches, had these high frequency discharges developed to such a degree that, in one test he was able to make the current leap a gap, twenty-five feet long, the sparks being two to three feet in diameter, and accompanied by a roar, which could be heard ten to twelve miles

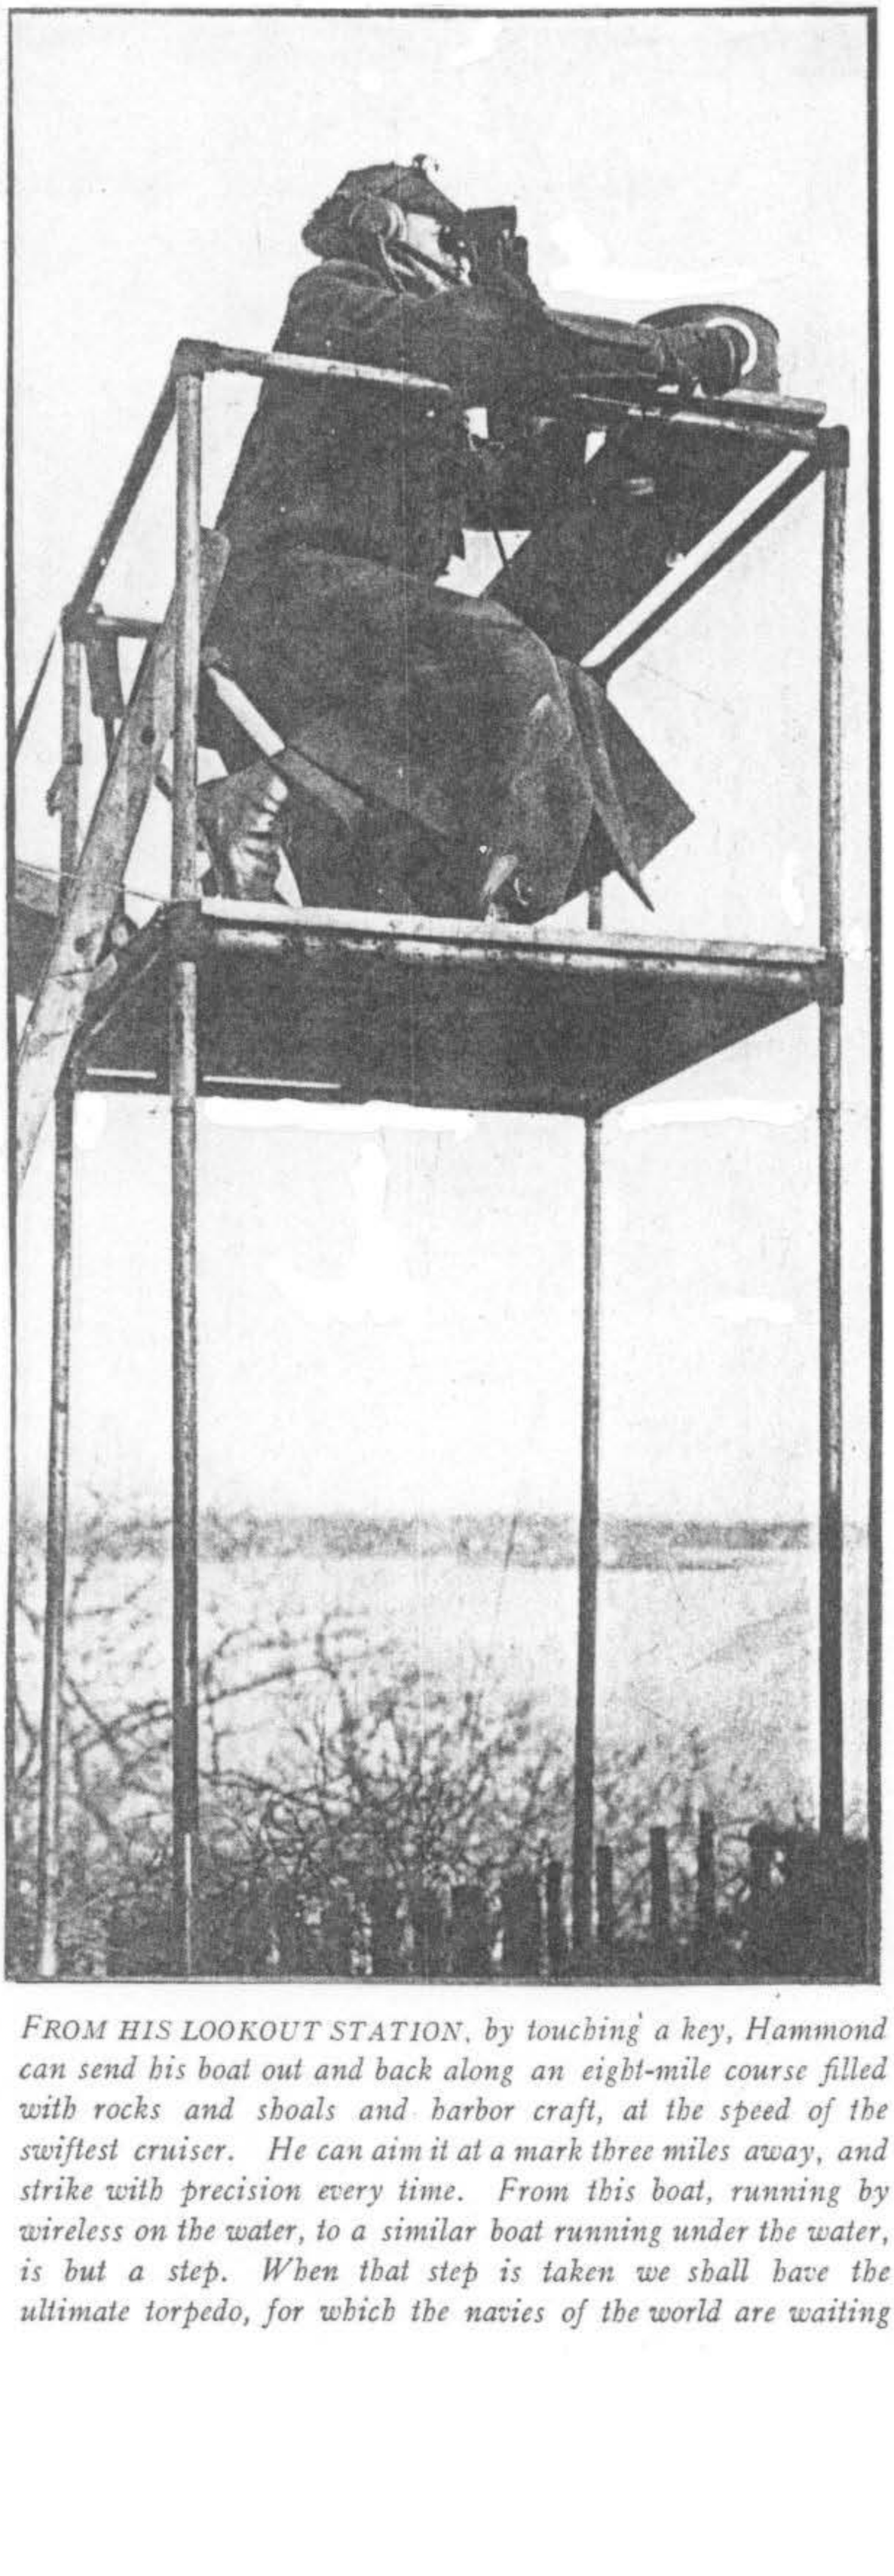
John Hammond and his electric dog

STEERED BY WIRELESS

The Triumph of a Man of Twenty-five

By CLEVELAND MOFFETT



A BOAT WITH NOT A SOUL ABOARD, HER LIGHTS BLAZING, HER ENGINE POUNDING, SHOOTING OUT TO SEA AT NIGHT WITH THE SPEED OF A RAILROAD TRAIN. . . . . .

. . . That is the achievement of young John Hays Hammond, Jr., who, working alone in Gloucester harbor, has evolved perhaps the most spectacular war device of history. As a school-boy, young Hammond made a written prediction that he would some day control a moving body at a distance by the sound of his voice. His boat "Radio" — the fulfilment of this prediction — represents a terrible new weapon for the navies of the world; a new kind of torpedo, so sure and so deadly that it will revolutionize war-making.

ONE of the first things a newcomer at Gloucester, Massachusetts, notices, as he glances across the marshes toward the sea, is the imposing height of two enormous masts that rise on a wooded cliff overhanging the harbor. Three hundred and sixty feet they tower above their granite base. No higher wooden masts have ever been erected (they are insured at Lloyd's for $10,000), and the traveler looks at them wonderingly.

"What are they? What are they for?" he asks, and learns that they are part of the wireless station from which John Hays Hammond, Jr., has, for some years now, been operating boats by wireless control, thus making for himself a local, a national,

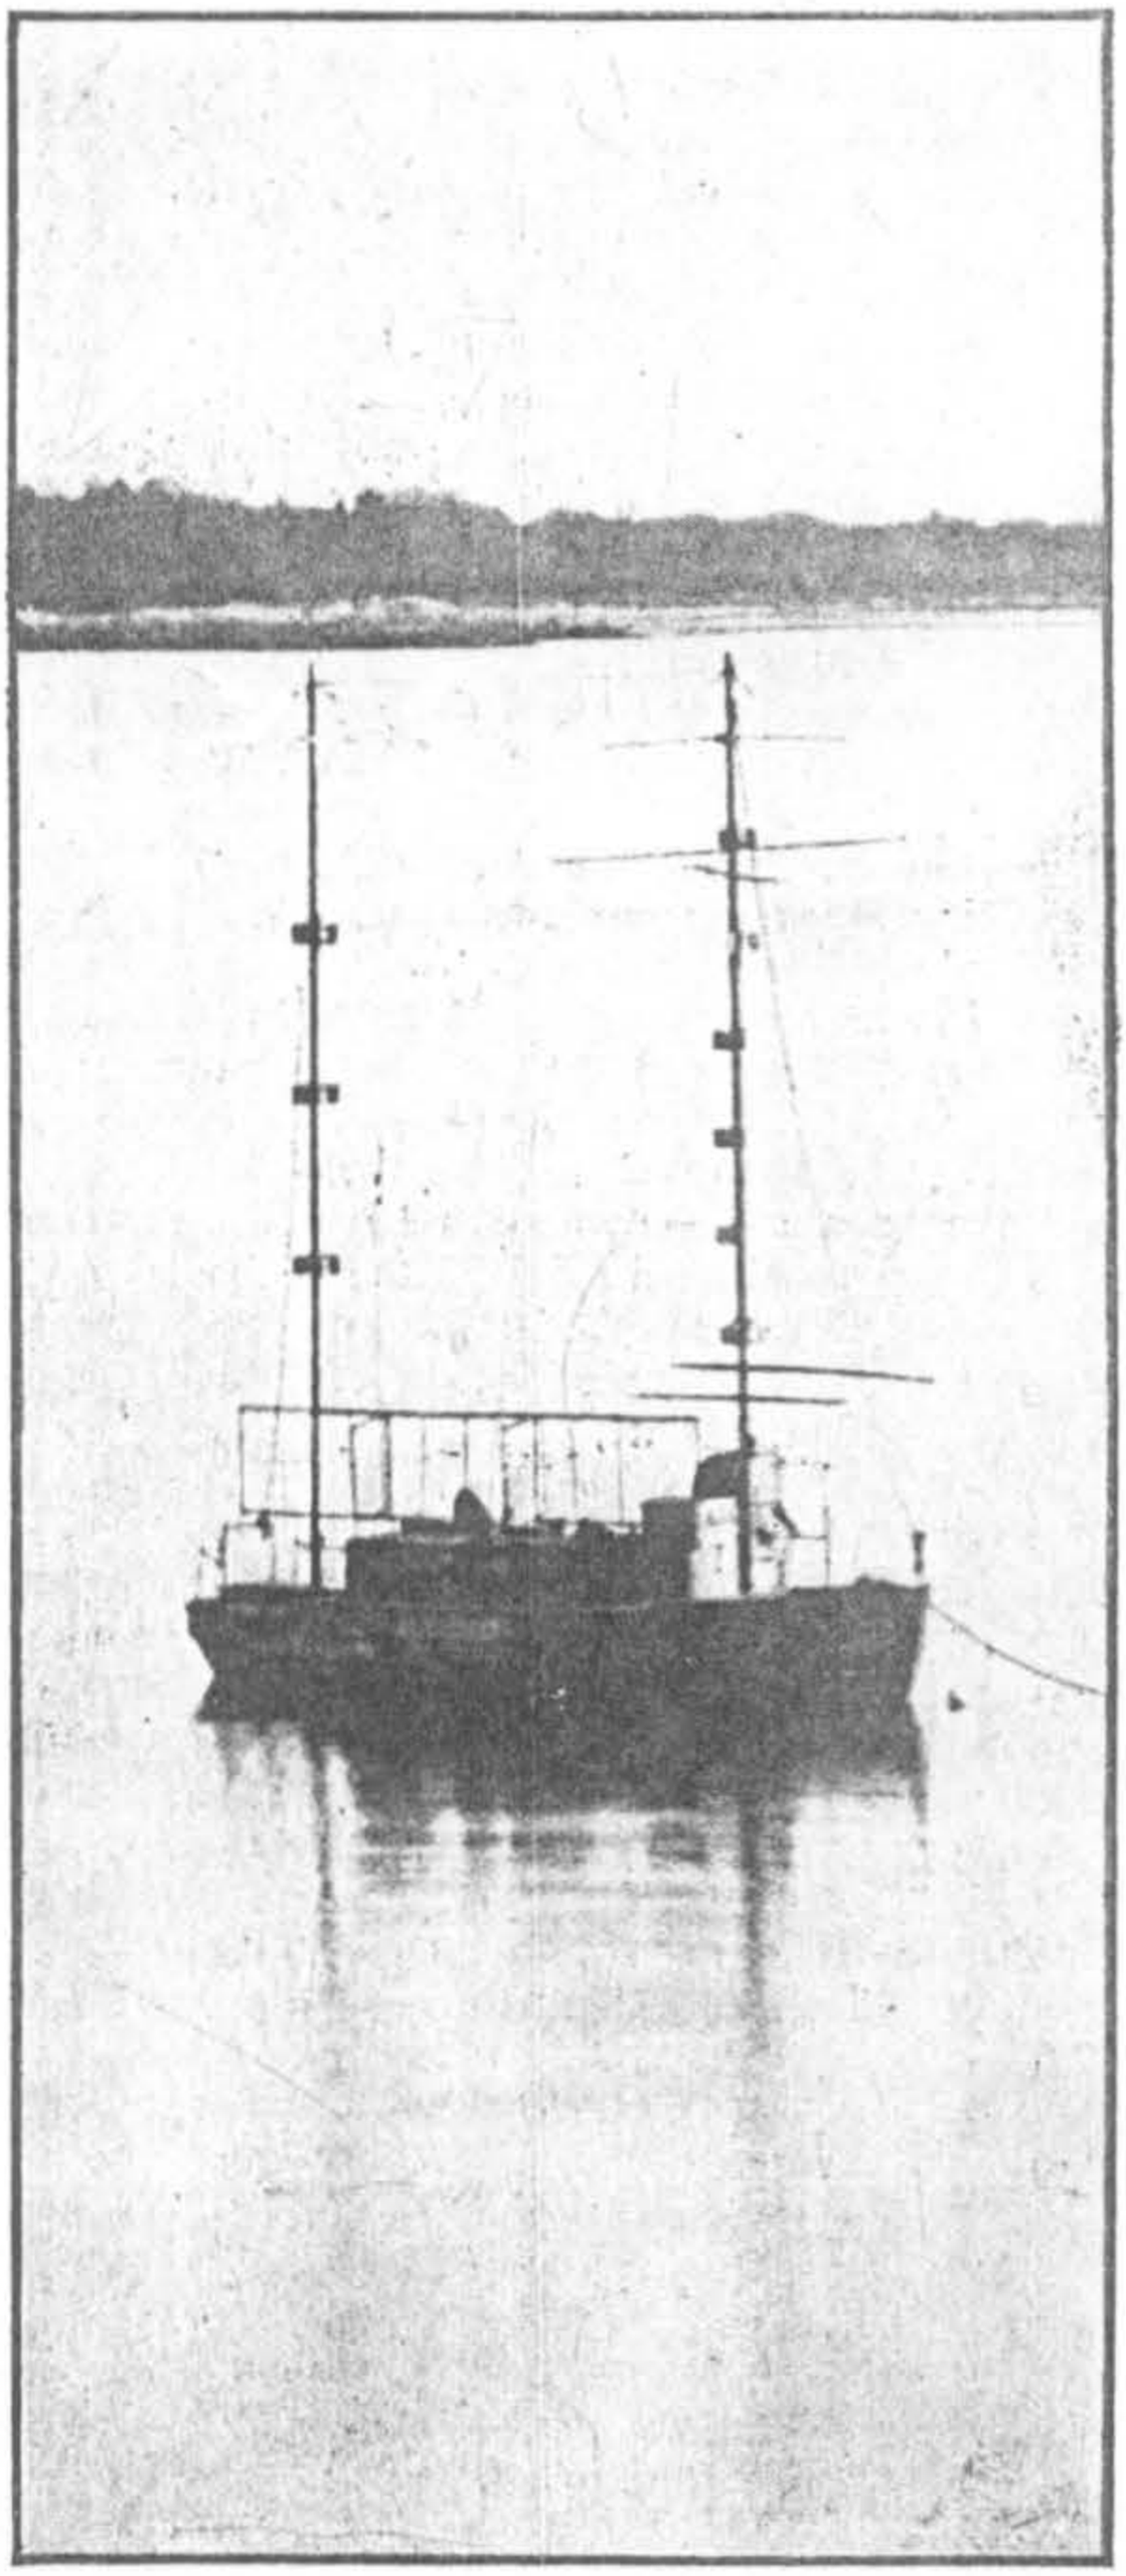
Copyright, 1914, by The McClure Publications, Inc. All rights reserved.

FROM HIS LOOKOUT STATION, by touching a key, Hammond can send his boat out and back along an eight-mile course filled with rocks and shoals and harbor craft, at the speed of the swiftest cruiser. He can aim it at a mark three miles away, and strike with precision every time. From this boat, running by wireless on the water, to a similar boat running under the water, is but a step. When that step is taken we shall have the ultimate torpedo, for which the navies of the world are waiting

and what promises to be an international reputation.

One night in December I had the unusual privilege of standing beside the lookout man on the cliff, the wireless steering man (in this case Captain Behr of the United States Army, stationed here by the coast defense authorities) who directs this far-flung guidance, and of observing what happened as he steered Mr. Hammond's boat out and back through the winter darkness, along an eight-mile tortuous way, steered her safely among rocks and shoals and harbor craft.

It must be understood that this wireless boat runs by the power of her own engines, as we walk by the power of our leg muscles, although the brain directs. The steering man on the cliff is the brain of this plunging boat that is miles away and helpless without him, but she carries her engine muscles with her.



The lookout house is a bare box of a place scarcely large enough for two to turn around in, and bitter cold of winter nights, so we are bundled in heavy coats. The steering man wears a telephone headpiece over his ears, so that he can hear the sounds of the wireless waves as they pulse from the antennae, a network of copper wires that stretch between the great masts behind us.

Now the lookout man touches a key that a child could press, and straightway the miracle begins. That touch has released a store of energy measured by the strength of hundreds of straining horses. We see nothing except some purple fringes of darting flame; we hear only a hissing breath of the wires, that comes each time as the key is touched; yet the whole power of whirling generators, that hum tirelessly in the power-house down the hill, has been hurled forth into space through the quivering antennae. It is this power that does the steering — that is, a small fraction of this power: for only a billionth part of it, Mr. Hammond says, ever reaches the boat. The rest is dissipated into space.

The boat lies below us at her moorings, ready to start. She is dazzling white in a cloud of steam from her exhausts, as the great searchlight plays over her. No battleship can boast such a searchlight. Five feet across is the spread of the silvered parabolic mirror that throws the brilliance of one hundred and eighty-six million candles seven miles out to sea. With a turn of his hand the lookout man directs this immense beam. One little crank lifts and lowers it, another moves it to right or left, these cranks being electrically connected with motors in the searchlight house some distance from us. If this searchlight were near, its dazzling light would blind the lookout man, who must work here in darkness (save for a tiny electric light that illumines his record page), so as to see with all his eyes out over the ocean. He is like the companion of a blind man — upon his vigilance depends the boat's safety, upon his spying out dangers in her course.

Now the boat is starting. Her engines sputter. Her two forty-foot masts shine like slim Christmas trees with clusters of electric lights. This is to make sure that the lookout man does not lose the boat in the ocean darkness, or confuse her with other vessels. In these practice runs, several experts, including Mr. Hammond himself, are aboard, watching the work of shore control, but taking no part in it. On occasions they let the wireless boat run ahead without a soul aboard her, and follow in a launch, to be present in case of an emergency.

Now she is moving at a good speed, headed toward the intermittent light that flashes its red warnings from Eastern Point. We zigzag her down the harbor course, steering her by spars and buoys, as a pilot steers. With a touch of the wireless key the captain turns her aside for a low-lying cargo-boat, and presently has her off the breakwater, where the steady white line shines. Far down the coast I make out white flashes that come — one, four, three — every ten seconds. It

THE FIRST WIRELESS BOAT. To demonstrate his spectacular invention, Hammond afterward built the "Radio," a forty-foot craft with a guaranteed speed of thirty-three miles an hour. Aboard this boat was everything that was known in the way of radio-dynamic apparatus, and much that was unknown; for the young inventor was facing new problems in electrical engineering, in marine engineering, and in radio engineering. Night after night, the wireless boat makes her trips with experts aboard

takes the greatest concentration of mind to count these flashes.

"We must watch out for that spar buoy off the breakwater," mutters the captain. "We ran into it one night — broke it clean off. Hello!"

He peers out intently through his binoculars, and sweeps the searchlight to the left. There is a beautiful effect of sea-mist drifting down the broad beam, like a river of silver, full of strange shapes and eddies, flowing far off into the sky and the sea and the night.

"What is it?"

"A sailboat 'way beyond the breakwater — three miles out. Those are the brutes we've got to look out for. They have the right of way, you know, and half of 'em come creeping along without any lights. We're headed straight toward her. See!"

"How far out is our boat?"

"Nearly three miles. I'll send her to the right a little. There she goes! See, her masts turn! Now she's running straight out in the open sea — two miles beyond the breakwater. Ah! She passed the sailboat two hundred yards to the left!"

From time to time the lookout man busies himself with his chart, noting down every significant phenomenon of the run for future study and comparison.

"She's getting her juice fine to-night. I'd hear it if she wasn't. There's the Boston boat — going to Portland. See her lights? She's five miles out. Hello!"

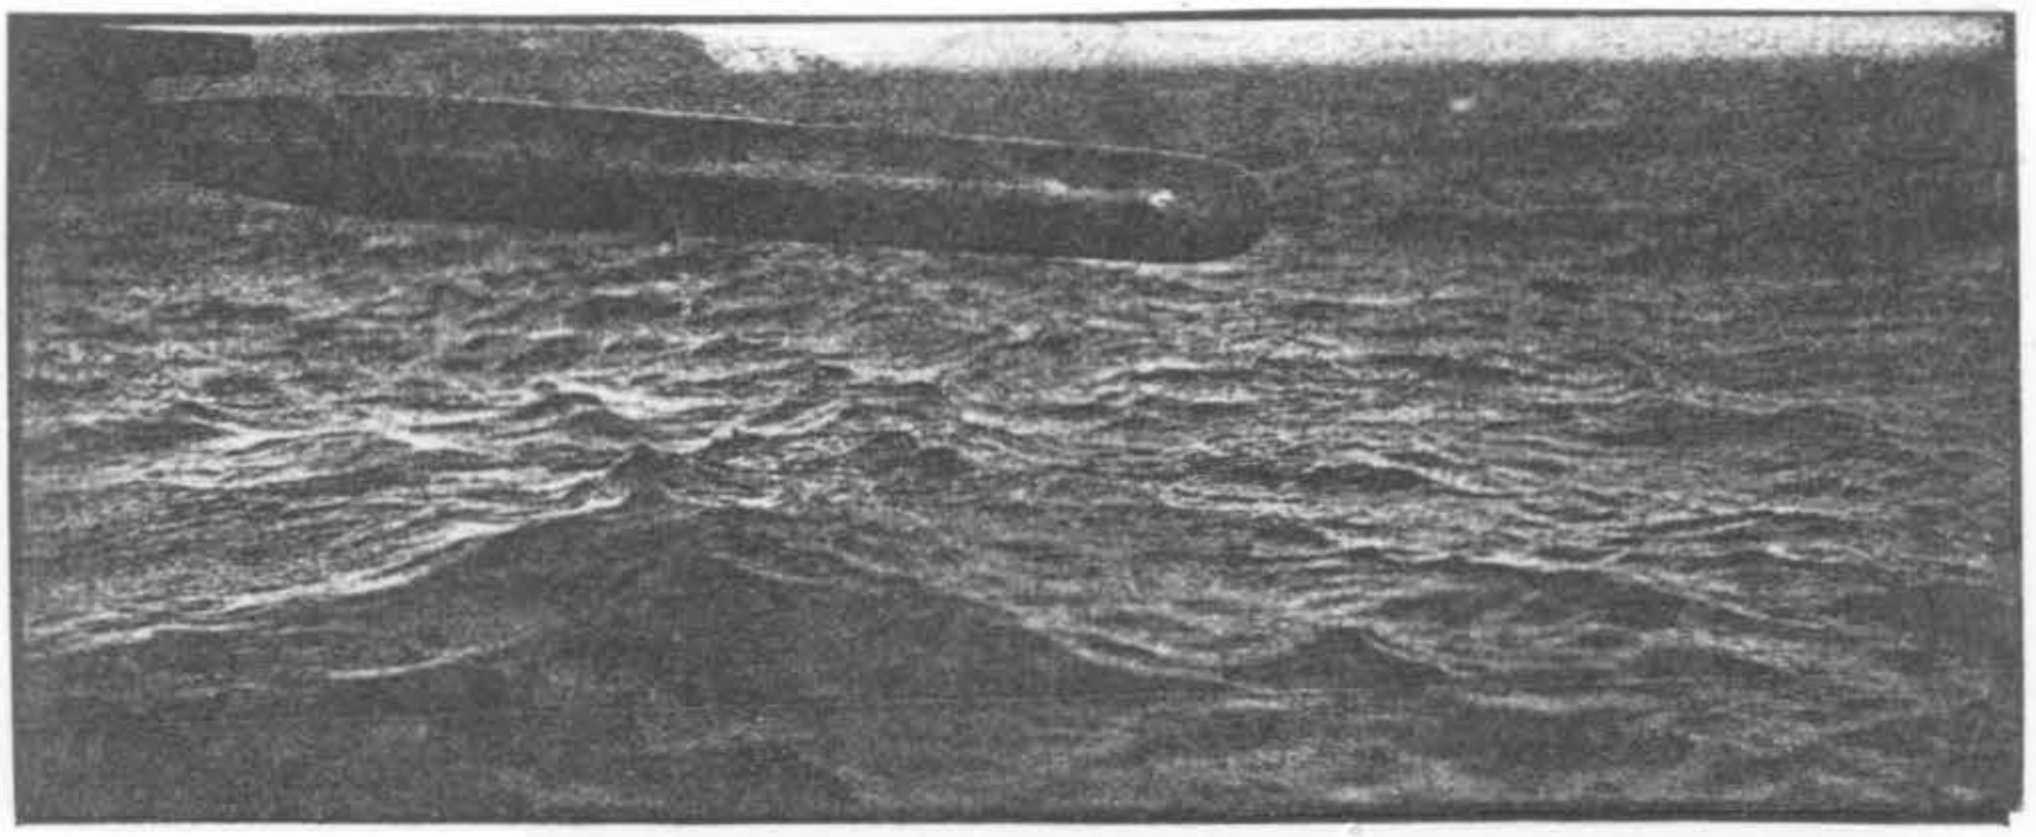
He sweeps the searchlight vigorously to the left. "What's that crazy tugboat trying to do — run into us? I'll turn our boat to the right. She's towing a cargo-boat with three hundred yards of towline for us to drag on. There!"

"How far out is our boat now?"

"Four miles easy. Would *you* like to turn her?"

"*Would* I?"

"Which way?" he asks.



"To the right."

"Good. Press your finger on the key — like this — just lightly. That's enough. Let her go. Now watch the boat."

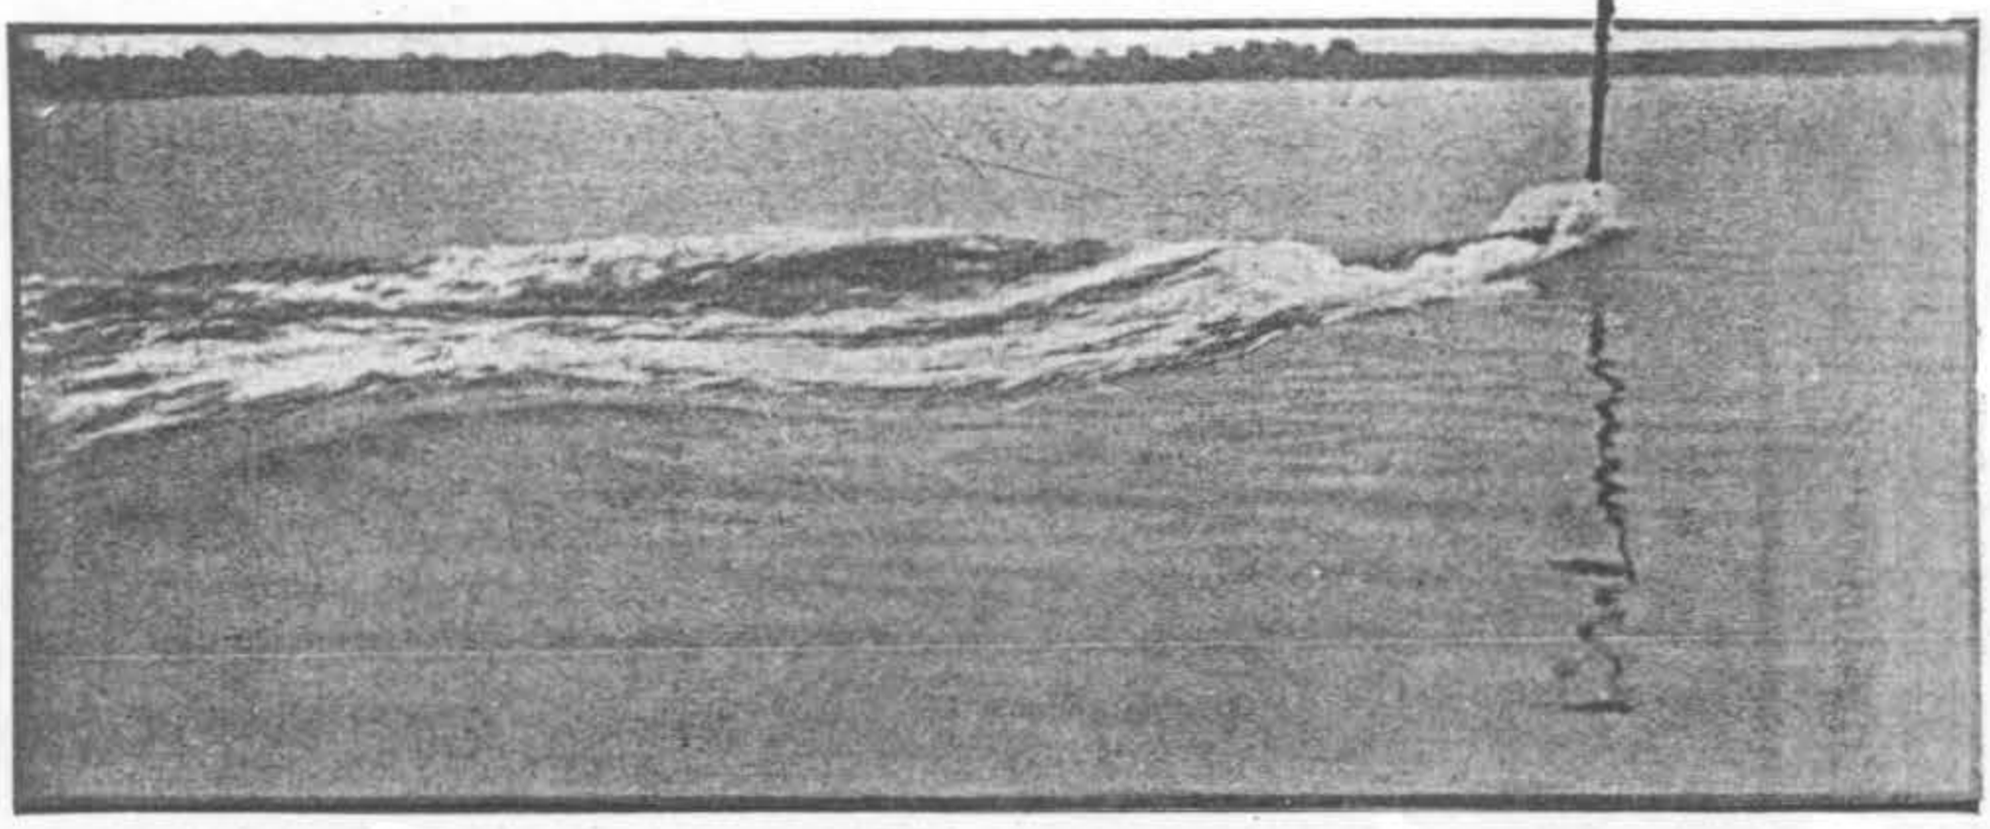
Sure enough, as I touch the key, the patch of light that marks our boat swerves sharply to the right full forty-five degrees. With the gentlest contact of my finger I have turned a vessel weighing five or six tons and four miles out in the Atlantic — I have turned her four points off her course!

The Second Chapter in Wireless

On another December night I was a fascinated passenger aboard this strangely conducted craft as she fared about the bay and out into the open sea, steered from the wireless station miles away. I saw her swing obediently to right and left, as a distant intelligence commanded, and thread her way unharmed over an eight-mile course among moving craft and perils of the darkness. I saw her aimed for a four-masted schooner lying at anchor half a mile away, and steered at the vessel unerringly, running up close to the side as if this were an enemy's battleship and we a torpedo trying to "make a strike." It was a startling experience — one that ranks in importance, no doubt, with another that I recall fourteen years ago, when, in Boulogne, France, I received, as the representative of McCLURE'S MAGAZINE, the first wireless message sent across the Channel. This message came from no less a person than Marconi himself, in Dover, England, who assured me that the time would come

PHOTOGRAPHS showing a moving torpedo of the old, wire-controlled kind,

when boats and torpedoes would move about the ocean under effective shore control. It is a pleasant coincidence that I am now able, in the same pages, to record the realization of that prophecy.



As to these new wonders, I may explain briefly that wireless control of a distant vessel (boat or torpedo) is accomplished by allowing wireless waves from a shore station to act upon a system of receivers and relays and motors in the vessel, each motor exercising some control over engine or rudder. Thus one turns the rudder to the left, another sets the engines at half speed, another at full speed, while another stops them. The current that operates these motors comes from generators carried by the vessel itself, and not from the wireless station on shore, which merely sends power enough to unlock the motor gates, as it were, by a delicate receiving apparatus, and let the current from the generators flow through.

This will seem clearer if one imagines a clock-hand made to turn (by wireless) over the face of a sort of dial. This clock-hand can be stopped, by movements of the sending key on shore, at any desired number on the dial, and, wherever it stops, current flows into a motor connected with that particular dial number. Thus the finger, stopping at three o'clock, might increase the boat's speed, or stopping at six o'clock might turn her to the left, or at nine o'clock might stop her, etc. If there are, let us say, five main controls on the boat,— "full speed," "half speed," "right," "left," and "stop," — then the wireless impulses from shore play upon these controls like fingers on a keyboard, invisible fingers. As the sending key is pressed in one way or another, the moving hand, stopping here or there on the dial, actuates this or that motor, and a definite work with rudder or engine is performed for the safe guidance of the vessel.

Hammond Prophesies His Own Career

In order to make this record of Mr. Hammond's achievement more complete, let us glance back over the inventor's earlier years and aspirations, and observe what manner of man John Hays Hammond, Jr., is, and how he came to conceive of this invention. It is certainly remarkable that a young man of twenty-five, scarcely four years out of college, should have attracted the attention of military authorities on the ground that he is in a fair way to change the conditions of naval warfare. That Hammond is taken seriously is indicated by the fact that in 1912 he was one of the American delegates to the Radio-Telegraphic Congress held in London, the other delegates being Rear-Admiral John R. Edwards, Captain David W. Todd, Dr. Louis W. Austin, Major George O. Squier, Commandant Edgar Russel, Commandant C. McK. Saltzman, John I. Waterbury, Dr. Arthur G. Webster, W. D. Terrell, Professor Willis L. Moore, John Q. Walton, and F. A. Kolster. Mr. Hammond is also a member of the Smithsonian Institution, and was recently made a member of the Royal Society for the Encouragement of Arts, Manufacturers, and Commerce.

John Hays Hammond, Jr., is the son of a rich and distinguished father who has given him every possible advantage in life. As a boy he traveled widely and studied in various foreign countries, including South Africa. He has a lively imagination, a keen sense of humor, and a decided literary taste. Once he wrote an epic poem.

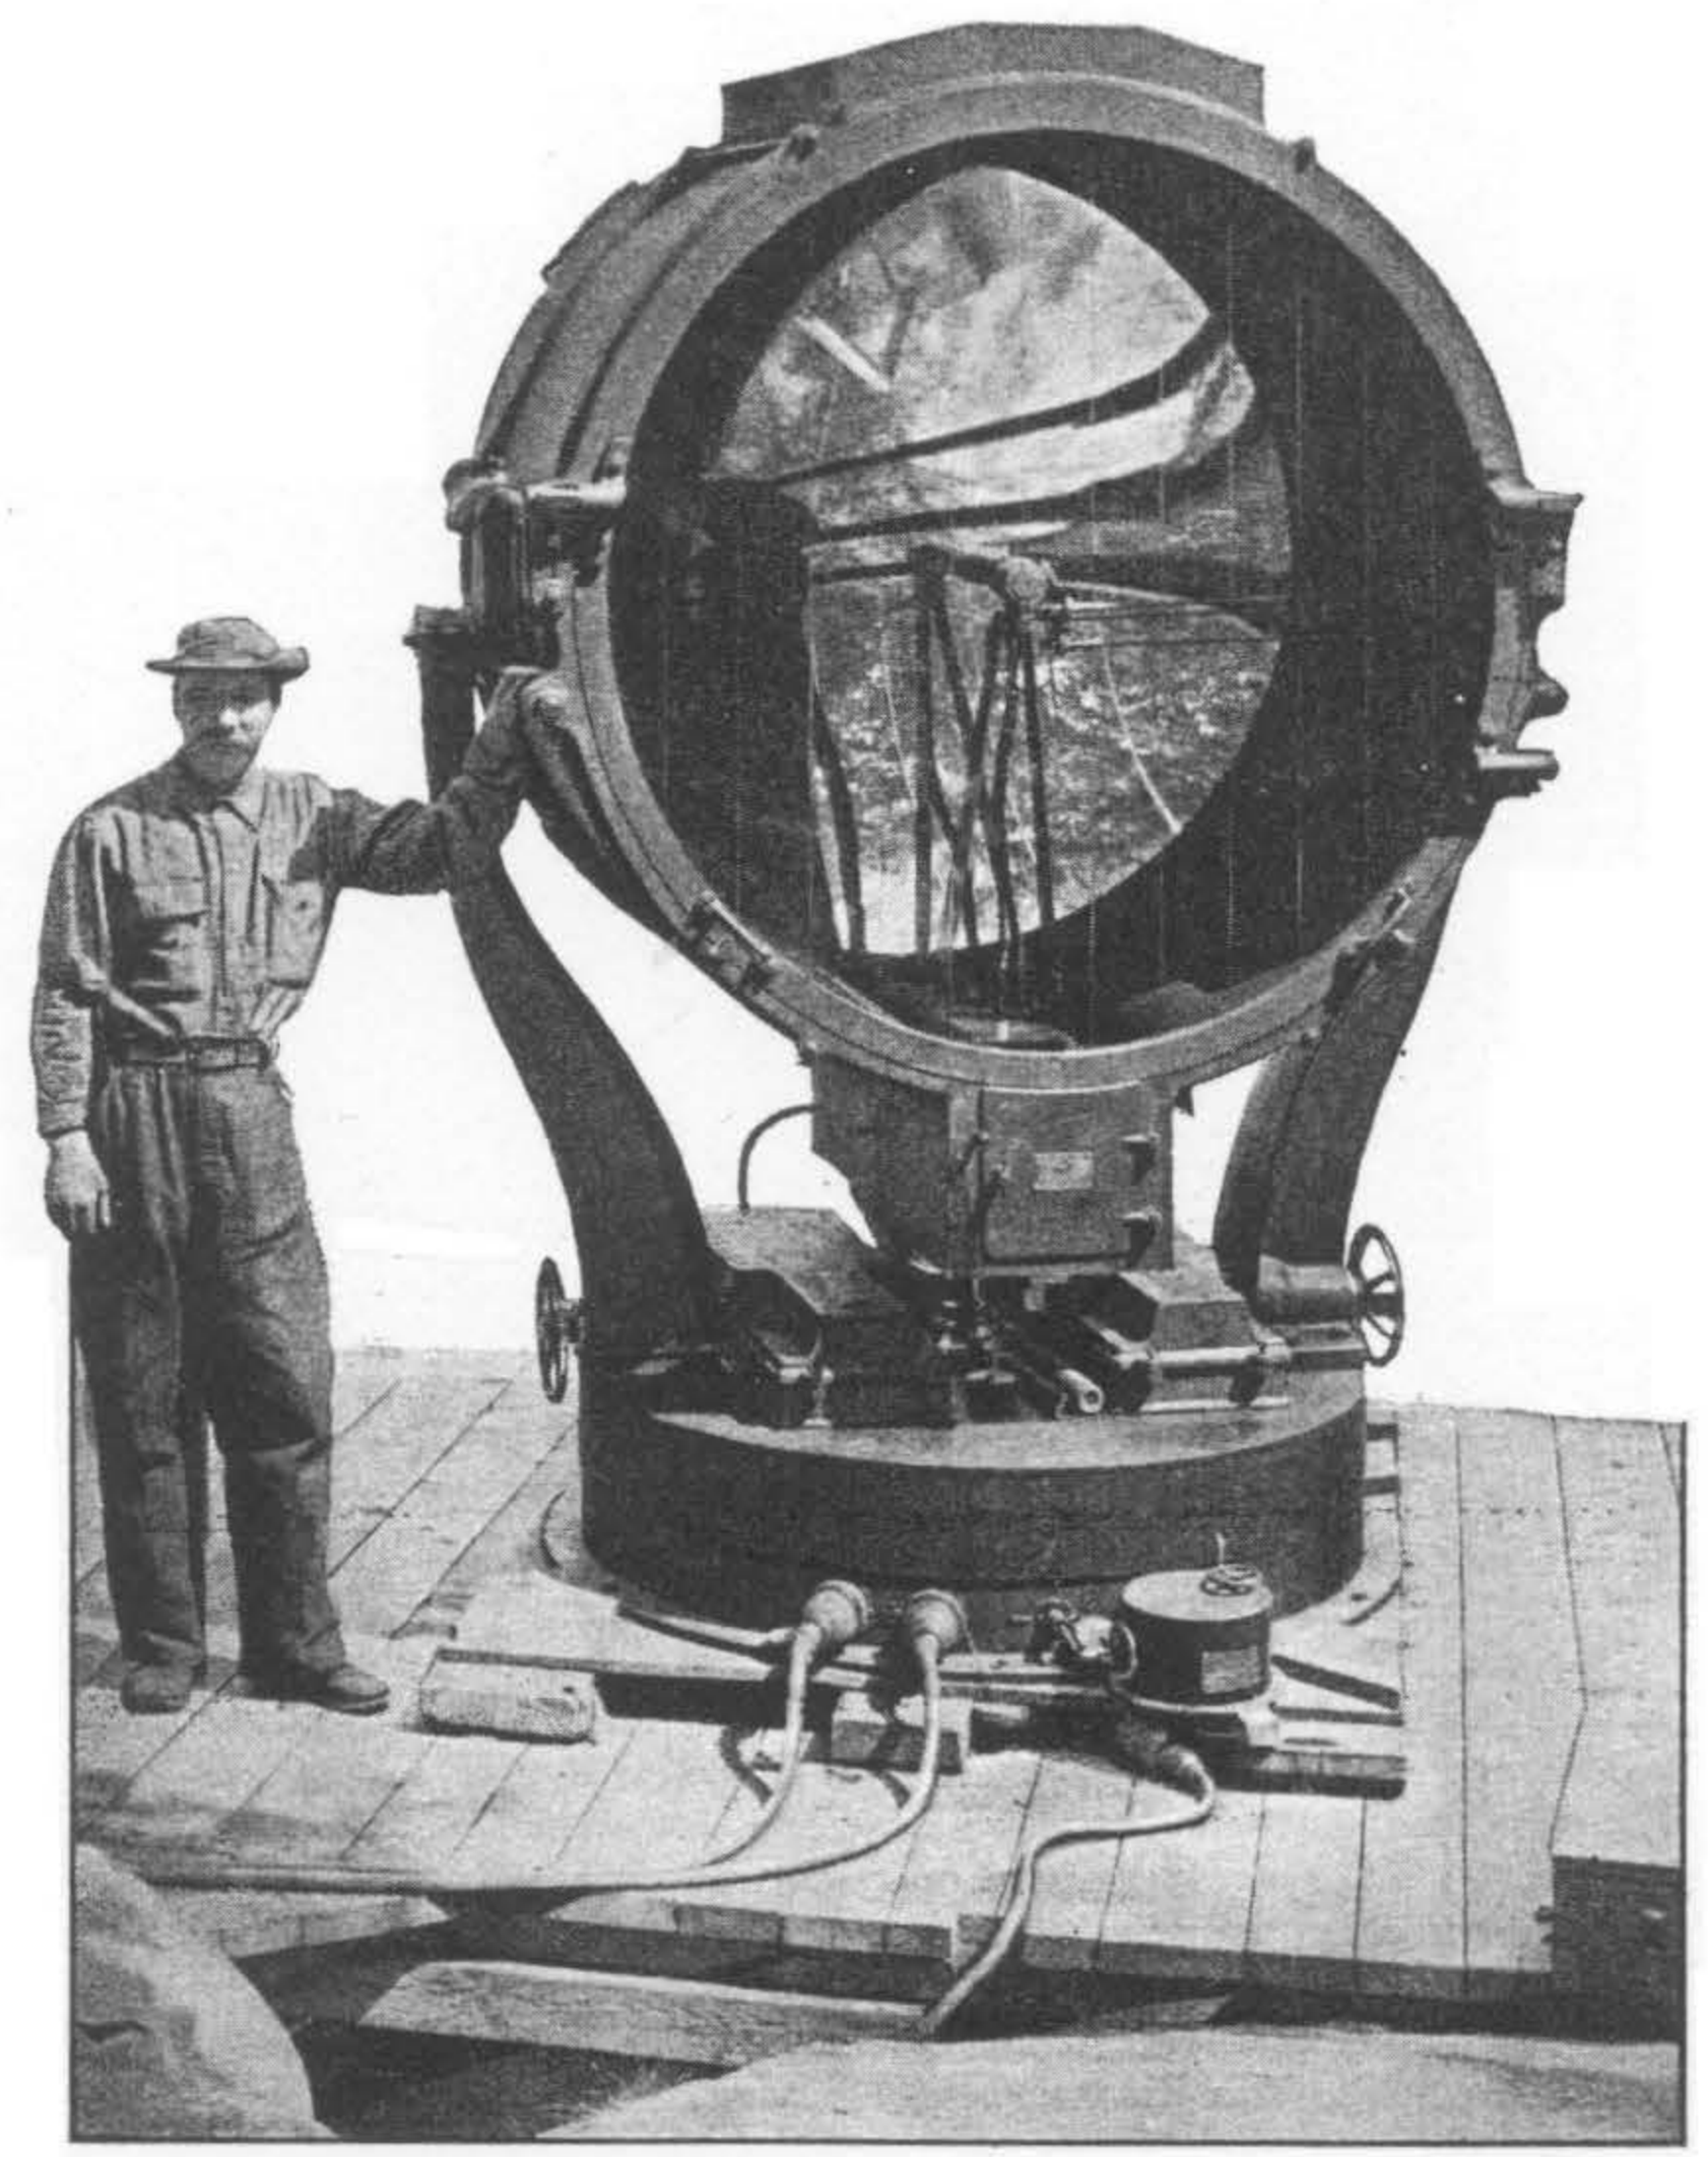
as it is being launched and as it goes through the water toward a mark

Hammond pursued his studies at the Sheffield Scientific School, from which he was graduated in 1910. An incident here shows the bent of his genius and his faith in his own destiny. One day he was chatting with a teacher of higher mathematics, when the talk turned upon inventions, with speculation about the future, dreams of possibilities. Suddenly Hammond said: "Some day I will control a moving body at a distance by the sound of my voice." He said this quite seriously, and asked that his prophecy, written down and duly witnessed, be given to the director of the school and preserved in the safe. This was accordingly done, a diagrammatic sketch of the proposed apparatus being furnished and duly filed away.

After his graduation Hammond decided to give his life to scientific work, not only because of an aptitude in that direction, but because he felt that here lay the best chance of giving to the world something of permanent value in return for what the world had given him.

With a fine concentration on work, Hammond settled down in Gloucester and devoted himself to the new and fascinating science of radio-dynamics or telautomatics, which means the operation of mechanisms by energy sent from a distance. And, presently, rumors began to spread of strange experiments at Lookout Hill, the Hammonds' summer home. A mast and cross-yard on the lawn were seen to do inexplicable things when a searchlight was thrown upon them. At the flash of this searchlight a horn on the mast would sound, or a charge of dynamite would explode, or electric lamps on the yard-arms would mysteriously change from red to green or from green to red.

The explanation of these mysteries on the lawn was simple enough. There was no connection between Hammond and the mast except the searchlight — no wires or hidden mechanism. There was, however, fixed to the mast, a piece of delicate electrical apparatus that received the searchlight rays and was stimulated by them, as will be presently explained, so that a magnet was energized or a motor was made to turn. By these agencies it was possible to do almost any kind of simple work like blowing a horn or exploding a charge of dynamite or moving a system of lamp switches. Hammond declared that, with this system, he could stand on the shore and steer a boat all around Gloucester harbor by simply throwing a searchlight upon her. And he did it, as we shall see.



Hammond's Electric Dog

Among other things that puzzled the visitors was a half toy (embodying the same scientific principle) that Hammond called his electric dog. The eyes of this melancholy creature are of bulging glass as large as saucers. His nose is a long thin strip of brownish reddish board. His body is an oblong mahogany box, and contains an electric motor, a storage battery, two selenium disks, two relays, and two solenoid magnets. This dog has no tail except an electric switch, and he runs on three brass wheels, two in front and one behind.

When the motor inside of the dog is started he will do some extraordinary things. If you walk before him carrying a lantern, he will follow you, turning to the right or left as you turn, although you neither touch him nor control him in any way that you can understand. Briskly he steers himself after you with a fidelity that is positively uncanny until you learn that what guides him is the lantern, through the sensitiveness to light of that strange element, selenium. If you move your lantern to the left, the left selenium cell receives more light and more stimulation than the right cell, and so allows more current from the storage battery to flow into the left-hand magnet, which then deflects the hind wheel to the left and the dog turns in that direction. For the same reason, when you move to the right the dog follows you. And, if you reverse the motor by pushing over the tail switch, you can make the dog back away most surprisingly in either direction when you advance upon him with the light.

Steering a Boat by Light Alone

In this experiment (which greatly interested Professor Jacques Loeb) Hammond had inadvertently made a mechanical demonstration of Loeb's theory that the attraction of moths and insects for light is due to the presence in their bodies of a photochemical substance that steers them as selenium steered the dog. Hammond subsequently applied this ingenious method in operating a boat from shore, using a powerful searchlight to stimulate selenium cells aboard her. He was entirely successful here, and steered his boat repeatedly all over the harbor by selenium, one might say; but, owing to the physical limitations of light due to the shadow effect,

THE GREAT SEARCHLIGHT which plays on the wireless boat when she is manoeuvering at night. No battleship can boast such a searchlight. The mirror is five feet across, and throws a light of 186,000,000 candle-power seven miles out to sea

ne soon discarded this plan in favor of control by wireless.

On another occasion Hammond invited some friends to a preliminary demonstration of his present boat-steering idea. In the big room of his Gloucester bungalow he had suspended a wireless transmitter from a rafter over the mezzanine gallery, while on a table underneath was a piece of apparatus like the steering parts of a boat with the rudder swung between two magnets. By manipulating a key he was able to energize these magnets from the transmitter overhead, and thus deflect the rudder to right or left, as he pleased, by means of wireless ir through the ether.

This was the first step in Hammond's effort to steer a vessel by wireless energy. He had not yet accomplished his purpose of voice control,— indeed, he saw that there was only a spectacular value in this,— but he had controlled a distant moving body by a wireless key, which was something. If he could move that rudder on the bungalow table by wireless impulses from the ceiling, why could he not steer a boat out in Gloucester Bay by wireless impulses from shore?

The Young Inventor's First Failures

When it came, however, to carrying out this purpose, the young inventor found that there is a vast difference between experiments with a laboratory model and experiments on a large scale. And for months, while he experimented with an open launch, his efforts failed entirely.

Hammond finally decided that he must have a larger boat to work with and an entirely new set of apparatus, the whole to be covered over against the weather and to form a sort of floating laboratory. So he picked up an old house-boat, the *Pioneer*, a queer craft with no more shape than a bale of hay, and proceeded to transform her into one of the most scientific vessels afloat, fitting her up with gas-engines, generators, batteries, relays, condensers, induction coils, micrometers, not to mention a new keel and two big receiving masts. Many a night this house-boat has threaded her course about the harbor, flopping along bravely, with wireless waves pursuing her and the searchlight dazzling her, wondering, perhaps, if this was the sort of thing a house-boat was intended for.

All this involved great expense and labor, but in the end Hammond triumphed. There came a day when, after months of groping and discouragement, the old house-boat responded to a wireless impulse. Hammond at the time was steering the boat from shore; and when he saw the distant craft answer his call, turn to the touch of his finger, he was so overjoyed that he almost ran her on the rocks. Later in the day he steered her all about the harbor by wireless, and it looked as if the problem was solved — Hammond had made good.

But alas for human hopes! Shortly after this early successful trip there came a great disappointment. The Marconi coherers that Hammond had used on his boat to receive wireless impulses from shore suddenly refused to function properly. They became quite unreliable, so that when the lookout man pressed his key for "right," the boat was as likely as not to go to the left; or, at other times, she would not receive the wireless impulses at all, but would plow straight ahead at the risk of smashing herself to pieces on the rocks. Without reliable receivers of the wireless impulses it was impossible to operate the boat. What was to be done?

In vain Hammond consulted the greatest authorities in the country on radio-telegraphy. He could find no substitute for the Marconi coherers. And finally, in desperation, he set forth on a pilgrimage abroad, visiting London, Paris, Berlin, St. Petersburg, where he sought out the men who had worked on lines similar to his own, and tried to discover what they had actually accomplished in the direction of wireless control for a moving vessel. He found that they had accomplished practically nothing except to make plans and claims very much like his own original project. They had not perfected their plans or justified their claims, nor could they tell him what to use as a substitute for the Marconi coherer.

So Hammond returned from Europe with only negative encouragement. It was true, these foreign scientists had come no nearer than he to the realization of their common dream of the ultimate torpedo, to be steered by wireless; indeed, he had outdistanced them, so far as he could learn, in actual achievement. He, at least, had steered by wireless a real boat on real water, holding her under perfect shore control over a two-mile course, while their steering had been done mostly on paper, or, if on the water, then in an unsatisfactory way for only a few hundred yards. This showed a field free from serious competition, but it showed nothing helpful in the matter of the defective coherer, and if Hammond was to operate a swift and delicately turning torpedo with any hope of success, he must have something better than this to receive the wireless impulses, something far more reliable than this. And he could find nothing; he could devise nothing.

In this emergency, the troubled inventor went to Washington, resolved to lay his case before one of our army authorities. For his own peace of mind he must know whether it was worth while continuing the struggle — whether his invention would be valuable, even if perfected; and, in some trepidation, he sought out General Weaver, Chief of the United States Coast Artillery.

General Weaver's Promise

"Would it interest you, General," the young man asked, "if I could show you a boat running thirty miles an hour that I could steer from shore without any physical connection and ——"

"*Did* you say thirty miles an hour?" interrupted General Weaver.

"Yes, sir. And make her do whatever I wanted, turn her against a battleship or — or anything? Would that interest you, sir?"

There was an anxious pause. The answer meant everything. It would have been easy for General Weaver to be sarcastic or discouraging; but he was not that kind of man. The General smiled good-naturedly, and assured his anxious visitor that if he could do what he said, or half as much, he would have accomplished something of real value in the military world.

Hammond's heart bounded with joy. These were the words he had been hungering for.

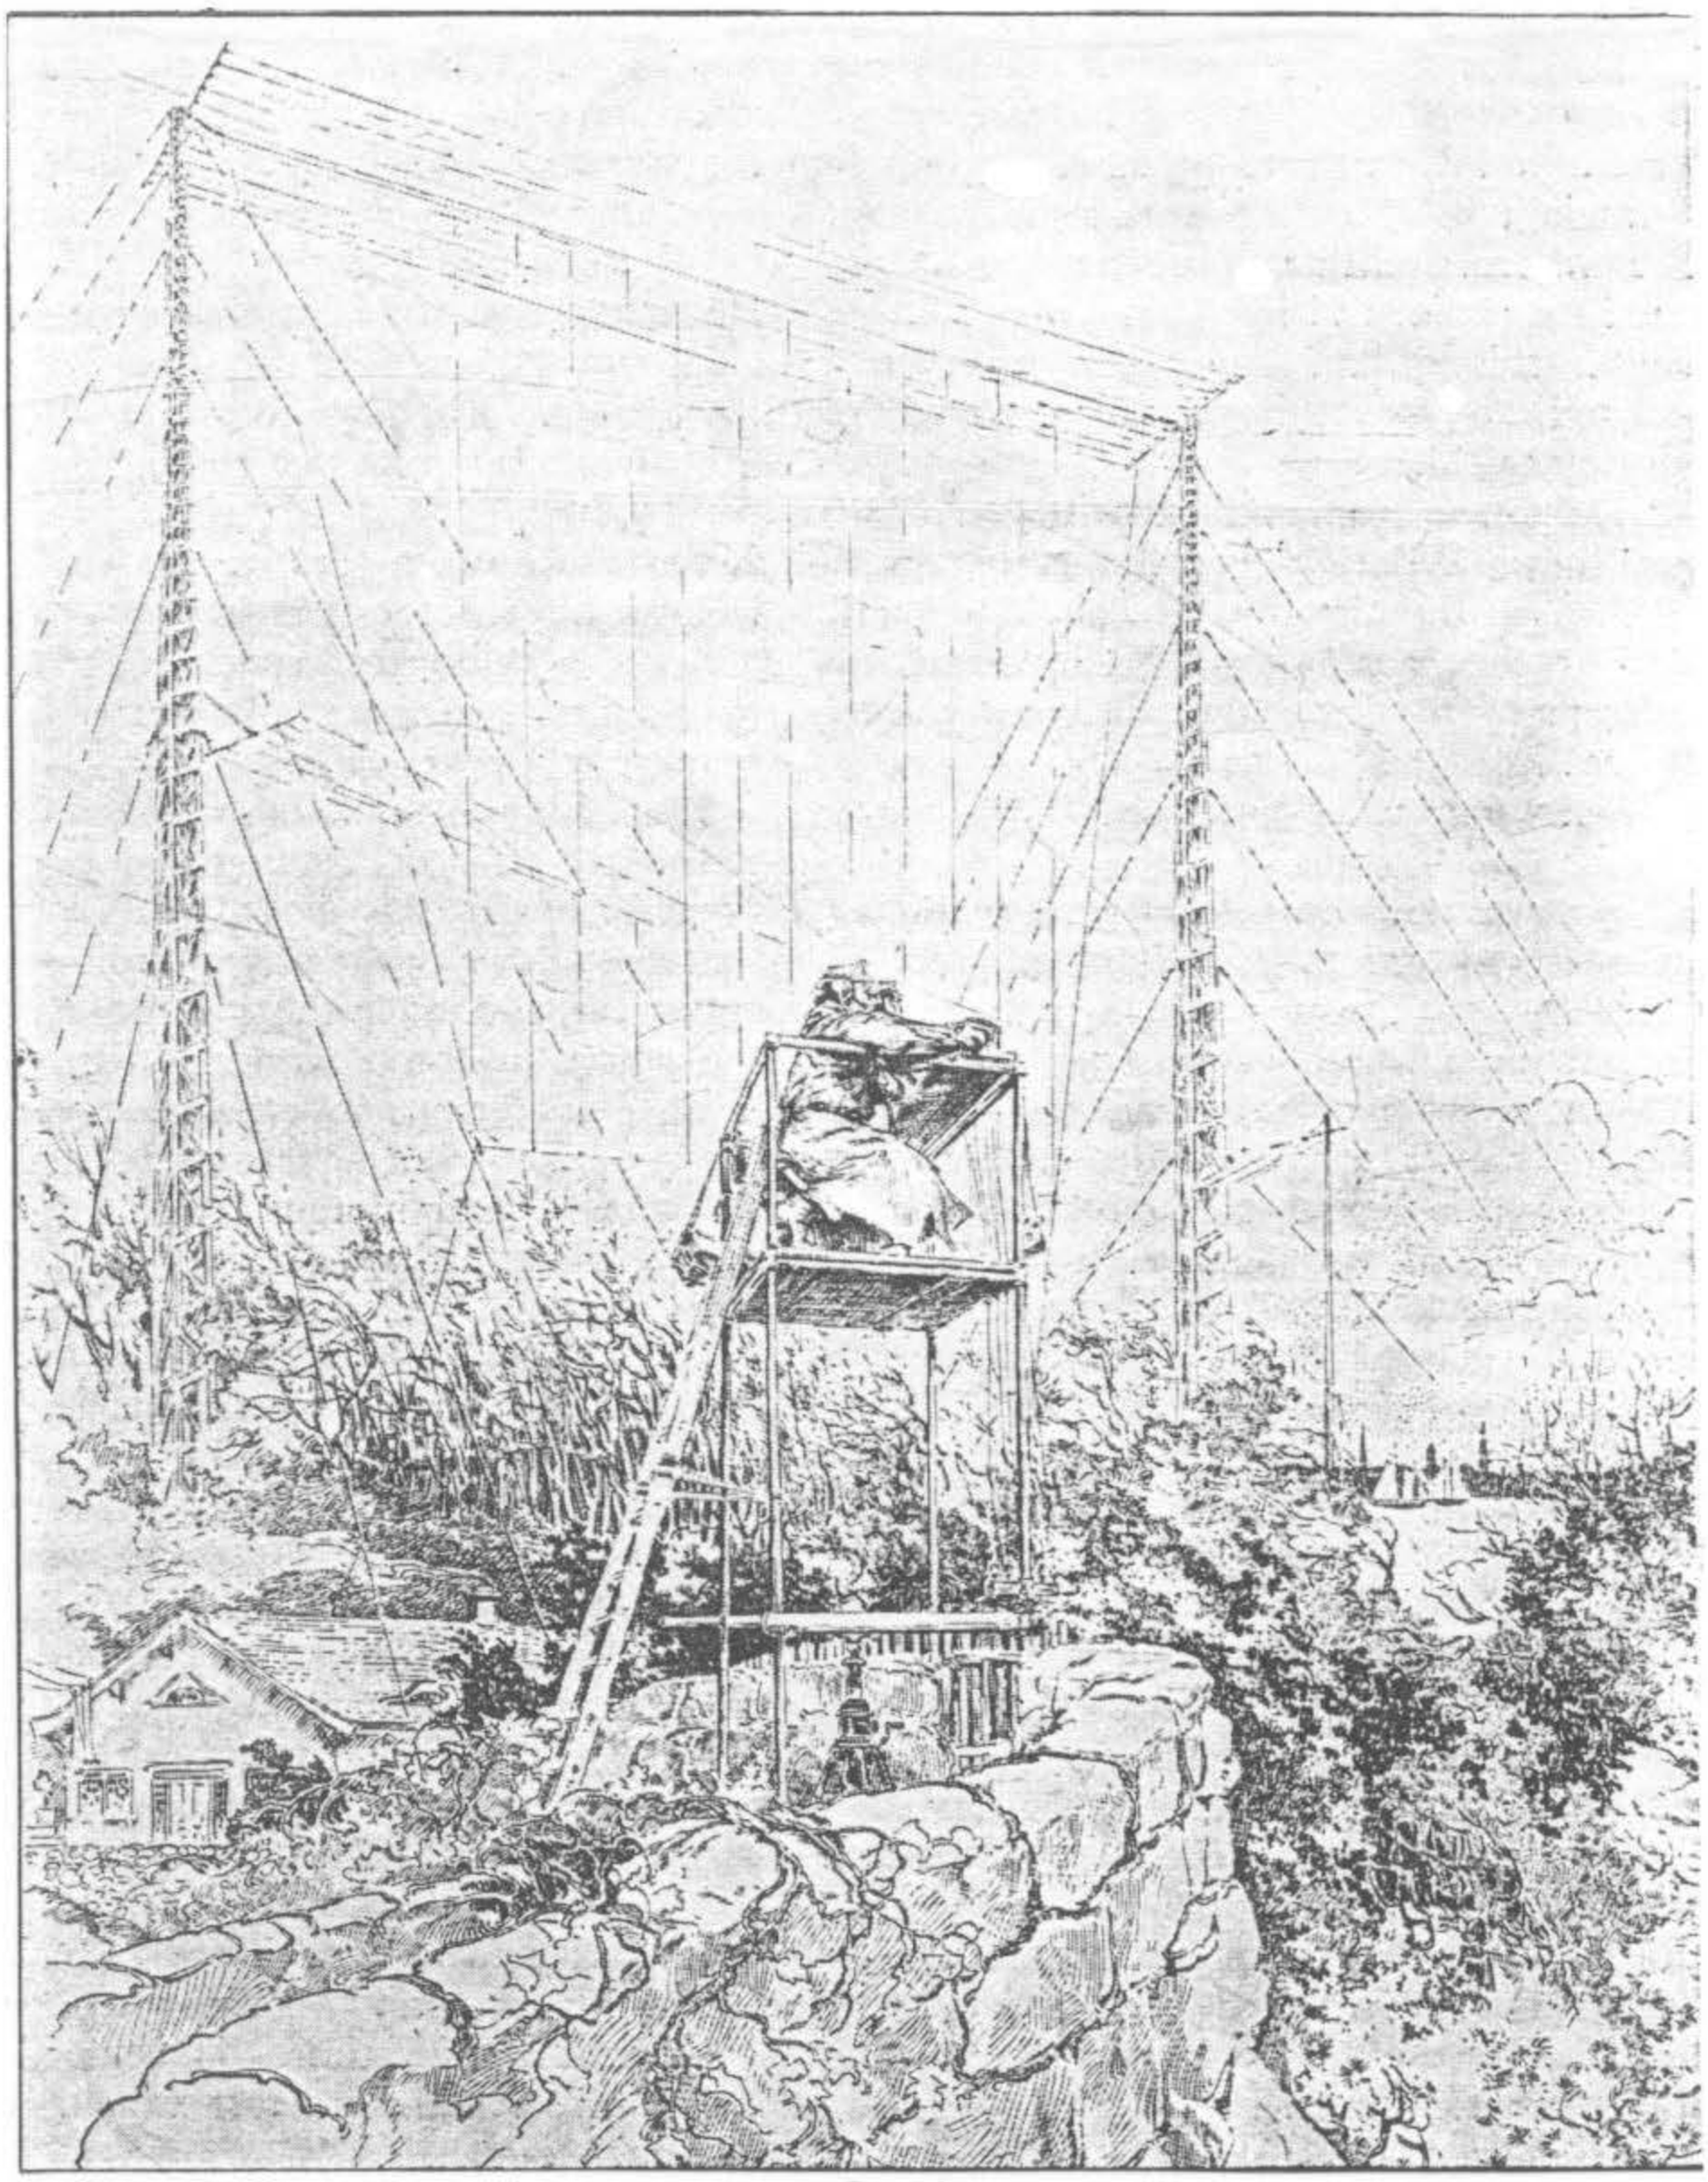
"And if I go away now, sir, and work hard at this, and after a while get something ready to show you, will you come up and see it?"

"I certainly will," promised the General. "I'll be glad to come."

That was all, but it made a world of difference to Hammond. Back he went to Gloucester with new courage in him, and worked for a whole year as he had never worked before. Nothing could stop him now. Starting with a promising detector that he had devised in New York for other electrical experiments, he was able, with the help of his laboratory staff and an expert from Harvard University, to perfect this detector so that it received the wireless impulses from shore with great reliability. When the lookout man on the cliff manipulated his key for "right" or "left," the boat went to right or left unfailingly. Needless to say, the construction of this new detector is one of Mr. Hammond's jealously guarded secrets, since his success depends upon it. The point is that this improved piece of electrical apparatus is efficient and reliable, whereas the old coherer, while admirable for the transmission of wireless messages, was inefficient and unreliable when used (as most inventors had tried to use it) for the wireless control of boats or torpedoes.

The Building of the "Radio"

This was an immense step forward, and it gave Hammond such exultant faith in his invention that he immediately set about equipping his wireless station on a larger scale, with a view to greater efficiency. The power-house was supplied with the fastest electric generators in the world, some of them turning seven hundred miles an hour — that is, they would cross the Atlantic in four hours if run on tracks. And he replaced the 150-foot sending masts with two monsters 360 feet high. Here is a sending station that can transmit ordinary wireless messages over a radius of two thousand miles, the most important private sending station in the world.



Hammond also proceeded to build a swift vessel to replace his slow-going house-boat. He must have a boat that would dart about the harbor with the speed of a railroad train. If they could control such a boat as that from the shore, they would have something worth showing. And so the *Radio* was born, a slim, rakish craft, forty feet long, with 180-horse-power engines in her, and a guaranteed speed of thirty-three miles an hour — three miles better than the promise to General Weaver.

There followed strenuous weeks in Gloucester harbor after the *Radio* began her evolutions. Aboard this boat was everything that was known in the way of radio-dynamic apparatus, and much that was unknown; for the young inventor, working with feverish energy, was facing new problems in electrical engineering, in marine engineering, in radio-engineering, and in military strategy, and was taking out a new patent every week as new discoveries called for protection. Again and again the flashing craft shot forth and manoeuvered about the harbor under invisible control, while natives of Gloucester gasped in amazement, ready to believe in any miracle — by wireless.

"That gol-derned feller," declared a grizzled fisherman, "if he saw a big liner comin' on the rocks in a storm, he'd jest ketch hold of her by wireless and turn her right plumb around and steer her out to sea again — by wireless, by gosh!"

At last everything was ready, and Hammond wrote to General Weaver, reminding him of his promise. Whereupon there was an anxious waiting time. Had the General forgotten? Had his interest waned? Would he come?

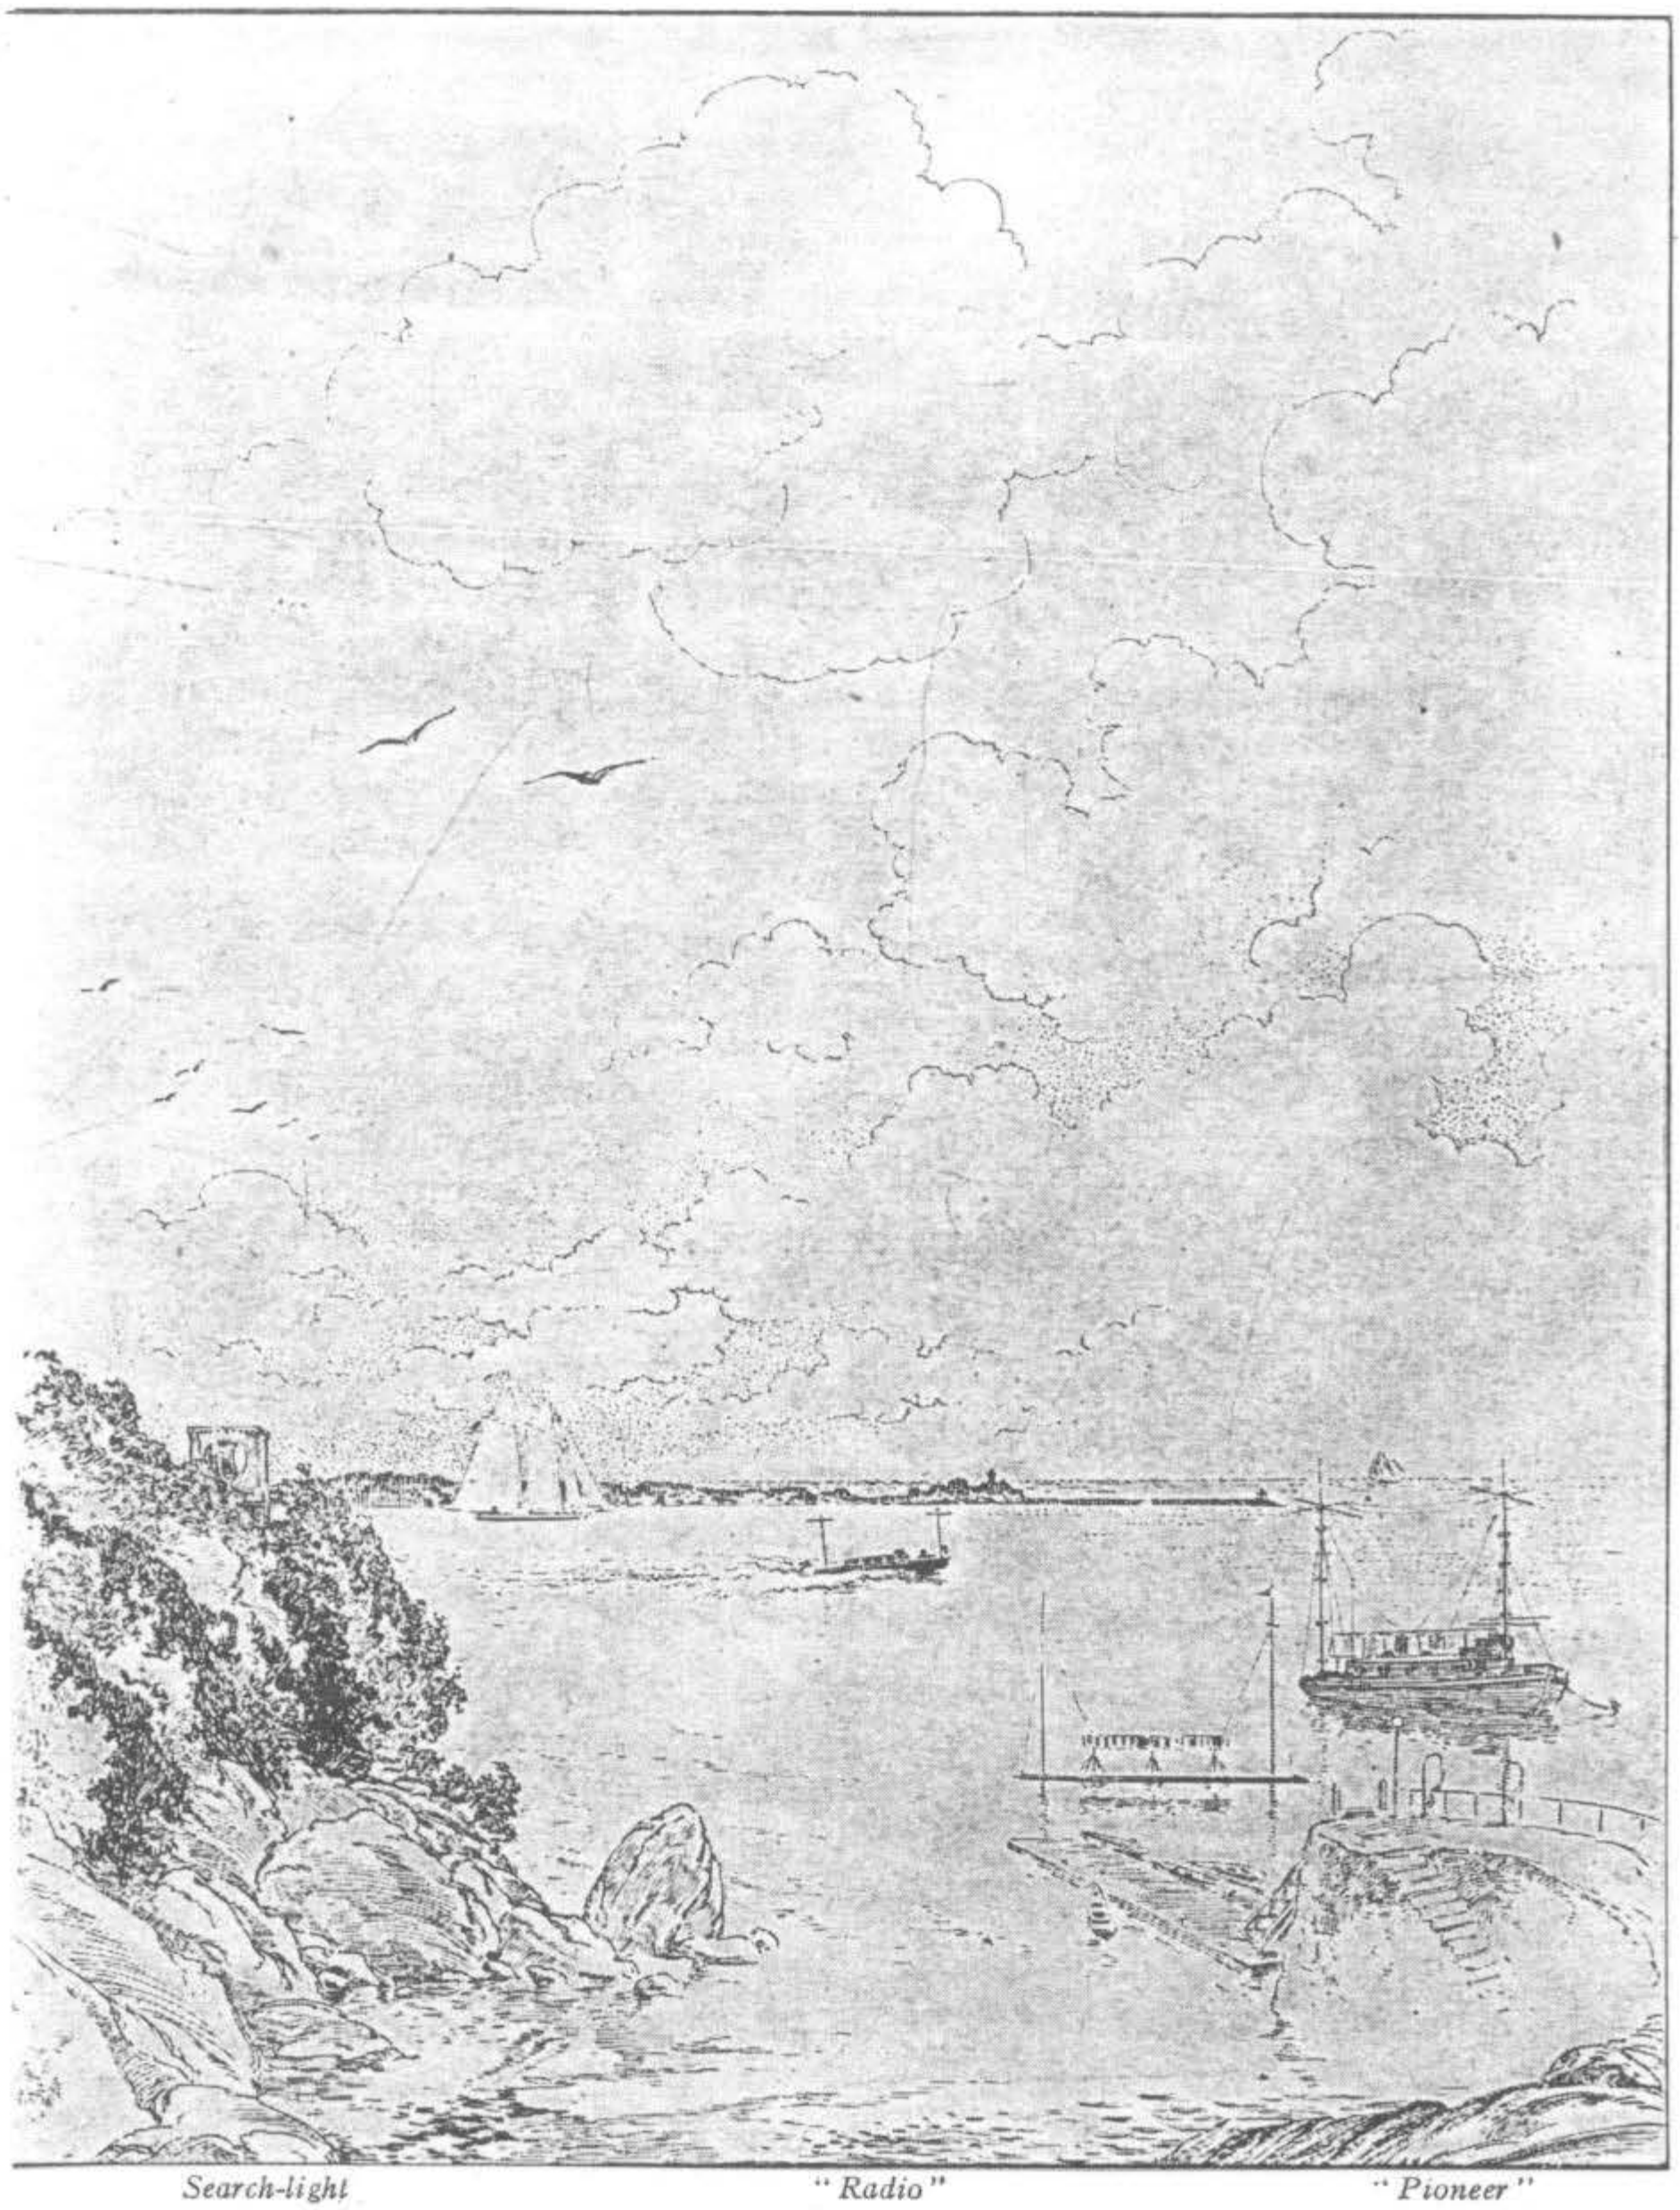
The General had not forgotten. He came, bringing with him Colonel R. P. Davis of the Coast Artillery Corps, an expert in these matters. Together they witnessed the demonstration. They saw a boat swifter than the swiftest cruiser dart about the harbor under perfect control. They saw her circle this way and that, turning instantly at the touch of a distant key. They saw her headed for a definite mark a mile away, two miles, three miles away, and strike it with precision every time — a mark that must have been blown into eternity had it been an enemy's battleship and the boat a torpedo loaded with dynamite.

Power Station *Control*

JOHN HAMMOND in his lookout station, steering his fast boat "Radio" about Gloucester of Hammond's wireless station — the most important private sending station in the world. on the "Radio" as she is sent about the harbor at night. The boat in motion is the "Radio," his wireless experiments, and with which he demonstrated to General Weaver, Chief of the United

General Weaver himself told me how, as he watched this wonderful boat, his sensations changed from skepticism to awakened interest, then to surprise, and finally to absolute amazement.

"Hold on!" he said. "I must understand this. Can you make her go to the right — now, when I say the word?"



"Certainly," said Hammond, and immediately the boat swung sharply to the right.

"Now make her go to the left."

"Left it is," said Hammond, touching the control key, and the boat obeyed.

"Make her cross the bow of that schooner."

"There, sir." As he spoke, the boat darted swiftly around the fishing-vessel, while the General stared.

Search-light *"Radio"* *"Pioneer"*

Bay by wireless. Behind Hammond are seen the power-house and the 360-foot sending masts Directly in front is the great search-light — greater than that of any battle-ship — which plays with a guaranteed speed of 33 miles an hour, which Hammond had specially constructed for States Coast Artillery, the practicability of a wireless torpedo which would revolutionize coast defense

Then Colonel Davis took a hand. "Now stop her," he said. "Now make her circle around in the opposite direction." And so on, while the boat obeyed each time.

More tests followed, full and severe tests. General Weaver himself took the key and steered the distant boat about the harbor by wireless, putting her through her evolutions with the touch of his own hand. Then Colonel Davis steered her. Then they both went aboard the *Radio* and watched, with keenest scrutiny, as she responded to the command of the distant key, as she turned swiftly this way or that with no hand directing her, but only the impulses from shore. There was no longer any possibility of doubting. The thing was done. The effective wireless control of a moving boat was an accomplished fact.

At the end of this demonstration General Weaver said things that made Hammond blush like a boy and thrill with the pride of achievement. The General was absolutely convinced. This was a most important invention. If nations could send out from their shores, at comparatively small cost, engines of destruction capable of outrunning and annihilating, one by one, the units of a hostile fleet, then the value of torpedo defense would be immensely increased. Even in the present state of the invention it would be possible to use in attack a swift boat like the *Radio*, carrying ahead a downward slanting spar with a mass of explosive at the end (this being under water) that could be steered against an enemy's ship and destroy it.

Since General Weaver's visit to Gloucester, the work has proceeded steadily under army supervision and great strides have been made along the lines of military effectiveness. Day by day and night by night, the wireless boat makes her trips with experts aboard and ashore, recording the results, noting every slightest fault in the transmitting or receiving apparatus, every error or inadequacy, so that these may be remedied and this invention stand upon a solid engineering basis. When that is accomplished (and the time is near) the wireless torpedo, running under water, will be built and operated in the same way, with the same machinery, the same electrical contrivances, and the same method of shore control.

How the Wireless Boat Will Be Used in War

"How far from shore will you be able to control a boat or a torpedo by wireless?" I asked Mr. Hammond.

"About seven miles," he said; "but that is only because of the limitation of human vision. The lookout man can see only seven miles over the ocean, and, of course, he can not steer a boat or a torpedo unless he can see it. As far as our sending station goes, we can throw out efficient guiding impulses over a radius of, say, fifty miles. Which means, from a military point of view, that one sending station is sufficient to defend a hundred miles of coast-line, fifty miles to the right and fifty miles to the left, but for each sending station there must be many lookout stations, each connected with a central source of electrical [wireless] supply."

"Could an enemy's ships disable a sending station by shooting at its high masts?"

"No; because our sending stations will be placed sufficiently inland to be out of range, or they will be protected by intervening hills. In certain cases it may be possible to equip a station with disappearing masts. I have patented such a device."

"How about counter-attack by an enemy's fleet upon these shore-controlled torpedoes?"

"That will be extremely difficult. It is true our torpedoes will be partly exposed above the water, that is, they will show two short receiving masts and a low white framework to carry guiding lights by night and to be seen itself by day. Of course, we must see our torpedoes in order to steer them; but there is a great difference between seeing a torpedo and hitting it. And if one torpedo should be struck, in spite of its speed and smallness, we would send out another and another. Or we would send out a whole flock of them at the same time, which would confuse the enemy. A dozen of these torpedoes will not cost one tenth as much as a single battleship."

The New Coast Defense

"Will this method of torpedo attack change the existing equipment of our coast defenses?"

"Only to the extent of becoming a valuable addition. Shore-controlled torpedoes, used conjointly with the existing system of coast defense, will constitute a practically impregnable barrier against an enemy."

"Is it possible to blow up a ship's powder magazines by projecting upon them wireless waves sent through the ether?"

"That is absolute nonsense. The experiments of an Italian engineer along this line, that have been so widely noticed in the American press, have been shown to be pure fakes. The man was ordered out of French territory as an impostor."

"How about interference with the wireless waves by opposing wireless waves? Could not an enemy create disturbances in the ether that would confuse or nullify the shore control?"

"You are asking a rather delicate question," answered Mr. Hammond, "but I will say this: that a land station has a great advantage over a vessel, because the electrical power and the electrical wave lengths that it can throw forth are unlimited, whereas in a vessel (owing to space restrictions) these are very decidedly limited. Furthermore, it is

possible for a land station to set up in the ether such a confusion of wave lengths that it would take the enemy hours or days, under favorable conditions, to discover which was the controlling wave length, and meantime the torpedo attack would have been made and the damage done. That, you know, is a matter of minutes."

Mr. Hammond went on to explain that he and his laboratory staff have studied every electrical move that an enemy could make against the attack of shore-controlled torpedoes, and have devised answering electrical moves to meet them.

Hammond Steers His Boat by the Sound of His Voice

I may note here, as an interesting fact, that Mr. Hammond, in fulfilment of his college promise, has finally succeeded in steering his wireless boat by the sound of his voice. He does this when the boat is several miles out at sea, standing on the cliff and speaking quietly into a telephone receiver, saying: "Right!" whereupon the distant boat turns instantly to the right, then saying, "Go left!" and she obeys his word, swinging sharply to the left.

This sounds like an impossible fairy tale; but it is a plain statement of fact. Nor is there anything complicated or mysterious in this operation. It is a perfectly simple thing to do. I did it myself. Mr. Hammond's cook did it. Any one could do it, the explanation being that, by a sound-amplifying device, the vibrating energy of spoken words (*any* words) is made to do the work usually done by the wireless key under pressure of a finger.

Similarly, Mr. Hammond has amused himself, and vastly astonished an audience, by saying, "Fire!" into the telephone receiver, whereupon a charge of dynamite in a distant room has promptly exploded. It would have exploded just the same if he had said, "Artichoke!" It could have been made to explode by a fly walking across a window-pane; for an infinitesimal force may close an electric circuit that will set free energy enough to blow up the Panama Canal.

A few weeks ago, in Washington, I had a talk with General Weaver regarding Mr. Hammond's invention.

"These shore-controlled torpedoes, if perfected," said the General, "will be an important addition to our means of coast defense. At present these means are threefold, namely: guns that fire directly at a vessel and aim to penetrate her side armor, mortars that fire high in the air and aim to penetrate her deck armor with falling projectiles, and mines laid to blow up a vessel passing over them. Of course the efficiency of submarine mines is limited by the fact that a vessel must come to them, whereas a dirgible torpedo will go to the vessel.

"We have always realized the desirability of submarine torpedoes controlled from shore, as affording a means of attack upon a vessel's submerged parts, but the difficulty has been to control these torpedoes in their courses. We have tried to steer them by wires unreeled from the torpedo or unreeled from shore, but the results have been unsatisfactory, owing to the disturbing influence of tides and currents. This wireless method of Hammond's, however, promises real precision in attack."

Here, then, is a very definite result of a school-boy's dream. The shore-controlled torpedo is passing through the last stages of its evolution. It is an easy step from the swift boat running *on* the water to a similar swift boat running *under* the water. Who can doubt that this step will be successfully taken? Think of the wonders of wireless already achieved! Clocks are run by wireless. The exact time is sent around the world by wireless. Photographs have been transmitted hundreds of miles by wireless. Bells on buoys have been made to ring their warnings to approaching vessels by wireless energy sent from those vessels. Locomotives have been operated by wireless, with no engineer at the throttle. Train signals are set by wireless. Soon, beyond question, we shall have the torpedo operated by wireless — the ultimate torpedo — and the navies of the world are waiting apprehensively for its appearance.

Tributes of Former Associates

It is not in one profession alone that the memory of Westinghouse will live. Kelvin said of him: "George Westinghouse is in character and achievement one of the great men of our time." Physically he was a big man; he also was great in character and mind. Interesting sidelights on his brilliant career contributed by men formerly associated with him and published herewith show how highly he was esteemed, and what was lost in his passing away.

From William Stanley

I can only add my appreciation of the great qualities of leadership that Mr. Westinghouse possessed. His strong, vigorous purpose, his wonderful grasp of the opportunities of life and his high courage overcame all obstacles and were of inestimable value to the electrical engineering profession and the world.

Great Barrington, Mass. WILLIAM STANLEY.

From Peter Cooper Hewitt

In George Westinghouse the world has suffered the loss of a great and valued citizen and much should be said in honor of his accomplishments and advancement of modern industry. Essentially an American, he had universal reputation and respect.

The vast and divers works which he pioneered give an idea of his force and energy and illustrate dominant characteristics. Every effort of his genius was expended for humanity in advancing the arts of civilization. As the problems involved in nature's secrets unfolded themselves before him he strained every effort and means at his disposal to turn their use to the benefit of mankind.

He appreciated the enormous danger to humanity that accompanies the harnessing of vast forces of nature for public use, and by his foresight and skill prevented disasters which might conceivably have been of enormous extent.

The memory of George Westinghouse will live through his appreciation of nature's forces and his love of mankind.

New York. PETER COOPER HEWITT.

From Nikola Tesla

The first impressions are those to which we cling most in later life. I like to think of George Westinghouse as he appeared to me in 1888, when I saw him for the first time. The tremendous potential energy of the man had only in part taken kinetic form, but even to a superficial observer the latent force was manifest. A powerful frame, well proportioned, with every joint in working order, an eye as clear as a crystal, a quick and springy step—he presented a rare example of health and strength. Like a lion in a forest, he breathed deep and with delight the smoky air of his factories. Though past forty then, he still had the enthusiasm of youth. Always smiling, affable and polite, he stood in marked contrast to the rough and ready men I met. Not one word which would have been objectionable, not a gesture which might have offended—one could imagine him as moving in the atmosphere of a court, so perfect was his bearing in manner and speech. And yet no fiercer adversary than Westinghouse could have been found when he was aroused. An athlete in ordinary life, he was transformed into a giant when confronted with difficulties which seemed unsurmountable. He enjoyed the struggle and never lost confidence. When others would give up in despair he triumphed. Had he been transferred to another planet with everything against him he would have worked out his salvation. His equipment was such as to make him win easily a position of captain among captains, leader among leaders. His was a wonderful career filled with remarkable achievements. He gave to the world a number of valuable inventions and improvements, created new industries, advanced the mechanical and electrical arts and improved in many ways the conditions of modern life. He was a great pioneer and builder whose work was of far-reaching effect on his time and whose name will live long in the memory of men.

The New York Herald March 23, 1914

MR. TESLA'S PATENTS

TO THE EDITOR OF THE HERALD:—

The reports contained in the HERALD and other journals regarding the issue of a recent wireless patent suit are of a nature to create an erroneous impression in of the patents mentioned, namely, No 11,913 and No. 609,154, granted, respectively, to William Marconi and Sir Oliver Lodge, are of no importance. but another patent of the former expert, dated June 25, 1900, contains arrangements on which I obtained full protection more than three years before. * * *

The apparatus described by me comprises four circuits, peculiarly tuned and carefully attuned so as to permit greatest possible flow of electrical energy through them. The generator is a transformer of my invention and the oscillations employed are of a kind which is now known in technical literature as the Tesla currents. Every one of these elements, even to the last detail is contained in the Marconi patent which was involved in the suit, and its use constitutes an infringement of all the fundamental features of my wireless system.

NIKOLA TESLA

NEW YORK CITY, March 20, 1914

LXV. *Induction-Coil Potentials.*

By E. Taylor Jones, *D.Sc., Professor of Physics in the University College of North Wales, Bangor* *.

[Plate VIII.]

THE present paper contains some further applications of the theory of electrical oscillations in coupled circuits, and is a continuation of two former papers † on the subject.

In the first of these it was shown that if a given current is interrupted in the primary of two coupled oscillatory circuits, the potential-difference, V_2, at the terminals of the secondary at any subsequent time t is theoretically given by an expression of the form

$$A_1 e^{-k_1 t} \sin(2\pi n_1 t - \delta_1) - A_2 e^{-k_2 t} \sin(2\pi n_2 t - \delta_2), \quad . \quad . \quad (1)$$

where n_1, n_2 are the frequencies of the two oscillations of the system, and the other six constants can be calculated from the capacities, inductances, and resistances of the circuits. This result was illustrated by a number of examples in which coupled air-core coils connected to condensers were used. The wave of potential represented by (1) was worked out for each case and compared with the experimental curve obtained with an electrostatic oscillograph.

In the second paper referred to, the expression (1) was further illustrated by experiments with an ordinary induction-coil with iron core, a number of cases being worked out in some of which the secondary coil, as well as the primary, was connected to a condenser. In these experiments, however, the primary (paraffin-paper) condenser was of considerably greater capacity than that generally used with an induction-coil.

Recently an expression of the form (1) has been given in an important paper by Dibbern ‡ for the potential-difference at the plates of the *primary* condenser, and the theoretical curves of both primary and secondary potential compared with the experimental curves obtained with a pendulum interruptor. In his experiments Dibbern used coils with air-cores, cores of iron-filings in paraffin-wax, of iron wire, and of solid iron. Good agreement was found between the

‡ E. Dibbern, *Ann. d. Physik*, xl. 4, p. 935 (1913); Inaug.-Diss., Kiel.

theoretical and experimental curves for the coils with air-core and with the core of iron-filings, fair agreement in the case of the iron-wire core.

In the present paper further tests are described of the applicability of the theory to the case of an induction-coil. In these, smaller primary capacities were used, and the constants of the circuits were determined in actual working conditions. The effect of varying the primary capacity is specially considered, and a view is put forward which differs from that usually held as to the function and the most effective value of this capacity.

There are two things which should be borne in mind in determining the constants of the primary and secondary circuits of an induction-coil. The first is that, owing to the variable permeability of the core, it is necessary to use mean values of the induction-coefficients, which can only be expected to give correct values for the secondary potential over a limited range of values of the primary current.

The other is that the induction-coil as generally used has the terminals of its secondary coil connected to bodies of very small capacity, *e. g.* spark-gap terminals, the electrodes of an exhausted tube, or an electrometer or electrostatic oscillograph of very small capacity. In these circumstances, the capacity of the secondary circuit is mainly distributed along the secondary coil, and when the oscillations are taking place and no discharge is passing, the current is not uniform throughout the length of this coil, but is greatest at the central winding and very nearly zero at the terminals *. The system is in fact similar to that of the oscillation transformer, or Tesla coil, the theory of which was given by Drude †.

The expression "mutual inductance" is not appropriate to such a system, but if (in Drude's notation) L_{12} is the coefficient of induction of the secondary on the primary, and L_{21} that of the primary on the secondary, then L_{12} is less than L_{21}. L_{12} is defined as the magnetic induction through the primary coil due to the secondary current divided by the value of the latter in the central winding. On the other hand, the terminals of the primary coil are connected to a condenser of considerable capacity, so that the current in this coil is uniformly distributed. The coefficient L_{21} is

* As the current varies (in its fundamental oscillation) as the cosine of an angle proportional to the distance from the central winding, this distribution of current will be referred to as a cosine distribution.

† Drude, *Ann. d. Physik*, xiii. p. 512 (1904).

therefore equal to the "mutual inductance" of the coils as usually defined, *i. e.* the induction through the secondary due to the primary current divided by the value of the latter.

For similar reasons the self-inductance L_2 of the secondary coil is less than the value for steady or for uniformly distributed currents, while L_1 has the usual meaning. The coefficient of coupling, k, of the coils is defined by

$$k = \sqrt{L_{12} \cdot L_{21}/L_1 L_2}.$$

The value of the secondary capacity, C_2, depends upon the manner in which the charge is distributed in the secondary coil, but it is unnecessary to determine it. For the purpose of calculating the secondary potential V_2 from the expression (1) it is sufficient to know the values of the six quantities L_1C_1, L_2C_2, L_{21}, k, R_1/L_1, R_2/L_2. R_1 and R_2 are the effective resistances of the primary and secondary circuits.

These six quantities were determined as described below for an 18-inch-spark coil *, with three primary condensers of capacities about 3, 2, and 1 microfarad respectively. These condensers had mica insulation, and for the sake of definiteness were connected directly across the terminals of the primary coil. If the condenser is connected across the interruptor in the usual manner, the primary circuit then includes the battery, amperemeter, and rheostat, and the self-inductance and resistance of the primary circuit will, therefore, be different in different experiments.

The secondary terminals were connected directly to the oscillograph, in parallel with which was a variable spark-gap consisting of two brass spheres, each 2 cm. in diameter, supported on ebonite pillars. The oscillograph has been described in a former paper †. The instrument has very small electrostatic capacity, and in its present form it can be used directly for potentials sufficient to give a 24-cm. spark between the ball electrodes.

Determination of L_{21}.

This coefficient, which, as explained above, is equal to the mutual inductance of the primary and secondary coils, was determined by two methods. In the first it was compared with a known mutual inductance by the ballistic galvanometer

* The primary coil was in four sections. Except where otherwise stated these were all in series.

† E. T. Jones, Phil. Mag. xiv. p. 238 (1907). *Cf.* also *l. c.* (2), p. 708.

deflexion method. The value so found was 20·4 henries for a primary current of 5 amperes. By comparison with this, the same method being used, values of L_{21} were then obtained for other values of the primary current i_0. The results are given in Table I.

TABLE I.

i_0, amperes.	L_{21}, henries.	i_0, amperes.	L_{21}, henries.
0·195	12·9	2·49	20·0
0·395	14·7	3·00	20·2
0·57	16·0	3·52	20·3
0·75	16·9	4·00	20·4
1·00	17·8	5·00	20·4
1·25	18·6	6·86	20·3
1·50	19·0	8·01	19·9
1·75	19·2	10·06	19·0
2·00	19·6	11·04	18·4

It will be seen from the table that L_{21} has its maximum value at 4 or 5 amperes, and that over the range 3 to 7 amperes it does not vary by more than 1 per cent. As most of the experiments described below were within this range, the value 20·4 was adopted for L_{21} in working out the theoretical expression (1) for the secondary potential.

The other method of determining L_{21} is to take the value of k^2 measured with a condenser of considerable capacity in the secondary circuit, as described in the next section, in which case

$$k^2 = M^2/L_1L_2 = L_{21}^2/L_1L_2.$$

The values of L_1, L_2 being found from the periods of oscillation of the primary and secondary circuits when connected to condensers of known capacity, L_{21} can then be calculated from

$$L_{21} = \sqrt{k^2 L_1 L_2}.$$

The values found were

$$k^2 = \cdot 839, \quad L_1 = \cdot 194 \text{ henry}, \quad L_2 = 2540 \text{ henries}.$$

Hence $$L_{21} = 20\cdot 3 \text{ henries},$$

which is almost identical with the maximum value found by the other method. It may be concluded that up to the frequencies used in this experiment the induction coefficients of the coils are not very different from their values for steady currents.

The Coefficient of Coupling.

The coupling coefficient, k, was determined by finding the frequency of the oscillations of the secondary coil (connected only to the oscillograph and ball electrodes), with the primary coil open and with the primary terminals connected by a short piece of wire. The ratio of the squares of these frequencies is $1-k^2$. These oscillations were started by sparking to the ball electrodes with two pointed conductors connected to a second induction-coil, and the curve of potential was photographed in the usual way. With the primary closed the oscillation curve only appeared with great difficulty, and many exposures were taken before a photograph sufficiently good for measurement was obtained. The amplitude of the curve was small, but was sufficient to allow the period to be determined with fair accuracy. The frequency was found to be 1246. With the primary open the frequency was 599·4. This was measured near the end of the curve where the amplitude, and consequently the magnetizing current, is small, in order to minimize as far as possible any error arising from the difference in the degree of magnetization of the core in the two experiments due to the shielding action of the induced current in the primary when on closed circuit.

These frequencies give the value ·768 for k^2. The value given in the former paper* for the same two coils was ·8142. This was determined by a similar method, in which, however, a condenser was connected to the terminals of the secondary coil. It appears, therefore, that the coefficient of coupling of the coils (for natural oscillations) is less when the terminals of the secondary coil are free or connected to bodies of very small capacity, than when they are connected to a condenser of considerable capacity, in which case the oscillating current in the secondary is more nearly uniformly distributed.

The matter was further tested by determining the coupling coefficient with the secondary coil connected to various capacities, the largest being a leyden-jar of about ·001 microfarad, and the smallest consisting of two tinfoil sheets, 19·94 square centimetres in area, separated by a glass plate

* *L. c.* (2), p. 716.

0·61 cm. thick. The results are given in Table II., the capacities being in descending order of magnitude.

TABLE II.

Condenser.	Frequency with primary open.	Frequency with primary closed.	k^2.
A	99·1	247·3	·839
B	218·0	519·0	·824
C	276·0	630	·808
D	355·6	792	·798
E	408·0	897	·793
F	455·0	989	·788
none	599·4	1246	·768

Specimens of the photographs used in these measurements are shown in Plate VIII. figs. 4 & 5. In fig. 4 the first three waves correspond to the exciting spark, the remainder to the free oscillation. The lower wave is the trace of a 768 tuning-fork photographed simultaneously. The numbers in the fourth column show a gradual falling off of the coefficient of coupling as the capacity connected to the secondary coil diminishes, *i. e.* as the current changes from the uniform to the cosine distribution. The question, however, arises whether this diminution of k^2 is due to the change in the distribution of the current, or whether it is not due to some other cause, *e. g.* to a falling off in the intensity of magnetization of the core as the frequency of the oscillation increases. For a given potential at the terminals of the secondary condenser the magnetizing current diminishes as the capacity of the condenser diminishes, being in fact inversely proportional to the frequency of the oscillations. Hence it might be expected that the permeability of the core, for oscillations of given amplitude, would fall off as the capacity of the condenser diminishes. The question whether this appreciably affects the value of k^2 was tested by repeating the experiment with the largest capacity (condenser A) with a much smaller potential. The method was the same, but a much smaller discharge was employed for starting the oscillation, and the most sensitive form of electrometer * was used for obtaining the curve. The potential and current in this experiment were not more than one-fifth of those employed in the former determination, and the value of k^2 obtained was ·820. Hence the

* *Cf.* Phil. Mag. xiv. p. 240 (1907).

diminution of the intensity of magnetization of the core with increasing frequency is not sufficient to account for the large falling off in the value of k^2 shown in Table II.; and we may conclude that the drop in k^2 is due to the change in the distribution of the current in the secondary coil, *i. e.* that as the current changes from the uniform to the cosine distribution, the coefficient L_{12} diminishes more rapidly than L_2. It would be interesting to make similar measurements of k^2 for coils of different dimensions and forms, especially coils with non-magnetic cores.

In the above method for measuring k^2 the oscillations were all started by sparking to the terminals of the secondary coil. There is, however, another way of setting up the oscillations with the primary coil closed, which may be referred to here. If the interruptor of an induction-coil is connected in a shunt across the primary coil, instead of being in the main circuit as usual, when contact is made the primary coil becomes short-circuited and its current begins to decay exponentially. At the same moment oscillations of small amplitude are set up in the secondary, and these are the natural oscillations of the secondary with the primary closed. The potential at the terminals of the secondary coil may be represented by the expression $ae^{-kt} + b \sin nt$, and the electrometer (being connected idiostatically) shows a deflexion which is proportional to the square of this quantity. This includes a term proportional to $\sin nt$, and another proportional to $\cos 2nt$. The curve should therefore show an oscillation of frequency $n/2\pi$ and another of twice this frequency. As a rule the slower oscillation is much the more prominent, though traces of the octave appeared in some of the photographs.

The most prominent feature of the curves obtained was, therefore, an oscillation of frequency $n/2\pi$, *i. e.* the frequency of the oscillations of the secondary with primary closed, and not twice this frequency as is the case in the sparking method.

This "short-circuiting" method was tried with various capacities in the secondary circuit. Owing to the smallness of the amplitude of the oscillations, the most sensitive form of electrometer had to be used. The potential at the secondary terminals was in fact not sufficient to produce a 1 mm. spark between the ball electrodes.

The frequencies obtained by both methods are given for comparison in Table III., and one of the curves obtained by the short-circuiting method (no condenser) is shown in Plate VIII. fig. 6.

TABLE III.

Condenser.	Frequency of secondary.	
	Sparking method.	Short-circuiting method.
A	247·3	245·9
B	519·0	517·8
C	630	636
F	989	1026
none	1246	1266

It will be seen that there is no great difference between the results obtained by the two methods. Such differences as exist are to be accounted for by the difference in the circumstances of the experiments. In the sparking method the iron core is initially unmagnetized, and the oscillations are accompanied by reversals of the induced magnetism. In the short-circuiting method the core is initially strongly magnetized, and as the magnetization decays the oscillations produce small fluctuations in its intensity. The difference between the two cases may be illustrated by saying that, if N is the total flux of induction in the core and i the current in the secondary coil, then in the sparking method the frequency depends upon the coefficient N/i, whereas in the short-circuiting method it depends upon dN/di, and the value of this latter coefficient will be modified to some extent by the hysteresis of the core.

The circumstances of the sparking method are in closer accord with those of the actual case of an induction-coil, and the result obtained by that method, viz. $k^2=\cdot768$, is therefore adopted in the calculations of potential described below.

Determination of L_1C_1, L_2C_2, R_1/L_1, R_2/L_2.

The expression (1) for the secondary potential was worked out for three cases in which mica condensers, of capacities stated to be 3, 2, and 1 microfarad respectively, were connected across the primary coil. These values were, however, not assumed, but rather the value of the product L_1C_1 was determined for each case. This was done by coupling the primary (with the condenser across its terminals) loosely with a secondary of many windings to the terminals of which the electrometer was connected. The most sensitive electrometer

was used in order that the coupling of the two coils might be made as loose as possible. The oscillations were started by interrupting a current of 5 amperes in the primary, and the curves were photographed and measured in the usual way. The product L_1C_1 was calculated from the frequency, the ratio R_1/L_1 from the logarithmic decrement, of the oscillation curve. The results of these measurements are given in Table IV. The corresponding quantities for the secondary circuit, L_2C_2 and R_2/L_2, were determined from the period and logarithmic decrement of the oscillation produced in the secondary when a current of 5 amperes in the primary was interrupted. In this experiment the primary condenser was removed, and the secondary coil was connected only to the electrometer and the ball electrodes, so that the secondary capacity was the same as in the final experiments. The values so determined are given under Table IV. It should be observed that these values of L_1C_1 and L_2C_2 are maximum values, *i. e.* they correspond to a magnetizing current of about 5 amperes in the primary coil.

The effective resistances of the coils in the circumstances of the present experiments, as determined from the damping of the oscillations, are much greater than their resistances for steady currents. The influence of these resistances on the periods of oscillation is, however, neglected in all calculations in the present paper, *i. e.* both in the determination of L_1C_1 and L_2C_2 described above, and in the calculation of the frequencies of the coupled system given in the next section. That no great error is thereby introduced is shown by the close agreement between the observed and calculated periods in the final experiments.

Calculation of the Secondary Potential.

The formulæ used in the calculation of the frequencies, amplitudes, and damping factors of the two oscillations are collected here :—

$$8\pi^2(n_1^2, n_2^2) = \frac{1}{1-k^2}\left[\frac{1}{L_1C_1} + \frac{1}{L_2C_2} \pm \sqrt{\left(\frac{1}{L_1C_1} - \frac{1}{L_2C_2}\right)^2 + 4k^2 \cdot \frac{1}{L_1C_1} \cdot \frac{1}{L_2C_2}}\right],$$

$$A_1 = \frac{2\pi L_{21} i_0 n_1 n_2^2}{(n_2^2 - n_1^2)\cos\delta_1},$$

$$A_2 = \frac{2\pi L_{21} i_0 n_1^2 n_2}{(n_2^2 - n_1^2)\cos\delta_2},$$

$$k_1 = 4\pi^2 n_1^2 \left(\frac{\theta_1+\theta_2}{2} - \beta\right),$$

$$k_2 = 4\pi^2 n_2^2 \left(\frac{\theta_1+\theta_2}{2} + \beta\right),$$

where

$$\theta_1 = \frac{1}{2} R_1C_1 = \frac{1}{2}\frac{R_1}{L_1} \cdot L_1C_1,$$

$$\theta_2 = \frac{1}{2} R_2C_2 = \frac{1}{2}\frac{R_2}{L_2} \cdot L_2C_2,$$

$$\beta = -\frac{2\pi^2 n_1^2 n_2^2}{n_2^2 - n_1^2}(\theta_1 - \theta_2)(L_1C_1 - L_2C_2),$$

and i_0 is the current interrupted in the primary.

These expressions are, with a change of notation, the same as those used in the former papers.

In the case of the phase-angles δ_1, δ_2, however, new formulæ are required owing to the fact that in the former papers no account was taken of the difference between the effective resistances and the steady-current values. This affects the initial conditions of the problem, which now become at $t = 0$,

$$-C_1\frac{dV_1}{dt} = i_0, \quad V_1 = R_0 i_0 *, \quad \frac{dV_2}{dt} = 0, \quad V_2 = 0,$$

where R_0 is the resistance of the primary for steady currents.

* If the condenser is connected across the interruptor in the usual way the corresponding initial condition is $V_1=0$, and the solution for this case may be obtained by putting $\theta_0=0$ in the final equation given below.

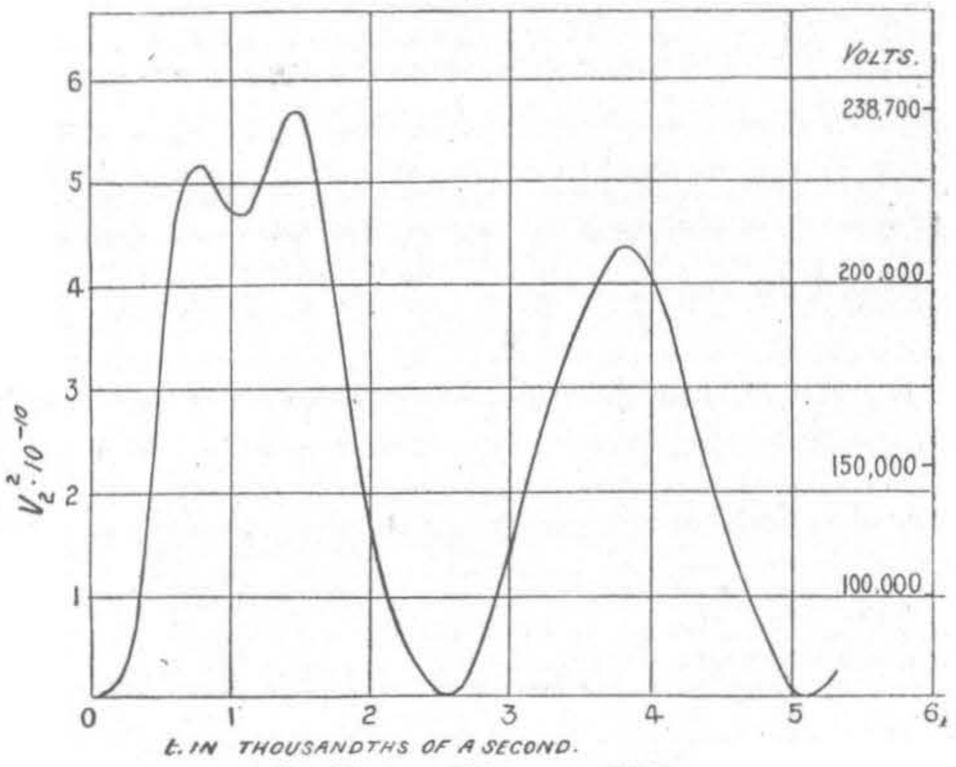
V_1 is the difference of potential at the terminals of the primary condenser which, for the reasons stated above, was connected directly across the primary coil.

The expression for V_2 was accordingly worked out afresh for these new initial conditions, and the results show that the values of δ_1 and δ_2 are considerably modified by the change in the conditions. The expressions arrived at are

$$\tan\delta_1 = 2\pi n_1\left\{2\beta \cdot \frac{n_1^2+n_2^2}{n_2^2-n_1^2} - (\theta_1 - 2\theta_0 - \theta_2)\right\},$$

$$\tan\delta_2 = \frac{n_2}{n_1} \cdot \tan\delta_1.$$

These reduce to the expressions used in the former papers if θ_1 is made equal to θ_0, *i. e.* R_1 to R_0.



In arriving at the above expressions the squares and product of θ_1, θ_2 are neglected. The fuller expressions for $\tan\delta_1$, $\tan\delta_2$, including these second order terms, were also, however, worked out for each of the three cases, and found to give values not differing greatly from those calculated from the above formulæ. The difference in δ_1 was in each case quite negligible, and in δ_2 less than 1° except in Case II., where it amounted to 2°·5. The values of δ_1, δ_2 given in Table V. are those given by the more exact formulæ. This table contains the values of the eight constants of the formula (1) for each of the three cases, the amplitudes being given in volts for $i_0 = 10$ amperes.

TABLE V.

	n_1.	n_2.	A_1.	A_2.	k_1.	k_2.	δ_1.	δ_2.

Final Experiments and Conclusions.

One of the experimental curves for each case is shown in Plate VIII. figs. 7, 8, 9 *. In obtaining them the external circuit (*i. e.* the battery branch) was made as nearly non-inductive as possible, the connecting wires being well twisted together and the current being varied by changing the number of battery cells, rather than by inserting resistance coils. This was necessary because the primary condenser was connected directly across the coil. If a large battery and rheostat is used there is much sparking at the interruptor, and the maximum secondary potential is small and not even approximately proportional to the primary current. Two forms of interruptor were used, one consisting of a steel rod making contact with an iron plate, the other of an amalgamated copper rod dipping into mercury, in each case under paraffin oil. Even when the external circuit was nearly non-inductive there was generally sparking at the interruptor with the stronger currents, but occasionally a sparkless interruption occurred, accompanied by an exceptionally high potential in the secondary coil. The amplitude of the electrometer curve

* The three photographs shown were obtained on different occasions, on which the electrometer had different degrees of sensitiveness.

was then unusually large, and these large amplitudes were alone selected for measurement. The iron-steel interruptor gave much more variable results than the other, but at its best was quite equal to the mercury interruptor.

A number of curves was first taken for different values of the primary current, in order to see whether the amplitude of the curve is proportional to the square of the current. Table VI. contains a set of results for Case I., the current being given in amperes and the amplitude A of the curve in millimetres.

TABLE VI.

i_0.	A.	$\sqrt{A}/i_0$.
1·83	3·1	·962
2·81	7·8	·994
3·75	14·0	·998
4·91	23·3	·983
4·91	10·5	·660
6·41	16·9	·641

The last two plates were taken after the sensitiveness of the electrometer had been reduced by tightening the strip. In cases where the deflexion on the plate is over 3 cm. the photograph is generally very faint, and such large angular deflexions of the reflected ray probably cease to be proportional to the deflecting force.

The numbers in the third column of Table VI. show that over the range of this set of readings the maximum potential V_m at the electrometer is within 4 per cent. proportional to the current interrupted in the primary coil. Similar results were obtained, within the same limits, from the plates taken for Cases II. and III. The numbers given in the table also point to a maximum value of the ratio V_m/i_0, in the neighbourhood of 4 amperes, a result which might be expected from the manner in which L_{21} varies with i_0, as shown in Table I.

A set of three plates was next taken for the three cases with the same primary current, in order to see whether the maximum potentials are proportional to the calculated values. The results are given in Table VII. in which V_c represents the calculated value in volts of the maximum potential. In each case i_0 was 3·0 amperes.

TABLE VII.

	A.	V_c.	$V_c/\sqrt{A}$.
Case I.	4·4	71610	34130
Case II.	6·9	87420	33310
Case III.	14·0	125700	33590

To within about 2·5 per cent., therefore, the calculated values of the maximum secondary potential are proportional to the values indicated by the electrometer.

With regard to the estimation of the absolute values of the potentials, no source of high potential suitable for standardizing the electrometer was available, and recourse was had to the method of spark potentials. It appears to be agreed that the potential difference required to produce a 1-centimetre spark, in air at atmospheric pressure, between ball electrodes 2 cm. in diameter, is not far from 31000 volts *.

The above theoretical expression for V_2 gives in Case I. a maximum value of 31000 volts at $i_0 = 1{\cdot}298$ amperes, but this is calculated on the assumption that the inductances are constant and equal to their maximum values. At this current, however, L_{21} is (from Table I.) about ·916 of its maximum value, and we may assume that L_1 and L_2 are altered approximately in the same proportion. Hence from the expressions for n_1, n_2, A_1, and A_2 we find that V_2 is approximately proportional, as far as small variations in the permeability of the core are concerned, to the square root of L_{21}. Assuming this result, the calculated value of the current required to give a maximum voltage of 31000 is $1{\cdot}298/\sqrt{\cdot 916}$, *i. e.* 1·356 amperes.

The least current observed to give a 1-cm. spark in Case I. was 1·36 amperes. This was repeated on many occasions and with both forms of interruptor, and found to be fairly definite. Sometimes the spark would not pass at less than 1·38 amperes, but on most occasions the result was as given above.

In Case II. the current giving 31000 volts, calculated

* Heydweiller (Wied. *Ann.* xlviii. 1893) gives 31290 volts, while according to C. Müller (*Ann. d. Physik*, xxviii. 1909) the voltage is 30240. An account of the results of different observers is given in Fleming's 'Principles of Electric Wave Telegraphy and Telephony,' 2nd ed., pp. 203–8.

with correction for permeability, was 1·132 amperes. The observed least current giving a 1-cm. spark was 1·13 amperes, but generally a little more current was required. In Case III. the values were ·815 ampere calculated, and ·86 ampere observed. The difference is much greater in this case, but the correction for permeability is also greater and probably not so reliable.

Of the three cases Case I. gives the most definite value for the least sparking current, and is the most suitable to adopt as a standard, while the numbers in Table VII. show that the potentials in the other two cases are fairly closely proportional to the calculated values. The above results show therefore that, so far as the 1-cm. spark potential may be taken as a guide, the theoretical expression (1) leads to approximately correct values (within about 2·5 per cent.) of the maximum secondary potential over the range of current and primary capacity covered in the present experiments.

Further support of the theory is afforded by the similarity in the forms of the calculated and experimental curves (figs. 1, 2, 3, and Plate VIII. figs. 7, 8, 9), and by the agreement between the observed and calculated values of the frequency of the longer wave in each case. Thus the calculated frequencies are (from Table V.) 194·3, 232·8, 304·4 ; the observed values, obtained by measurement of the photographs, 193·9, 232·3, 301·6.

Possibly still closer agreement between the calculated and observed results would have been found if second-order quantities (*e. g.* θ_1^2, θ_2^2) had been retained throughout, but the additional labour involved in the calculations would make the method too cumbersome to be of much value. What is more required at present is a simplified expression which will give approximately the maximum secondary potential, or an upper limit to its value which is not very greatly in excess of the actual value.

Such an upper limit may be arrived at by neglecting the resistances of the circuits so that k_1, k_2, δ_1, and δ_2 all become zero. If we further assume that the maxima of the two potential waves in the secondary occur simultaneously, the expression for the maximum potential becomes

$$2\pi L_{21} i_0 \frac{n_1 n_2^2 + n_1^2 n_2}{n_2^2 - n_1^2},$$

i. e.

$$2\pi L_{21} i_0 \frac{n_1 n_2}{n_2 - n_1}.$$

This may also be expressed in terms of the ratio $L_2C_2L_1C_1$.

Calling this m, and writing a for $1/8\pi^2 L_2 C_2(1-k^2)$, we have

$$n_1^2 = a\left(m+1-\sqrt{(m-1)^2+4k^2m}\right),$$
$$n_2^2 = a\left(m+1+\sqrt{(m-1)^2+4k^2m}\right).$$

Thus

$$\begin{aligned} n_1^2+n_2^2 &= 2a(m+1), \\ n_1^2 n_2^2 &= a^2\{(m+1)^2-(m-1)^2-4k^2m\}, \\ &= 4ma^2(1-k^2), \\ (n_2-n_1)^2 &= 2a(m+1)-4a\sqrt{m(1-k^2)}, \\ \frac{n_1^2 n_2^2}{(n_2-n_1)^2} &= \frac{2ma(1-k^2)}{m+1-2\sqrt{m(1-k^2)}}, \end{aligned}$$

and the upper limit to V_2 is, for given L_{21}, L_2C_2, and i_0, proportional to the square root of this quantity.

If we wish to consider the effect of varying the primary capacity only, then the upper limit to V_2 is proportional to the square root of

$$\frac{m}{m+1-2\sqrt{m(1-k^2)}},$$

or if

$$u = \frac{1}{m} = \frac{L_1C_1}{L_2C_2},$$

to the square root of

$$\frac{1}{1+u-2\sqrt{u(1-k^2)}}.$$

This expression has a maximum value of $1/k^2$ at $u=1-k^2$, and is equal to unity when $u=0$, *i. e.* when $C_1=0$. Consequently, if the resistances of the coils were negligible, the secondary potential might be expected to be greatest when the primary capacity C_1 has a value of about $L_2C_2(1-k^2)/L_1$, and this maximum value would be about $1/k$ times the value the potential would have if the primary condenser were removed altogether.

It is well known that for a given primary current there is a certain value of the primary capacity that gives a maximum secondary sparking distance with an ordinary interruptor *, but it has been usual to attribute the inferiority of smaller capacities to their failure to prevent sparking at the interruptor, and the view appears to be generally accepted that with a sufficiently rapid interruption of the primary current

* *Cf.* Walter, Wied. *Ann.* lxii. 1897; Mizuno, Phil. Mag. xlv. 1898.

the best effects would be obtained without any condenser. The above theory, however, points to a maximum spark-length with a certain condenser, at any rate in the case of negligible resistances, even with a perfectly sudden interruption.

The following experiments were therefore undertaken with a view to testing this point by observing the lengths of spark obtained with various capacities and different forms of interruptor. The condenser used was a subdivided mica microfarad, in which the fractions could be connected either in parallel or in cascade. This was in each case connected directly across the interruptor. The electrometer, though not used in these experiments, was left connected to the secondary coil in parallel with the ball electrodes, so that L_2C_2 and k^2 had the same values as in the experiments described above.

Experimenting first with the mercury interruptor and one secondary cell (i_0 about 1·1 amperes), no amperemeter or rheostat being included in the circuit, it was found that the mica condenser was as a rule sufficient to prevent any visible spark at the interruptor, even when all its sections were in cascade. There was occasionally a spark at the interruptor but no account was taken of the result when this occurred. The capacities were taken in pairs, each two being tried alternately many times at the same distance. Thus ·5 mfd. was found to give a longer spark than 1 mfd., ·3 longer than ·5. The longest spark was given by ·05 mfd. Special attention was given to this capacity and ·025 mfd., which were tried on many occasions. A distance could always be found at which ·05 gave a spark every time, while ·025 always failed. The distance was not the same on all occasions but was generally about 19·5 mm., and the difference of the sparking distances for these two capacities was about 1·5 mm. A longer spark was given by ·05 than by ·1 mfd., while ·025 and ·02 did not show any appreciable difference. A smaller capacity, in the form of an oil condenser of about ·002 mfd., was tried, but in this case there was always sparking at the interruptor.

With the mercury break and one cell, therefore, the most effective capacity was about ·05 mfd.*, but there were indications of a second (smaller) maximum at about ·3 mfd. this capacity giving consistently a rather longer spark than ·2 mfd.

When tried with two cells, an amperemeter and a rheostat being connected in the primary circuit and the current kept at 2·0 amperes, similar results were obtained. At 103 mm. sparks passed freely with ·05 mfd., none with ·025. The smaller capacity also failed at 98 mm. At this current also ·05 was superior to ·1, and there was again a smaller maximum at about ·3 mfd.

* The same result was found with a motor interruptor of the centrifugal type.

In the next experiments Lord Rayleigh's method of cutting the primary circuit with a projectile was followed, the object being to compare the two cases $C_1 = ·05$ mfd., and $C_1 = 0$. An air-gun was first used, which fires a pellet at about 500 feet per second. With one cell 19-mm. sparks were obtained every time with the condenser, none without the condenser at this distance or at 18 mm.

Still following Lord Rayleigh's plan * a service rifle was next used. It was said to fire a bullet at 2000 feet per second. Again with one cell, at 19 mm. there was sparking every shot with the condenser, none with the condenser removed. With the condenser sparks also passed at 2 cm. Similar results were obtained with bullets reduced to about one-half, sparks passing at 19·6 mm. with the condenser, none without. At this distance ·025 mfd. also failed.

With two cells (i_0 about 2·2 amperes) the sparking distance was not so steady, and it was consequently more difficult to fix upon a distance which enabled one to decide in favour of the presence or absence of the condenser. The results were therefore not so conclusive, but whenever a difference was shown at consecutive shots it was always in favour of the condenser. Thus, of three successive shots with the balls at 125 mm., the first and third being without, the second with the condenser (·05 mfd.), the second alone gave a spark. The longest spark obtained without the condenser was 120 mm.

When an amperemeter and rheostat were connected in the primary circuit, and the current was kept at 2·0 amperes, the same condenser gave a spark at 111 mm., while at shots immediately before and after no spark appeared without the condenser. Again, at 107 mm. (reduced charge) no spark passed without the condenser, while at two shots with the condenser (before and after) a spark passed each time. In other instances two consecutive shots at the same distance showed a superiority of the condenser; in no such case did a spark pass without the condenser when it failed with the condenser †.

* Phil. Mag. ii. p. 593 (1901).

† I am indebted to my colleague Mr. A. H. Ferguson, and to Mr. J. A. Owen, who joined me in the rifle experiments and verified the observations. I also wish to thank Sergt.-Major McCracken, of the College O.T.C., for his assistance in these experiments.

As far as these experiments go they do not support the view that the longest spark can be obtained without any primary condenser, but rather indicate a most effective capacity at about ·05 mfd.

The theory also points to this result. For, returning to the expression for the upper limit to V_2, which may be written $L_{21}i_0U/\sqrt{L_2C_2}$, where

$$U^2 = \frac{m}{m+1-2\sqrt{m(1-k^2)}},$$

and $m = L_2C_2/L_1C_1$, we find that in the present case U has a maximum at $m = 4{\cdot}31$, *i. e.* $C_1 = {\cdot}144$ mfd., but that it does not vary by more than 3 per cent. over the range $C_1 = {\cdot}3$ to ·05 mfd.

Now the expression for U is arrived at on the supposition that the maxima of the two waves occur simultaneously, and these coincidences will take place (the resistances being neglected) when $n_2/n_1 = 3, 7, 11, \ldots$. The values of n_2/n_1 for various values of m can be calculated from the equation

$$\frac{n_2^2}{n_1^2} = \frac{m+1+\sqrt{(m-1)^2+4k^2m}}{m-1-\sqrt{(m-1)^2+4k^2m}}.$$

The least value of n_2/n_1 occurs at $m=1$ (*i. e.* $L_1C_1 = L_2C_2$), and is 3·896 at $C_1 = {\cdot}62$ mfd. The ratio $n_2 = 3n_1$, therefore, does not occur.

The next coincidence ($n_2 = 7n_1$) occurs at $m = 9{\cdot}798$, giving $C_1 = {\cdot}063$ mfd., and this is the coincidence which comes nearest to the maximum value of U. It is also within the range over which U is practically constant and equal to its greatest value. The longest spark should therefore be given by a primary capacity of about ·06 mfd. As described above the value actually found was ·05 mfd.

At $n_2 = 5n_1$, ($C_1 = {\cdot}154$ mfd.) the maximum of the long wave occurs simultaneously with a minimum of the other, and a shorter spark is to be expected. At $C_1 = {\cdot}3$ mfd. ($n_2/n_1 = 4{\cdot}194$) the maximum potential will be rather greater than at ·154 mfd. in consequence of the closer proximity of the maxima. These two cases were worked out by the expression (1), the damping factors k_1, k_2, and the phase angles δ_1, δ_2 being neglected, with the result that ·3 mfd. gives a maximum potential about 5 per cent. higher than that given by ·154 mfd. A similar calculation shows that the maximum potential in the case $L_1C_1 = L_2C_2$, *i. e.* $C_1 = {\cdot}62$ mfd., is about 10 per cent. less than that given by ·3 mfd. The theory thus accounts for the observed

principal maximum spark-length at about $C_1 = {\cdot}05$ mfd., and for the second (smaller) maximum at about $C_1 = {\cdot}3$ mfd.

Other cases may be obtained by varying the self-inductance of the primary circuit. If, for example, the four sections of the primary coil are connected in parallel L_1 is reduced to approximately one sixteenth, L_{21} and L_{12} to one quarter, of their former values, and k^2 is unaltered. Calculating as above, we find that the maximum value of U is given by $m = 4{\cdot}31$, *i. e.* $C_1 = 2{\cdot}304$ mfd. The nearest coincidence ($n_2 = 7n_1$) occurs at $m = 9{\cdot}798$, or $C_1 = 1{\cdot}013$ mfd., and the longest spark should be given by a capacity of about this value. By experiment the longest sparks were found to occur at $C_1 = 1{\cdot}025$ mfd., the variation being however very slight over the range 1·0 to 1·05 mfd.

A case of special interest is obtained by diminishing the coefficient of coupling so as to bring in the ratio $n_2/n_1 = 3$. The least possible value of n_2/n_1 is $\sqrt{(1+k)(1-k)}$, consequently in order that n_2 should be equal to $3n_1$, k must not be greater than ·8. In this case it is also possible to make the maximum value of U, and the ratio $n_2/n_1 = 3$, occur at the same value of the primary capacity. The necessary value of k^2 is found by eliminating m between

$$m = \frac{1}{1-k^2}$$

and

$$\frac{m+1+\sqrt{(m-1)^2+4k^2m}}{m-1-\sqrt{(m-1)^2+4k^2m}} = 9.$$

This leads to the equation

$$91k^4 - 164k^2 + 64 = 0$$

for k^2, giving $k^2 = {\cdot}571$, the other root being greater than unity.

Consequently with $k^2 = {\cdot}571$ ($k = {\cdot}756$), and $L_1C_1 = {\cdot}429\ L_2C_2$, an exceptionally high secondary potential should be given by an induction-coil.

The most effective way of diminishing k^2 is to introduce external self-inductance into the primary circuit, since this does not involve any diminution of L_{21}. In the present case (primary sections in series) the value of L_1 required to give $k^2 = {\cdot}571$ is ·241 henry, and the primary capacity ($C_1 = {\cdot}429\ L_2C_2/L_1$) is ·198 mfd. On trying the experiment it was found that by introducing the necessary external self-inductance the maximum spark-length for a given primary current was considerably increased. Thus at

$i_0 = 1{\cdot}25$ amp. and without the external inductance the maximum spark-length ($C_1 = {\cdot}05$ mfd.) was 2·81 cm.; with the external inductance and the same primary current the longest spark was 5·36 cm., and the most effective capacity for this case was ·2 mfd.

The experimental results therefore agree with the theory in indicating that the most effective adjustment of the system (from the point of view of spark-length) is that in which $n_2 = 3n_1$, and U is at its maximum. It is probable that most induction-coils have coefficients of coupling which are greater than ·8, and in such cases the method here described may be used for making the coil give a longer spark with a given primary current, or a given spark-length with a smaller current.

The actual values of the secondary potential can only be calculated when the effective resistances are determined for each case, but it is not probable that these latter results would be greatly modified by their introduction. On the whole the evidence tends to show that the theory described in this and the two former papers is sufficient for the calculation of the secondary potential of an induction-coil and the most effective value of the primary capacity.

TESLA DOES NOT SEE WAR

INVENTOR, A SERVIAN, TALKS OF THE ASSASSINATION.

He Thinks That Fighting Will Not Follow the Death of Archduke Francis Ferdinand, but if There Is War He Believes It Will Assume European Proportions.

Nikola Tesla, the inventor, who was born in Servia, said to-day that if fighting followed the demonstrations against Servians, resulting from the assassination of the Archduke Francis Ferdinand, the war would quickly assume European proportions. Incidentally, Mr. Tesla said that his uncle, the Metropolitan of the Greek Church in Sarajevo, had been instrumental in bringing about the annexation of Bosnia and Herzegovina in 1908 by Austria—a political change that rankles in the breasts of the Servians.

Mr. Tesla deprecated the assassin's act, saying he was profoundly sorry that an irresponsible fanatic, one of his own countrymen, should have committed such a crime. He believed that the excitement would soon subside. At the same time, he pointed out that Servia was a hotbed of bitterness, and that hatred engendered by the Balkan war still smouldered, largely because Servia's efforts to gain an Adriatic port were frustrated by the attitude of Austria-Hungary.

He said also that Archduke Ferdinand realized the hatred of the Servians, and had proposed liberal reforms in regard to the Slavs, which should have made him more popular.

"My uncle," he added, "was a Metropolitan in Sarajevo, where the Archduke was assassinated. That title is held by the small group of men next in power to the Patriarch of the Greek Church. He was largely responsible for the annexation to Austria-Hungary of Bosnia and Herzegovina, and through his skill, it is currently believed to-day, war was averted at a time when Servia had no army to speak of, and when all of the Balkan states could have been easily conquered.

"Previous assassinations have shown, as I hope this one will, that bomb-throwing and shooting at royal personages rarely precipitate war. They create excitement, which soon dies away. The assassins are deluded and irresponsible young men, acting in the belief that they are giving up their lives for a great cause. Yet the situation is very serious because of popular tension in Servia, and a war now is unthinkable which does not assume the proportions of a European war.

'In 1908 Servia was on the brink of war. The people themselves were emphatically opposed to annexation, but one or two persons high in the Church saw that this was the only means of saving the country. At that time the Croatians, who are virtually the same people, were in favor of annexation, because they believed that ultimately Dalmatia, Croatia, and Bosnia Herzegovina would be united under the nominal rule of Austria-Hungary, while remaining actually independent."

The New York Post June 30, 1914

PUPIN REPLIES TO TESLA

INSISTS THAT ASSASSIN WAS AN AUSTRIAN SUBJECT.

Head of Serb Alliance in This Country Asserts that Inventor Confused the Terms "Serb" and "Servian" in His Interview on the Killing of Archduke Francis Ferdinand.

Prof. Michael Pupin, of Columbia University, president of the Serb Federation of America, and president of the Serbo-American Educational Alliance, sends to the *Evening Post* the following letter, dated yesterday, in answer to the interview with Nikola Tesla, published in last evening's edition of this newspaper. Professor Pupin's letter is as follows:

"In your issue of to-day appears an interview with Mr. Tesla regarding the tragic death of the Archduke Ferdinand of Austria. In this interview Mr. Tesla is described as a native of Servia, and he is quoted as expressing a profound sorrow that an irresponsible fanatic, one of his own countrymen, should have committed such a crime. The inference is, that a native of Servia assassinated the heir to the Austrian throne. Such, however, is not the case; it was a Serb, a native of proud Herzegovina, who committed this violent act. Servia and the Serbs of Servia, that is, the Servians, stand with their hands clean.

"This violent act of assassination should not be placed at their door by a misleading interchange of the words 'Serb' and 'Servian.' Serb is a racial name, and applies to the people living in Bosnia, Herzegovina, Dalmatia, Croatia, Slavonia, Servia, Montenegro, Macedonia, etc. The name Servian, on the other hand, is a political name, and belongs specifically to the Serbs who live in the kingdom of Servia, just as the name Montenegrin belongs to the Serbs who live in the kingdom of Montenegro. It was a Serb of Herzegovina, a province of Austria; that is, it was a subject of the Austrian Empire who shot the heir to the Austrian throne.

TRIALS OF THE SERBS.

"It looks as if the misleading interchange of the two words might be indulged in intentionally, in order to cast a shadow of suspicion upon the kingdom of Servia and the men who guide its destinies. Recent dispatches from Vienna display this tendency in an increasingly marked degree, where the word Servian is substituted in seven cases out of ten for the word Serb and where, also, violent attempts are made to connect the tragedy of Sarayevo with Belgrade and Servia. If the Serbs of Bosnia and Herzegovina believe in acts of violence, let them be responsible for it, and let them appeal to their own local conditions to furnish proof which will, in their opinion, justify their crime.

"The Servians, that is, the Serbs of Servia, have been sorely tried during the last two years, and it is still fresh in the memory of everybody that they stood their trials with wonderful patience and heroic tact. To conquer impenetrable Albania in the face of a raging winter, and to seize the Albanian coast after incredible hardships and enormous sacrifices required an heroic spirit of the most extraordinary kind on the part of the Servian peasant soldier. He rose equal to the occasion and astonished the whole civilized world. But he did it because economic slavery to Austria for centuries made him look to the ancient Serb town of Durazzo on the Adriatic coast for a gate which leads to a road of economic freedom. Then, suddenly, Austria's warlike trumpets sound the command that the Servian peasant soldier must leave the Adriatic coast and give up the dream of his life.

THE PEASANT'S SAD RETREAT.

"The brave fellow discovers presently that Austria's arrogant command is the wish of Europe, and he bows to it without a murmur. He admits, with Christian fortitude, that the interests of Europe are more momentous than his own long-cherished hopes and aspirations, and he retraces his steps over the bleak and hostile crags of Albania. The retreat of Napoleon's army from Moscow is a gay wedding procession in comparison with the sad march of retreat of the Servian peasant army from Albania. It has no parallel in all history, and it represents the greatest moral victory that any army ever achieved. Let not shadow of dark suspicion, produced by misleading interchange of words 'Servian' and 'Serb,' connect the Servian peasant soldier with the tragedy of Sarayevo. He undoubtedly has much cause to long for revenge, but if he should ever seek revenge he will get it by open war and not by assassination.

"I permit me, also, to express my astonishment at Mr. Tesla's reference to his uncle, the late Orthodox Metropolitan of Sarayevo, as being chiefly responsible for the Austrian annexation of Bosnia and Herzegovina in 1908. The whole world understands to-day that this annexation is and always was considered by every true Serb as one of the greatest national calamities, and nobody felt this more than the Serbs of Bosnia and Herzegovina who represent the finest flower of the Serb race. If Mr. Tesla's uncle, the late Orthodox Metropolitan of Sarayevo, was instrumental in bringing about this awful national calamity then he will certainly be considered forever after the Benedict Arnold of the Serb race. Does not Mr. Tesla see that he is compromising the Orthodox Church of Bosnia, and preparing another tragedy for the golden city of Sarayevo?

"Mr. Tesla's startling information about the high dignitaries in the Orthodox Church and their connection with the Austrian annexation of Bosnia and Herzegovina may be sweet music to the ears of the Austrian diplomats, but where does it leave the influence of the Serb Orthodox Church with the Serb people of Austria-Hungary?"

The New York Evening Sun July 6, 1914

News of the Theatres

Rehearsing While You Wait at the Longacre Theatre.

Electrified Dressing Room Coming to the Palace.

Manager Frazee has hit upon a happy way of obtaining the "A Pair of Sixes" players for the companies that will tour the country this fall. Instead of looking around the theatrical world and selecting a host of promising actors and actresses in May, signing contracts with them then with orders to rehearse in August with the expectation of releasing some of them in that late summer month and leaving them high and dry with no engagement in sight, Mr. Frazee is able to play the part of a philanthropist, the role of a lover of his professional brothers and sisters. He is able to be so altruistic through the happy fact that "A Pair of Sixes" is now playing at the Longacre Theatre. Here is the programme that is followed for engaging men and women to act in the new "A Pair of Sixes" companies.

Applicants for the different positions are put through their paces at once. There is no delay. First, they are invited to see the play acted by the New York company. After that, they read the play through carefully at home. Then some one hears each one go through his part and if he is not too awful he soon gets an opportunity to rehearse with the understudies of the company. If he is the right person for one of the parts he receives a contract and can rest in peace until the season begins. If he is the wrong person, he has lost only a week or ten days instead of being kept on tenterhooks for three or four months.

Eighty-four people are going through this sifting out process now at the Longacre Theatre. This includes persons for all the parts except the principal one. To fill these players are engaged whose work is well known. But this weeding out plan for filling the other characters of the several casts gives a good opportunity for discovering really clever people who have not attracted much attention because of lack of opportunity.

The cast for the Chicago company now includes Frank McIntyre, Joseph Kilgour, Sam Hardy, Oza Waldrop, Elizabeth Nelson, Louie Emery as *Toddles*, Jack Jarrett, Jack Raffael and Elmer H. Brown. Those engaged thus for for the Western company are Paul Nicholson, Miss Norton, Reginald Fife, Helen Hilton and Katherine Blair. Joseph Coyne will be in the London company and so will Orlando Daly and Thomas Meighan. Mr. Frazee leaves for England on Aug. 11, via the Mauretania, and will engage the rest of the English company after he arrives in London.

An experiment that would have been tried out in one of the public schools of this city if the parents of the school children had not proved highly sensitized on the subject is to be attempted in the Palace Theatre. A high tension dressing room is being installed for the electrifying of performers before they go upon the stage. The room will contain a powerful Tesla coil and the walls will be wound with heavy insulated copper wire carrying high frequency currents. Tired artists, it is predicted, will enter this room and emerge filled with ozone and thoroughly electrified. It is declared that a short visit to the so-called "pop house" by performers will start any act on the stage keyed up to blowing off steam pressure.

Here are a few of the things that Mortimer Norden, chief electrician for the B. F. Keith circuit, says about the experiment after taking a trip to Walter J. Kingsley's own high tension press room:

"The high tension dressing room at the Palace Theatre will be an entering wedge for the greatest blessing electricity has brought to mankind. High potential electricity will do away with bromides, phosphates, pick-me-ups, pepsin tablets and all the other dope that people take for nervous and stomach troubles. Every theatre will be wired for high frequency currents and both the performers and the public will be keyed up to dazzling pitch. There is nothing harmful in all this. We simply take a short cut to nature's reservoir of power and instead of getting all our vitality from food and air and sunshine, we get it in delightful dosage direct from electric currents which intensify cerebration, make one talk in epigrams, give a keen sense of humor, bring happiness, and kindle brain activity to a point equalling that of the most brilliant. Living in an electrified room is to receive lasting benefits and to make life burn with a bright and steady flame."

Now, who ever heard an electrician talk like that before? One holds one's breath when one considers what might happen if Walter Kingsley should take a dose of the electrified ozone. It would be a case of electrifying a "live wire." But Nikola Tesla's plan seems to be a scientific success. The Palace Theatre management is to be congratulated upon its enterprise in placing at the service of its vaudeville artists this latest and highest form of electric massage.

Carl Stail, who was one of the boys in the original "Florodora" sextette, will sing and act the part next season of *Racz*, the Gypsy musician, in the operetta "Sari."

Henry W. Savage will have two "Sari" companies for the new season, one company in the comedy, "Along Came Ruth," and one company in the morality play, "Everywoman."

Rozsika and Yansci Dolly, featured entertainers at William Morris's Jardin de Danse, will take one hundred Hungarian children from the Madison street settlement, in two large tallyhos, to Central Park to-morrow. Later the children will be brought to the New York Theatre, where the Dolly Sisters, Harry Fox and others will provide a special vaudeville entertainment, in addition to the regular performance.

The New York Press July 26, 1914

"Pep Room" in the Palace Is Much Better Than Champagne

VAUDEVILLE artists playing in the Palace Theatre are enthusiastic over the benefits derived from the gigantic electrical installation for medical purposes which was opened in Room 19 last Monday. In this "electrical cage" sick or tired actors and actresses are given from 100,000 to 1,000,000 volts of electricity and saturated with enormous volumes of "juice" vibrating hundreds of millions of times a minute. The huge coil generates liberal quantities of ozone, which opens up the throat and lungs, and artists who enter the room unable to go on the stage quit it in a few minutes prepared to give the best performance of their lives.

Eddie Foy, who has christened the plant the "pep room," swears by it, and has arranged with House Electrician Edwards to visit the Palace weekly for treatments when he is playing elsewhere. Joan Sawyer, who is exhausted from overwork, goes to the high tension electric bath before every performance, and has grown so enthusiastic that she brings parties of her friends to the Palace for high potential treatment. Chief Electrical Inspector Timmany has passed the apparatus, and declares that it meets with his hearty approval and will prove a blessing to the artists. "I wish," he says, "that every school and every home had a plant for producing high frequency currents. They are healthful in the highest degree."

Electrical experts visit the Palace "pep room" daily, and its use bids fair to become a fad. The gigantic resonator is a startling spectacle when in action, as it throws off five-foot sparks and makes a deafening roar. Artists have to be convinced by demonstration that they can take the tremendous discharges with entire safety. Once convinced they return again for treatment.

The current from the street service is received at the transformer, 220 volts, A. C., 60 cycles. The transformer is 3,000 Watt closed core, dry type. There is a variable secondary on these two windings, one of 20,000 volts and the other of 30,000 volts. There is also a condenser, consisting of 6½-gallon Leyden jars filled with a saturated solution of salt and water. Connected to this condenser is a large resonator 3 feet high by 9 inches in diameter. This resonator has a variable primary winding of the heavy wire type, consisting of 14 turns of No. 8 aluminum wire. The secondary winding of the resonator is 2,500 turns of No. 22 wire. The E. M. F. of the transformer is 1,000,000 volts.

There is a brush discharge when in operation of about 7 feet at the top of the resonator, which seeks a path on the side of the machine to copper wire gauze frames 10 feet long by 3 feet wide, which makes an electrical lane. These frames are suspended alongside of the apparatus, placed about 3 feet apart, making a lane 10 feet long and 3 feet wide between the gauze frames.

When the machine operates the entire space between these gauze frames is saturated with electrical waves jumping from frame to frame across the resonator. The air is highly charged with ozone and the effect of the entire treatment is very pleasant. On the left hand side of the room there is a switchboard for regulating the intensity of the current, which can be reduced or increased at will.

Nikola Tesla, the first man to demonstrate the efficacy of high voltages, and Superintendent Maxwell of the New York Public Schools, are watching the experiments with great interest. It has long been Superintendent Maxwell's ambition to install a similar room in each public school for backward children.

The plant in the Palace Theatre, though expensive, has already proved its value, and will be retained as a permanent addition to the stage. It bids fair to inaugurate a craze for high potential bathing that will be taken up all over the country. There is no denying the fact that a visit to the spectacular room all ablaze with fiercely crackling blue flames invigorates one, stimulates the brain and gives renewed efficiency to tired cells.

Servians Here Believe War Would Be the Greatest in History

Serb Consul Considers Conflict Inevitable as Result of Intolerable Demands Made by Austria, and Predicts That Other Powers Would Be Drawn Into the Clash.

If the excitement and enthusiasm which have stirred the Servians in New York into a warlike mood is a criterion there will be thousands ready to return to the fatherland to bear arms in case of war. Not only was the Servian colony in a turmoil, but the Bulgarians and the Greeks also were excited. The chief centre of Servian interest, however, was at the consulate at No. 143 West Twenty-second street. Through the afternoon and far into the evening the throngs of Servians came there in search of the latest news from Europe and to discuss the developments in the strained situation.

That Austria had acted without due provocation and had made demands with which no country would comply was the opinion of all. Although there are only 800 Servians in this city, there are many thousands scattered throughout the country, and it was the opinion everywhere that Servia had been so insulted by Austria's actions that all would rally to the defence of their country.

Believes War Inevitable.

Although he did not care to say anything authoritative for fear of exaggerating the seriousness of the situation before he received official despatches, Paul H. Pavlovitch, secretary in charge at the Servian Consulate, said:—"From what we know here there is no doubt that war between Austria-Hungary and Servia is inevitable. It has come down to the question of whether Austria will recede from her domineering position, or Servia give in to her demands. I am sure that the latter will not be the case.

"If it had not been for Austria there would have been no war between Servia and Bulgaria. The empire started that contest for her own ends, thinking that the Servians would be beaten. They were not, and therefore Austria feels that she has suffered. Since that time she has been searching for an excuse to further trouble us.

Of the many Servians seen yesterday Nikola Tesla, the famous engineer and electrician, seemed to think that there would be no war. When seen at the Waldorf he told the HERALD:—"Austria has created a very dangerous situation through her peremptory note to Servia, which reads like a document of the Napoleonic régime.

"It is wrong of the imperial government in Vienna to implicate the Servian government in the assassination of Prince Ferdinand, for it must be apparent to all intelligent men of both parties that this deplorable act was altogether against Servian interests.

Between Slav and Teuton.

"Although the state of things forebodes a national imbroglio, it must be recognized that if it comes to a war it will be a clash between Slav and Teuton. Therefore if this calamity is to be averted we must look to Berlin and St. Petersburg. Personally I am convinced, despite all indications to the contrary, that there will be no war, and I think my faith is largely in the Emperor of Germany.

"This is a man of extraordinary powers, whose ambiton seems to be to achieve greatness by maintaining peace. If it were otherwise Germany would long ago have clashed with other nations, for she has a military organization and war equipment such as the world has never seen before. There are, however, other forces which will tend to prevent a conflict against which the greatest wars in history would be like mere skirmishes. When we consider that Russia has available from five million to six million men, Germany five million, France four million, Austria two million, Italy nearly as much and the Balkans about two million, an international struggle of this kind would involve more than twenty million combatants. And the expenditure would be from $300,000,000 to $400,000,000 a day.

"In view of this, no man in power in any country would dare to take so consequential an initiative. And it is precisely because of this that one is amazed to read Austria's dictatorial note.

"In every difficulty suddenly precipitated the most important thing is to avoid immediate explosion. If shots are not exchanged across the Danube within the next forty-eight hours the war is as good as averted. In all probability Austria will make some modifications in her demands and the Servian government will make every effort to comply as far as possible."

Herald View Indorsed by Mr. Tesla; Sees Peace Near

Inventor Believes Magnitude of the Great European Struggle Makes It Almost Impossible—Resources of Nations Soon Would Be Exhausted.

THINKS THAT AUSTRIA WILL SOON BACK DOWN

Indorsing the HERALD's editorial as summarizing the situation in Europe, that war inevitably means devastation, destruction and death, Mr. Nikola Tesla, the inventor, last night at the Waldorf-Astoria Hotel made a plea for peace. He believes it appalling that a political condition could be brought about through local disturbances that would ultimately cause the loss of millions of lives, millions of dollars and a physical reconstruction or absorption of nations.

"I have been following very closely the events of the week and up to this very hour," said Mr. Tesla, "and while they are serious and while actual reprisals have been reported, I am convinced that war will be averted. The mobilization of armies must be looked upon so far merely as demonstrative and unavoidable in the circumstances. The very immensity of the danger involved is the best guarantee for peace.

"The situation with which we are confronted so suddenly is a great lesson to the world, showing how far we have progressed. The ideal theoretical conditions for the maintenance of peace would require that any local disturbances would have as a result the division of the whole power of nations into equal halves, one standing for one contestant and the other for the second.

Germany's Shrewd Move.

"That we are approximating a condition in which a slight disturbance will involve the whole world is manifest. Only a few days ago Austria declared war against Servia. The papers reported that Austria had Germany's support. This could not have been true. The first overt act of Germany was her refusal of interference. It was a shrewd move, calculated to obtain the advantage for Germany and her ally merely by potential energy without dynamic effort. This would have confined the war to Austria and Servia and enabled the former country to carry on its unfair designs. But the scheme did not work, for Russia decided to interfere.

"In an editorial on July 29 the HERALD asked the pertinent question:—'Can war be localized?' This was answered in the negative by Russia's mobilization, and from that moment the only possibility was a European war or no war at all. The interceding of Russia made it necessary for Germany to decide for peace or war. And in this lies one of the chief assurances that there will be no international conflict.

"In the first place the Germans are a peace loving people and the policy of the Emperor has been so far eminently pacific. Germany has everything to gain from peace. During the last forty years she has advanced steadily, commercially and industrially, to such a point that her superiority is conceded everywhere. Why should Germany go into a hazardous struggle when she is conquering the world slowly but surely by arts of peace?

An Unfavorable Time.

"But suppose that she were bent upon war, could she have chosen a more unfavorable time? The Triple Entente is in every way superior to the Triple Alliance, the existence of which is now doubtful in view of the attitude of Italy. Germany is hemmed in on land and sea. In the west she has her bitter enemy who has been preparing for years for revenge; a nation highly cultured and resourceful, capable of putting 4,000,000 men in the field. In the east, her opponent is three times greater in population, incomparably greater in resource, absolutely unconquerable. Germany's superior army would in all probability obtain great victories, but she could not wrest from Russia any territory or obtain indemnity. Any injury she might inflict would involve injury to herself which would be felt all the more because she is smaller.

"This only goes to show her objective point of attack, France. But she is not strong enough to conquer that country and expose herself at the same time to Russia. In Austria she has an ally of doubtful capacity, so the entire burden falls upon her shoulders. Although her navy is efficient it is pretty safe to conclude that she is not able to grapple with England successfully. The English have no aversion toward the Germans as a people, but the bitter feeling exists and England will not feel safe until the danger of German invasion is disposed of.

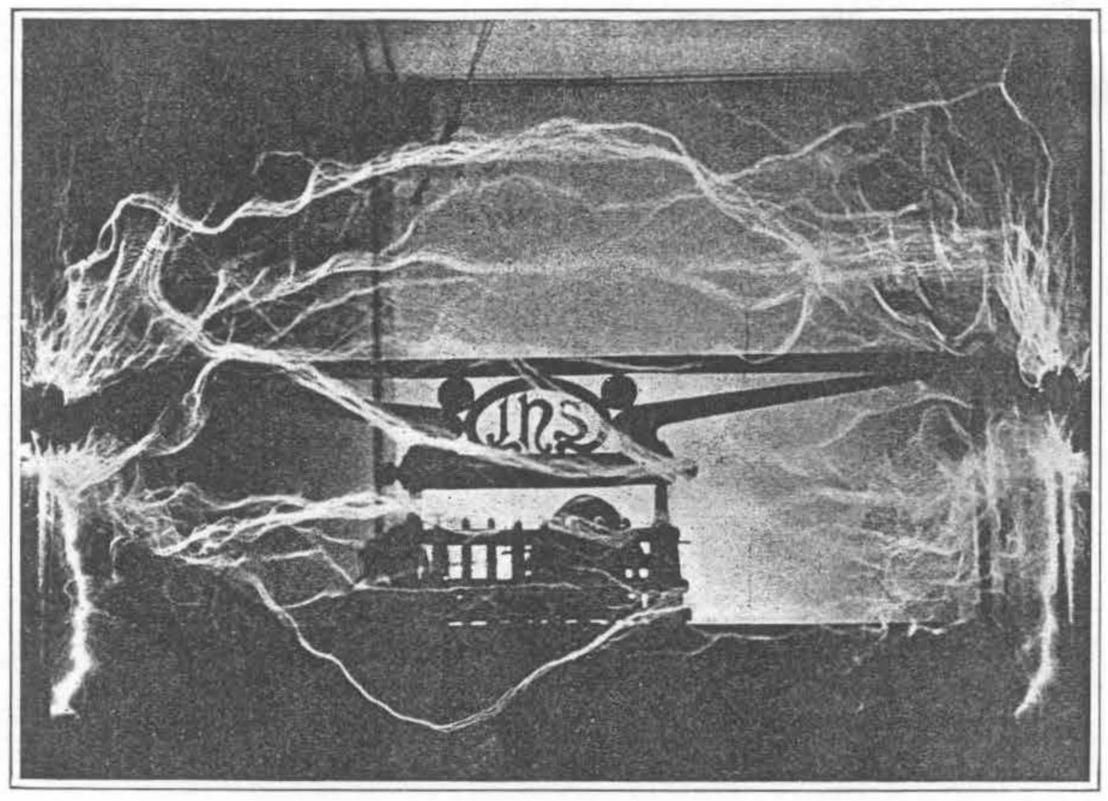
"The second guarantee for peace lies in the fact that Austria will recognize in the withdrawal of her army from Servia the only means of saving herself. A European war will have as the unavoidable result the dismemberment of the dual monarchy. The crossing of the border by the Russian army will create a wave of enthusiasm throughout the Slav population and the entire fabric will crumble. Austria has undertaken to crush Servia, not so much with the view to acquiring territory as to wreak vengeance on a small nation striving for freedom, whose resistance to the Asiatic hordes has made the present monarchy possible. In trying to destroy Servia she has plunged headlong to her own destruction. This is admirably forecasted in the HERALD editorial.

"I would repeat that, all indications to the contrary, an international conflict on such a scale is impossible from purely physical reasons. The expense involved in maintaining the forces and the destruction of life and property are such that in a few weeks all resources would be exhausted. It is impossible to believe that with this realization before the eyes of the leaders common sense would not prevail."

A Huge Tesla Apparatus

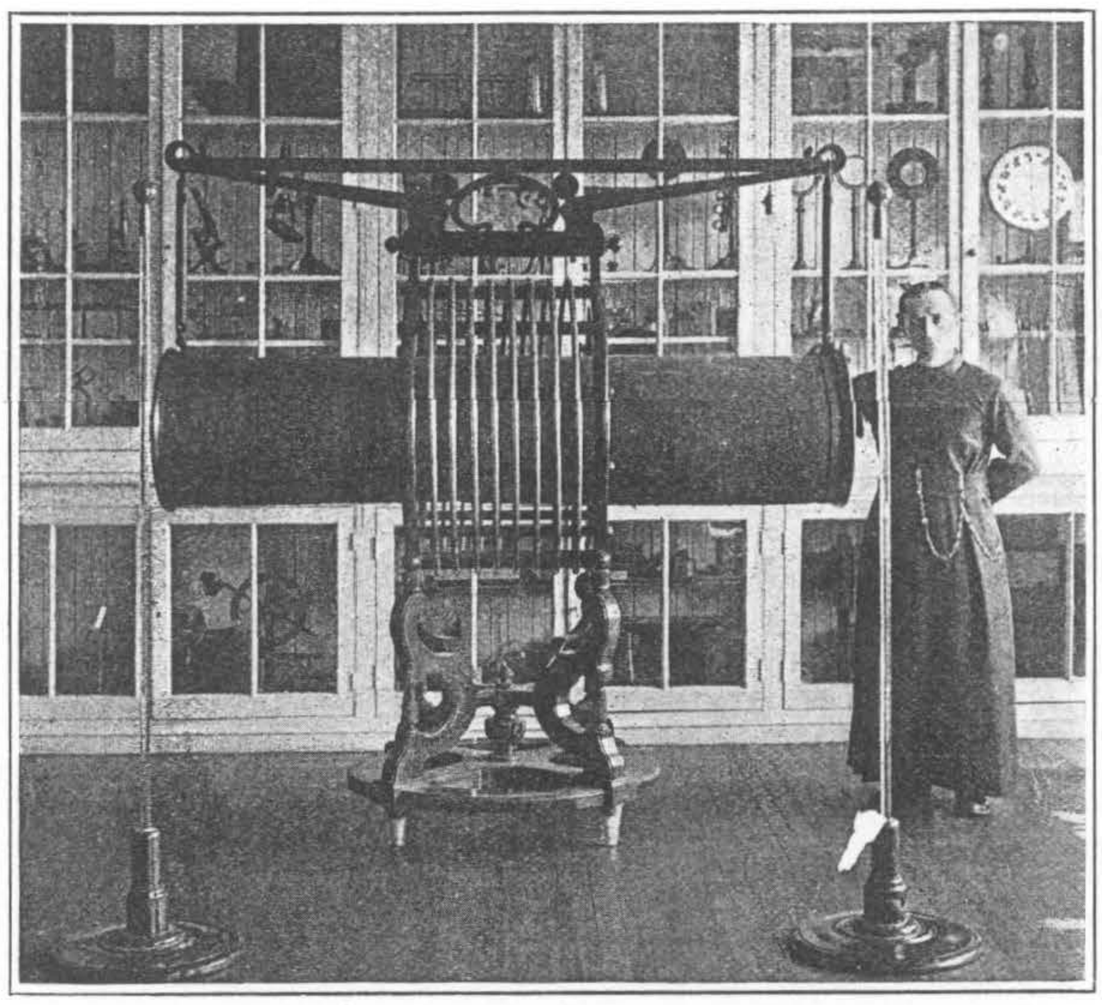
A Coil With a Seven-foot Spark Gap

By Father Francois Magri, S. J.



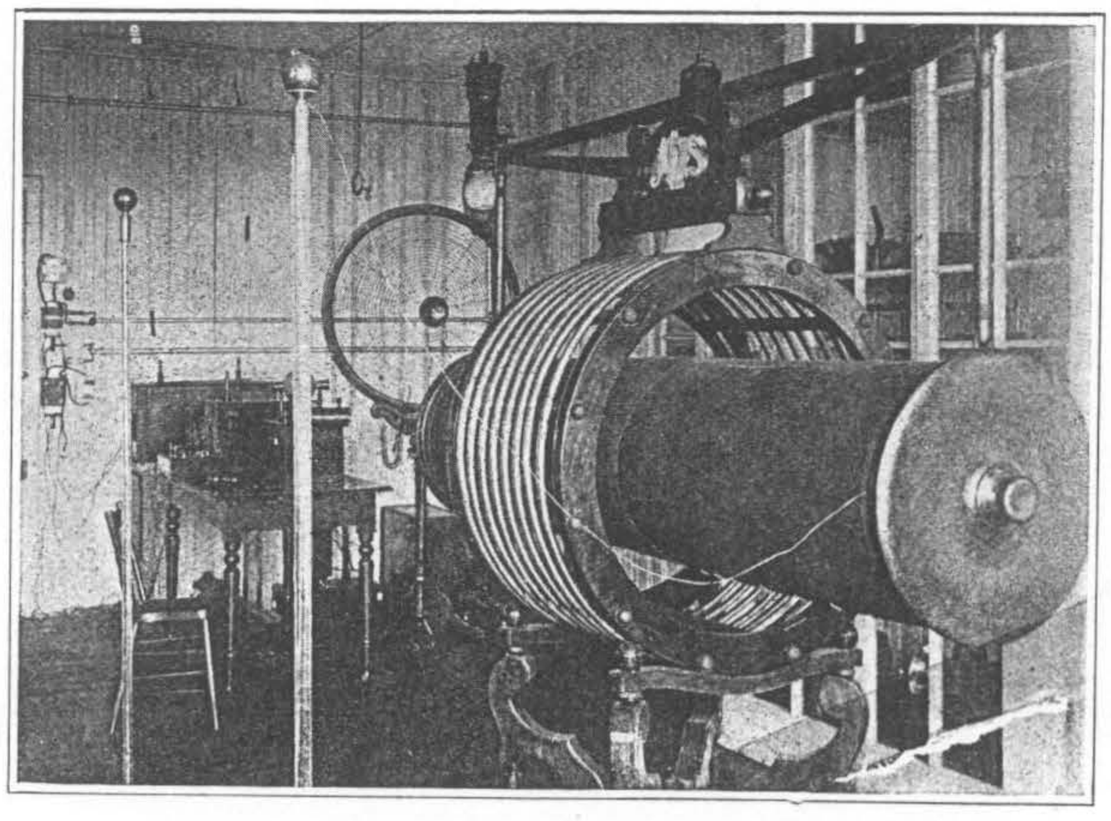
THE great Tesla apparatus of our physical laboratory, at the College of the Immaculate Conception, Montreal, was designed by my predecessor, Father Gendreau, and was constructed by his pupils.

The current of low frequency which energizes the Tesla coil proper, is furnished by a 7-kilowatt transformer, entirely immersed in insulating oil in a glass case, which measures 27 inches in length, and 17 inches in width and height. Its primary coil is connected to the city lighting circuit of 115 volts and 60 cycles, from which it takes a current of 60 amperes. The voltage of the secondary current exceeds 65,000 volts, as is proved by the length of the spark, which has the flame-like appearance shown in one of the photographs. This secondary current passes into the primary coil of the Tesla transformer, which is connected with a condenser of 144 Leyden jars. These jars are filled with and surrounded by salt water, which takes the place of the customary metallic coatings, and which is covered by a thin layer of oil to prevent evaporation and incrustation. A rotary interrupter, driven by an electric motor, is employed in order to increase the frequency.



I have made important changes in the apparatus, entirely reconstructing the primary of the Tesla, and improving the insulation by mounting the wooden base on glass supports. The apparatus is more than 7 feet long. A cylindrical cage, 33 inches in diameter, composed of 12 longitudinal bars, 22 inches long, carries the primary coil, which consists of 8 turns of brass tubing, separated by intervals of 1½ inches. The diameter of the tube is ⅔-inch, and its total length is 74 feet. Its ends are connected with the condenser and the rotary interrupter. Above this coil is a bridge, from the ends of which the secondary coil is suspended inside the primary by means of two ebonite rods 19 inches long. The secondary coil is nearly 7 feet long and more than 17 inches in diameter. It is composed of more than 1,000 turns of fine, enameled copper wire, insulated by layers of tarred paper and cloth. The maximum sparking distance is 6 feet 8 inches usually, but it has exceeded 7 feet. The spark resembles a flash of lighting and, with its deviations, attains a total length of nearly 10 feet. It produces a sound like a thunder clap that startles persons in the street, 400 feet distant. Although the apparatus is not connected either with an antenna or with the earth, the sound of the discharge is heard very distinctly through the telephonic receiver at the wireless station of the Polytechnic School, a mile and a half away, this receiver also being disconnected from its antenna and the earth.

What, then, would be the result of connecting this powerful apparatus to earth and to our experimental antenna, consist- of three wires, each 700 feet long? The discharge would certainly produce a potential difference of at least five million volts, but we have no apparatus with which this theoretical deduction can be verified.



The discharge of the primary coil alone produces a deafening noise. This coil, by induction alone, heats to incandescence a 50-volt lamp, inserted in a little coil of three turns at a distance of 3½ feet. A 25-volt lamp glows brightly at the same distance, and a 12-volt lamp is heated to whiteness at a distance of 5¼ feet. When the terminals of the primary are connected by a coarse iron wire 8 feet long, the wire is almost instantly heated to incandescence and fused. Sixteen 115-volt lamps glow white when they are connected in series between the terminals of the primary.

Discharging across a seven-foot gap.

Giant Tesla coil capable of giving a seven-foot spark.

View of the primary and movable electrodes.

The New York Herald August 19, 1914

$70,000,000,000 Waste Is Mr. Tesla's Estimate

Inventor Figures War's Damage Will Equal Almost One-Quarter of the Total Wealth of the World if the Conflict Continues for Six or Seven Months.

After a careful study of the financial and sociological questions involved in the present European war, Nikola Tesla, the inventor, estimates that the waste incident to it cannot be less than $70,000,000,000, or almost twenty-five per cent of the total wealth of the world. He takes issue with Professor Charles Richet in the latter's estimate of $50,000,000 a day, stating that would cover the cost of military operations. In connection with the matter Mr. Tesla said last night:—

"The HERALD of August 2 contains an itemized estimate by Professor Charles Richet of the cost of the war on a colossal scale such as the present, which may involve 20,000,000 combatants. He finds a total of $50,000,000 a day. While most of the figures, given may be correct, it is certain that some are altogether too low. For instance, he places the number of those disabled through wounds and disease, at 500,000.

"This is less than two and one-half per cent. It will be recalled that in the recent war in the Balkans, which furnishes the best data in this respect, the casualties were more than twenty-five per cent that is, ten times greater in proportion. He values the public and private properties destroyed at $2,000,000 a day. Observe that according to reports only in Belgium a loss of $300,000,000 resulted from less than two weeqs' fighting.

"There were no large cities in the path of the total force engaged in this stupendous conflict. Professor Richet also ignores the time element, which has a very decided bearing on the cost, and considers a purely hypothetical case of constant performance. It is evident that before such an estimate can be made the duration of the war must be known, from which the daily average can be computed.

Estimating Energy of War.

"Armed conflict is essentially a discharge of accumulated war energy. The rate at which this energy is released determines what may be called the power of war. An international combat may be of great energy and yet of small power, or it may be of small energy and still of great power, and the daily cost will vary accordingly.

"Conceive that a definite quantity of war energy is expended in perpetual strife. Then the daily cost will be nil. Assume, on the other hand, that the same energy is all used in, say one day. Then the daily cost would be nearly equal to the total cost, which might amount to several billion dollars.

"The Franco-German and Balkan wars may serve to fix these conceptions. The former was of greater energy, but the latter was of much greater power. The development of military science and perfection of arms is ever tending to increase the intensity and to reduce the duration of the struggle, and in times to come, when the comparatively crude implements of today will be replaced by subtle and infinitely more effective electrical means of destruction, and time and space are annihilated, wars, if they do happen, will be settled with a swiftness now inconceivable.

"The chief thing to point out is, however, that Professor Richet's estimate is not one of the cost of war, as put forth, but rather the cost of military operation, which represents but a small fraction of the total waste.

"To measure the losses due to war merely by statistical standards is absurd. An example will make this clear. The strain imposed upon a country in a state of siege is compelling of strict economy. The savings thus affected go to offset the drain of war. Theoretically, it is possible for a nation, by living on bread and water and curtailing all expenses, to accumulate enough for not only meeting the cost of military operations but leaving a surplus besides. From the point of view of the statistician such a war, far from being costly, would be the very means of creating wealth!

Figuring Excess of Waste.

"It is equally unreasonable to define the waste of international conflict as the excess of waste in time of war over that in time of peace. A quantity 'b' may be deducted from a quantity 'a,' and the difference will be 'a—b' on the supposition, however, that the quantities are composed of identical units.

"Now, while the same human beings are concerned both in peace and war, thes two states bear no resemblance to each other. In one, reason and sober sense, a feeling of safety and desire to do justice prevail; in the other these beneficial influences are weakened, and folly, fear and greed assert themselves. War changes individuals as well as values.

"A true appreciation of the enormous losses which are likely to result from this unprecedented calamity can only be gained by taking into account its effect on all phases and conditions of individual and national existence. Stated in the order of their magnitude these losses may be enumerated as follows—

"First, temporary or permanent shrinkage of the wealth of nations as distinct from negotiable securities. The total wealth of the countries involved is about three hundred billions of dollars. Assume only a moderate production of ten per cent, and suppose further that the war should last from six to seven months, or about 200 days, as forecast by experts, then the daily shrinkage will amount to $150,000,000. To be sure such depreciation of physical possessions is mostly due to ignorance and faintheartedness of the people, for the properties are there and some are indestructible. But just the same the warring nations will lose credit and purchasing power and will be subjected for an indefinite period to sufferings and privations, all of which must be interpreted as loss of so much money.

Losses in Industrial Pursuits.

"Second—All losses, individual and collective, caused by interference of war with the wheelwork of manufacture, industry and commerce. These reflect particularly on the market value of negotiable securities, which constitute from twenty to thirty per cent of the whole national wealth. For obvious reasons they are apt to be very large, and the shrinkage may easily amount for the above period to $100,000,000 a day.

"Third—Specific losses due to destruction of existing private and public property, including implements and materials of war. These will greatly depend on the circumstances, but may be placed at from $50,000,000 to $75,000,000 a day.

"Fourth—Loss of life and disabling through wounds and disease. Judging from the data of the Balkan War, the casualties cannot be taken at less than fifteen per cent, making the total of 3,000,000. Assuming an average of $2,500 per individual, this waste will be nearly $14,000,000 a day.

"Fifth—Daily cost of military operations, which may amount from $25,000,000 to $50,000,000.

"According to this rough estimate the total waste cannot be much less than $70,000,000,000, making almost twenty-five per cent of the total wealth of the countries in the world. In the best circumstances it will take from forty to fifty years to repair the financial damage, not to speak of the injury to the races and retardation of social progress in all directions."

NIKOLA TESLA TO FIGHT MARCONI PATENT SUIT

Noted Inventor to Aid German Alleged to Have Used Infringement.

Lawyers for Fritz Lowenstein, a German engineer, against whom the Marconi Wireless Telegraph Company has begun suit for an injunction, alleging that certain wireless parts he has sold to the United States Navy Department for use on its battleships are infringements on its patents, may subpœna Nikola Tesla, the noted electrician, as a witness for Mr. Lowenstein when the case comes to trial in the United States Circuit Court, Brooklyn.

Mr. Tesla said yesterday that a careful search of the patent records at Washington will show that he was the first to invent certain wireless devices used by Mr. Lowenstein in his apparatus, on which the Marconi company claims there has been an infringement. Mr. Lowenstein was formerly Mr. Tesla's assistant.

"Mr. Lowenstein operates under broad patents granted to me on the wireless art," says Mr. Tesla in a letter to THE SUN. He has, however, with rare ingenuity and skill worked out certain practical details, and how much the advantages of the apparatus he manufactures are appreciated is best evidenced by the statement of the Secretary of the Navy, which you have quoted.

"My patents referred to bear the numbers 645,576 and 649,621 and describe a new and original wireless system characterized by the employment of four circuits in perfect resonance, a condition essential to successful practice. Long after their grant to me Marconi filed an application and secured a patent (No. 763,772) which covers exactly the same fundamental arrangements and forms the basis of the present suit.

"Such cases happen occasionally, as it is quite impossible for the examiners in the Patent Office to keep abreast with workers in new and special fields. A notable instance of this kind is my single phase induction motor, on which a celebrated inventor obtained a patent which was subsequently invalidated through my earlier application.

"In a recent suit in France involving the same or corresponding patents the highest court, acting on a statement submitted by me, decided against Marconi and recognized fully my priority of invention in all the important features. I have every reason to expect that when the same facts are presented here a similar conclusion will be reached by the Supreme Court."

Experimental Electricity Course

By S. Gernsback and H. Winfield Secor

LESSON 13.

THE X-RAY (Concluded).

In practice, however, the concentration is never accurate in ordinary tubes, a compromise being made between the sharpness of focus, and the heating effect. From this it is evident, that anything which enables the anode to lose its heat rapidly, or to stand a high temperature without being damaged, also allows of a more accurate concentration of

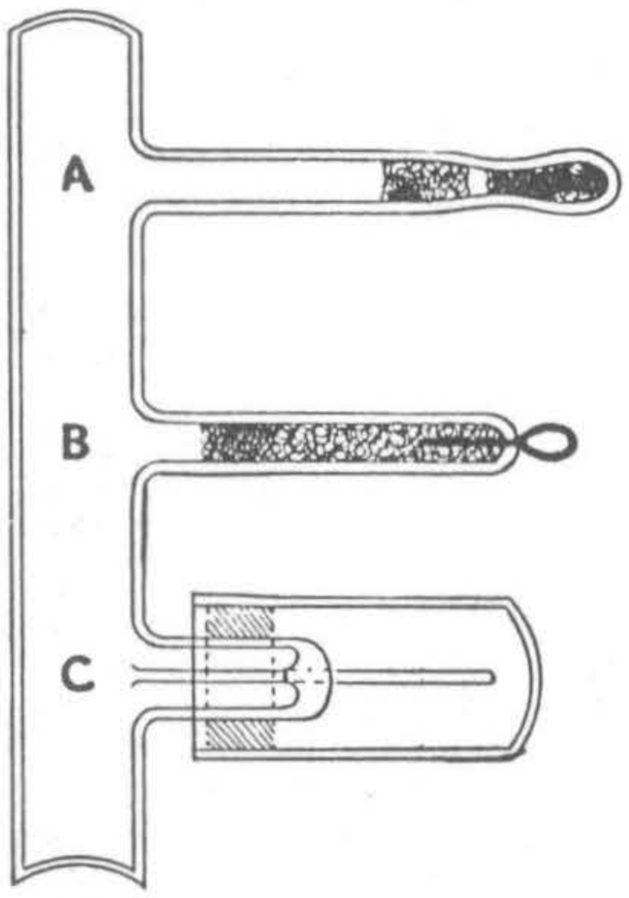

Fig. 9

the cathode stream, and a greater sharpness in the effects produced. Also, such non-damageable anodes permit of a

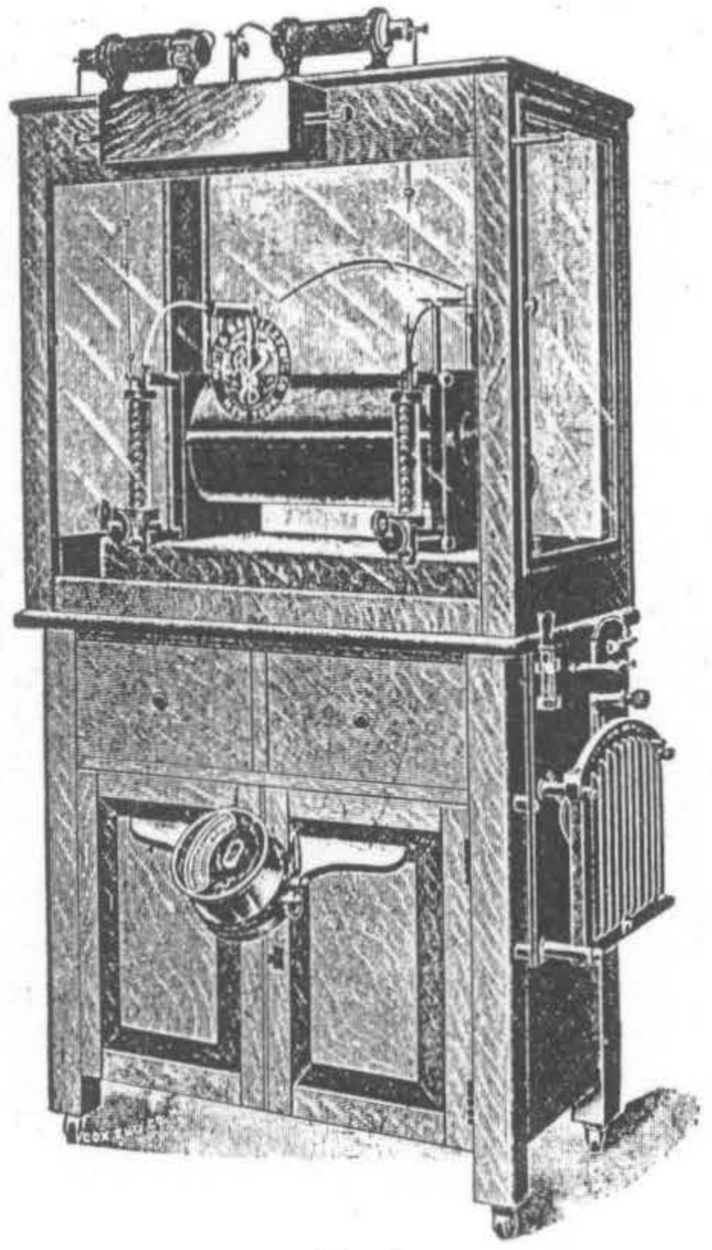

Fig. 10

heavier discharge thru the tube and therefore of greater energy of radiation.

The anode or anti-cathode as it is sometimes called, consists usually of a small plate of metal fixed opposite to the centre of the cathode, and mounted at an angle of about 45 degrees with the axis of the tube.

The X-Rays which are produced radially from it, are thus directed outwards through the side of the bulb, where no electrodes, thickened glass, or other obstructions are met with.

The material employed for the construction of the anode electrode makes a considerable difference in the efficiency of the tube, as found by Roentgen. He states that there is a difference in degree of X-Ray emission, by anodes of different materials, and that at the point of impact of the cathode stream, platinum radiates much more powerfully than aluminum; platinum having a very high melting point (3,000 degrees Fahrenheit), is usually chosen for the material out of which to make the anode electrode.

Excellent results have been obtained with iridium used as a small centre in a disc of platinum.

X-Ray bulbs tend to raise their vacuum after continued use, and change from a soft low vacuum, to a hard high vacuum. There are various methods in vogue for regulating the vacuum of tubes automatically and otherwise. Three principal schemes employed are depicted by the cut fig. 9, at A, is represented the chemical regulator, which requires the application of external heat to them, to become operative. The sealed glass chamber shown, contains potassium chlorate or manganese dioxide, which liberates oxygen gas when heated by the application of a spirit lamp to the outer surface of the glass tube.

The construction shown at B is like the one just described with the exception that a platinum wire is sealed into the portion of the tube containing the chemical. Sparks from the exciting apparatus are allowed to pass into the tube thru the platinum wire, and gas is formed and liberated. The tube can thus be regenerated at will.

The vacuum regulator illustrated at C, is known as the "Osmotic type." It is comprised of a very small tube of metallic Palladium sealed into the side of the X-Ray bulb. The inner end of the metal tube is open and the outer end closed. The tube is covered ordinarily by a glass cap. If this cap is removed, and the flame of a spirit-lamp applied to the closed outer end of the Palladium tube, hydrogen Ions from the interior of the flame will be drawn thru the intermolecular spaces of the heated metal, into the exhausted X-Ray bulb. This form of regulator has the advantage over the proceeding two types, in that the vacuum of the X-Ray bulb, can be adjusted any number of times, but the first two are limited by the amount of chemical in the end of the regulator tube, which is sealed off air tight.

X-Rays present a very entrancing field for unlimited experiment and study, but caution should be observed in subjecting the skin to long exposures of the rays, as they have a property of producing serious sores or growths, which if not checked quickly are incurable. Grave effects are caused on the trophic nerves, and vital resistance of the superficial tissues of the body, followed in a week or more by severe inflammation and necrosis.

A large X-Ray generator with regulating rheostat, ammeter, etc., are shown in fig. 10.

LESSON 14.

HIGH FREQUENCY CURRENTS.

HIGH frequency currents represent the most advanced field of electrical experimentation, and but very few of the wonders of these currents, especially when produced at high potential are known. Hence, a wide scope is given to the investigator and experimenter, in the evolving of new laws and phenomena, from researches in this most interesting and growing branch of the electrical art.

The production of high frequency currents for experimental research, is usually accomplished by the aid of a Tesla coil, which takes its name from Nikola Tesla, a famous authority and investigator on this subject. Two of the principal scientists who have given us data and explanations of these currents are Tesla and Elihu Thompson, who independently and simultaneously obtained practically similar results.

Before delving into the more intricate details concerning the arrangement and operation of Tesla coils, Oudin coils, etc., a few paragraphs will be devoted to the elucidation of the meaning and scope of high frequency as applied to the

currents in question. It may be stated firstly, that high frequency currents are invariably oscillatory in Nature, or alternating from positive to negative, and back again, many hundred times per second. In the diagram, fig. 1A, is given a graphical representation of the "wave form" and time value, of an ordinary alternating current, such as used for commercial lighting, running motors, power transmission, etc. This current is known as a standard 60 cycle current; one cycle meaning the time consumed for the current to rise from zero to maximum positive value, back to zero, then to negative maximum to zero again. The time consumed by the current rising from zero to positive maximum then to zero, is referred to as an alternation; two alternations comprising a cycle. Hence, a 60 cycle current is one having also 120 alternations, and the time for this series of changes to take place is one sixtieth of a second. Also 60 cycles will take place in 1 minute. One alternation or ½ cycle requires for its transpiration 1/120 of a second.

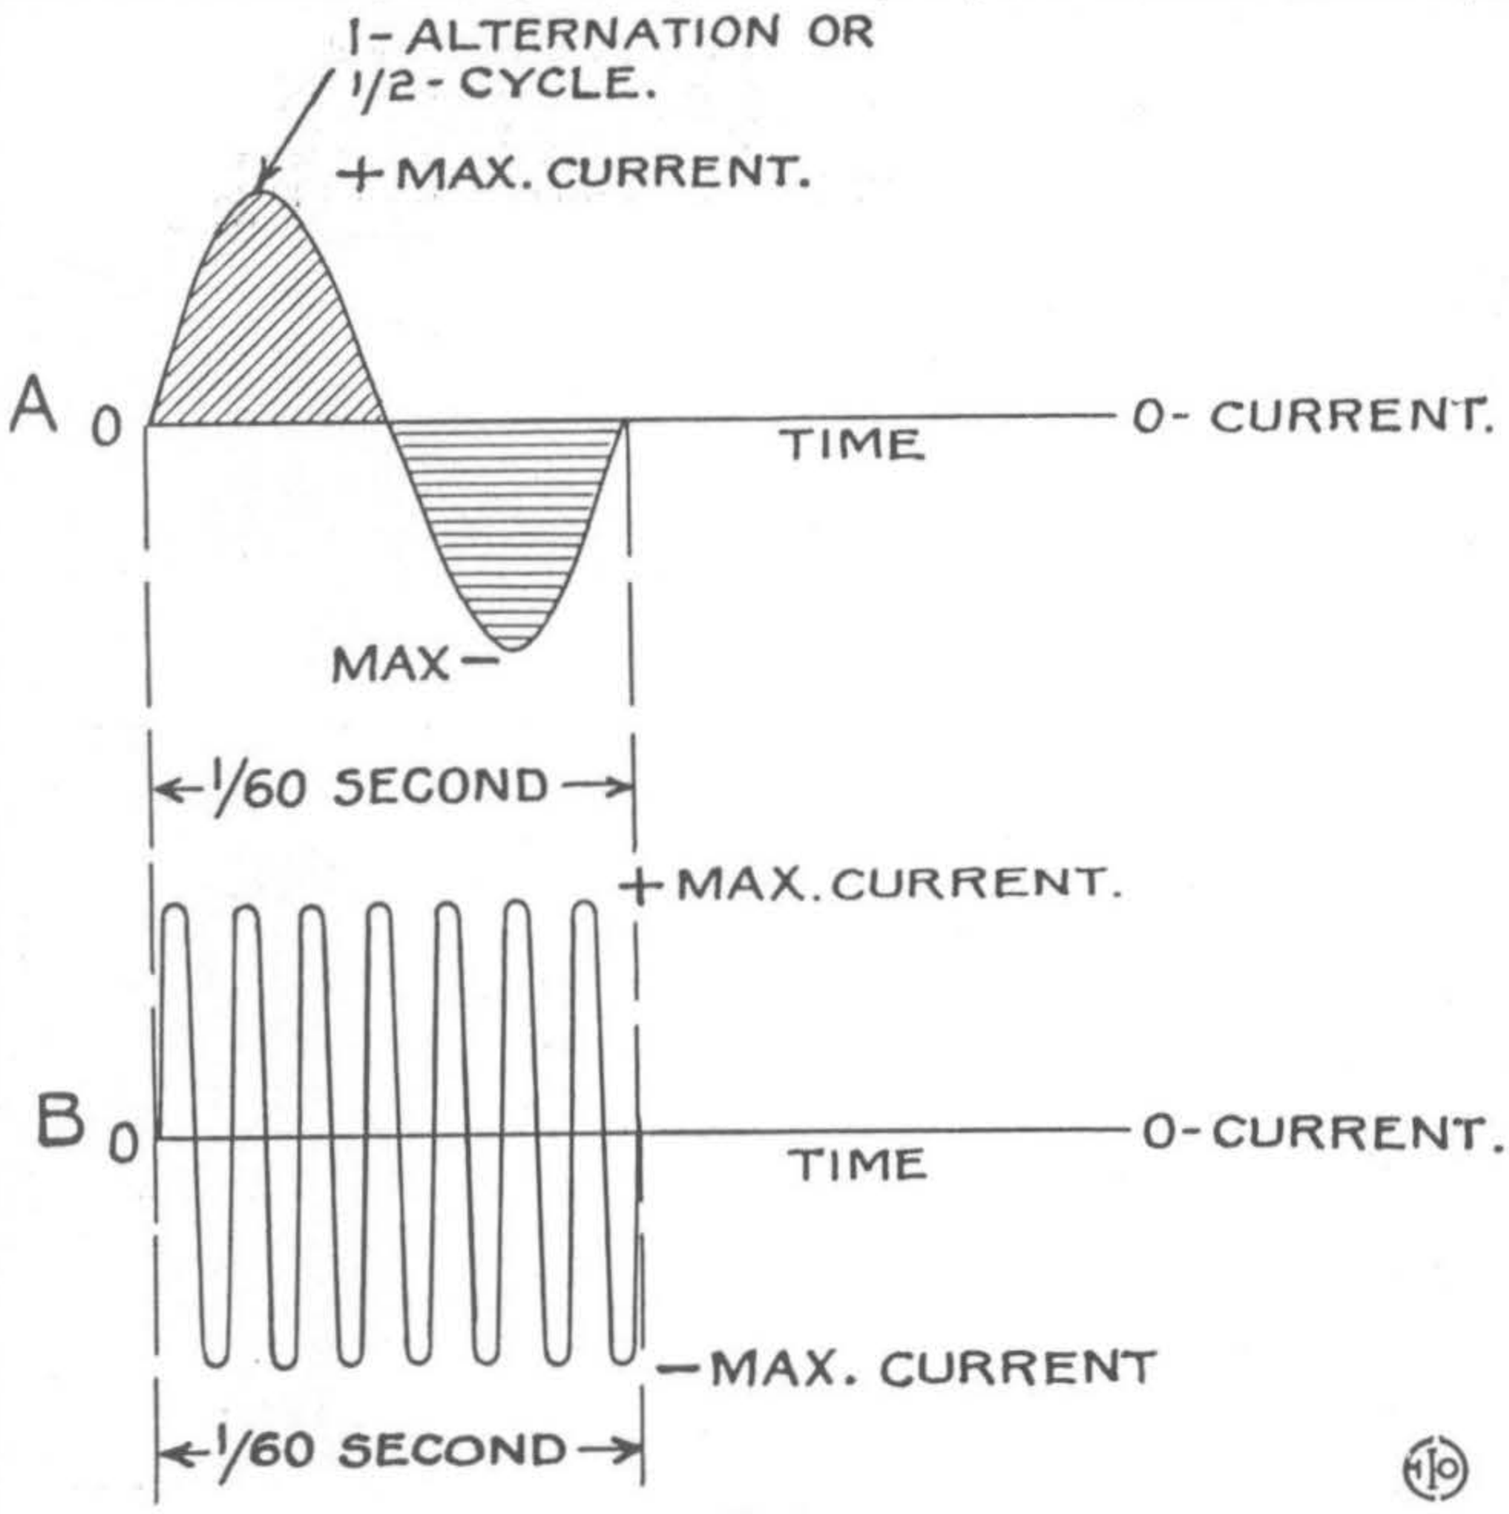

Fig. 1

In the curve of fig. 1 B, is depicted a higher frequency current than the 60 cycle just discussed, or as seen in the same time interval, viz., 1/60 second, seven times as many complete cycles have occurred, or the frequency per second is 7 times 60 or 420 cycles per second. Likewise, this frequency is equivalent to 840 alternations per second, or also 25,200 cycles per minute. Commercial lighting currents usually have a frequency of 3,600 cycles or 7,200 alternations per minute.

This explanation is for the purpose of making clear the exact meaning of the term high frequency. In actual practice, the term high frequency is invariably understood to mean a current whose frequency is somewhere between 10,000 and 1,000,000 cycles per second.

When such frequencies as these are employed, many wonderful and hitherto unlooked for phenomena appear. Among other features which they possess, are those permitting of passing it thru or rather over the human body, at a potential of half a million volts, or more. Tesla, Thompson and others have often demonstrated the feat of passing a million volts thru the body from hand to hand without experiencing the slightest harm or ill feeling. Ordinarily as in the electrocution of criminals, where low frequency alternating current of 60 to 120 cycles is employed, such potentials as 2,000 volts are sufficient to kill the subject. Generally but ¼ to ½ ampere passed thru the heart is sufficient to cause death. With high frequency currents, however, the current strength as indicated by a hot-wire ammeter may easily reach several amperes.

Currents of such frequencies as these, no longer obey the laws governing those of low frequency. For one thing, they travel principally over the surface of conductors, not thru them; penetrating but a few thousandths of an inch, this depending upon the frequency value. The higher the frequency, the less the penetration. From this it is evident that solid conductors for high frequency currents are a waste of material and thin walled or hollow ones of large diameter, are the best. Stranded conductors are always better than solid ones of similar capacity, as the former has much greater surface area for a given cross-section, and this is what counts in this case.

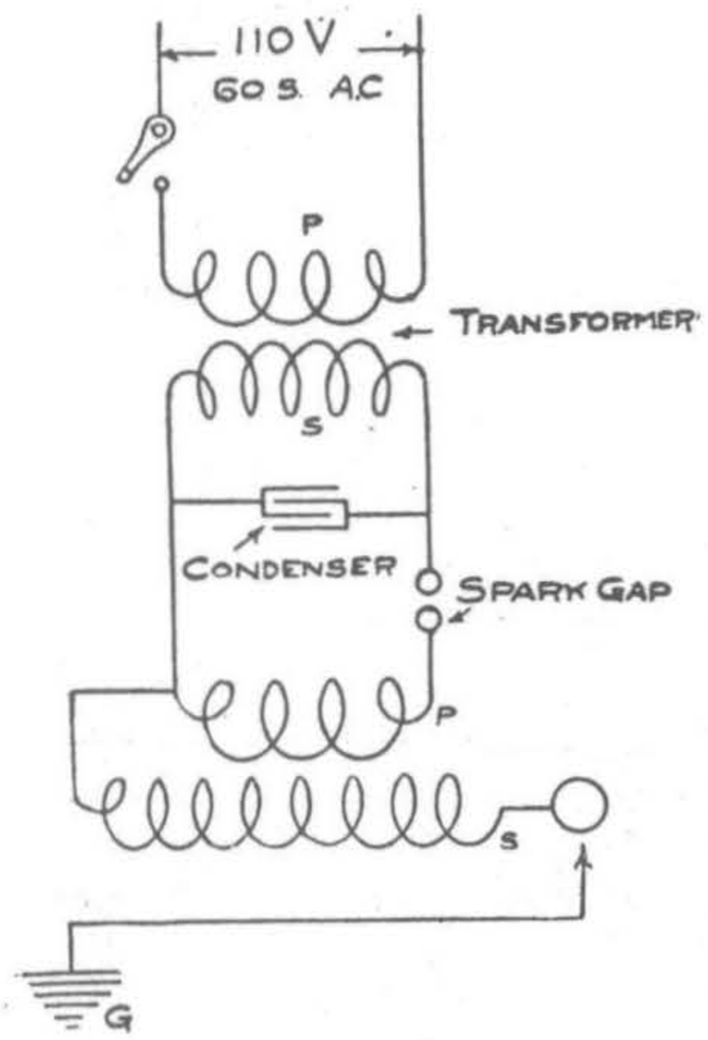

Fig. 3

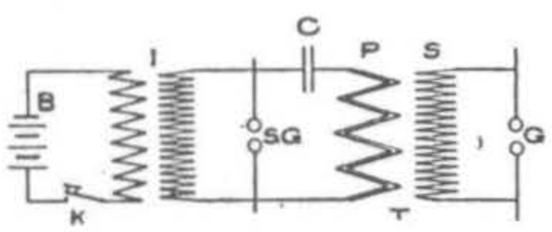

Fig. 2

High frequency currents can be produced in several ways, the principal methods being those involving the use of an Elihu Thompson generator, a Fessenden high frequency dynamo, or by means of the Tesla disruptive discharge set.

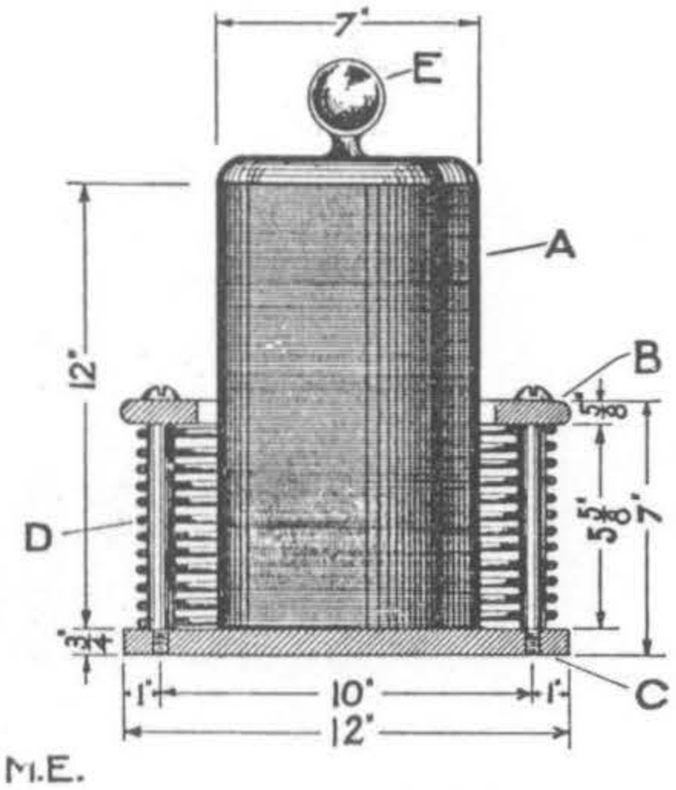

Fig. 3. An Oudin Coil

The New York Herald September 1, 1914

Letters from Herald Readers

Mr. Tesla Asserts Priority in Patent on Which Mr. Marconi Has Brought Action.

TO THE EDITOR OF THE HERALD:—

The HERALD of even date contains a report to the effect that the Marconi Wireless Telegraph Company has begun a suit for infringement against Mr. Fritz Lowenstein, the well known German engineer, formerly my assistant. Mr. Lowenstein operates under broad patents granted to me on the wireless art; he has, however, with rare ingenuity and skill, worked out certain practical details, and how much the advantages of the apparatus he manufactures are appreciated is best evidenced by the statement of the Secretary of the Navy which you have quoted.

My patents referred to bear the numbers 645,576 and 649,621 and describe a new and original wireless system, characterized by the employment of four circuits in perfect resonance, a condition essential to successful practice. Long after their grant Mr. Marconi filed an application and secured a patent (No. 763,772), which covers exactly the same fundamental arrangements and forms the basis of the present suit. Such cases happen occasionally, as it is quite impossible for the examiners of the Patent Office to keep abreast with workers in new and special fields. A notable instance of this kind is my single phase induction motor on which a celebrated inventor obtained a patent which was subsequently invalidated through my earlier application.

In a recent suit in France involving the same or corresponding patents the highest court, acting on a statement submitted by me, decided against Marconi and recognized fully my priority of invention in all the important features. I have every reason to expect that when the same facts are presented here a similar conclusion will be reached by the Supreme Court.

NIKOLA TESLA.

NEW YORK, Aug. 28, 1914.

Experimental Electricity Course

By S. Gernsback and H. Winfield Secor

LESSON 14.

HIGH FREQUENCY CURRENTS (Concluded).

High frequency currents can be produced in several ways, the principal methods being those involving the use of an

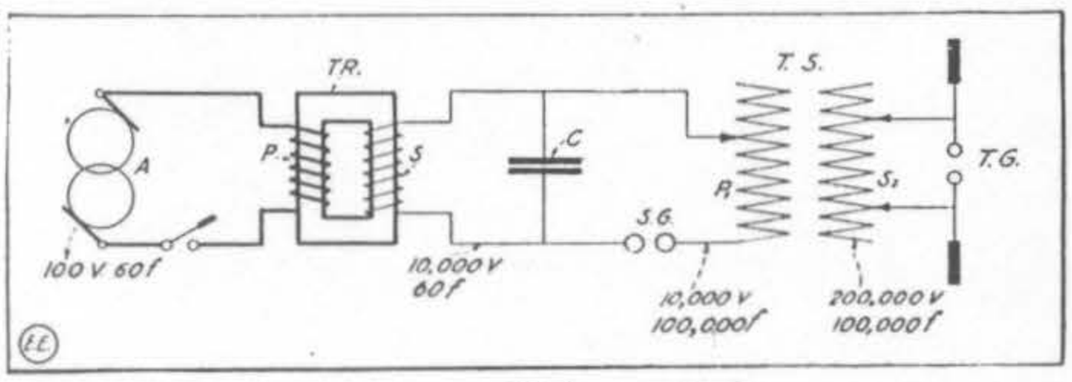

Fig. 4

Elihu Thompson generator, a Fessenden high frequency dynamo, or by means of the Tesla disruptive discharge set. The latter is the commonest and easiest method of producing such currents, and is widely utilized for lecture work, electro-therapeutics, exciting X-Ray tubes, etc.

The general arrangement of the functional parts composing the complete set is outlined in fig. 2.

Referring to the diagram, I is an induction or spark coil, preferably of not less than 2″ spark capacity. T is an air-core transformer, which serves the purpose of stepping up the voltage of the current delivered by the secondary of the induction coil, to many times its original value. At C is a condenser composed of Leyden jars, or glass plates, coated on both sides with tinfoil. A spark gap is placed at S G between whose electrodes the disruptive discharge of the condenser takes place. G is the discharge air gap of the Tesla coil secondary, across which the high frequency oscillations surge.

The functions of the various parts of the apparatus and their inter-relation is as follows: The induction coil or transformer I is excited from the battery shown at B, or the regular line feed wires; and its secondary current at 10,000 volts or more pressure is caused to charge the condenser C, which immediately discharges itself thru the primary coil P of the Tesla transformer and the spark gap SG. Now due to the conditions imposed by such circuit, the condenser discharge becomes not a single discharge for each cycle of induction coil secondary coil, but many times greater; so that with certain proportions to the circuits, as regards the capacity and inductance, the frequency of the current passing thru the Tesla coil primary may easily reach a million and more cycles per second; rendering the current harmless owing to the "skin effect" already mentioned. The currents thus produced are of course highly damped, i. e., the series of oscillations corresponding to each cycle of exciting current, dies down to zero, before the next series of oscillations start.

Fig 5

The frequency of the Tesla currents produced obey a certain law, which is as follows: They vary as the square root of the product of the capacity and inductance in the closed oscillating circuits. The frequency in cycles per second is found by dividing 10^6 times 5.033 by the square root of the capacity, multiplied by the inductance; where the capacity is in microfarads, and the inductance in centimeters. For further particulars see "Wireless Course" chapters 17 and 19. Also "Construction of Induction Coils and Transformers," by H. W. Secor.

Another form of high frequency transformer employed extensively for electro-therapeutical applications, is the Oudin coil. Its appearance and connections are given at fig. 3. As

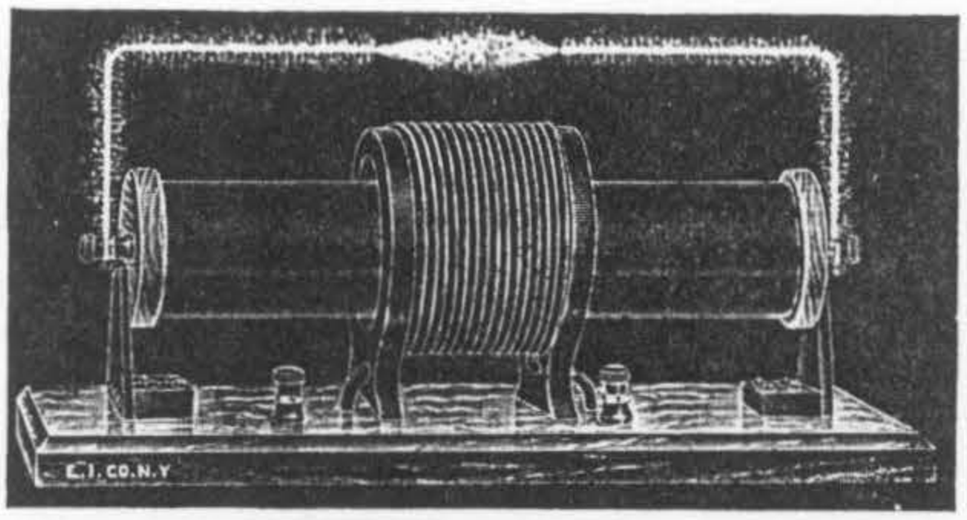

Fig 6

seen the bottom of the primary and secondary coils are joined together. Any Tesla coil becomes an Oudin type, if the primary or heavy wire winding is simply placed at the end of the secondary, instead of at the center as usual.

The relation of the frequencies and voltages will be more readily understood quite probably by inspecting fig. 4. It is seen that the coils or transformers do not change the frequency in themselves at all but only the voltage, which is dependent upon the relative amount of turns of wire upon the different coils. (See Lesson No. 4 in Nov., 1913, *Electrical Experimenter*, on "Transformers.") A cut of a powerful high frequency generator designed by Dr. Frederick Strong, for electro-therapeutical purposes, is illustrated by fig. 5.

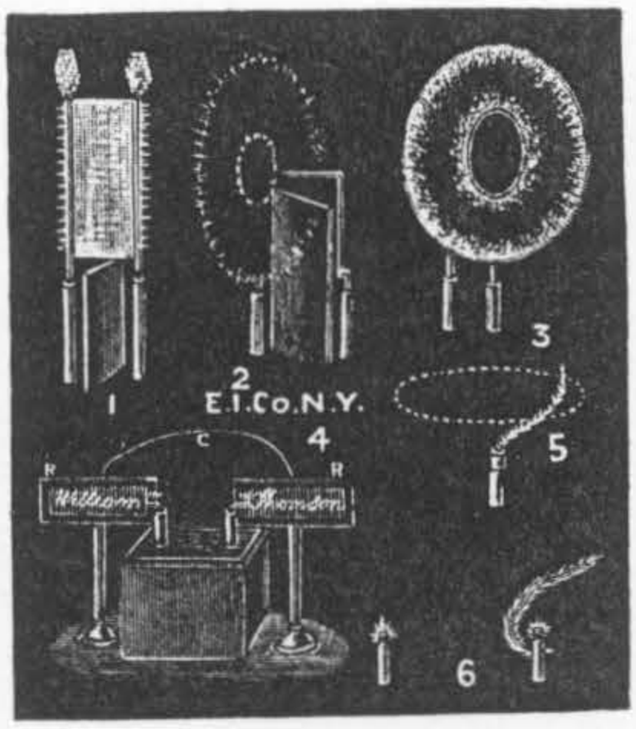

Fig. 7

For experimental research a very neat and efficient form of Tesla transformer is depicted at fig. 6. It is built by the well known electrical firm, The Electro Importing Co., of New York City, and sells for a very reasonable price, in comparison to the wonderful results attainable with it. In full activity, when excited from a 2″ spark coil operating on batteries, it takes on the appearance displayed in fig. 6, but the life and beauty of the discharge can only be fully appreciated by actual observation, and not from a mere black and white print. This coil is admirably suited to the requirements of the private laboratory, the School lecture platform, and demonstrations in general. A larger exciting coil may be employed than that mentioned, and of course the effect is greatly enhanced. (See the Feb., 1914., E. E. for a special article on "Currents of Ultra-High Frequency and Potential.")

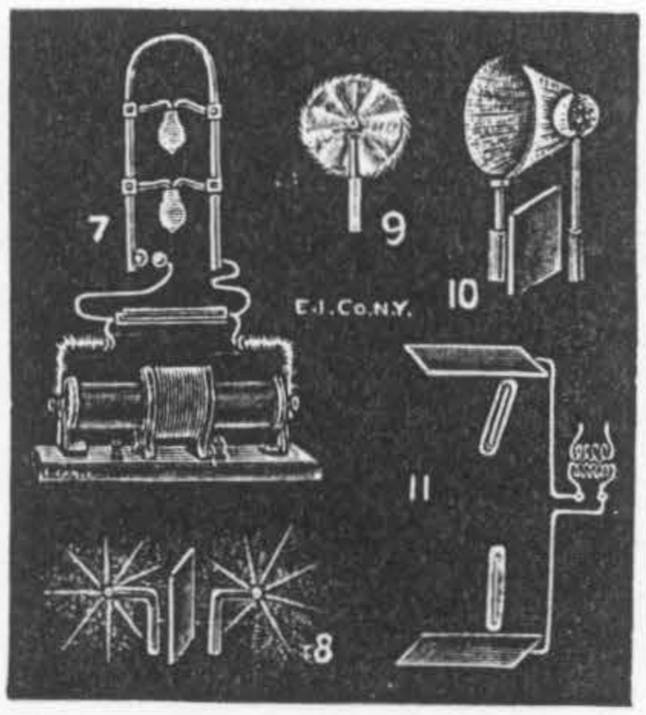

Fig. 8

The adjustment of the circuits of Tesla or Oudin coils has

to be carefully tried out by experiment to attain the maximum results. The length of the spark gap, the amount of condenser capacity and number of Tesla coil primary turns in circuit, all have a direct influence upon the final high frequency discharge, and they should be carefully adjusted simultaneously or successively, until the best high frequency discharges are obtained.

A rotary spark gap is best for the oscillating circuit, as it keeps very cool, and prevents the gap from arcing, which lowers the frequency. The shorter the gap the higher the frequency, and vice versa.

Having described the Tesla transformer, its action and connections, a few experiments of interest will be given: It may be well to state that the most spectacular results are only obtainable in a good dark room or hall. When the high frequency current is to be handled by the body, an unpleasant shock is experienced if the Tesla spark is allowed to jump direct to the skin; and a piece of metal held in the hand, or a Geissler tube, or even an incandescent lamp is best; the brush or spark being absorbed by them, and communicated to the body without shock. Geissler tubes and the like are very useful for demonstration, as whenever the discharge is absorbed thru them they light up brilliantly, making visible the great activity occurring. Several people may be placed in a circle and a Geissler tube placed in the hands of every couple. When the current is applied to the persons at the ends of the circle, the Geissler tubes all way around will simultaneously light up, making an impressive effect.

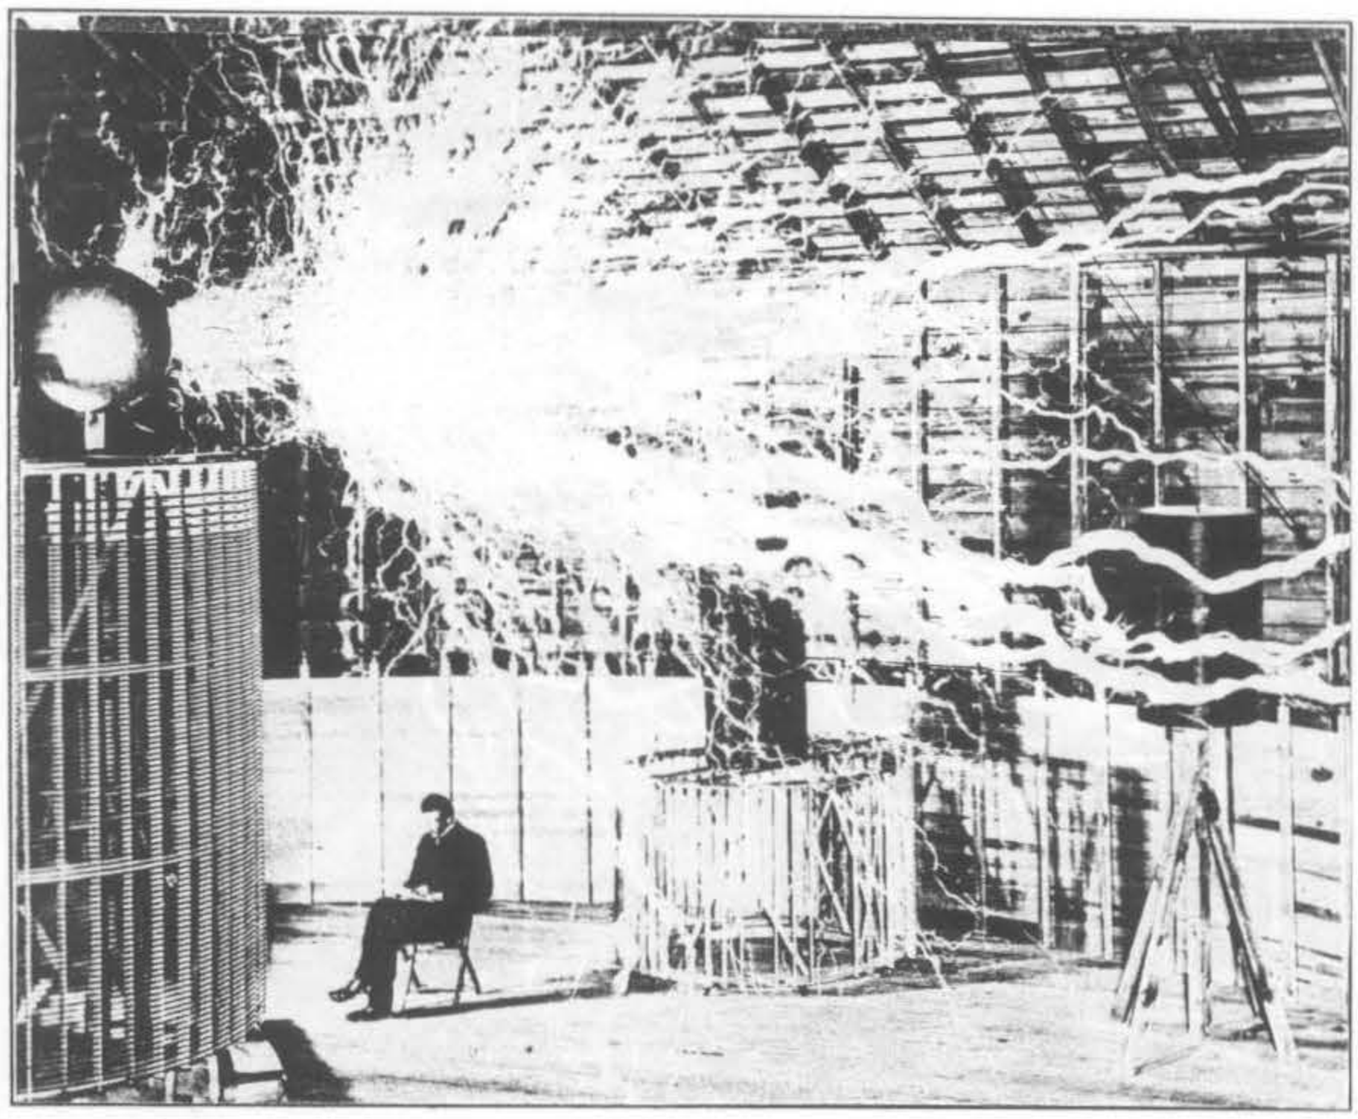

Fig. 9

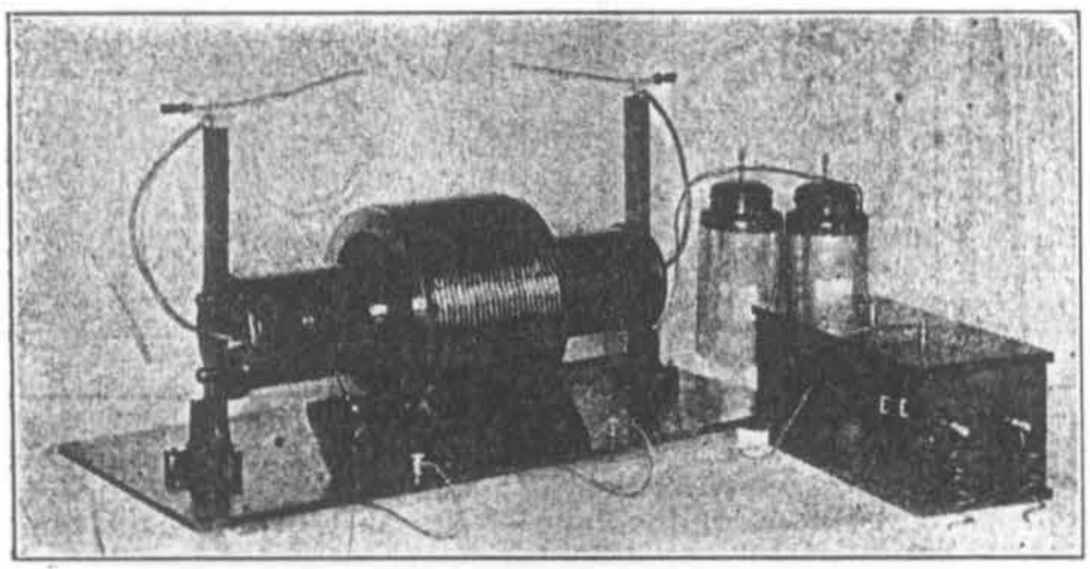

Fig. 11. A Large "Electro" Tesla Coil

In Fig. 7 are shown a number of interesting experiments which can be performed with the Tesla coil illustrated in fig. 6. At 1, fig. 7 is an experiment requiring the use of two vertical copper wires as nearly parallel as possible. When the apparatus is working in good shape, with the frequency high, the space (2-4 inches) between the two wires is filled with light, while the ends show a heavy brush discharge.

The experiment seen at 2 is performed by arranging two loops of copper wire, and attaching them to the secondary terminals of the Tesla coil. A similar arrangement is that seen at 3, but here the inner loop is 30 centimeters in diameter (1 inch equals 2½ cms.), while the larger loop is 80 centimeters in diameter. The space between the concentric loops is filled with millions of fine sparks, presenting a very pretty effect.

Illuminated names are produced as shown at 4, fig. 7. The names are made of fine copper wire, placed on one side of glass plates. The backs of the glass plates are coated with tinfoil a little smaller than the glass itself. One terminal of the Tesla secondary is connected to the wire name, and the other terminal to the opposite wire name. The tinfoil coatings on the back of the glasses are connected together by a piece of copper wire. When the current is turned on the names are illuminated. Hard rubber may be employed in place of the glass.

The rotating wire, 5, at fig. 7, is very amusing to observe. The wire must be quite fine, and the length determined by experiment. When of the right length, the wire will swing around a circle continually. It is connected to one terminal. A short piece of thin, cotton covered copper wire when attached to one terminal of the coil, gives out a beautiful flame effect, seen at 6.

One of the most astounding stunts performed with high frequency, high potential currents, is that known as "The impedance bridge or shunt," seen at 7, fig. 8. A heavy piece of copper wire or brass rod may be bent into a U-shape as shown, and when shunted by a low voltage lamp bulb, the lamp will light up brightly; the high frequency current preferring to traverse the comparatively high resistance path of the lamp instead of the low resistance offered by the brass rod. This is

(Continued on page 87)

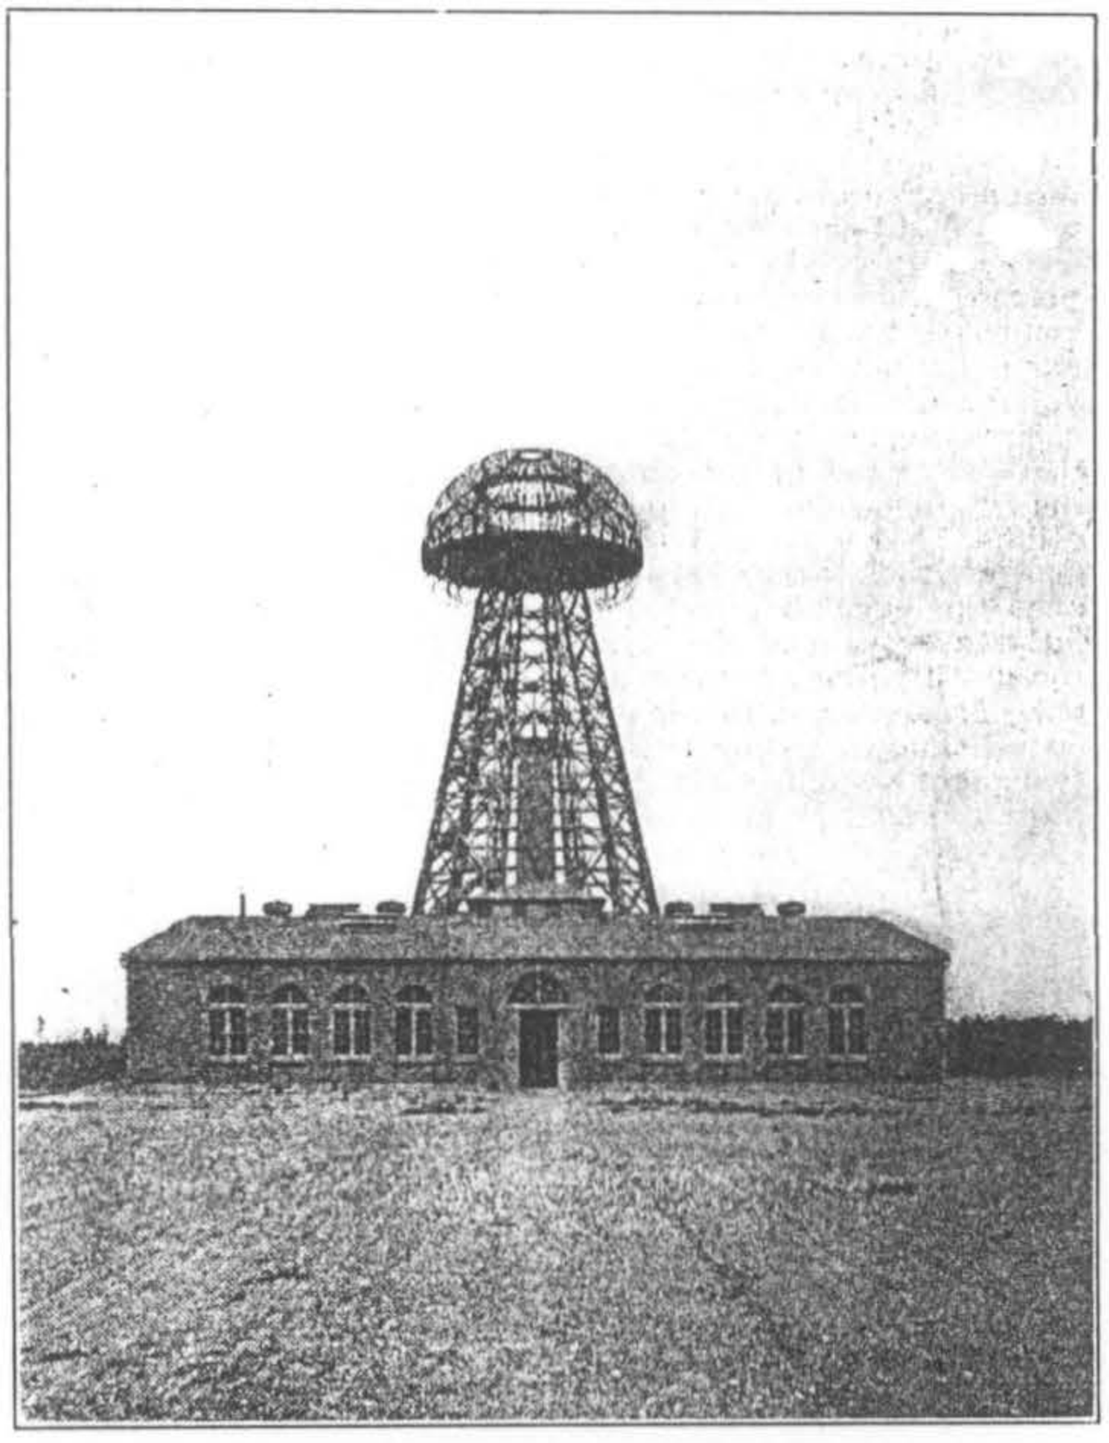

Fig. 10. Tesla's "World Wireless" Tower on Long Island, N. Y.

EXPERIMENTAL ELECTRICITY COURSE.

(Continued from page 85)

probably similar to lightning effects, etc., where it is seen that such high frequency surges, tend to take the shortest path, irrespective of resistance. For this reason lightning rods are always run in as short and straight a path as possible, avoiding sharp bends. In the Tesla coil experiment here mentioned, a Leyden jar or other condenser is connected across the secondary coil terminals, with a spark gap in one of the leads going to the copper bar. The terminals of the 20 volt lamps are tried in different positions, until the maximum brightness is obtained.

At 8, Fig. 8, is a display of weird appearance, called the "Electrical Phantom." Two thin metal discs, about 1" diameter, are connected to the two secondary terminals of the Tesla Transformer. Their edges are ground thin. With the voltage at a high value, white rays or threads of light strike out from the edges of the discs, which are sometimes of considerable length.

Electrical wind, as performed with static machines, is also reproduceable from the Tesla coil. Its effect is illustrated at 9. A small sharp toothed aluminum disc, about 1/64 inch thick, is mounted on an axle, having very little friction, and when the current is turned on, the little disc will rotate at high speed, becoming enveloped in sparks.

An illuminated cone of light is made by having a wire ring connected to one terminal of the Tesla coil and a metal ball of ¼ the ring diameter, connected to the other terminal. When current is applied the space between the ring and ball is filled with multitudinous fine sparks, giving a unique and beautiful display.

At 11 is depicted Nikola Tesla's ideal wireless light for illumination. Evacuated glass tubes are placed in proximity to the charged metal plates, connected to a source of high frequency, high potential electric current. The lamps are thus illumined by induction, without any metallic connections whatever being made to them.

Just what can be accomplished when large amounts of electrical energy is transformed into high frequency, high potential form, may be gleaned from the photograph of some electrical discharges of this nature, at fig. 9. This is from some of Tesla's experiments. The sparks shown were 25 feet long, the potential several billion and the amperage 800. Tesla's laboratory and tower erected some years ago on Long Island, for experimenting with world wave telegraphy, is depicted at fig. 10.

(To be continued)

The New York American December 6, 1914

Tesla Has Wireless to Light Whole Ocean

"I have invented and patented an apparatus for transmitting electrical energy without wires which will not only revolutionize the present wireless systems, but will make it possible to cast light from shore that will make the Atlantic steamship lanes safe," declared last night Nikola Tesla, on his return from Washington, where the invention was patented.

He said that his apparatus would give the wireless unlimited sending power and messages around the world would be a matter of course.

The New York American December 7, 1914

TESLA LIGHT TO ROB OCEANS OF EVERY DANGER

Electric Waves Will Also End War, Make Rain and Transform the Earth, Inventor Says.

Nikola Tesla, scientist and inventor, at the Waldorf last night told the New York American that he saw the end of war in the application of new principles of electrical construction he has discovered and with which he expects to revolutionize many of the activities of life.

"Apparatus designed in accordance with my invention, even if it be of small dimensions, is capable of transforming energy of tens and hundreds of thousands horsepower," said Mr. Tesla.

"The lighting of the ocean, which was mentioned in The American of this morning, is only one of the less important results to be achieved by the use of this invention. I have planned many of the details of a plant which might be erected at the Azores and which would be amply sufficient to illuminate the entire ocean so that such a disaster as that of the Titanic would not be repeated. The light would be soft and of very small intensity, but quite adequate to the purpose.

"A very timely application could just now be made in England, where a plant could be provided for illuminating London and the country in general at night to rob an attack by Zeppelins of its principal terrors. I have calculated that a plant of 75,000 horsepower would be required for the Azores, but much less power would do for the London application.

"One of the even more valuable uses to which this invention can be put is the transmission of the human voice or any kind of picture or image from one to any other point of the globe, absolutely irrespective of distance. Lighting of isolated and inaccessible places on land or sea can be effected by this new means in cheap and satisfactory manner.

"The employment of apparatus involving the same principles will, I am satisfied, lead to undreamed of achievements. For example, it will be the power of man to precipitate rain, to draw unlimited quantities of water rfom the ocean. Lakes and rivers will be created in this manner and the whole globe transformed, all the work being performed by the sun, men simply controlling the process.

"Perhaps the greatest results will be in the destruction of the atom and the release of its immense energy. This discovery will make the gun obsolete. The battles of the future will be fought with electrical waves. The destructive power under control will be so prodigious that on this account alone war will become an impossibility."

The New York Herald December 28, 1914

Letters from Herald Readers

Thanks the Herald for Editorial and Calls Attention to Needs of Servia.

TO THE EDITOR OF THE HERALD:

I feel sure that I am voicing the sentiments of all my countrymen in thanking you heartily for your timely and helpful editorial of yesterday calling attention to the present urgent needs of Servia. Hardly ever was there a people so sorely tried or one which has more valiantly fought for individual uplift and national independence. The American press has been unanimous in bestowing unstinted praise upon the little nation for its energy and courage in resisting a powerful enemy, but precisely because of their marvellous successes the impression has been created here that the Servians are fully able to take care of themselves. It should be remembered, though, that Servia's victory is like that of Fabricius. She might survive one more like the last, but no more than one.

The great perfection of modern arms equalizes individuals as fighting units, and forced defensive has but a slight advantage over offensive. This is well shown in the present conflict. The French are certainly excellent in the defensive and admirably well led, yet they have lost almost as many men as the invaders. So too, in Poland every German advance is invariably turned into a German defeat. The ultimate victory must inevitably be with the greater number. The Austrian casualties in the Servian campaign are estimated at 140,000 men, a loss great, to be sure, but one which can be easily borne by a power having still millions in reserve. For Servia half of that number means one-third of her active force.

Not only has Servia to meet now all the terrible difficulties resulting from war, but she has to use every ounce of her strength to train a new army and make ready for a fresh assault of an infuriated enemy twenty times stronger.

As to prisoners, of the eighty thousand which the Servians have captured at least sixty thousand are their own brethren. They are not prisoners, but rather unwelcome guests, and a burden hard to carry.

NIKOLA TESLA

NEW YORK CITY, Dec. 27, 1914.

THE

LONDON, EDINBURGH, AND DUBLIN

PHILOSOPHICAL MAGAZINE

AND

JOURNAL OF SCIENCE.

[SIXTH SERIES.]

JANUARY 1915.

I. *On the most Effective Adjustment of an Induction-coil.* *By* E. TAYLOR JONES, *D.Sc., Professor of Physics in the University College of North Wales, Bangor* *.

[Plate I.]

IN a recent paper † it was shown that the secondary potential and spark-length developed by an induction-coil, when a given current is interrupted in the primary circuit, are greatest under the following conditions :—

(1) The ratio n_2/n_1 of the two frequencies of electrical oscillation of the system has one of the values 3, 7, 11, ... ;

(2) $L_1C_1=(1-k^2)L_2C_2$ ‡.

The first is the condition that maxima of the two potential waves in the secondary circuit should occur simultaneously, the second that the sum of the amplitudes of the two waves should be a maximum for a given value of k.

It was further stated that the most effective of the ratios specified in (1) is $n_2/n_1=3$, and that in this case the conditions are satisfied by the adjustment $k=\cdot756$, $L_1C_1=\cdot429\ L_2C_2$.

* Communicated by the Author.

† Phil. Mag. xxvii. pp. 580–586, April 1914.

‡ L_1, L_2 are the self-inductances, C_1, C_2 the capacities, and k is the coupling coefficient of the primary and secondary circuits.

The physical meaning of the above results may be further considered in the light of what goes on in the *primary* circuit after the interruption of the current. An expression for the potential-difference V_1 of the plates of the primary condenser, at any time t after the interruption of the current i_0, has been given by Dibbern *. If the resistances of the circuits are neglected, Dibbern's expression becomes

$$V_1=\frac{2\pi i_0 n_1 n_2^2}{C_1(n_2^2-n_1^2)}\left(\frac{1}{4\pi^2 n_2^2}-L_1C_1\right)\sin 2\pi n_1 t - \frac{2\pi i_0 n_1^2 n_2}{C_1(n_2^2-n_1^2)}\left(\frac{1}{4\pi^2 n_1^2}-L_1C_1\right)\sin 2\pi n_2 t.$$

If n_2/n_1 has one of the values 3, 7, 11, ..., then at the time $t=1/4n_1$, $\sin 2\pi n_1 t=1$, and $\sin 2\pi n_2 t=-1$. Consequently the value of V_1 becomes at this instant

$$\frac{i_0}{2\pi C_1}\cdot\frac{1}{n_2-n_1}-2\pi i_0 L_1\cdot\frac{n_1 n_2}{n_2-n_1}.$$

This may be expressed in terms of the ratio L_2C_2/L_1C_1. Calling this m, and writing a for $\dfrac{1}{8\pi^2 L_2C_2(1-k^2)}$, we have

$$n_1n_2=2a\sqrt{m(1-k^2)},$$

$$n_2-n_1=\sqrt{2a(m+1)-4a\sqrt{m(1-k^2)}}\ \dagger.$$

Hence $$V_1=\frac{i_0\{1-8\pi^2 L_1C_1 a\sqrt{m(1-k^2)}\}}{2\pi C_1\sqrt{2a(m+1)-4a\sqrt{m(1-k^2)}}}.$$

Inserting the value of a and condition (2), *i. e.* $m=\dfrac{1}{1-k^2}$, we find that this expression vanishes.

It appears, therefore, that if conditions (1) and (2) are satisfied, the amplitudes of the two potential waves in the primary circuit are equal, and that at the instant in question the potentials are at their maxima, but in opposite phase. The primary condenser is therefore uncharged, while at the same moment the secondary potential is at its maximum ‡, the two waves in the secondary circuit being then at their maxima and in the *same* phase. Further, since $dV_1/dt=0$, and $dV_2/dt=0$, there is no current in either circuit. The whole of the energy therefore exists at this moment in the

* E. Dibbern, *Ann. d. Physik*, xl. 4, p. 938 (1913); Inaug. Diss., Kiel.

† *L. c.* p. 581.

‡ *L. c.* p. 581.

electrostatic form in the secondary circuit, and the secondary potential must in these circumstances have its greatest possible value for a given initial energy-supply $\frac{1}{2}L_1i_0^2$.

It was shown in the previous paper to which reference has been made * that the value of this maximum secondary potential, still on the assumption that the resistances are negligible, is

$$V_{2m}=i_0\cdot\frac{L_{21}}{\sqrt{L_2C_2}}\cdot\frac{1}{k} \quad . \quad . \quad . \quad . \quad (3\,a)$$

$$=i_0\sqrt{\frac{L_{21}}{L_{12}}}\cdot\sqrt{\frac{L_1}{C_2}}. \quad . \quad . \quad . \quad (3\,b)$$

The energy equation is therefore

$$\tfrac{1}{2}L_1i_0^2=\tfrac{1}{2}C_2V_{2m}^2\cdot\frac{L_{12}}{L_{21}}.$$

The factor L_{12}/L_{21} arises from the manner in which the capaciiy C_2 of the secondary circuit is defined. It is the charge on one-half of the secondary coil (and the bodies connected to its terminal), divided by the difference of potential of the terminals. The charge on this portion of the secondary circuit is C_2V_{2m}, but as some of this charge is at a lower potential than that of the terminals, the energy must be less than $\frac{1}{2}C_2V_{2m}^2$. The correcting factor is L_{12}/L_{21}.

There are many values of k and L_1C_1/L_2C_2 which satisfy the above conditions. The first four, probably the only ones having any practical importance, are given in Table I.

If we define the efficiency of an induction-coil as the ratio of the maximum electrostatic energy in the secondary to the electrokinetic energy in the primary circuit just before the interruption of the current (*i. e.*, $\frac{1}{2}L_1i_0^2$), then the efficiency

* *L. c.* pp. 581, 584.

is unity in each of the adjustments specified in Table I. if the resistances of the circuits are negligible. But it is easy to see that of these adjustments the first (*i. e.*, $n_2/n_1=3$, $L_1C_1=\cdot429\,L_2C_2$) is the one which gives the longest spark *for a given primary current*. For let us suppose that an induction-coil is so constructed, and the primary condenser so chosen, that $k=\cdot914$ and $L_1C_1=\cdot164\,L_2C_2$. This is the second adjustment of Table I., and it allows the whole of the primary energy $\frac{1}{2}L_1i_0^2$ to be converted at a certain moment after the interruption into electrostatic energy in the secondary circuit. Now by inserting coils of suitable self-inductance, say l_1, in the primary circuit (coils which do not act inductively on the induction-coil) we can reduce the coupling coefficient to ·756 ; and if the primary condenser is chosen so that $(L_1+l_1)C_1=\cdot429\,L_2C_2$, we then have the first adjustment, with $n_2/n_1=3$. The system has again unit efficiency, but the maximum electrostatic energy in the secondary is now $\frac{1}{2}(L_1+l_1)i_0^2$, and is greater than the former value in the ratio of L_1+l_1 to L_1. The capacity C_2 of the secondary coil being unaltered, the secondary potential is increased in the ratio $\sqrt{L_1+l_1}$ to $\sqrt{L_1}$. The 3/1 adjustment is thus more effective (though not more efficient) than the others because it allows a greater quantity of initial energy to be converted into electrostatic energy in the secondary circuit, in which therefore the charge and potential developed are greater than in the other cases.

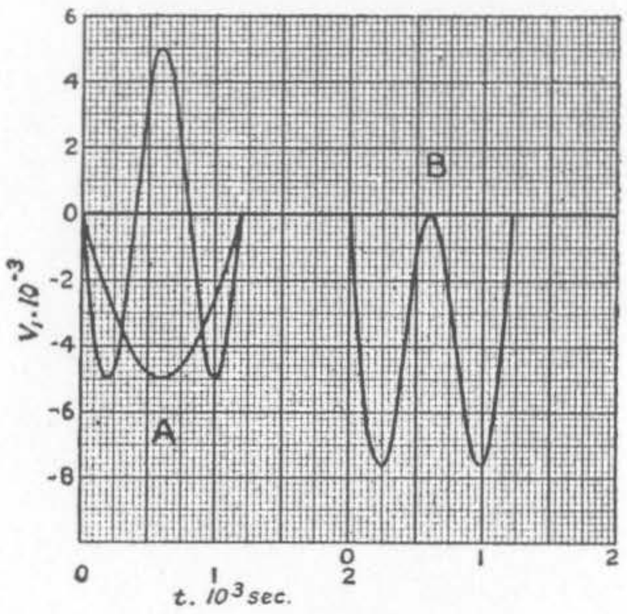
There are other ways in which the coupling coefficient could be reduced (*e. g.*, from ·914 to ·756), but none of them are so effective as the plan of introducing external inductance into the primary circuit. For instance*, external inductance may be introduced in the *secondary* circuit. This increases C_2, and to some extent L_{12}, without altering L_1 and L_{21}, and therefore, by (3 *b*), lowers the secondary potential. Again, k may be reduced by removing a part of the iron core. This diminishes L_1 without causing any increase in L_{21}/L_{12}, or any change in C_2, and therefore, by (3 *b*), reduces V_{2m}. The reduction of the coupling may also be effected by withdrawing the primary coil with the core to a suitable distance along the axis of the secondary. This process reduces L_{12}, L_{21}, and L_2, without changing L_1, and should cause no change in the secondary potential except such as may be due to a slight diminution of C_2 or of the ratio L_{21}/L_{12}.

It should be clearly understood that these reductions of the coupling are supposed to bring the system from

* In each of these supposed modifications the primary capacity is to be adjusted so that $L_1C_1=(1-k^2)L_2C_2$.

one state of unit efficiency to another, *e. g.* from the second to the first adjustment of Table I., for it is only in these states that equations (3 *a*), (3 *b*) hold. If, on the other hand, k lies between two of the unit-efficiency values, the spark-length for a given current may be increased by withdrawing the primary coil and core to a suitable distance along the axis of the secondary. For example, the coil with which I have experimented has a coupling coefficient of ·876, and the longest spark occurs when the primary capacity is about ·06 microfarad*. A marked increase is, however, produced in the spark-length by withdrawing the primary coil and core to a distance of 36·5 cm. from its nearly symmetrical position in the secondary, and increasing the capacity to ·15 microfarad.

We may conclude that any induction-coil in which the coupling is greater than ·756 can be improved in spark-length by connecting external series inductance in the primary circuit so as to reduce the coupling to this value. An induction-coil should not be constructed so that the coupling is less than ·756, for there is no convenient way of increasing the coupling to this value. Nor should the coupling coefficient of the primary and secondary *coils* have precisely this value, though if no external coils are used this is the best arrangement. Better effects are obtained by coupling the coils more closely than this, and adding series inductance to the primary circuit so as to reduce k to this value. The ratio L_1/C_2 is thereby increased, and it is upon this quantity, when the adjustments (1) and (2) are effected, that the maximum secondary potential for a given primary current chiefly depends.



In fig. 1 (A) are shown curves representing the two potential waves in the primary circuit of an induction-coil in which the above adjustment has been effected, and in which the damping of the oscillations is negligible. The amplitude of each wave is taken as 5000 volts, and the periods are ·0024 sec. and ·0008 sec. These values are chosen so as to correspond approximately (for $i_0=10$ amperes) with those found in an actual case, as described below. Fig. 1 (B) shows the result of superposing the two curves of (A). The equation to curve (B), the ordinate of which represents the potential of the primary condenser t seconds after the interruption, is

$$V_1=-5000\sin 150{,}000\,t-5000\sin 450{,}000\,t,$$

the angles being given in degrees.

* It was explained in the previous paper (*l. c.* pp. 584, 585) how the most effective primary capacity in any such case can be calculated.

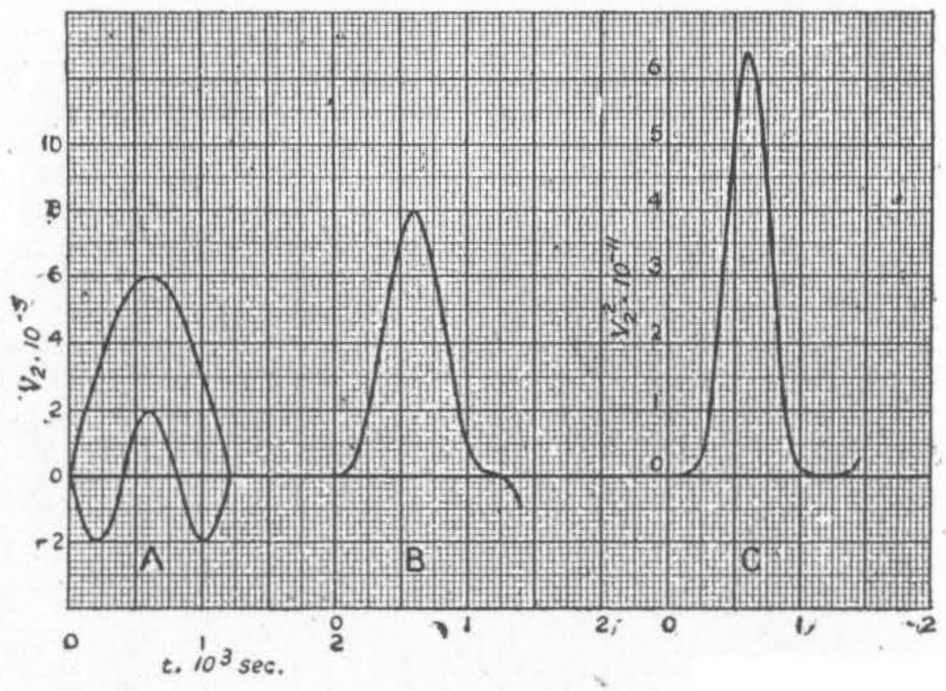


Fig. 1.

Primary potential.

The curves in fig. 1 cover one half-period of the longer wave ; their continuation in the second half-period is merely a repetition with the ordinates reversed in sign.

Fig. 2.

Secondary potential.

Fig. 2 (A) shows the corresponding potential waves in the secondary circuit ; fig. 2 (B) the effect of their superposition. The amplitudes here are taken as 600,000 and 200,000 volts

respectively. It will be seen that the two positive maxima coincide at ·0006 sec. after the interruption, giving the maximum potential of 800,000 volts at the secondary terminals. At this moment the potential of the primary condenser is zero. Fig. 2 (C) shows (for comparison with the oscillograph curves described below) the curve obtained by squaring the ordinates of fig. 2 (B).

The above theoretical conclusions apply strictly only to the case of an ideal induction-coil, in which the resistances of the circuits and other causes of damping of the oscillations are negligible. Some applications of the theory were, however, given, in the former paper referred to *, in which it was shown that the results of the theory agree closely with experiment in so far as they concern the *conditions* under which the greatest spark-length is given by an induction-coil. The *value* of the secondary potential is of course greatly modified by the damping.

Another experiment will now be described, from the results of which some further information may be gathered as to the working of an induction-coil when in its most effective adjustment.

The coil experimented upon was the one employed in the previous experiments, viz. : an 18-inch coil in which the coefficient of coupling of the primary and secondary coils (the secondary terminals being connected to the oscillograph and to a variable spark-gap) is ·876. The primary circuit was fed by a number of storage-cells, and included an amperemeter, a rheostat, and a slow interruptor which broke the current about once per second. The condenser was connected directly across the interruptor.

The experiment consisted in increasing the self-inductance of the primary circuit by the addition of air-core coils, and varying the capacity of the condenser, until the longest spark was produced by a given primary current. The curve of secondary potential was then photographed, and the constants of the circuits determined. The best effect was found to be obtained with four extra coils in the primary circuit, and with a condenser of ·2 microfarad capacity. It was not very easy to decide with great exactness upon the best self-inductance and capacity, owing to the fact that the spark-length varies slowly with these quantities in the neighbourhood of the maximum. A difference of ·025 mfd. either way in C_1 caused no appreciable change in the spark-length. From the practical point of view this slow variation near the maximum is in itself no disadvantage, since very exact

* *L. c.* pp. 582–586.

adjustment is not necessary in order to produce a spark-length practically equal to the maximum.

The constants of the circuits were measured by methods which were fully described in the previous paper, and found to be as follows :—

$$\frac{1}{L_1C_1} = 19{\cdot}57 \,.\, 10^6 \text{ c.g.s.},$$

$$\frac{1}{L_2C_2} = 8{\cdot}763 \,.\, 10^6 \quad ,,$$

$$k = {\cdot}748,$$

$$L_{21} = 20{\cdot}4 \text{ henries},$$

$$\frac{R_1}{L_1} = 680,$$

$$\frac{R_2}{L_2} = 825.$$

R_0, the resistance of the primary circuit for steady currents, was 8 ohms.

Hence

$$\theta_1 = \tfrac{1}{2}R_1C_1 = 1{\cdot}738 \,.\, 10^{-5} \text{ c.g.s.}$$

$$\theta_2 = \tfrac{1}{2}R_2C_2 = 4{\cdot}709 \,.\, 10^{-5} \quad ,,$$

$$\theta_0 = \tfrac{1}{2}R_0C_1 = \quad 8 \,.\, 10^{-7} \quad ,,$$

The quantities R_1/L_1, R_2/L_2, were determined from the decay factors of the circuits when oscillating separately. The effective resistances R_1, R_2, are much greater than the steady-current values ; they depend also upon losses due to leakage, hysteresis, and absorption. A considerable part of R_2 is probably due to leakage through the electrometer. The decay factors are not constant ; the values of R_1/L_1, R_2/L_2 given above prevail during oscillations of fairly large amplitude in the primary and secondary circuits respectively.

The calculated frequencies are :

$$n_1 = 413{\cdot}9,$$

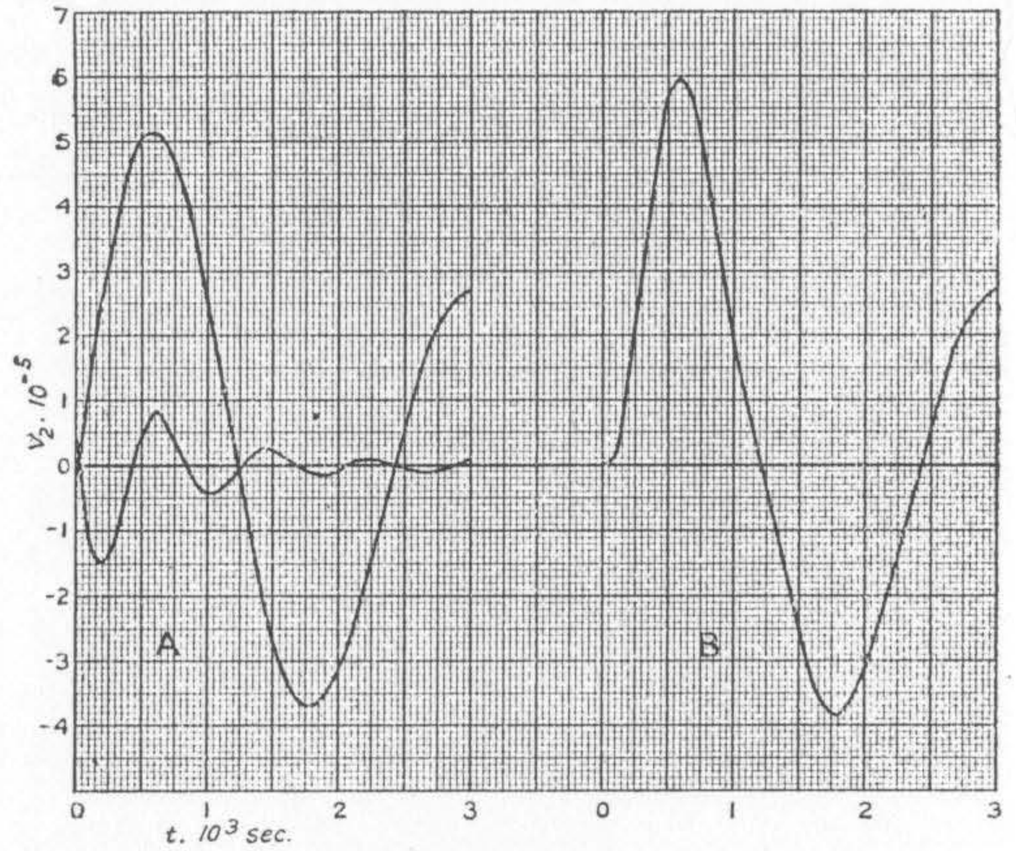
$$n_2 = 1208,$$

giving $$n_2/n_1 = 2{\cdot}919.$$

Also $$L_1C_1/L_2C_2 = {\cdot}448,$$

while $$1-k^2 = {\cdot}440.$$

The differences between these values and those of the ideal case ($n_2/n_1=3$, $k={\cdot}756$, $L_1C_1/L_2C_2={\cdot}429$) are within the limits of experimental error, and may be due to the above-mentioned difficulty of adjusting L_1 and C_1 accurately



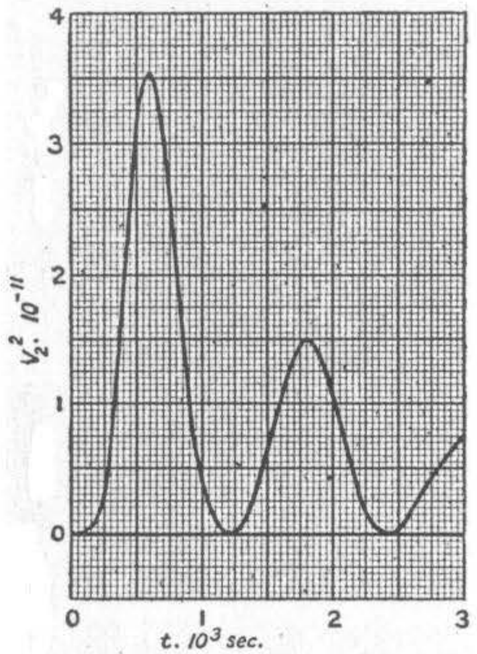
to give the best effect. If L_1 and C_1 were reduced, by amounts which would cause no appreciable change in the spark-length, the differences would disappear.

From the above data the secondary potential can now be calculated *, and the result, expressed in volts for $i_0=10$ amperes, is

$$V_2 = 601300 \,.\, e^{-2\epsilon 6\, t} \sin (149000\, t - 1{\cdot}95)^\circ$$
$$- 206900 \,.\, e^{-1410 t} \sin (435000\, t - 5{\cdot}7)^\circ.$$

From this expression values of V_2, the difference of potential at the secondary terminals t seconds after the interruption of the primary current, were calculated for

Fig. 3.



Secondary potential.

various values of t up to ·003 second, a time covering rather more than one whole period of the longer wave. The results are exhibited in fig. 3, in which (A) shows the two oscillations

* The general expression for V_2 is given in the previous paper, *l. c.* pp. 565, 574. The statement in the footnote on p. 574 requires correction. When the condenser is connected directly across the interruptor, so that the battery (e.m.f. E) is included in the primary oscillating circuit, we have initially $V_1=0$, but finally $V_1=-E$. The results as given on pp. 574, 575, apply to this case provided V_1 is taken as E+the potential-difference of the primary condenser.

of the secondary circuit separately, and (B) the result of their superposition. It will be seen that two positive maxima in the oscillations agree at about $t=\cdot0006$ sec., giving rise to the maximum secondary potential (596900 volts) at this time. Fig. 4 shows the square of the secondary

Fig. 4.

Square of secondary potential.

potential plotted against the time. This curve shows clearly the peaked maxima and the flattened zeroes which are characteristic of the 3/1 ratio.

In Plate I. figs. 6 and 7 are shown photographic records of the secondary potential wave obtained with the oscillograph. In these curves the ordinates are proportional to the square of the secondary potential, owing to the idiostatic connexion of the instrument, and these curves are therefore directly comparable with fig. 4. The currents interrupted when these photographs were taken were 1·5 and 2·0 amperes respectively *. It will be seen that the greatest ordinates of the curves are proportional to the squares of the currents. In period †, rate of decay, and form the calculated curve of fig. 4 agrees well with the photographs. The photographic curves are perhaps rather more

* The greatest spark-length for 2 amperes, between spark-balls 2 cm. in diameter, was 18·2 cm. The external inductance being removed, and the primary coil being still in its symmetrical position within the secondary, the greatest spark-length at 2 amperes ($C_1=0·6$ mfd.) was 12·8 cm. No sparks passed when the photographs shown were taken.

† The time curve shown on the photographs has a period of 1/768 sec.

peaked at the summits, and more flattened at the zeroes, than the calculated curve, which indicates that the calculated damping factor of the shorter wave is rather too great in comparison with that of the slower oscillation. This may possibly be due to the existence of an appreciable difference (arising from various causes) between the values of the effective resistances of the circuits when oscillating separately, and their values when the circuits are oscillating as a coupled system.

Turning now to the primary circuit, Dibbern's formula allows the potential wave in the primary condenser to be calculated *. Using the values given above for the constants of the circuits, and taking i_0, the primary current interrupted, as 10 amperes, Dibbern's expression becomes in the present case

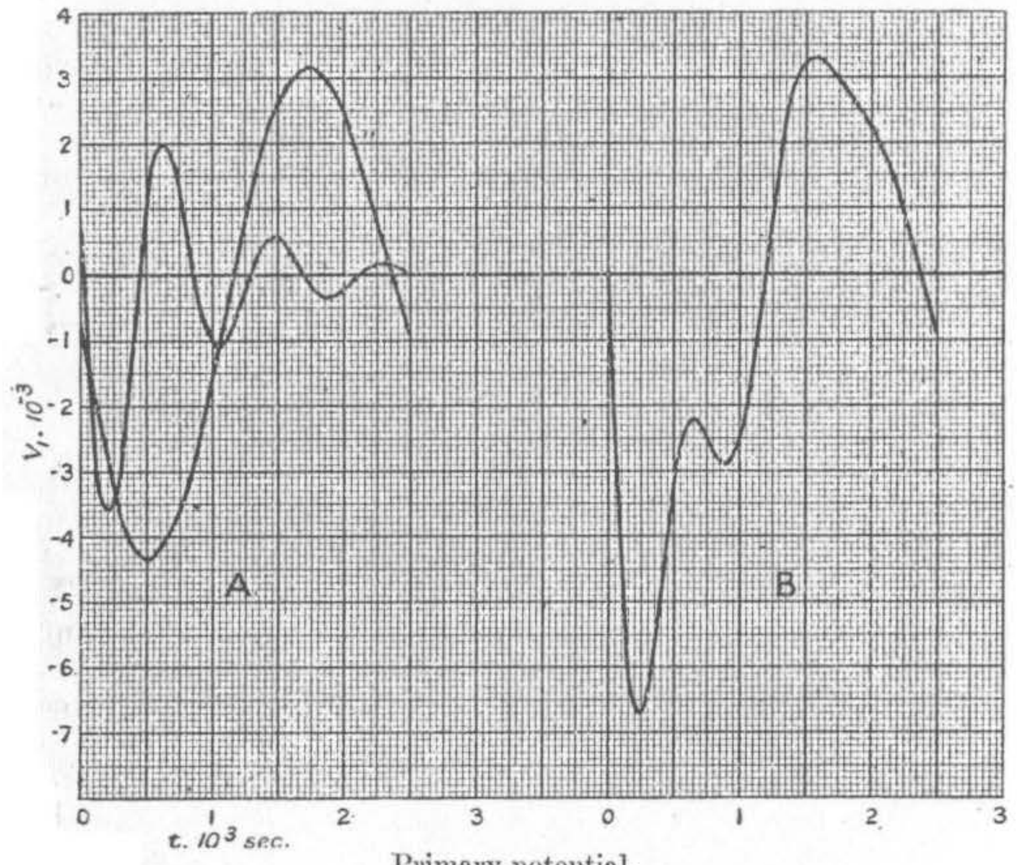
$$V_1\dagger = -5020\, e^{-266\,t} \sin (149000\,t+8·02)^\circ$$
$$-4940\, e^{-1440\,t} \sin (435000\,t-9·07)^\circ, \quad . \quad . \quad (4)$$

where V_1 is the primary potential in volts.

The amplitudes of the two oscillations in the primary circuit are thus nearly equal, as required by condition (2).

The two oscillations represented by (4) are shown in fig. 5 (A), the result of their superposition in fig. 5 (B). It will be seen that the negative potential‡ of the primary condenser reaches a maximum of 6800 volts at about ·00025 sec., and a minimum of 2250 volts at about ·00065 sec. after the interruption. Thus, at the moment at which the secondary potential reaches its greatest value the primary condenser, instead of being uncharged as would be the case in an ideal induction-coil, is still charged to about 2250 volts, and this is due almost entirely to the difference in the damping factors of the two oscillations.

The effective resistances of the circuits therefore act in two ways in reducing the efficiency of the arrangement. First, they give rise to dissipation of energy and consequent decay of the amplitudes of both oscillations. Second, owing to the difference between the damping factors of the two oscillations, there is some energy stored in the primary condenser at the moment when the secondary potential is at its maximum.



* The existence of the two oscillations in the primary circuit after the interruption is well shown by a current oscillogram taken by Wertheim-Salomonson, *Physik. Zeitschr.* xi. p. 539, fig. 1 (1910).

† As explained in the footnote on p. 9 above, V_1 here means E+ the potential of the condenser. E is here 80 volts.

‡ The potential of the primary condenser is taken negative when it opposes the battery E.M.F.

The efficiency is easily calculated in the present case. The maximum secondary potential, for $i_0=10$ amperes, is 596900 volts. If the resistances were negligible, and if the system

Fig. 5.

Primary potential.

were exactly in the first unit-efficiency adjustment, the maximum secondary potential would be, by (3*a*), 798700 volts. Consequently the efficiency is $\left(\frac{5969}{7987}\right)^2 = \cdot 559$.

The energy originally in the system is $\frac{1}{2}L_1 i_0^2$, *i. e.* since L_1 is about ·255 henry, 12·75 joules. The maximum electrostatic energy in the secondary circuit is therefore $\cdot 559 \times 12 \cdot 75$, or about 7·1 joules. The energy then stored in the primary condenser (capacity ·2 mfd.) is $\frac{1}{2} . \cdot 2 . 2250^2 . 10$ ergs, or about ·5 joule.

Consequently of the original 12·75 joules rather over 5 are dissipated, half a joule is stored in the primary condenser, and the remaining 7 joules are available to provide for the secondary discharge at the moment of maximum potential.

The charge then on the secondary is C_2V_2 and may be calculated when the capacity C_2 is known. If we knew the value of the ratio L_{21}/L_{12} the capacity could be at once

determined from the known values of k^2, L_1, L_{21}, and L_2C_2, since

$$C_2 = \frac{L_{21}}{L_{12}} . \frac{L_1}{L_{21}^2} . k^2 . L_2C_2. \quad . \quad . \quad . \quad . \quad (5)$$

With regard to the ratio L_{21}/L_{12}, this differs from unity because the current in the secondary coil during the oscillations is not uniformly distributed, but is greatest at the central winding and nearly zero at the ends. If all the windings of the secondary had equal inductive effects on the primary, when reckoned per unit current, and if the current in a turn of the secondary at a distance z from the central winding were proportional to $\cos\frac{\pi z}{h}$, where h is the length of the secondary coil, it is easily seen that L_{21}/L_{12} would be equal to $\pi/2$. In the actual case, however, the inductive effect of the secondary windings (per unit current) diminishes from the centre towards each end. This was tested by ballistic galvanometer experiments in which the mutual inductance of the primary and a single turn of wire, wound on the secondary (or primary) in various positions, was compared with its value for the central position. From the results of these measurements it was found that this mutual inductance could be represented approximately by the expression $a-bz^2-cz^4$ *. Consequently L_{12} is proportional to

$$\int_{-h/2}^{+h/2} (a-bz^2-cz^4) \cos\frac{\pi z}{h} dz,$$

while L_{21} is proportional to

$$\int_{-h/2}^{+h/2} (a-bz^2-cz^4) dz,$$

since the current in the primary coil is uniformly distributed. The value of L_{21}/L_{12} is thereby reduced from $\pi/2$, and becomes in the present case $\cdot 95\,\pi/2$.

Another correction is necessary if, as in the present experiments, the secondary terminals are connected to a capacity which is not negligible in comparison with that of the coil. In this case the secondary current is not quite zero at the ends of the coil, but should be represented as proportional to $\cos\frac{\pi z}{h'}$, where h' is greater than h. The value

* The dimensions of the coils are:—primary, length 90 cm., mean diameter 6·9 cm.; secondary, length (between the terminals) 51 cm., diameter (outside) 24 cm.

of h' may be estimated if we know the ratio of the external capacity C_e to the total capacity C_2. If C_e is small in comparison with C_2 the approximate value of the latter (obtained from equation (5) by neglecting the present correction) may be used here. If the current in the secondary windings varies as $\cos \frac{\pi z}{h'}$, the charge per unit length will be proportional to $\sin \frac{\pi z}{h'}$. Hence the ratio of C to C_2 is equal to the ratio of

$$\int_{h/2}^{h'/2} \sin \frac{\pi z}{h'} . dz \qquad \text{to} \qquad \int_{0}^{h'/2} \sin \frac{\pi z}{h'} dz,$$

$$i.\,e. \qquad \frac{C_e}{C_2} = \cos \frac{\pi h}{2h'}.$$

This determines h'/h, and we then have

$$\frac{L_{12}}{L_{21}} = \frac{1}{h}\int_{-h/2}^{+h/2} \cos \frac{\pi z}{h'} dz$$

$$= \frac{2}{\pi} \cdot \frac{h'}{h} \cdot \sin \frac{\pi h}{2h'}.$$

In the present experiments C_e is the capacity of the electrometer and the spark-gap terminals, and this is about one-sixth of the total secondary capacity C_2, the value of which is already known approximately. Hence $\cos \frac{\pi h}{2h'} = \frac{1}{6}$, and $\frac{h'}{h} = 1{\cdot}12$, from which $\frac{L_{12}}{L_{21}} = 1{\cdot}10 \cdot \frac{2}{\pi}$. The effect of this correction is therefore further to reduce L_{21}/L_{12} by about 10 per cent.

Taking both corrections into account we have approximately

$$L_{21}/L_{12} = {\cdot}85\pi/2 = 1{\cdot}335,$$

from which by (5)

$$C_2 = {\cdot}000052 \text{ microfarad.}$$

The charge of the secondary circuit at the moment of maximum potential is therefore $5{\cdot}2 \times 5{\cdot}969 \times 10^{-7}$ c.g.s., or $31 . 10^{-6}$ coulomb. If the whole of this charge escaped from the terminals, in the form of a spark or other discharge, the discharge current would be, at n interruptions per second, nC_2V_2. Further experiments are, however, required in order to decide whether this complete discharge takes place, or whether some of the electricity does not return through the secondary coil and continue to oscillate in it.

The conditions for maximum potential are the same when a rapid interruptor is employed as for the slow break used in the above experiments. They also hold whether the primary current is supplied by a small storage-battery, a 100-volt battery, or the 200-volt mains. Plate I. fig. 8 shows the course of the secondary potential at two successive "breaks" effected by a motor mercury interruptor. The effect of the small potential at the "make" is also noticeable. On this occasion the 100-volt battery was used to supply the primary current, the total (steady-current) resistance in the primary circuit being 11 ohms. The greatest spark-length was 18·4 cm., and the mean primary current, as indicated by an amperemeter in the primary circuit, was ·3 ampere. The current immediately before interruption would, however, be over 2 amperes.

Bangor, November 1914.

Did the War Cause the Italian Earthquake?

"The Explosion of Mines, Torpedoes, Mortars and Guns Develops Reactive Forces on the Ground Which Are Measured in Thousands of Tons and Make Themselves Felt all Over the Globe. If the Concussions Happen to Be Properly Timed Their Combined Action Could Start Tectonic Adjustments in Any Part of the Earth and the Italian Calamity May Thus Have Been the Result of Explosions in France," *Mr. Tesla Declares.*

By Mr. Nikola Tesla

The Distinguished Scientist, Electrical Expert and Inventor.

EVERY living being is an engine geared to the wheelwork of the universe. Though seemingly affected only by its immediate surrounding, the sphere of external influence extends to infinite distance. There is no constellation or nebula, no sun or planet, in all the depths of limitless space, no passing wanderer of the starry heavens, that does not exercise some control over its destiny—not in the vague and delusive sense of astrology, but in the rigid and positive meaning of physical science.

More than this can be said. There is no thing endowed with life—from man, who is enslaving the elements, to the numbiest creature in all this world that does not sway it in turn. Whenever action is born from force, though it be infinitesimal, the cosmic balance is upset and universal motion results.

Herbert Spencer has interpreted life as a continuous adjustment to the environment, a definition of this inconceivably complex manifestation quite in accord with advanced scientific thought, but, perhaps, not broad enough to express our present views. With each step forward in the investigation of its laws and mysteries our conceptions of nature and its phases have been gaining in depth and breadth.

In the early stages of intellectual development man was conscious of but a small part of the macrocosm. He knew nothing of the wonders of the microscopic world, of the molecules composing it, of the atoms making up the molecules and of the dwindlingly small world of electrons within the atoms. To him life was synonymous with voluntary motion and action. A plant did not suggest to him what it does to us—that it lives and feels, fights for its existence, that it suffers and enjoys. Not only have we found this to be true, but we have ascertained that even matter called inorganic, believed to be dead, responds to irritants and gives unmistakable evidence of the presence of a living principle within.

Thus, everything that exists, organic or inorganic, animated or inert, is susceptible to stimulus from the outside. There is no gap between, no break of continuity, no special and distinguishing vital agent. The same law governs all matter, all the universe is alive. The momentous question of Spencer, "What is it that causes inorganic matter to run into organic forms?" has been answered. It is the sun's heat and light. Wherever they are, there is life. Only in the boundless wastes of interstellar space, in the eternal darkness and cold, is animation suspended, and, possibly, at the temperature of absolute zero all matter may rife.

Man as a Machine.

This realistic aspect of the perceptible universe, as a clockwork wound up and running down, dispensing with the necessity of a hypermechanical vital principle, need not be in discord with our religious and artistic aspirations those undefinable and beautiful efforts through which the human mind endeavors to free itself from material bonds. On the contrary, the better understanding of nature, the consciousness that our knowledge is true, can only be all the more elevating and inspiring.

It was Descartes, the great French philosopher, who, in the seventeenth century, laid the first foundation to the mechanistic theory of life, not a little assisted by Harvey's epochal discovery of blood circulation. He held that animals were simply automata without consciousness and recognized that man, though possessed of a higher and distinctive quality, is incapable of action other than those characteristic of a machine. He also made the first attempt to explain the physical mechanism of memory. But in his time many functions of the human body were not as yet understood, and in this respect some of his assumptions were erroneous.

Great strides have since been made in the art of anatomy, physiology and all branches of science, and the workings of the man-machine are now perfectly clear. Yet the very fewest among us are able to trace their actions to primary external causes. It is indispensable to the arguments I shall advance to keep in mind the main facts which I have myself established in years of close reasoning and observation and which may be summed up as follows:

1. The human being is a self-propelled automaton entirely under the control of external influences. Willful and predetermined though they appear, his actions are governed not from within, but from without. He is like a float tossed about by the waves of a turbulent sea.

2. There is no memory or retentive faculty based on lasting impression. What we designate as memory is but increased responsiveness to repeated stimuli.

3. It is not true, as Descartes taught, that the brain is an accumulator. There is no permanent record in the brain, there is no stored up response to disturbances directly received on the knowledge. Knowledge is something akin to an echo that needs a disturbance to be called into being.

4. All knowledge or form conception is evoked through the medium of the eye, either in retina or to their fainter secondary effects and reverberations. Other sense organs can only call forth feelings which have no reality of existence and of which no conception can be formed.

5. Contrary to the most important tenet of Cartesian philosophy that the perceptions of the mind are illusionary, the eye transmits to it the true and accurate likeness of external things. This is because light propagates in straight lines and the image cast on the retina is an exact reproduction of the external form and one which, owing to the mechanism of the optic nerve, can not be distorted in the transmission to the brain. What is more, the process must be reversible, that is to say, a form brought to consciousness can, by reflex action, reproduce the original image on the retina, just as an echo can reproduce the original disturbance. If this view is borne out by experiment an immense revolution in all human relations and departments of activity will be the consequence.

Natural Forces Influence Us.

Accepting all this as true let us consider some of the forces and influences which act on such a wonderfully complex automatic engine with organs inconceivably sensitive and delicate, as it is carried by the spinning terrestrial globe in its lightning flight through space. For the sake of simplicity we may assume that the earth's axis is perpendicular to the ecliptic and that the human automaton is at the equator. Let his weight be one hundred and sixty pounds, then, at the rotational velocity of about 1,520 feet per second with which he is whirled around, the mechanical energy stored in his body will be nearly 5,780,000 foot pounds, which is about the energy of a hundred-pound cannon ball.

This momentum is constant as well as the upward centrifugal push, amounting to about fifty-five hundredth of a pound, and both will probably be without marked influence on his life functions. The sun, having a mass 332,000 times that of the earth, but being 23,000 times farther, will attract the automaton with a force of about one-tenth of one pound, alternately increasing and diminishing his normal weight by that amount

Though not conscious of these periodic changes, he is surely affected by them.

The earth in its rotation around the sun carries him with the prodigious speed of nineteen miles per second and the mechanical energy imparted to him is over 25,160,000,000 foot pounds. The largest gun ever made in Germany hurls a projectile weighing one ton with a muzzle velocity of 3,700 feet per second the energy being 429,000,000 foot pounds. Hence the momentum of the automaton's body is nearly sixty times greater. It would be sufficient to develop 762,400 horse-power for one minute, and if the motion were suddenly arrested the body would be instantly exploded with a force sufficient to carry a projectile weighing over sixty tons to a distance of twenty-eight miles.

This enormous energy is, however, not constant, but varies with the position of the automaton in relation to the sun. The circumference of the earth has a speed of 1,520 feet per second, which is either added to or subtracted from the translatory velocity of nineteen miles through space. Owing to this the energy will vary from twelve to twelve hours by an amount approximately equal to 1,533,000,000 foot pounds, which means that energy streams in some unknown way into and out of the body of the automaton at the rate of about sixty-four horse-power.

But this is not all. The whole solar system is urged towards the remote constellation of Hercules with a speed which some estimate at twenty miles per second, and owing to this there should be similar annual changes in the flux of energy, which may reach the appalling figure of over one hundred billion foot pounds. All these varying and purely mechanical effects are rendered more complex through the inclination of the orbital planes and many other permanent or casual mass actions.

The automaton is, however, subjected to other forces and influences. His body is at the electric potential of two billion volts, which fluctuates violently and incessantly The whole earth is alive with electrical vibrations in which he takes part. The atmosphere crushes him with a pressure of from sixteen to twenty tons, according to barometric conditions. He receives the energy of the sun's rays in varying intervals at a mean rate of about forty foot pounds per second, and is subjected to periodic bombardment of the sun's particles, which pass through his body as if it were tissue paper. The air is rent with sounds which beat on his eardrums and he is shaken by the unceasing tremors of the earth's crust. He is exposed to great temperature changes, to rain and wind.

What wonder then that in such a terrible turmoil, in which cast iron existence would seem impossible, this delicate human engine should act in an exceptional manner? If all automata were in every respect alike they would react in exactly the same way, but this is not the case. There is concordance in response to those disturbances only which are most frequently repeated, not to all It is quite easy to provide two electrical systems which, when subjected to the same influence, will behave in just the opposite way.

MR. NIKOLA TESLA.

So also two human beings, and what is true of individuals also holds good for their large aggregations. We all sleep periodically. This is not an indispensable physiological necessity any more than stoppage at intervals is a requirement for an engine. It is merely a condition gradually imposed upon us by the diurnal revolution of the globe, and this is one of the many evidences of the truth of the mechanistic theory. We note a rhythm, or ebb and tide, in ideas and opinions, in financial and political movements, in every department of our intellectual activity.

How Wars Are Started.

It only shows that in all this a physical system of mass inertia is involved which affords a further striking proof. If we accept the theory as a fundamental truth and, furthermore, extend the limits of our sense perceptions beyond those within which we become conscious of the external impressions, then all the states in human life, however unusual, can be plausibly explained. A few examples may be given in illustration.

The eye responds only to light vibrations through a certain rather narrow range, but the limits are not sharply defined. It is also affected by vibrations beyond, only in a lesser degree. A person may thus become aware of the presence of another in darkness, or through intervening obstacles, and people laboring under illusions ascribe this to telepathy. Such transmission of thought is absurdly impossible.

The trained observer notes without difficulty that these phenomena are due to suggestion or coincidence. The same may be said of oral impressions, to which musical and imitative people are especially susceptible A person possessing these qualities will often respond to mechanical shocks or vibrations which are inaudible.

To mention another instance of momentary interest reference may be made to dancing, which comprises certain harmonious muscular contractions and contortions of the body in response to a rhythm. How they come to be in vogue just now can be satisfactorily explained by supposing the existence of some new periodic disturbances in the environment, which are transmitted through the air or the ground and may be of mechanical, electrical or other character.

Exactly so it is with wars, revolutions and similar exceptional states of society.

Though it may seem so, a war can never be caused by arbitrary acts of man.

It is invariably the more or less direct result of cosmic disturbance in which the sun is chiefly concerned.

In many international conflicts of historical record which were precipitated by famine, pestilence or terrestrial catastrophies the direct dependence of the sun is unmistakable. But in most cases the underlying primary causes are numerous and hard to trace.

In the present war it would be particularly difficult to show that the apparently wilful acts of a few individuals were not causative. Be it so. The mechanistic theory, being founded on truth demonstrated in everyday experience, absolutely precludes the possibility of such a state being anything but the inevitable consequence of cosmic disturbance.

The question naturally presents itself as to whether there is some intimate relation between wars and terrestrial upheavals. The latter are of decided influence on temperament and disposition, and might at times be instrumental in accelerating the clash, but aside from this there seems to be no mutual dependence, though both may be due to the same primary cause.

What can be asserted with perfect confidence is that the earth may be thrown into convulsions through mechanical effects such as are produced in modern warfare. This statement may be startling, but it admits of a simple explanation.

Earthquakes are principally due to two causes—subterranean explosions or structural adjustments. The former are called volcanic, involve immense energy and are hard to start. The latter are named tectonic; their energy is comparatively insignificant and they can be caused by the slightest shock or tremor. The frequent slides in the Culebra are displacements of this kind.

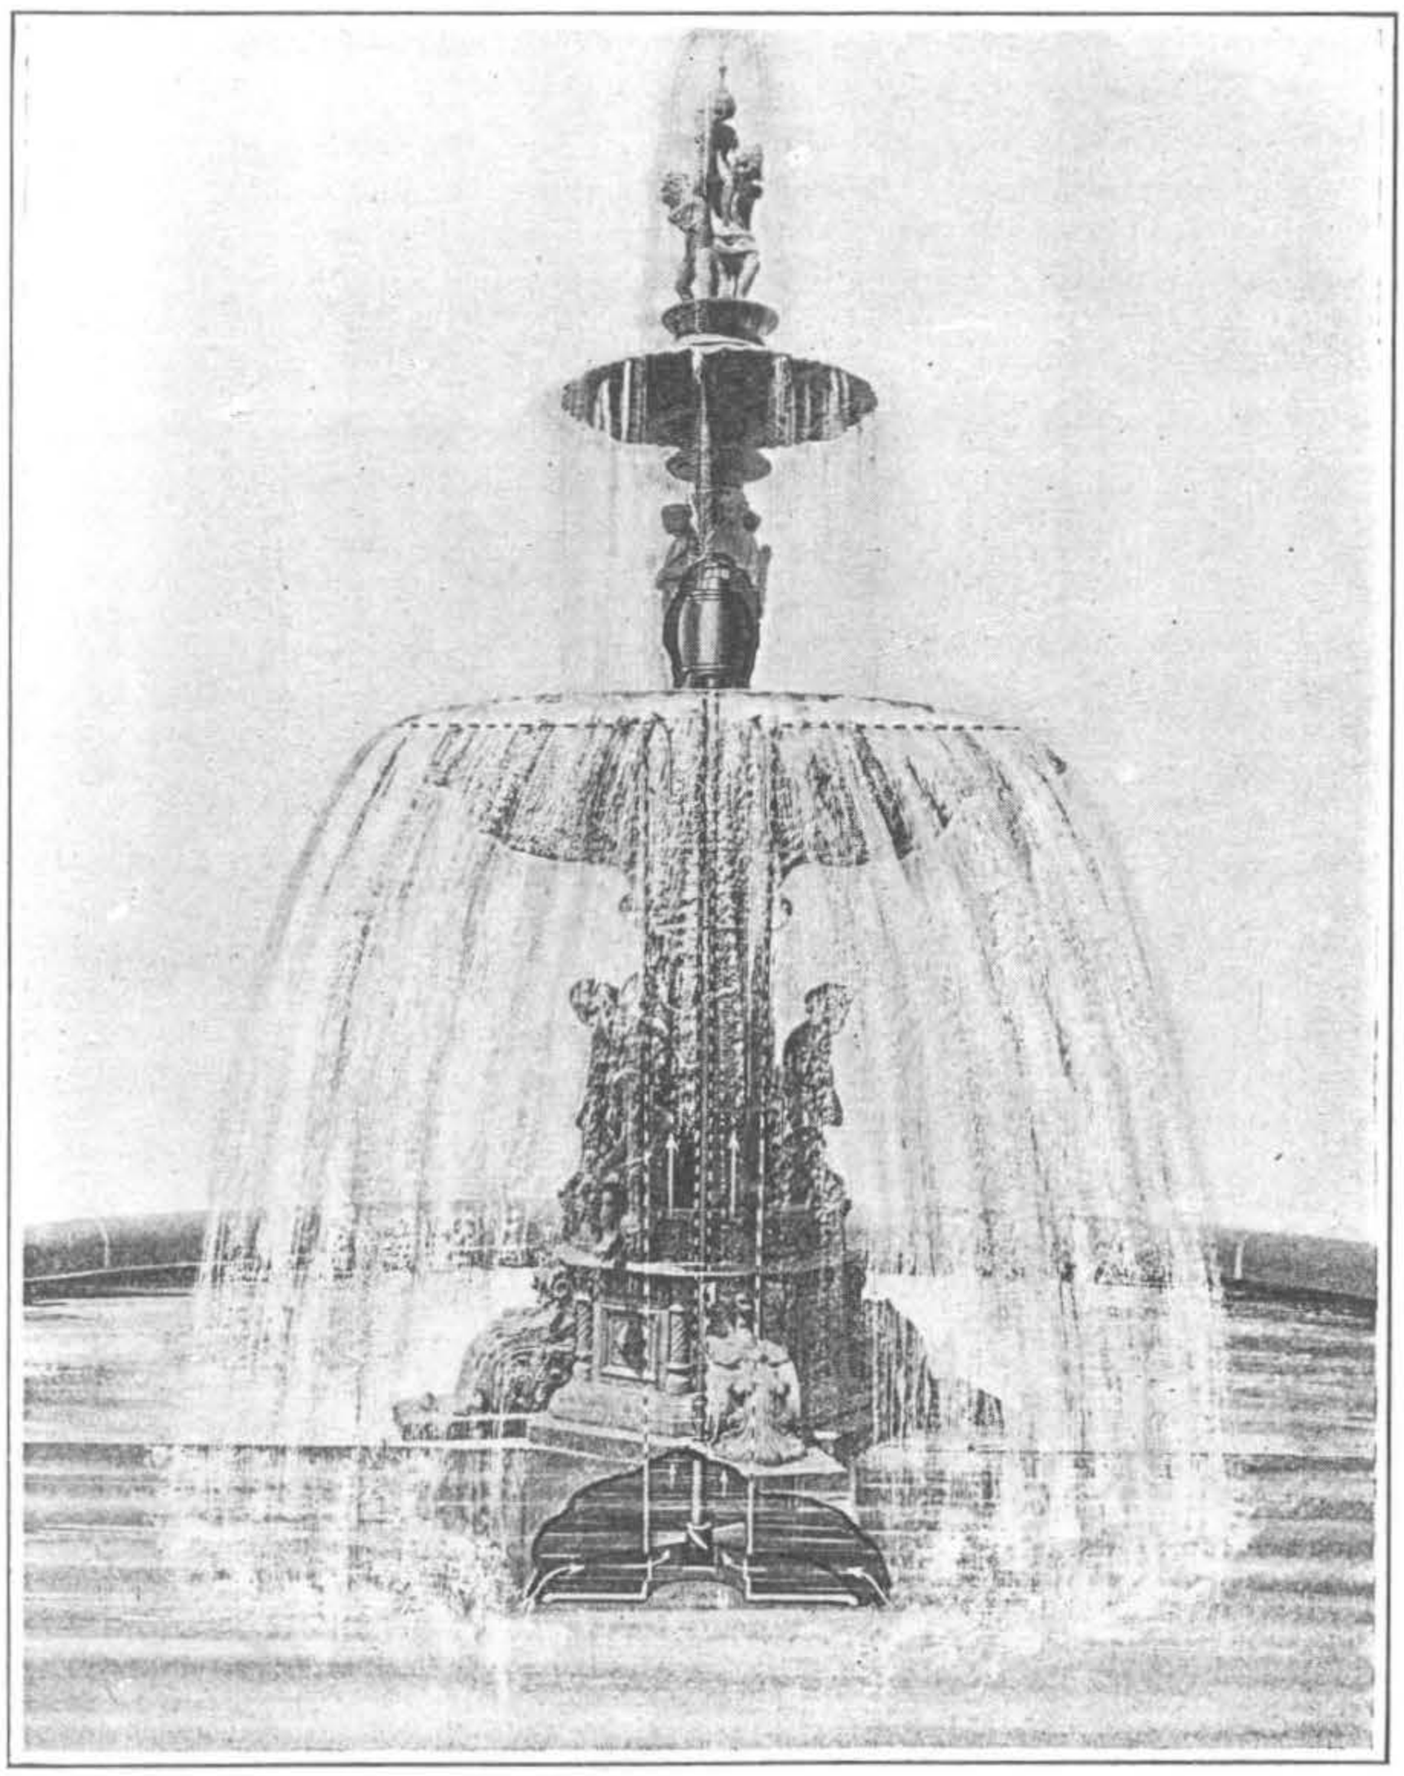
War and the Earthquake

Theoretically, it may be said that one might think of a tectonic earthquake and cause it to occur as a result of the thought, for just preceding the release the mass may be in the most delicate balance. There is a popular error in regard to the energy of such displacements. In a case recently reported as quite extraordinary, extending as it did over a vast territory, the energy was estimated at 65,000,000,000,000 foot tons. Assuming even that the whole work was performed in one minute it would only be equivalent to that of 7,500,000 horse-power during one year, which seems much, but is little for a terrestrial upheaval. The energy of the sun's rays falling on the same area is a thousand times greater.

The explosions of mines, torpedoes, mortars and guns develop reactive forces on the ground which are measured in hundreds or even thousands of tons and make themselves felt all over the globe. Their effect, however, may be enormously magnified by resonance. The earth is a sphere of a rigidity slightly greater than that of steel and vibrates once in about one hour and forty-nine minutes.

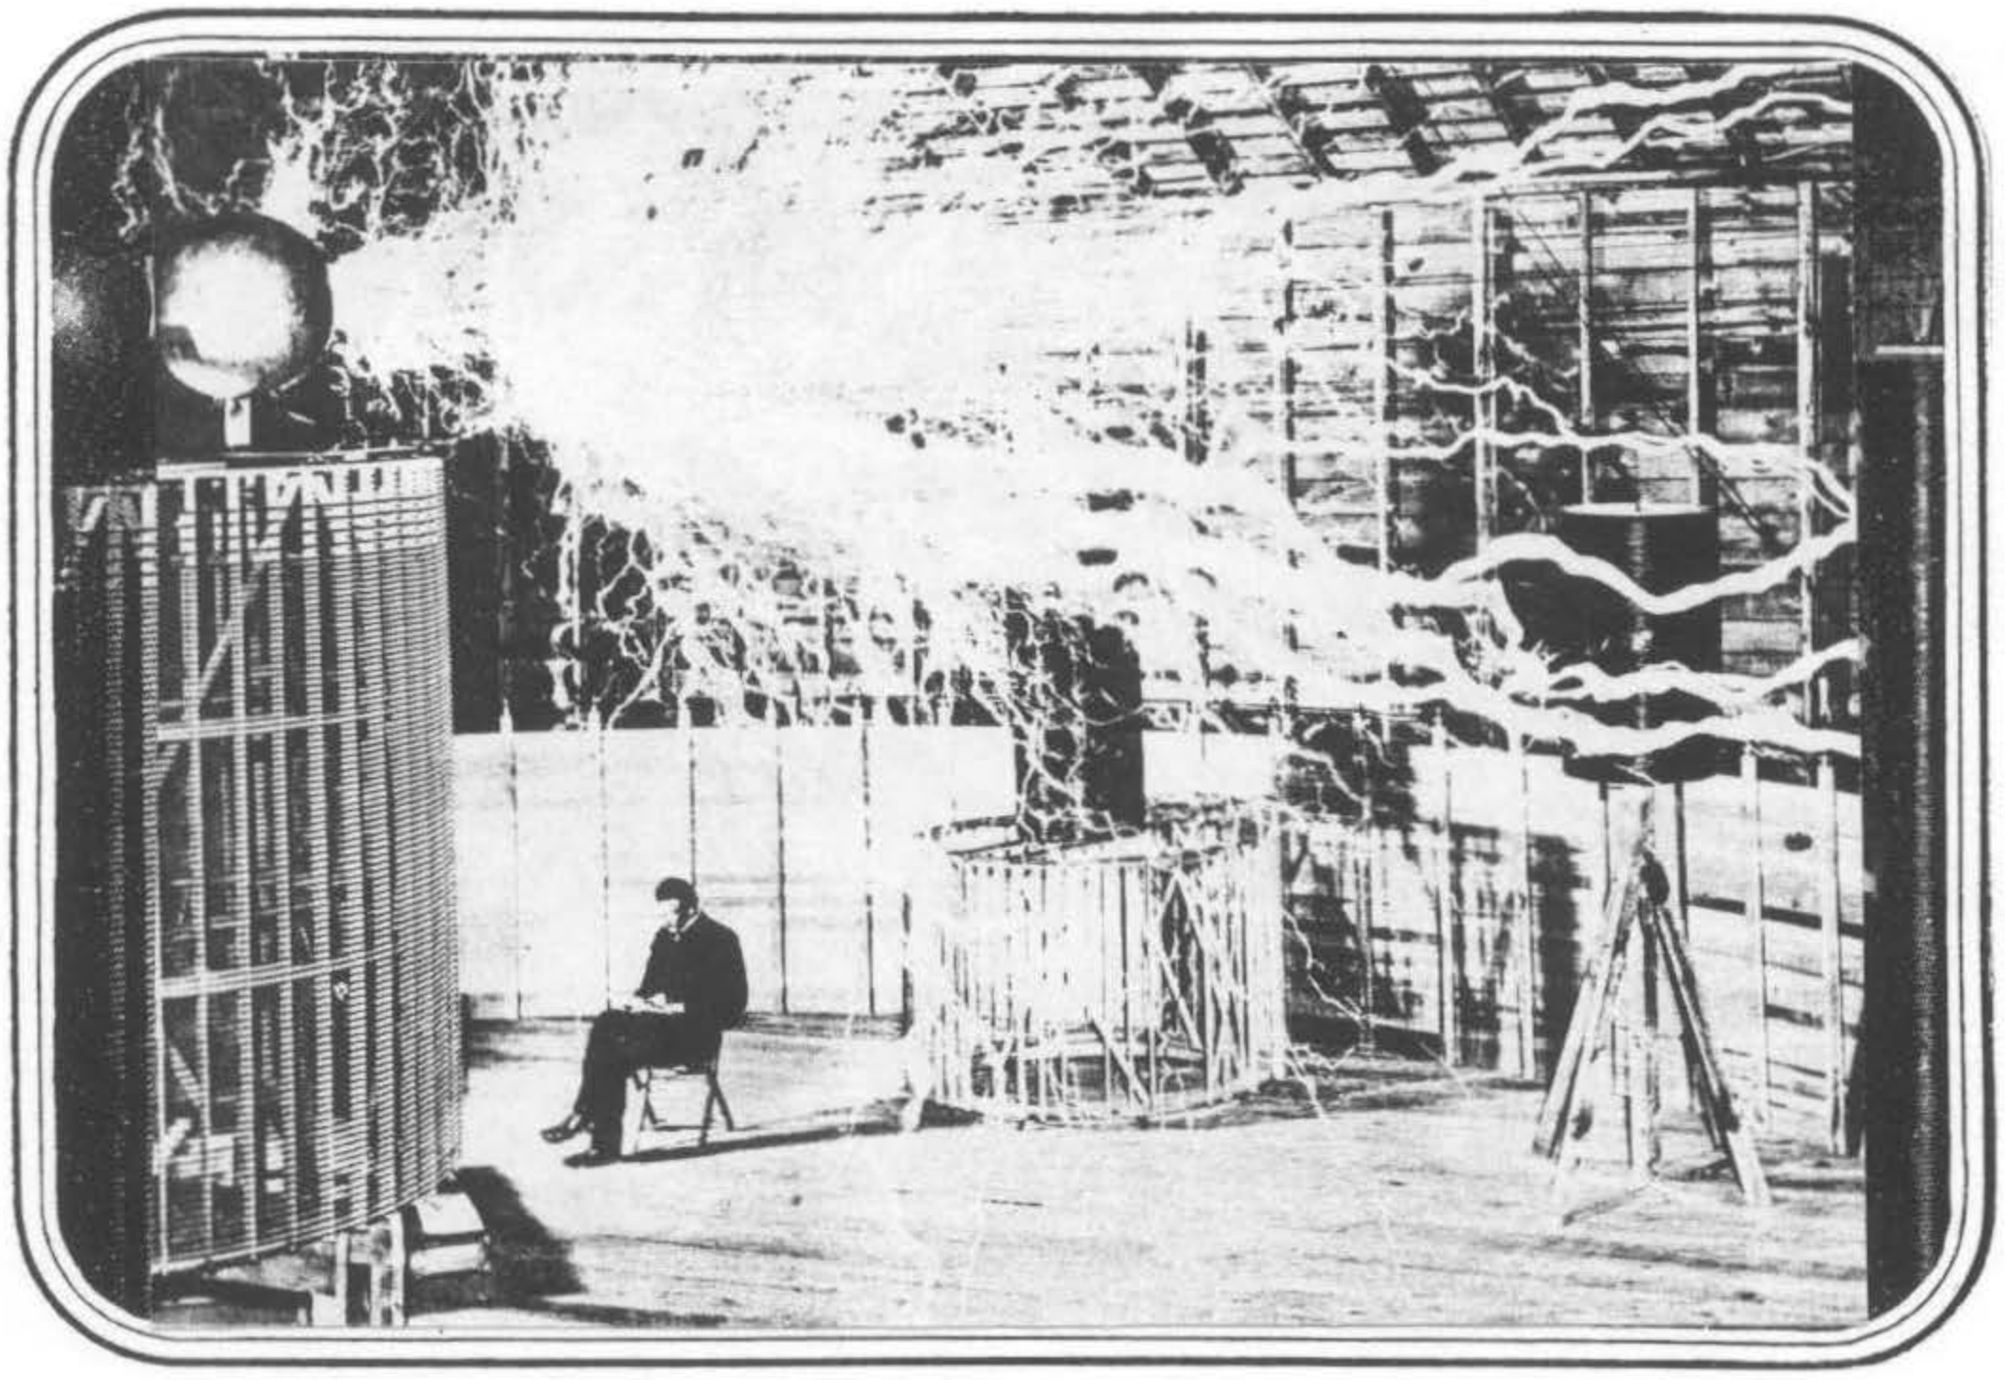
If, as might well be possible, the concussions happen to be properly timed their combined action could start tectonic adjustments in any part of the earth, and the Italian calamity may thus have been the result of explosions in France. That man can produce such terrestrial convulsions is beyond any doubt, and the time may be near when it will be done for purposes good or evil.

Nikola Tesla's Fountain



IT is a curious fact that, old as fountains are, they have remained essentially unchanged in principle for centuries. Artists have lavished all their skill upon them to make them beautiful, but engineers have neglected them. To be sure independent pumps of small volumetric capacity have been used to create artificial waterfalls and to use the same water over and over again. But this principle is old and the spectacle offered to the eye not a great improvement over the fountains of olden times.

Two types of fountain have chiefly prevailed—the cascade in which a moderate volume of water falls in thin but brilliant sheets over multiplied obstructions—steps, basins, rocks, etc.—always in a framework of architecture with abundant obstructive accessories; and the isolated or central fountain, in which one or many jets, spouted upward, fall into the highest of a series of superposed bowls of marble or bronze and then into a larger one below and so on into a broad basin at the ground level. Although every effort was made to save water and to obtain the maximum effect, still we find that in most European cities, fountains are allowed to play only on certain days of the week, and then only for a few hours. It may be safely said that not since the days of the Italian Renaissance has any really startling improvement been made in the hydraulics of fountains.



Into this neglected field, Mr. Nikola Tesla, the distinguished engineer, has entered, and as might be expected of him, with very strikng results. He has recently patented a fountain of entirely new principle, and one moreover in which imposing effects are obtained with very simple apparatus and with a very small volume of water. The accompanying illustration pictures the very simplest form of fountain which can be constructed, according to Mr. Tesla's ideas. A shaft runs vertically through the central column of the fountain, carrying at its lower end a propeller, and at its upper end an electric motor, suitably braced. In our illustration we show this propeller shaft contained in a tube, the bottom of which is provided with inlets for the water in the main bowl. As the propeller is made to revolve the water is sucked in by the propeller blades through the inlets, and is urged upward in the direction of the arrows. It fills the upper bowl and then overflows in a miniature waterflow of impressive size.

As the circulation is extremely rapid, the total quantity of water required is comparatively small. About one tenth of that delivered per minute will be generally sufficient. In this fountain then, we find a great mass of water propelled by the use of only such power as is required to lift it from its normal level through a relatively short space to that from which it overflows and descends as a waterfall or cascade. In that sense it is a radical departure from historic fountains.

The apparatus not only makes the breeding of insects impossible, but is in a sense a very efficient trap.

Nikola Tesla's fountain, in which remarkable results are obtained with little water.

Discharge of a Tesla induction-coil of great power

The tension is about twelve million volts. The volume of the current that leaps across the air space is equal to eight thousand 16-c.p. incandescent lamps, and the roar of the discharge can be heard for miles

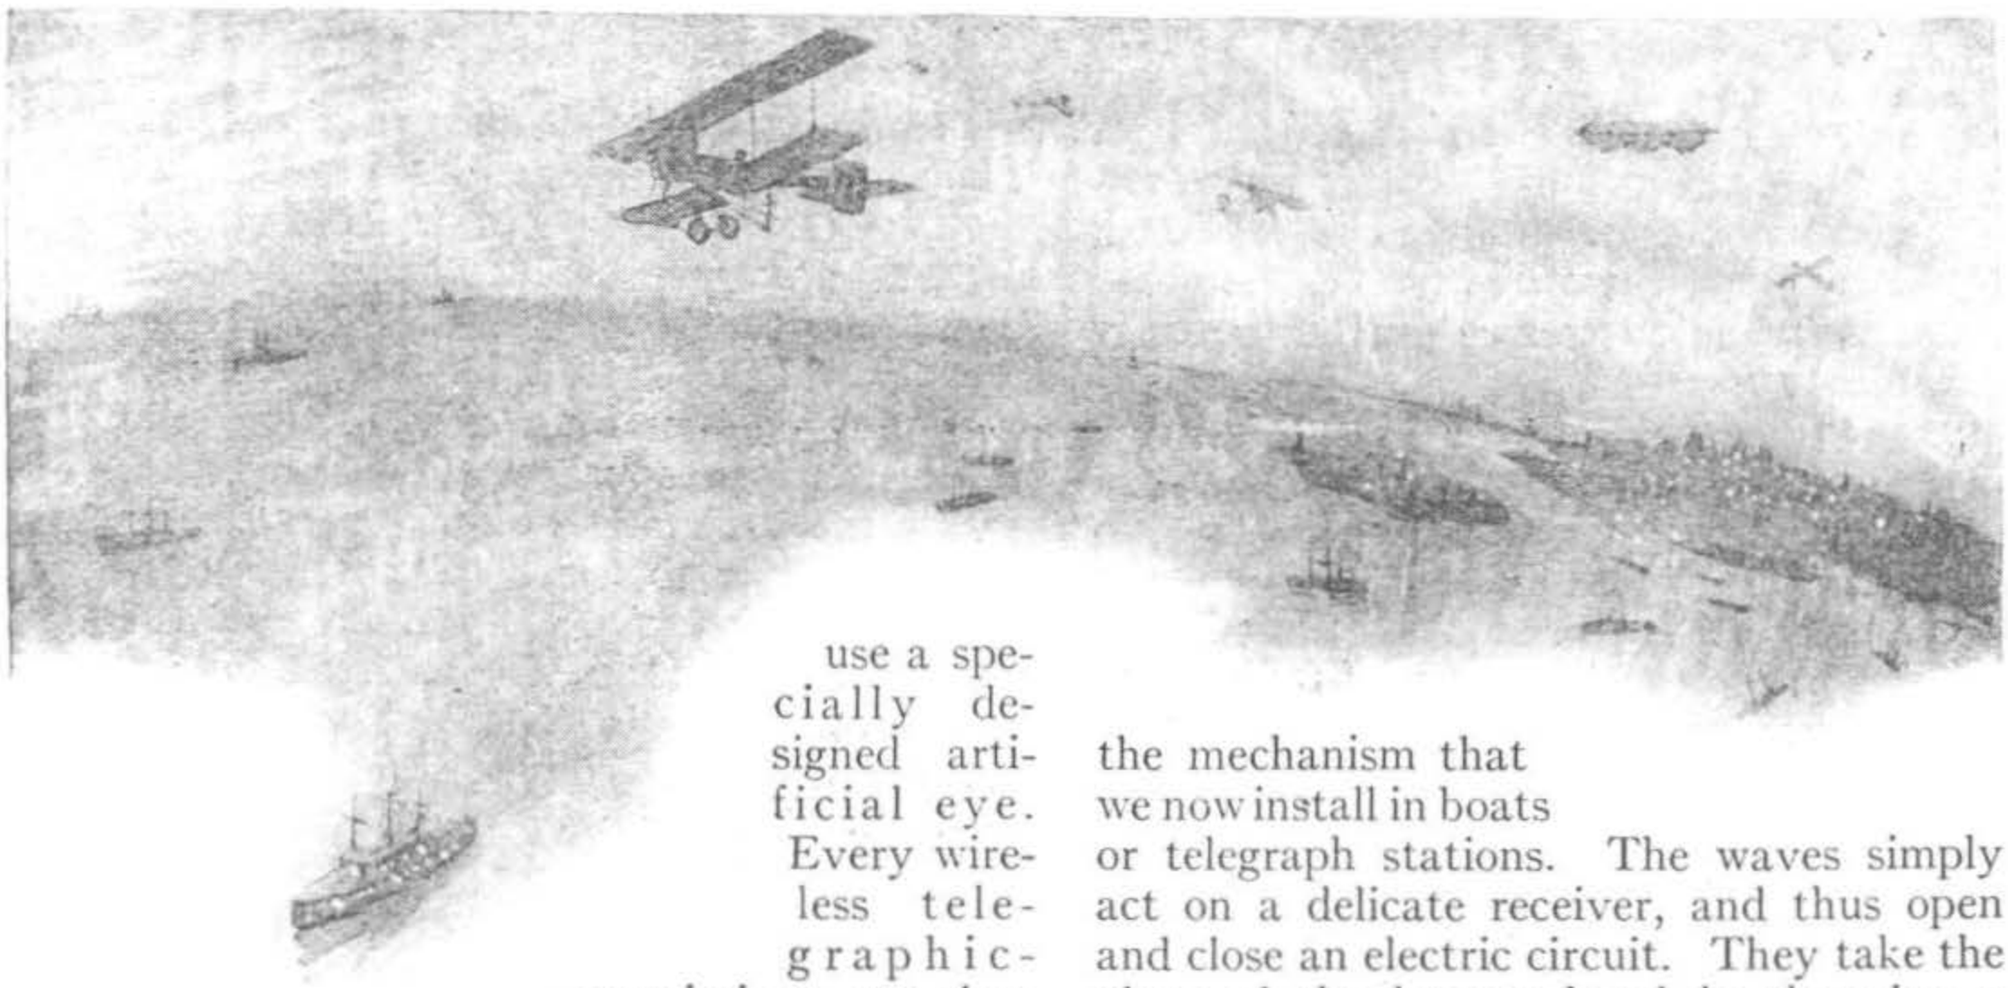
To-morrow's Wireless

By Waldemar Kaempffert

EDITOR'S NOTE—This article describes the most recent developments of telautomatics, or telemechanics, the art of performing work at a distance from the source of power, which is transmitted by ether-vibrations known as "wireless waves." It takes one to the very limits of the imagination to picture the transformation of every-day life that will follow upon the successful application of Mr. Tesla's new invention, while the achievements of Mr. Hammond and others in this field of science foreshadow novel apparatus and processes of great usefulness and value to engineering and the other practical arts.

TO flash electricity wirelessly through the globe, not in driblets but in millions of horse-power, and to transform this earth from a globular crust, on which men move and live, into a planetary power-house from which Fiji Islanders and Parisians alike may draw what energy they need is a vision which has haunted Nikola Tesla for years. When it comes, that wireless millennium, the cumbrous machinery and the tangle of electric conductors that serve us now will be swept away. In far-off Tibet or near-by Chicago, in northern Hammerfest or southern Melbourne, we shall warm ourselves, cook our food, drive our street-cars, and light our houses with energy generated in stations which have a horse-power twice that of Niagara Falls, and which is transformed into electric currents undulating through the earth with the speed of light. We shall converse with one another with telepathic directness and swiftness; we shall see one another with keen, scientifically constructed eyes, although oceans and continents separate us; we shall travel through the air in marvelously constructed air-craft which will derive their power from the earth; we shall convert night into day with illuminants which will be mere tubes and globes of cold light—gas-filled or vacuum tubes through which currents measured by millions of volts will flash.

Part of the mechanism with which these stupendous results are to be achieved was disclosed in a United States patent granted



Steel tower, designed by Tesla to contain induction-coils which will transmit electrical energy to the greatest distances on the earth

to Tesla on December 1, 1914. That patent bears the simple title, "Apparatus for Transmitting Electrical Energy." To the government officials who granted it and to the university physicist who troubled to read it, the document must have seemed like many another of its kind. Yet this "apparatus for transmitting electrical energy" is the principal element in a whole system of artifices which, when developed to their fullest possibilities, will make electricity as essential in our lives as the air we breathe.

To understand this transformation of the future, we must begin with wireless telegraphy—not because it bears any similarity to the principles which Tesla seeks to apply but because it is so different.

Throw a pebble into a pool of water. Little waves will ripple out in ever-widening circles and finally die away. An electric spark—a miniature artificial flash of lightning—sends forth similar ever-widening electrical waves at the tremendous velocity of one hundred and eighty-six thousand miles a second. Because our retinas are not constituted to see these waves, we must

use a specially designed artificial eye. Every wireless telegraphic-receiving station contains such an eye to visualize the Morse signals flashed by the electric spark in the transmitting station.

Because electrical waves represent energy, not a few inventors have tried to use them for other purposes than flashing the dots and dashes of the Morse code. Probably the most conspicuous of these men is John Hays Hammond, Junior, whose crewless, wirelessly directed boat and electric "dog" have attracted much attention. Although he is not the first in the field, he has progressed far in what has been called "telautomatics" and "telemechanics." His unmanned boat proceeds in the direction wirelessly willed by the operator on land with a precision that is uncanny, and his "dog" is far more obedient to the electric waves which he sends out than the average domestic bull pup to his master's call. Others who have experimented in this field are Branly, a wireless pioneer, who has succeeded in firing guns, starting and stopping machine-tools, controlling clocks, and lifting heavy weights with the aid of electric waves; Knudsen, who has made some imperfectly successful attempts to transmit pictures by wireless, and Hirth, who is working along the same lines as Hammond.

But all this is scarcely a world-wide distribution of power. Without exception, these inventors are dealing with wireless signals. The waves sent out from their transmitters are not directly utilized to run a motor or light a lamp but to control electrical machinery with which we are all familiar. In crewless submarine boats, in picture-recording apparatus wirelessly operated, we find, in the receiving station, all the mechanism that we now install in boats or telegraph stations. The waves simply act on a delicate receiver, and thus open and close an electric circuit. They take the place of the human hand in throwing a switch—nothing more.

In a large sense, all these men are sending energy without wires through space. But what a wasteful method—wonderful as it is! Of all the energy rippling out from the transmitting spark, not one part in one hundred million parts reaches the particular receiver to be affected. When the key of the transmitter is depressed, as much as fifty horse-power must be projected into space in order that an infinitesimal part of it may be feebly detected as a signal by an instrument three thousand miles away.

Other wastes, too, must be reckoned with by the designer of wireless-telegraph apparatus besides the waste in electric waves. When a powerful spark is to be employed for long-distance signaling, there is a leakage of current which it is impossible to control. Besides, every building, every obstacle on the face of the earth absorb part of the energy sent forth.

If there were only some way of sending this energy into the earth, of directing it from South Africa to Buenos Aires, there to be tapped off and utilized, what a saving there would be! But waves of a different kind would have to be generated—how, is partially told in the patent that has now been granted to Tesla after years of waiting and laboring.

If you would understand, in a general way, the manner of realizing this amazing possibility, you must understand the full meaning of resonance. Begin with the swinging pendulum of your clock. What keeps it going? Nothing but a little push mechanically delivered at the right time. Any freely swinging object can be kept in

motion, even though it weigh tons, if it is given the slightest push by a single finger, but always at the right moment. Indeed, the amount of swing can be increased enormously by successive pushes correctly timed.

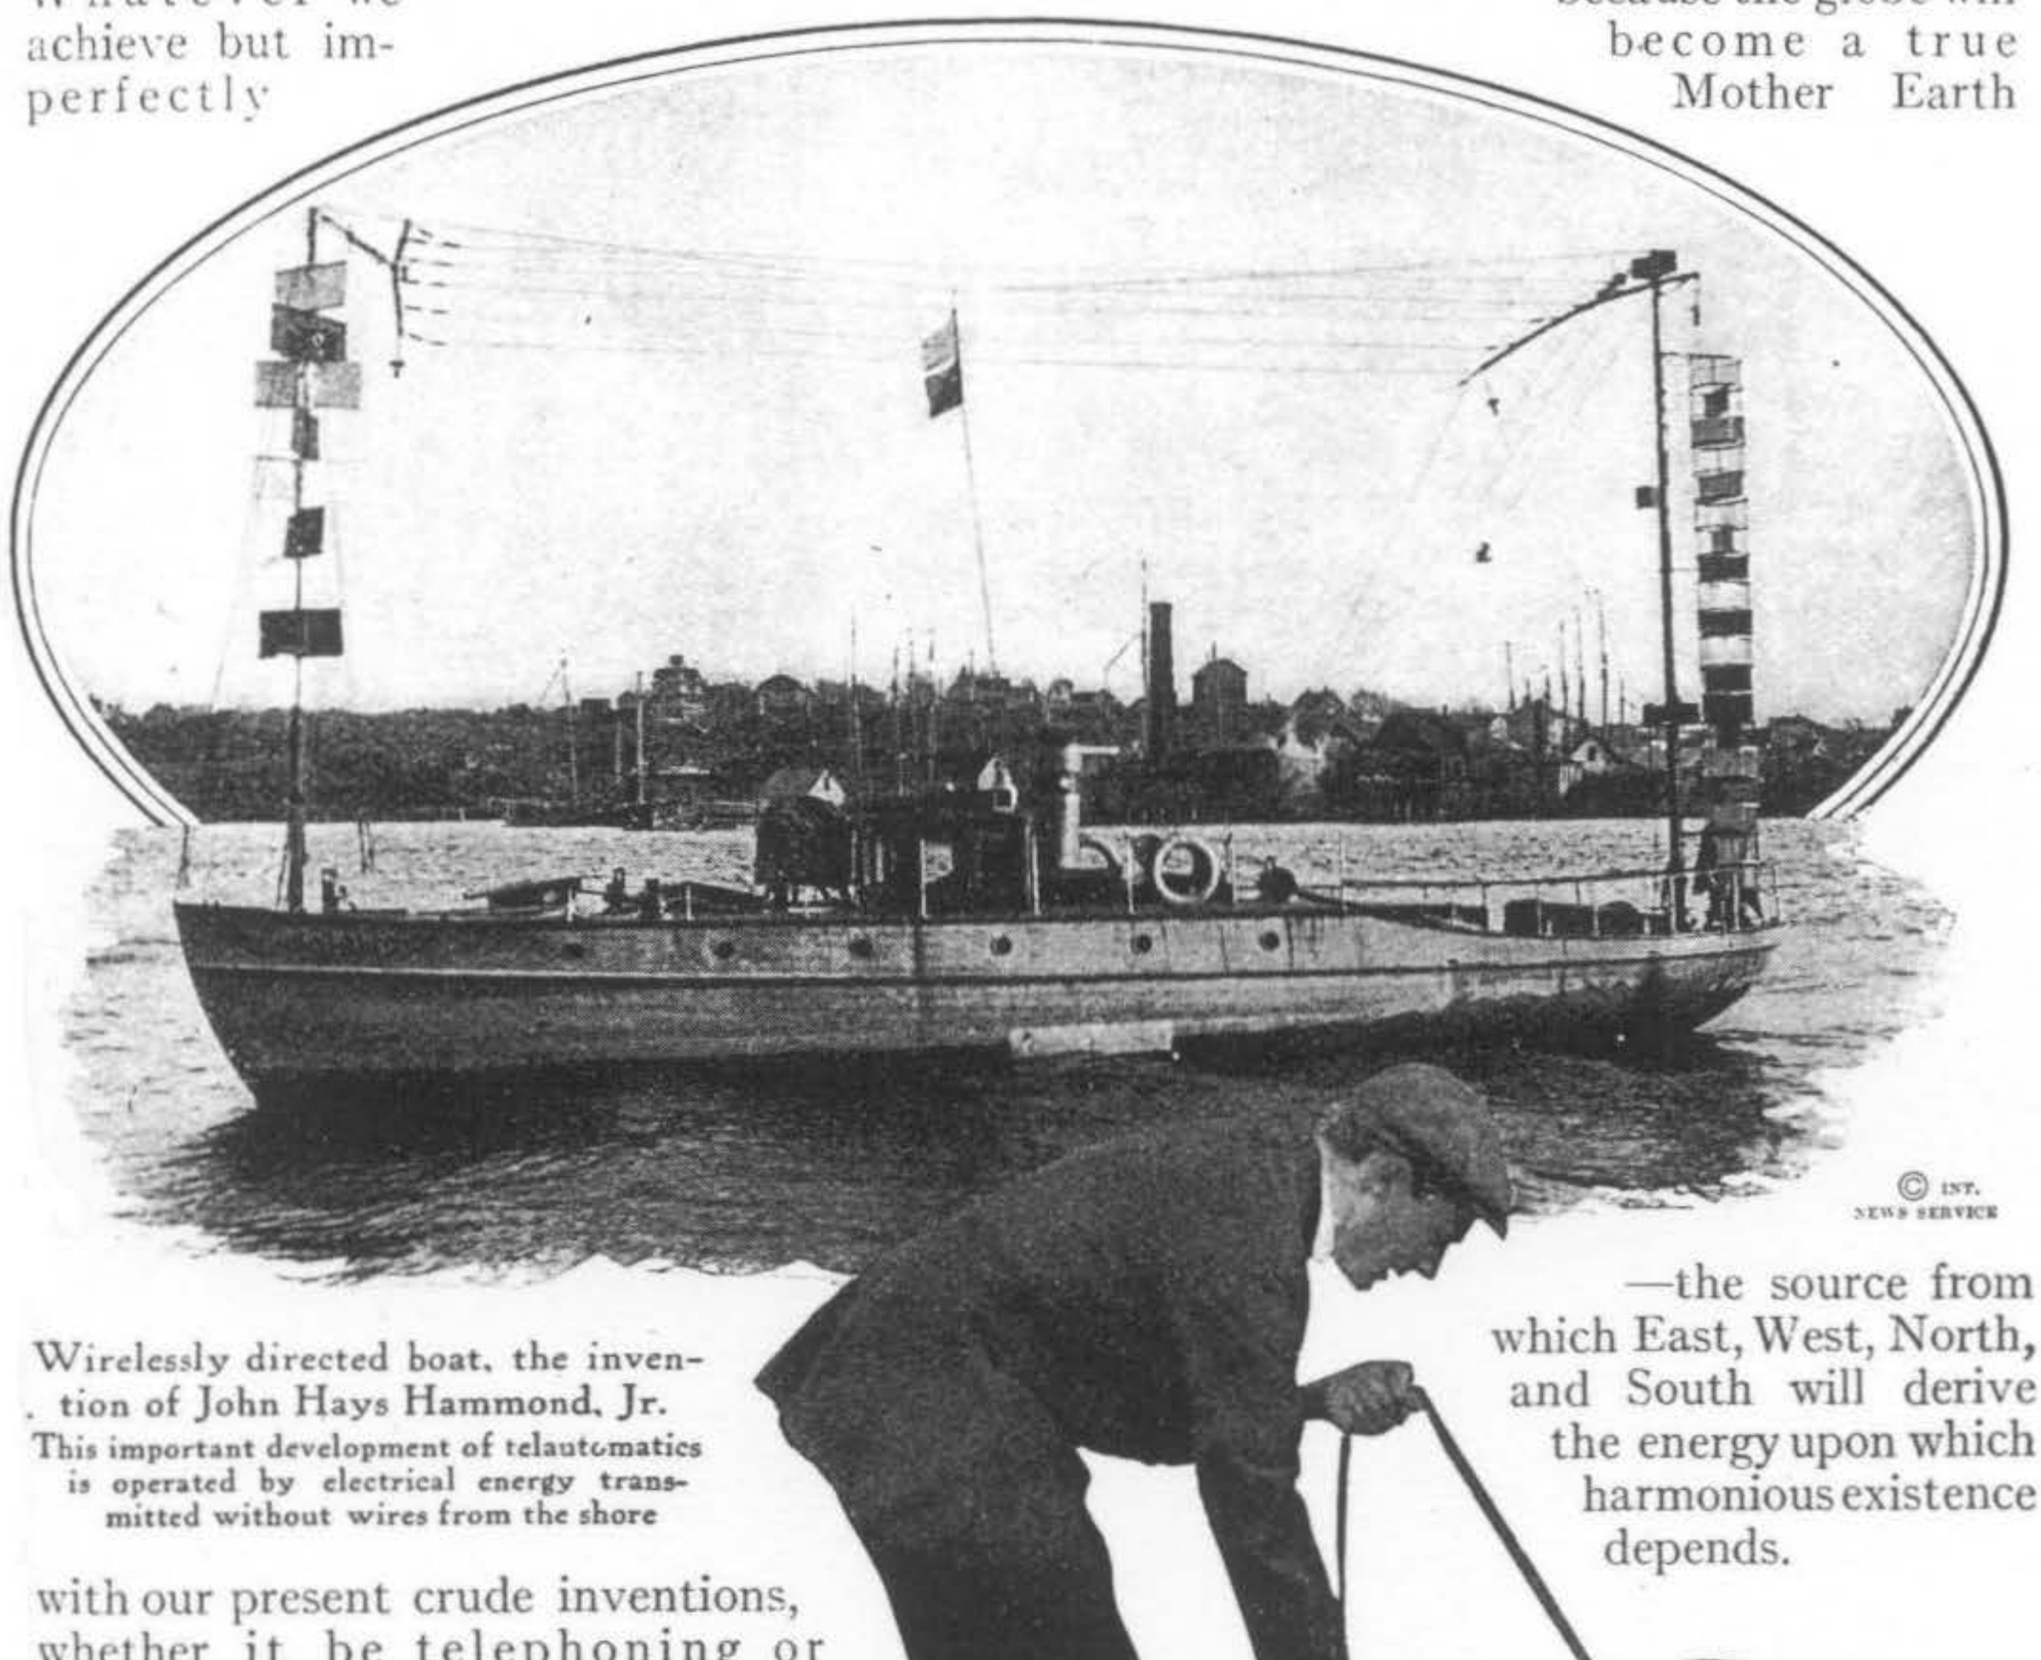
Everything in the world has a natural period of vibration. A hundred men can capsize a twenty-thousand-ton battle-ship by running rhythmically from one side of the deck to the other and carefully timing their movements to the frequency of rolling. If the natural period of a fifty-story sky-scraper's vibration were known, a boy with a tack-hammer might shake down the entire structure by persistent tapping at correct intervals. Such is the cumulative effect of many little blows.

This principle of timing small impulses so as to produce large effects is the principle of resonance. When you rub the rim of a wine glass with your finger and make it ring with a clear musical note, you apply it in producing sound-waves. You can also apply it in producing electrical waves, and that is what Tesla has done.

TESLA'S GREAT INVENTION

Sixteen years ago, while conducting some experiments in the high altitude of Colorado, Tesla found that the entire earth is electrically resonant to certain vibrations. Suppose it were possible to construct an apparatus which would set up electrical waves in the earth, with an apparatus which would be the electrical equivalent of the boy's tack-hammer that could throw down the monster sky-scraper; suppose that it were possible to pile electric impulse on electric impulse until the accumulation of them all would represent millions of horse-power in electric oscillations; suppose that you had a way of turning a tiny part of that unthinkable amount of power into a motor to run a street-car, light electric lamps, and perform other useful work; suppose that you could impress the faint modulations of your voice upon the electrically vibrating globe—surely that would be the millennium of electricity; surely that would be the most stupendous achievement in the annals of engineering. Yet that dry, uncommunicative patent granted to Tesla discloses a means of setting up the waves to which the earth is electrically resonant.

Preliminary experiments have been made which convince Tesla that power can be wirelessly transmitted through the earth. They have enabled him, so he assures us, to light electric lamps at short distances without any metallic conductor between them and the source of power. So far cheaper will this system be that, even if it were only one per cent. efficient, it would deserve every encouragement.



But the designing of an apparatus for emitting waves to which the earth is electrically responsive is only a part of the inventor's task. He must transmit his energy without loss to the point where it is wanted, which he claims is feasible. He must invent some way of individualizing the energy intended for you and for me—some way, for example, of confining a telephone conversation between New York and Peking to the speaker and his listener. In that, too, he has made progress. Strike a tuning-fork, so that it vibrates and emits a musical note, bring that vibrating fork near a piano, and you will find that of all the strings in the piano just one will sing in sympathy. A similar but much more elaborate system, a combination of sympathetic receivers, must be employed. Spencer's clear and suggestive exposition of the human nerve-mechanism gave him "the fundamental idea of employing a number of distinctive elements, cooperatively associated for the purpose of isolating the energy transmitted," Tesla states.

A NEW VISION OF THE FUTURE

It will be a marvelously different globe from that which we know if Tesla's vision is realized. As a wine-glass vibrates with sound when its rim is rubbed, so the earth will vibrate electrically when it is subjected to the action of millions of impulses correctly timed. And those impulses will be imparted by gigantic induction-coils incorporated in immense, towering steel cages, each not unlike the steel skeleton of a huge office-building in course of construction. In every large city, you will see such a steel frame, projecting far up into the sky, overtopping houses and buildings—an electrically throbbing heart whose electric beat can be felt like a pulse in the uttermost confines of the earth. In each home, you will find cheap devices for utilizing what small portion of the power thus transmitted it may need. Wherever you will go, there you will witness a marvel of wireless engineering. In smokeless factory-towns, thousands of

wheels will be turned—all with power taken from a conductor that runs into the ground. Canal-digging exploits will be performed compared with which the excavating of a waterway across the isthmuses of Suez and Panama will seem as slow as the picking of a granite wall with a needle—so limitless are the possibilities of designing machinery driven by earth-power. Farming will become as easy as gardening with the aid of mechanism so cheaply operated that less energy will be consumed in plowing an acre than is now required to operate a vacuum cleaner. Whatever we achieve but imperfectly with our present crude inventions, whether it be telephoning or transmitting pictures electrically, railroading or automobiling, housekeeping or mining, will be accomplished with wireless energy with a completeness and simplicity that will seem positively esthetic.

The greatness of an invention or an engineering project may often be measured by its sociological effect. It brings alien races closer together, which, in turn, means better propagation of knowledge. But what may not be expected when the new branch of electrical engineering that Tesla has created is fully developed, when every one of us will have as much and more power at his command as New York requires to propel trains through its subway? Electrically considered, the earth shrinks to a little ball on which Zulus and Frenchmen, Maoris and Russians, Patagonians and Eskimos are mere neighbors. A complete community of interest will prevail on the earth when his power-plants are installed, Tesla imagines, not because a distant extinction stares us in the face but because the globe will become a true Mother Earth—the source from which East, West, North, and South will derive the energy upon which harmonious existence depends.

WIRELESS DEPARTMENT

TESLA HAS WIRELESS TO LIGHT WHOLE OCEAN.

"I have invented and patented an apparatus for transmitting electrical energy without wires which will not only revolutionize the present wireless systems, but will make it possible to cast light from shore that will make the Atlantic steamship lanes safe," declared Nikola Tesla, on his return from Washington recently, where the invention was patented.

He stated that his apparatus would give the wireless unlimited sending power and messages around the world

would be a matter of course. With a plant in the Azores he said he could project light rays over the Atlantic Ocean.

THEORY OF THE TESLA TURBINE.

IN our issue of November 10, 1911, we gave a short account of the Tesla turbine, and showed that even under ideal conditions the hydraulic efficiency of a turbine of this kind cannot possibly exceed 50 per cent. In a paper published last June in the *Revue de Mécanique*, and since reproduced in a number of the French technical journals, Professor E. Mérigeault, of the École Nationale des Mines de St. Etienne, combats this conclusion, maintaining the contrary view, that the efficiency may be very high, and will be the higher the higher the friction! This extraordinary conclusion is arrived at in an article with numerous equations occupying in all over seven pages of the journal in which it appeared. Nevertheless it merely demonstrates once more that the value of the result finally delivered by the mathematical process depends entirely on the legitimacy of the original hypotheses to which it is applied. It is here that Professor Mérigeault has gone wrong, and as his results are being quoted by those who are apparently too impressed with his analysis to venture to question his premises, it may be well if we point out exactly the nature of the fundamental error serving as the basis for his mathematical superstructure. To clarify ideas, we reproduce from ENGINEERING, *loc. cit. supra*, three views illustrating the construction of the Tesla turbine. It consists of a series of twenty-five discs, 18 in. in diameter, mounted side by side on a shaft and having a small clearance between them. Steam is admitted tangentially by the nozzle on the right, and flowing through the interspace between the discs, finally escapes at the centre, carrying the rotor round by its frictional drag on the surface of the discs. The appliance is, it will be seen, a true turbine. The potential energy of the steam is converted into kinetic energy, and this, again, into useful work. The steam enters the moving element at a high speed, and passing through it without change of pressure, is delivered at a reduced velocity at the inner periphery.

Fig. 1.

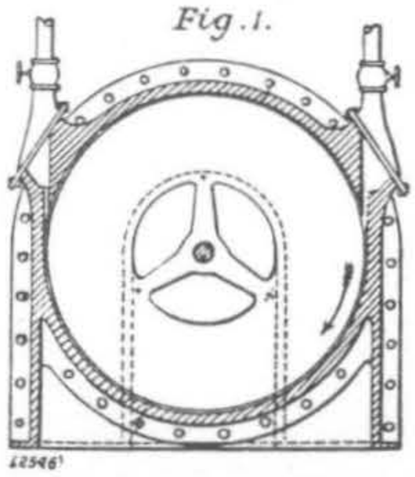

Fig. 2.

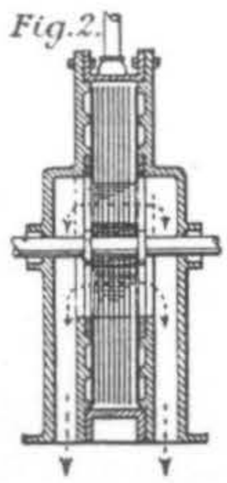

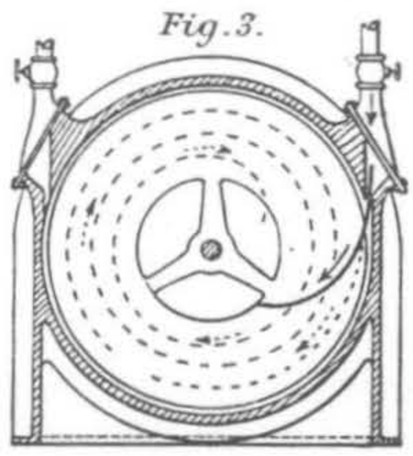

Fig. 3.

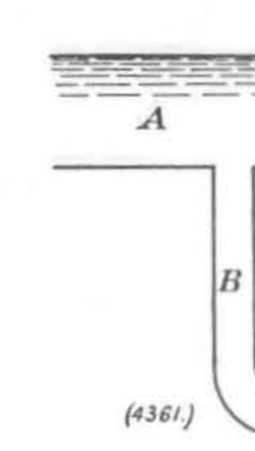
The mechanical analogue on which Professor Mérigeault bases his reasoning satisfies none of these conditions. It is not merely not analogous to the Tesla turbine, but is not analogous to any turbine of any kind, but to a pressure engine. He assumes, in fact, that the Tesla turbine can, for the purpose of mathematical treatment, be replaced by the tank A, fixed pipe B, and moving pipe C. The latter is supposed to slide without friction and without leakage in the horizontal part of B, and to be connected in any suitable way to the mechanism to be driven. The pipe B may, for the purpose of argument, be considered frictionless, while C is a rough pipe. As the water flows through C, the frictional drag on its rough walls provides the force needed to drive the mechanism to which it is supposed to be connected. Then by a series of equations Professor Mérigeault demonstrates that the higher the friction between the water and the wall of the moving element the greater is the efficiency of the appliance. This, however, is sufficiently obvious without any mathematics at all. Assume, for example, that the friction is so great that there is no slip between the moving water and the wall. The two will therefore move together exactly as if C were closed with a solid plug, and the efficiency then is unity. The appliance has, however, at the same time become a water-pressure engine of a very common type.

If, without going to the extreme of assuming no slip between the fluid and the walls, we admit that slip exists, we are obviously working in the same condition as if the pipe C were smooth, but closed with a leaky plug, and the efficiency will obviously be smaller the greater the slip or the greater the leakage. In short, Professor Mérigeault's analogue is not a turbine at all, but a water-pressure engine with a leaky plunger, and obviously the efficiency will be higher the smaller the leakage—that is to say, the smaller the slip and the greater the friction. In fact, the fluid passes through his moving element without change of velocity, but merely with change of pressure. The true analogy to the Tesla turbine is represented in Fig 5, where a jet of water issuing from a nozzle D enters a pipe E sliding without friction in the sleeve F. As in Professor Mérigeault's analogue, the pipe E constitutes the moving element, and is to be coupled in any appropriate manner to the machine to be driven. Falling to the bottom of this pipe, the water travels on, its velocity being continually reduced by the friction until it finally escapes at the outer edge as indicated. The frictional drag between the water and the pipe provides the force necessary to overcome the resistance of the machine driven. In the conditions stated the pressure of the fluid is atmospheric at both ends of E, which is, in fact, traversed without change of pressure, the energy required to drive it being obtained at the expense of the kinetic energy of the jet.

The efficiency of this device is easily calculated.



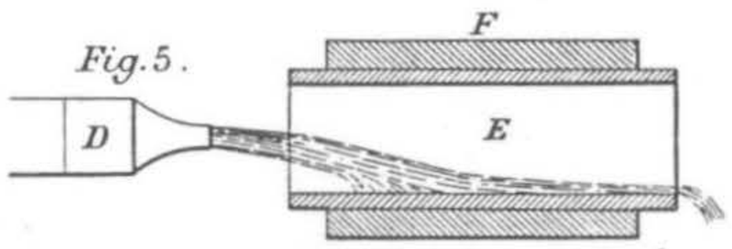


Fig. 4.

Fig. 5.

Let v_0 be the absolute velocity of the fluid as it issues from D, and v_1 its final absolute velocity as delivered at the further end of the pipe E. Then if W be the weight of the water discharged per second, the change of momentum effected per second by the friction of the pipe is $\frac{W}{g}(v_0 - v_1)$. Hence the force F, which has acted on the fluid so as to change its momentum by this amount, is $F = \frac{W}{g}(v_0 - v_1)$, and since action and reaction are equal and opposite, this is also the propelling force which acts on the pipe. Hence, if the latter moves at the speed s, the useful work done per second will be $F\,s = \frac{W}{g}(v_0 - v_1)\,s$.

Now v_1 must always be greater than s, or the water could not escape from the delivery end. Assume that in the limit it may be equal to s, a condition which can be approximated to by using a sufficiently large pipe. Then, in this limiting condition, the useful work done is $\frac{W}{g}(v_0 - s)\,s$, which is easily seen to be a maximum when $s = \frac{v_0}{2}$. Adopting this value, the useful work done becomes $\frac{W\,v_0^2}{4\,g}$, whilst the kinetic energy expended is $\frac{W\,v_0^2}{2\,g}$. Hence, in the stated limiting condition of $v_1 = s$, the maximum possible efficiency is 50 per cent. That the efficiency will be reduced if v_1 is equal to s is easily shown as follows:—Keeping s constant, assume v_0 to be increased to $v_0^1 = v_0 + y$. Then, by reducing the length of the pipe to compensate for the increase of friction with the increased velocity, we can make $v_1^1 = v_1 + y = s + y$, since v_1 was equal to s.

Hence the propelling force acting on E is now

$$F = \frac{W}{g}\left(v_0^1 - v_1^1\right) = \frac{W}{g}\left(v_0 + y - s - y\right)$$
$$= \frac{W}{g}(v_0 - s),$$

or exactly the same as before.

Hence, s being constant, the useful work done is also exactly the same as before, but the energy expended has gone up from

$$\frac{W\,v_0^2}{2g} \text{ to } \frac{W\,(v_0^1)^2}{2g}.$$

The efficiency is therefore reduced by making v_1 greater than s. It cannot be less than s, or the fluid could not escape, and since, when it has a limiting value equal to s the efficiency is only 50 per cent., the hydraulic efficiency of any turbine of the Tesla type must in practice be less than 50 per cent.

As stated, the Tesla turbine is of the impulse type. It hardly seems feasible to construct a reaction turbine operating by frictional drag, but were it possible to do this, the efficiency would be even lower than it is with the impulse form. The frictional drag and the reaction of the jet would, in a reaction machine, act in opposite directions and mutually oppose each other.

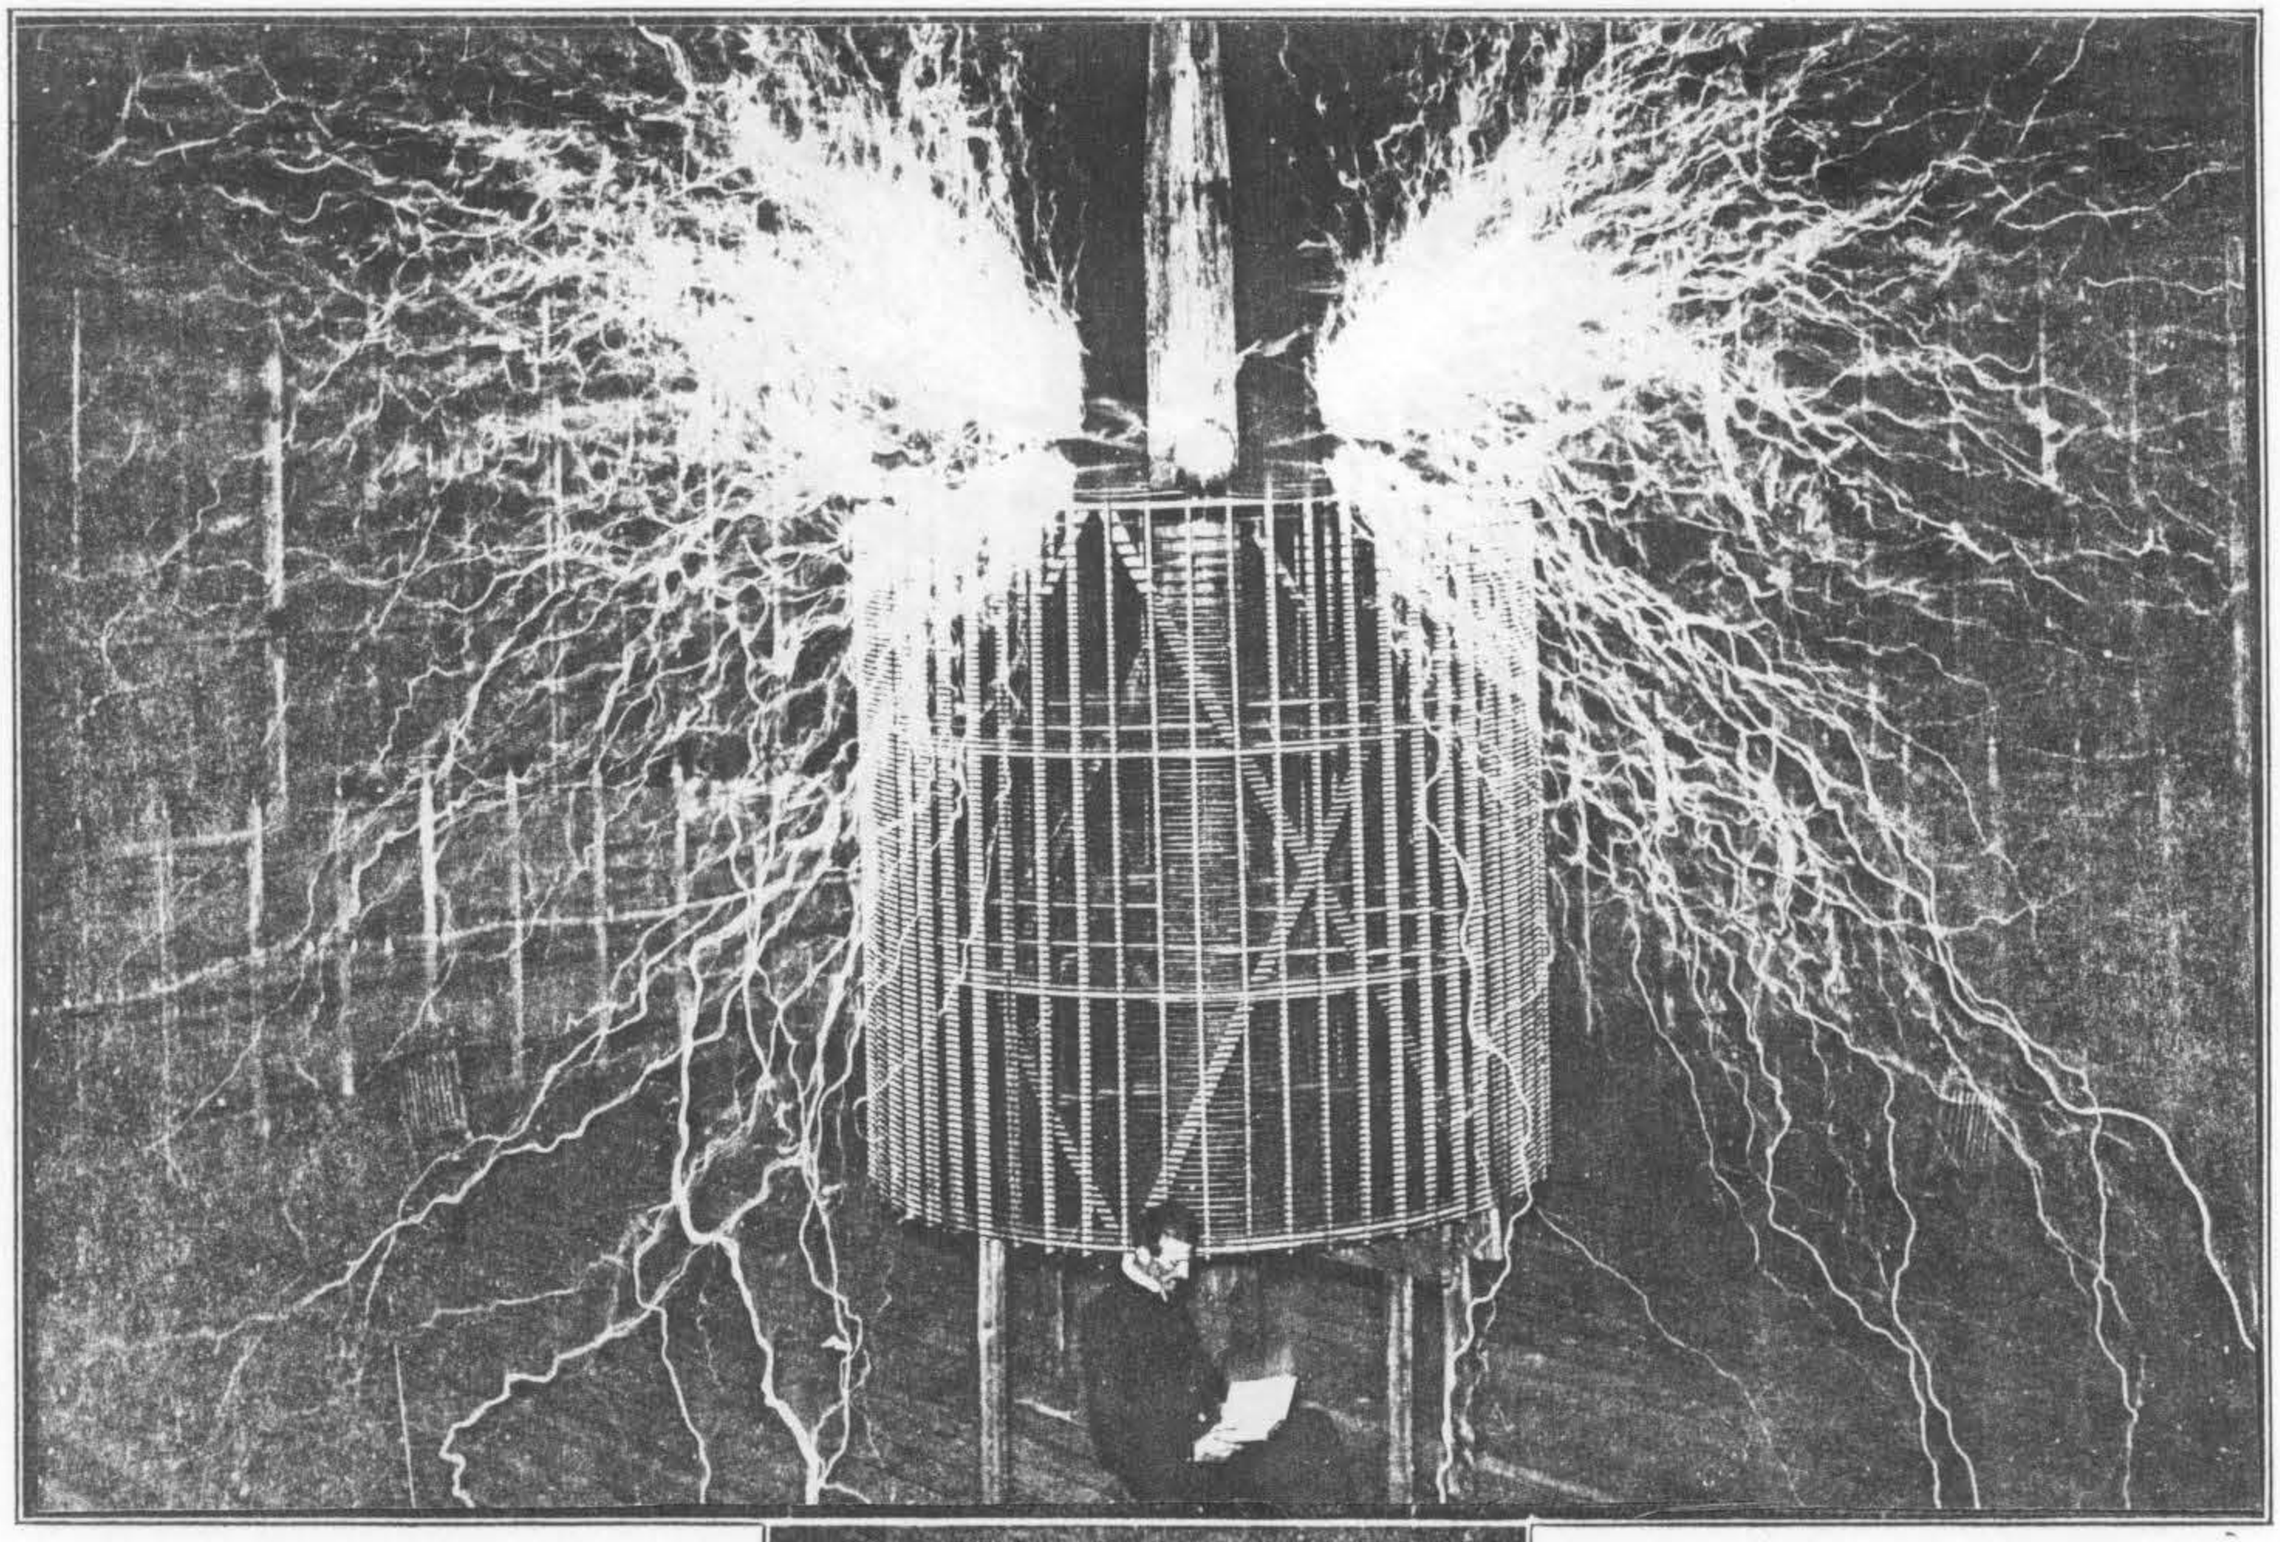
The Los Angeles Examiner May 13, 1915

Prof. Pupin Now Claims Wireless His Invention

(By International News Service)

NEW YORK, May 12.—Testifying in the suit of Wm. Marconi against the Atlantic Communication Company, the Telefunken System, Prof. Michael Pupin of Columbia University declared that he had invented the wireless before either Marconi or Nicola Tesla had discovered it and had given it unreservedly to the world.

Prof. Pupin said that in his experiments he had found a wireless wave but had not realized its importance. Tesla, he declared, had given his discoveries to mankind, and this is one of the points on which the Atlantic Company experts expect to deny the clams of Marconi to certain wireless patents.



An Interview With Nikola Tesla, Electrical Wizard

By Samuel Cohen

THERE is no doubt about it—your heart does beat faster when you are about to meet a famous electrical scientist, one of the foremost in the world. Before you go you don't think so. It didn't beat a second faster when you entered the outer office, perhaps; but as I stood on the threshhold of the big waiting room where Mr. Nikola Tesla does his day's work my nerves were highly strung. Why? Why hadn't I felt like this when I had talked to other great inventors and scientists? I had been impressed, truly, by these men, but not to any such extent as when I entered the room where the master electrical wizard lives; he who has produced electrical discharges resembling lightning bolts.

After a few minutes, I was ushered into the presence of Mr. Nikola Tesla, who stood in the corner of the room awaiting me. I asked him regarding his latest achievements, but Mr. Tesla only smiled and told me first of some of his experiences some years ago, when he produced some of the largest electrical discharges ever attempted by man. He spoke of some of his wonderful experiments with high frequency currents at high potentials, which he made in 1899. The photograph Fig. 1, herewith shown, is one of the large Tesla apparatus for the production of very high frequency, high tension currents. This apparatus was built in 1899 for his plant at Colorado Springs. At this plant and in the same year he made a number of valuable discoveries. Among these was one on which a patent was recently granted to him. This patent covers the method of production of extra large electrical discharges, such as here shown.

This display of sparks will be the more appreciated when it is stated that the streamers from end to end measure 70 feet and the current leaping into the air is

Top Photo Shows Largest Sparks Ever Produced by Man. Mr. Tesla is Seen Sitting. Seventy Feet Across Spark Streamers. Lower Photo. Mr. Tesla and His Marvelous Wireless Light.

800 amperes, with a maximum potential of 12,000,000 volts. The power supplied to this machine was 300 kilowatts. These voltages are high enough, but Mr. Tesla designed larger apparatus capable of reaching a tension of 100,000,000 volts. A machine of such power must be handled with the utmost care, as the slightest carelessness may kill the experimenter; even if he were at a considerable distance from the machine. Mr. Tesla stated that he had had several narrow escapes while experimenting in 1899, caused by "balls of fire" striking out into the atmosphere.

The metal balls of the coil here shown are 80 cm. in diameter. The current oscillates at a frequency of 75,000 cycles per second. Some of these discharges were two and one-half times as large as common lightning discharges, and they could be heard twelve miles away from the apparatus. Mr. Tesla is observed seated and reading one of Faraday's scientific books.

This remarkable man has spent a fabulous amount of time and money in perfecting his apparatus for the transmission of electrical energy without the aid of any wires. The smaller photo, Fig. 2, shows Mr. Tesla holding in his hands a 14-inch glass bulb, which is highly exhausted and containing a drop of mercury. The electrical power received by this tube is obtained from a loop of wire located behind the screen, which is supplied with an ultra-high frequency current. The tube was not connected in any way to the apparatus. As soon as the current was sent through the wire loop a high potential current was induced in the bulb, which vaporized the drop of mercury, causing it to give forth a blinding light of thousands of candle-power. The photograph was taken by the light of this tube, with an instantaneous or snap-shot exposure. Mr. Tesla has a

(*Continued on page* 45.)

AN INTERVIEW WITH NIKOLA TESLA.

(*Continued from page 39.*)

number of startling new discoveries and inventions in the electrical field, which he does not care to announce at present, and he considers these latter of greater moment than any electrical work he has so far done. He intends in the near future to transmit wirelessly speech and energy around the world from his very powerful electric wave station on Long Island, which is as yet not completed, but which will be finished soon undoubtedly. Mr. Tesla stated, "that the day will soon come when he will show the world that the transmission of power and speech without the aid of any wires is possible."

Mr. Tesla was the first inventor of the induction motor and the system of alternating current power transmission, popularly known as two-phase, three-phase, or poly-phase systems, which created a revolution in electrical engineering and are now universally adopted.

His most important recent work is the discovery of a new mechanical principle which he has embodied in a great variety of machines, such as reversible gas, steam and water turbines, mechanical transformers and transmitters of power, etc. This principle enables the production of prime movers capable of developing ten horsepower, or even more, for each pound of weight in the machine. His present prime mover could be very successfully used in the propulsion of vessels at extremely high speeds, he explained.

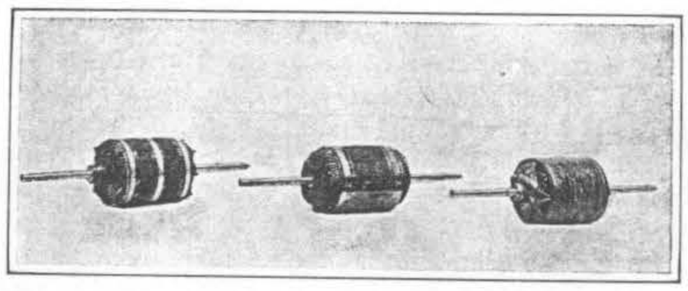
The allotted time grew short, and in a few minutes the great inventor bid me adieu and I left the presence of one of the world's most distinguished scientists of whom it has rightly been said: "He lives a hundred years ahead of his time."

Some Personal Recollections

An Autobiographical Sketch

By Nikola Tesla

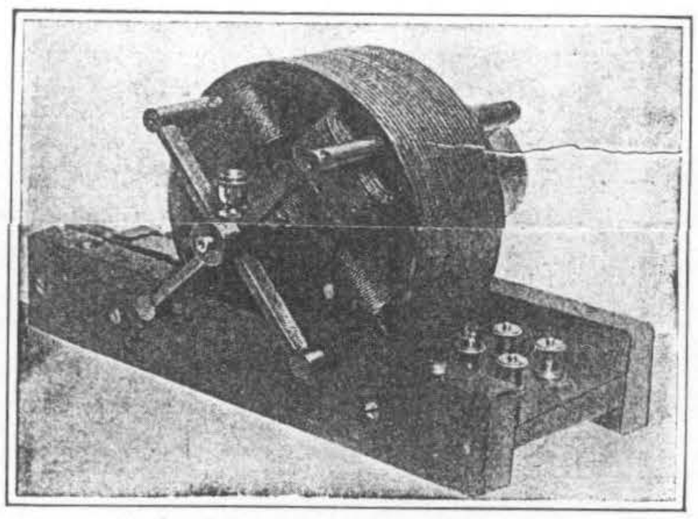
I AM glad to be accorded this opportunity for two reasons. In the first place I have long since desired to express my great appreciation of the SCIENTIFIC AMERICAN and to acknowledge my indebtedness for the timely and useful information which its columns are pouring out in a steady stream. It is a publication remarkable for the high quality of special articles as well as for the accurate review of technical advances. The knowledge it conveys is always reliable and rendered still more valuable through the scrupulous observance of literary courtesy in the quotation of the sources. The services it has rendered in helping invention and spreading enlightenment are inestimable. The SCIENTIFIC AMERICAN is a periodical ably and conscientiously conducted, measured and dignified in tone to the point of serving as a model, and in these features, as much as in the wealth and excellence of its contributions, it reflects great credit, not only on its staff and publishers, but on the whole country. This is not an idle compliment, but a genuine and well-deserved tribute to which I add my best wishes for continued success on this memorable occasion.



The second reason is one that concerns me personally. Many erroneous statements have appeared in print relative to my discovery of the rotating magnetic field and invention of the induction motor which I was compelled to pass in silence. Great interests have waged a long and bitter contest for my patent rights; commercial animosities and professional jealousies were aroused, and I was made to suffer in more than one way. But despite of all pressure and efforts of ingenious lawyers and experts, the rulings of the courts were in support of my claims for priority in every instance without exception. The battles have been fought and forgotten, the thirty or forty patents granted to me on the alternating system have expired, I have been released of burdensome obligations and am free to speak.

Every experience which I have lived through bearing on that early discovery is vividly present in my memory. I see the faces of the persons, the scenes and objects of my attention, with a sharpness and distinction and in a fullness of light which is astonishing, and is a measure of the intensity and depth of the original impressions. I have always been fortunate in ideas, but no other invention, however great, could be as dear to me as that first one. This will be understood if I dwell briefly on the circumstances surrounding it and some of the phases and incidents of my young life.

From my childhood I had been intended for the clergy. This prospect hung like a dark cloud on my mind. After passing eleven years at a public school and a higher institution, I obtained my certificate of maturity and found myself at the critical point of my career. Should I disobey my father, ignore the fondest wishes of my mother, or should I resign myself to fate? The thought oppressed me, and I looked to the future with dread.

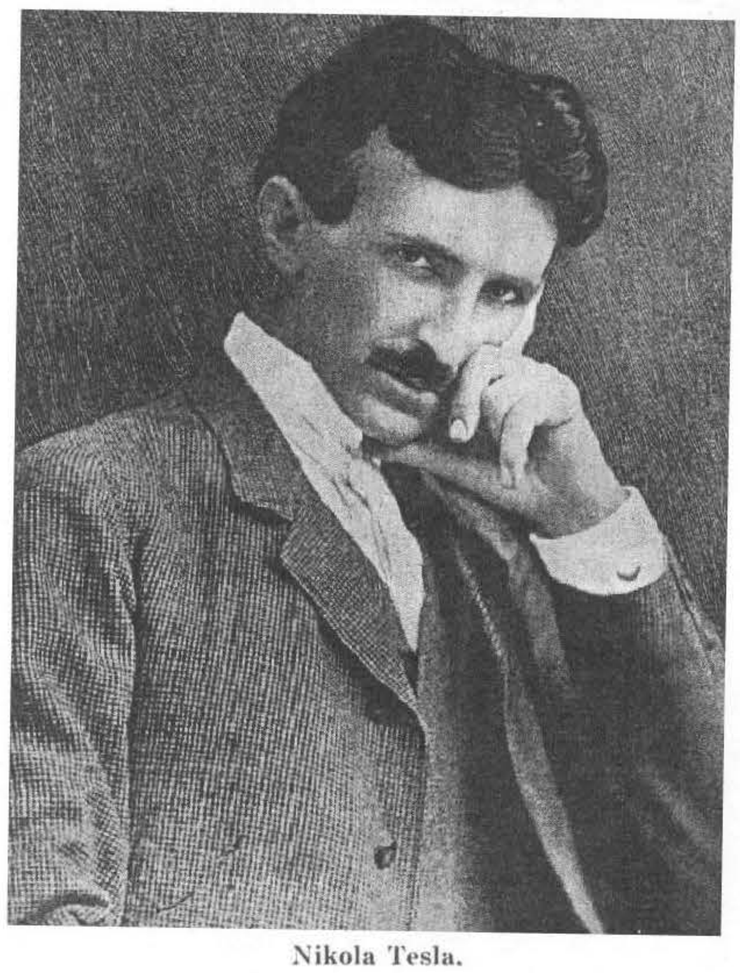


Just at that time a terrible epidemic of cholera broke out in my native land. People knew nothing of the character of the disease and the means for sanitation were of the poorest kind. They burned huge piles of odorous shrubbery to purify the air, but drank freely of the infected water and died in crowds like sheep. Contrary to peremptory orders from my father I rushed home and was stricken down. Nine months in bed with scarcely the ability to move seemed to exhaust all my vitality, and I was given up by the physicians. It was an agonizing experience, not so much because of physical suffering as on account of my intense desire to live. On the occasion of one of the fainting spells my father cheered me by a promise to let me study engineering; but it would have remained unfulfilled had it not been for a marvelous cure brought about by an old lady. There was no force of suggestion or mysterious influence about it. Such means would have had no effect whatever on me, for I was a firm believer in natural laws. The remedy was purely medicinal, heroic if not desperate; but it worked and in one year of mountain climbing and forest life I was fit for the most arduous bodily exertion. My father kept his word, and in 1877 I entered the Joanneum in Gratz, Styria, one of the oldest technical institutions of Europe. I proposed to show results which would repay my parents for their bitter disappointment due to my change of vocation. It was not a passing determination of a light-hearted youth; it was iron resolve. As some young reader of the SCIENTIFIC AMERICAN might draw profit from my example I will explain.

When I was a boy of seven or eight I read a novel entitled "Abafi"—The Son of Aba—a Servian translation from the Hungarian of Josika, a writer of renown. The lessons it teaches are much like those of "Ben-Hur," and in this respect it might be viewed as anticipatory of the work of Wallace. The possibilities of will-power and self-control appealed tremendously to my vivid imagination, and I began to discipline myself. Had I a sweet cake or a juicy apple which I was dying to eat I would give it to another boy and go through the tortures of Tantalus, pained but satisfied. Had I some difficult task before me which was exhausting I would

Three rotors used with the early Tesla induction motor shown below.

attack it again and again until it was done. So I practised day by day from morning till night. At first it called for a vigorous mental effort directed against disposition and desire, but as years went by the conflict lessened and finally my will and wish became identical. They are so to-day, and in this lies the secret of whatever success I have achieved. These experiences are as intimately linked with my discovery of the rotating magnetic field as if they formed an essential part of it:



One of the earliest of Tesla's induction motors.

Although it weighed only a little over 20 pounds, it developed ¼ horse-power at a speed of 1,800 revolutions, a performance considered remarkable at the time.

but for them I would never have invented the induction motor.

In the first year of my studies at the Joanneum I rose regularly at three o'clock in the morning and worked till eleven at night; no Sundays or holidays excepted. My success was unusual and excited the interest of the professors. Among these was Dr. Allé, who lectured on differential equations and other branches of higher

Nikola Tesla.

mathematics and whose addresses were unforgetable intellectual treats, and Prof. Poeschl, who held the chair of Physics, theoretical and experimental. These men I always remember with a sense of gratitude. Prof. Poeschl was peculiar; it was said of him that he wore the same coat for twenty years. But what he lacked in personal magnetism he made up in the perfection of his exposition. I never saw him miss a word or gesture, and his demonstrations and experiments always went off with clocklike precision. Some time in the winter of 1878 a new apparatus was installed in the lecture room. It was a dynamo with a laminated permanent magnet and a Gramme armature. Prof. Poeschel had wound some wire around the field to show the principle of self-excitation, and provided a battery for running the machine as a motor. As he was illustrating this latter feature there was lively sparking at the commutator and brushes, and I ventured to remark that these devices might be eliminated. He said that it was quite impossible and likened my proposal to a perpetual motion scheme, which amused my fellow students and embarrassed me greatly. For a time I hesitated, impressed by his authority, but my conviction grew stronger and I decided to work out the solution. At that time my resolve meant more to me than the most solemn vow.

I undertook the task with all the fire and boundless confidence of youth. To my mind it was simply a test of will-power. I knew nothing of the technical difficulties. All my remaining term in Gratz was passed in intense but fruitless effort, and I almost convinced myself that the problem was unsolvable. Indeed, I thought, was it possible to transform the steady pull of gravitation into a whirling force? The answer was an emphatic no. And was this not also true of magnetic attraction? The two propositions appeared very much the same.

In 1880 I went to Prague, Bohemia, carrying out my father's wish to complete my school education at a university. The atmosphere of that old and interesting city was favorable to invention. Hungry artists were plentiful and intelligent company could be found everywhere. Here I made the first distinct step in advance, by detaching the commutators from the machines and placing them on distant arbors. Every day I imagined arrangements on this plan without result, but feeling that I was nearing the solution. In the following year there was a sudden change in my views of life. I realized that my parents were making too great sacrifices for me and resolved to relieve them of the burden. The American telephone wave had reached the European continent, and the system was to be installed in Budapest. It appeared an ideal opportunity, and I took the train for that city. By an irony of fate my first employment was as a draughtsman. I hated drawing; it was for me the very worst of annoyances. Fortunately it was not long before I secured the position I sought, that of chief electrician to the telephone company. My duties brought me in contact with a number of young men in whom I became interested. One of these was Mr. Szigety, who was a remarkable specimen of humanity. A big head with an awful lump on one side and a sallow complexion made him distinctly ugly, but from the neck down his body might have served for a statue of Apollo. His strength was phenomenal. At that time I had exhausted myself through hard work and incessant thinking. He impressed me with the necessity of systematic physical development, and I accepted his offer to train me in athletics. We exercised every day and I gained rapidly in strength. My mind also seemed to grow more vigorous and as my thoughts turned to the subject which absorbed me I was surprised at my confidence of success. On one occasion, ever present in my recollection, we were enjoying ourselves in the Varos-liget or City Park. I was reciting poetry, of which I was passionately fond. At that age I knew entire books by heart and could read them from memory word by word. One of these was Faust. It was late in the afternoon, the sun was setting, and I was reminded of the passage:

"Sie rückt und weicht, der Tag ist überlebt,
Dort eilt sie hin und fördert neues Leben,
Oh, dass kein Flügel mich vom Boden hebt
Jhr nach und immer nach zu streben!

* * * * * * *

Ach, zu des Geistes Flügeln wird so leicht
Kein körperlicher Flügel sich gesellen!"

As I spoke the last words, plunged in thought and marveling at the power of the poet, the idea came like

(*Concluded on page 576.*)

Some Personal Recollections

(*Concluded from page 537.*)

a lightning flash. In an instant I saw it all, and I drew with a stick on the sand the diagrams which were illustrated in my fundamental patents of May, 1888, and which Szigety understood perfectly.

It is extremely difficult for me to put this experience before the reader in its true light and significance for it is so altogether extraordinary. When an idea presents itself it is, as a rule, crude and imperfect. Birth, growth and development are phases normal and natural. It was different with my invention. In the very moment I became conscious of it. I saw it fully developed and perfected. Then again, a theory, however plausible, must usually be confirmed by experiment. Not so the one I had formulated. It was being daily demonstrated every dynamo and motor was absolute proof of its soundness. The effect on me was indescribable. My imaginings were equivalent to realities. I had carried out what I had undertaken and pictured myself achieving wealth and fame. But more than all this was to me the revelation that I was an inventor. This was the one thing I wanted to be. Archimedes was my ideal. I admired the works of artists, but to my mind, they were only shadows and semblances. The inventor, I thought, gives to the world creations which are palpable, which live and work.

The telephone installation was now completed and in the spring of 1882 an offer was made me to go to Paris, which I accepted eagerly. Here I met a number of Americans whom I befriended and to whom I talked of my invention, and one of them, Mr. D. Cunningham, proposed to form a company for exploitation. This might have been done had not my duties called me to Strasburg, Alsace. It was in this city that I constructed my first motor. I had brought some material from Paris, and a disk of iron with bearings was made for me in a mechanical shop close to the railroad station in which I was installing the light and power plant. It was a crude apparatus, but afforded me the supreme satisfaction of seeing, for the first time, rotation affected by alternating currents without commutator. I repeated the experiment with my assistant twice in the summer of 1883. My intercourse with Americans had directed my attention to the practical introduction and I endeavored to secure capital, but was unsuccessful in this attempt and returned to Paris early in 1884. Here, too, I made several ineffectual efforts, and finally resolved to go to America, where I arrived in the summer of 1884. By a previous understanding I entered the Edison Machine Works, where I undertook the design of dynamos and motors. For nine months my regular hours were from 10:30 A. M. till 5 A. M. the next day. All this time I was getting more and more anxious about the invention and was making up my mind to place it before Edison. I still remember an odd incident in this connection. One day in the latter part of 1884, Mr. Bachelor, the manager of the works, took me to Coney Island, where we met Edison in company with his former wife. The moment that I was waiting for was propitious, and I was just about to speak, when a horrible looking tramp took hold of Edison and drew him away, preventing me from carrying out my intention. Early in 1885 people approached me with a proposition to develop an arc light system and to form a company under my name. I signed the contract, and a year and a half later I was free and in a position to devote myself to the practical development of my discovery. I found financial support, and in April, 1887, a company was organized for the purpose, and what has followed since is well known.

A few words should be said in regard to the various claims for anticipation which were made upon the issuance of my patents in 1888, and in numerous suits conducted subsequently. There were three contestants for the honor, Ferraris, Schallenberger and Cabanellas. All three succumbed to grief. The opponents of my patents advanced the Ferraris claim very strongly, but any one who will peruse his little Italian pamphlet, which appeared in the spring of 1888, and compare it with the patent record filed by me seven months before, and with my paper before the American Institute of Electrical Engineers, will have no difficulty in reaching a conclusion. Irrespective of being behind me in time, Prof. Ferraris's publication concerned only my split-phase motor, and in an application for a patent by him priority was awarded to me. He never suggested any of the essential practical features which constitute my system, and in regard to the split-phase motor he was very decided in his opinion that it was of no value. Both Ferraris and Schallenberger discovered the rotation accidentally while working with a Gaullard and Gibbs transformer, and had difficulty in explaining the actions. Neither of them produced a rotating field motor like mine, nor were their theories the same as my own. As to Cabanellas, the only reason for his claim is an abandoned and defective technical document. Some over-zealous friends have interpreted a United States patent granted to Bradley as a contemporary record, but there is no foundation whatever for such a claim. The original application only described a generator with two circuits which were provided for the sole purpose of increasing the output. There was not much novelty in the idea, since a number of such machines existed at that time. To say that these machines were anticipations of my rotary transformer is wholly unjustified. They might have served as one of the elements in my system of transformation, but were nothing more than dynamos with two circuits constructed with other ends in view and in utter ignorance of the new and wonderful phenomena revealed through my discovery.

The New York Times July 23, 1915

TORPEDO BOAT THAT FLIES.

Admiral Fiske Invents a Craft to Attack Fleets in Harbors.

WASHINGTON, July 22.—An aerial torpedo boat for attack on ships in protected harbors is projected in patents just issued to Rear Admiral Bradley A. Fiske of the Navy War College. The plan contemplates equipping a monster aeroplane with a Whitehead torpedo of regulation navy type. Swooping down at a distance of five miles from the object of attack, the air craft would drop its deadly passenger into the water just as it would have been launched from a destroyer. The impact sets the torpedo's machinery in motion and it is off at a speed of more than 40 knots toward the target.

Admiral Fiske believes the flying torpedo boat would make it possible to attack a fleet even within a land-locked harbor. The range of the newest navy torpedoes is 10,000 yards, and even the older types will be effective at 7,000 yards. Carried on a huge aeroplane, the 2,000-pound projectile would be taken over the harbor defenses at an altitude safe from gunfire. Once over the bay, the machine would glide to within 10 or 20 feet of of the water, the torpedo rudders would be set, and it would be dropped to do its work while the aeroplane rose and sped away.

Aeroplanes to carry a ton of dead weight have been perfected by several countries.

It is proposed to drop from aeroplanes a torpedo that can be guided by radio impulses during its fall and sent with absolute certainty to its mark.

The New York Times July 24, 1915

ADMIRAL EXPLAINS AIR TORPEDO BOAT

His Invention Requires Considerable Space for Attacks, Says Bradley A. Fiske.

STUDIED WIRELESS IN 1897

At That Time He Devised Plan to Guide Projectiles Since Developed by Hammond.

Rear Admiral Bradley Allen Fiske of the Navy War College yesterday explained to THE NEW YORK TIMES some of the details of his recently patented invention, which is in effect an aerial torpedo boat—a hydroplane from which a torpedo may be discharged into the water. He also discussed another invention of his, which he said had been since elaborated by John Hays Hammond, Jr., and which enables an operator on shore, on the deck of a ship, or even on an aeroplane to steer by wireless a torpedo after it has been launched.

"I want to correct a misapprehension in the first place," said Admiral Fiske, "about the possibilities of an aerial torpedo boat. It was stated in a dispatch from Washington to today's TIMES that it could be used to attack a fleet in a landlocked harbor. This would, of course, be difficult to achieve without the destruction of the aeroplane which probably would be destroyed before reaching the fleet. What I had in mind was rather an attack on a fleet in the open sea, or one which had taken refuge in a large inland body of water of considerable size, where the aeroplanes could rise over the intervening hills and would have plenty of room and some opportunity to discharge their torpedoes before the gunners of the fleet could attack them.

"With regard to steering torpedoes by wireless—I first became interested in this matter in July, 1897, when I was stationed at Chemulpo, Korea, and read of the work that had been done by various scientists in sending an electric spark across space. Edison and Sims had already worked on the plan of steering a torpedo by wire, and it occurred to me that this could be simplified by doing it without wires.

Had Device to Steer Torpedoes.

"I invented at that time a device for wireless steering of torpedoes, and sent it to the offices of the Western Electric Company at Chicago, with which firm I had already had some relations. They thought it too visionary at the time, however, and let it pass. But after the battle of Manila Bay, when the whole country was enthusiastic, President Barton of the Western Electric Company decided that he would take the matter up and try to have my device patented simply because I was a naval officer. So my application was submitted to the Patent Office on Sept. 7, 1898, and that was the last I heard of it for the time.

"In 1900 I read that Nicola Tesla had just patented a device for the same purpose—the steering of torpedoes by wireless. I then began to wonder what had become of my application, and went to Washington with some officials of the Western Electric Company. We found at the Patent Office that my application had simply been overlooked; and to make amends the authorities decided to give me a broader patent—two patents, in fact—one covering the method and one the apparatus which I had devised. These were issued in October, 1900.

"I had neither the time, nor the money, to follow up this invention, but since then Mr. John Hays Hammond, Jr., has done splendid work based on my original patent. A torpedo is steered by wireless through the means of two solenoids which are affected by impulses transmitted by Hertzian waves of varying periodicity. Thus the touching of one key at the sending station will turn it to the right and another to the left. Mr. Hammond, I understand, can control torpedoes by wireless at a distance as great as twenty-eight miles if need be; he can make any ordinary torpedo into a dirigible by the use of certain slight modifications. I understand that as a matter of experiment he has found that he can even control torpedoes by his voice, pitching it on different notes to affect the steering apparatus in various ways.

Don't Have to Trust to Luck.

"Now the uses of such a torpedo are obvious. You do not have to aim a torpedo and trust to luck that the ship you are shooting at will be in the line on which the torpedo is going when the torpedo gets there. You can even fire a torpedo from the opposite side of your ship to that on which the enemy is situated, directing the torpedo clear around your own ship and then sending it at the enemy. As he turns, you can turn your torpedo. Besides from a ship it could be operated from shore or from an aeroplane. In coast defense, especially of some such body of water as Chesapeake Bay, it would be invaluable, for from small hidden stations on the shore torpedoes could be discharged as well as from destroyers or submarines. It may be said that under such conditions the chances of hitting the mark would be slight. That difficulty will be obviated by the use of 'spotting' aeroplanes, such as are now used in artillery firing—an airman high above the enemy's position signals back to the battery far away in his rear, what changes in elevation should be made in order to drop the shells with better effect. So a spotting aeroplane could signal back to the shore station from which the torpedo is directed; or when a torpedo is once launched from shore it could be steered by an apparatus in the aeroplane.

"The hydroplane torpedo boat after rising to a great height could direct its own torpedo in this way."

Admiral Fiske said he had some reason to believe that torpedoes had been launched from aeroplanes during the present war. "It is the natural tendency of the American people," he continued, "to expect their inventors in time of war to think up devices which will offset the initial superiority of their enemies."

Admiral Fiske has taken out fifty-seven patents already and has three more pending. In 1890 he invented what has come to be known as the Sir Percy Scott method of pointing guns on shipboard, and in 1904 he invented the turret range finder.

Philosophical Magazine August 1915

XIX. *On the most Effective Primary Capacity for Induction-coils and Tesla Coils.* *By* E. Taylor Jones, *D.Sc., Professor of Physics in the University College of North Wales, Bangor*†.

IN the theory put forward in recent papers‡ by the writer the induction-coil is regarded as an oscillation transformer, in which the two circuits are closely coupled, and in which the secondary potential arises from the superposition of two oscillations differing in amplitude,

* J. Chadwick, Phil. Mag. vol. xxiv. p. 594 (1912).

† Communicated by the Author.

‡ Phil. Mag. xxii. p. 706 (1911) [with D. E. Roberts]; xxvii. p. 565 (1914); xxix. p. 1 (1915).

frequency, and damping coefficient. The expression for the secondary potential was worked out in certain cases from the "constants" of the circuits, and found to agree closely with experiment both in wave-form and in maximum potential as deduced from the observed spark-length.

According to this theory the secondary potential at time t after the interruption of the primary current is represented, if the resistances of the circuits are neglected, by the expression

$$V_2=\frac{2\pi L_{21}i_0n_1n_2}{n_2^2-n_1^2}(n_2\sin 2\pi n_1t-n_1\sin 2\pi n_2t), \quad . \quad (1)$$

in which L_{21} is the coefficient of induction of the primary coil on the secondary, i_0 is the primary current interrupted, and n_1, n_2 are the two frequencies of oscillation of the system ($n_2 > n_1$). For given values of L_{21}, i_0, n_1 and n_2, the value of V_2 is stationary at times given by $dV_2/dt=0$, *i. e.*

$$\cos 2\pi n_1t-\cos 2\pi n_2t=0, \quad . \quad . \quad . \quad . \quad (2)$$

or

$$\sin \pi(n_1+n_2)t\,.\,\sin \pi(n_2-n_1)t=0. \quad . \quad . \quad . \quad (3)$$

The stationary values of V_2 therefore occur at the times

$$\left.\begin{array}{ll} & t=0,\ \dfrac{1}{n_1+n_2},\ \dfrac{2}{n_1+n_2},\ \dfrac{3}{n_1+n_2},\ \ldots\ldots \\ \text{and} & \dfrac{1}{n_2-n_1},\ \dfrac{2}{n_2-n_1},\ \dfrac{3}{n_2-n_1},\ \ldots\ldots \end{array}\right\} \quad . \quad (4)$$

At any stationary value we have, by (2),

$$\sin 2\pi n_2t=\pm\sin 2\pi n_1t, \quad . \quad . \quad . \quad . \quad (5)$$

the upper sign giving the numerical minima of V_2, the lower sign the maxima.

Substituting in (1) we find that the numerical maxima lie on the (t, y) curve

$$y=2\pi L_{21}i_0\frac{n_1n_2}{n_2-n_1}\sin 2\pi n_1t, \quad . \quad . \quad . \quad . \quad (6)$$

the minima on the curve

$$y=2\pi L_{21}i_0\frac{n_1n_2}{n_1+n_2}\sin 2\pi n_1t. \quad . \quad . \quad . \quad . \quad (7)$$

In dealing with the greatest sparking potential of an induction-coil we are only concerned with the greatest maximum of V_2 in the first half-period of the slower oscillation. Even though there should be a closer coincidence of maxima of the two waves in some subsequent half-period, the amplitudes are by this time so much reduced by the

damping that the potential seldom, if ever, reaches a value equal to the greatest in the first half-period.

The *principal maximum* of V_2 is the maximum which occurs nearest to the first summit of the curve (6), *i. e.* at the time nearest to $t=1/4n_1$. The first maximum occurs at the time $t=\dfrac{1}{n_1+n_2}$, and this is the principal maximum if the frequency-ratio n_2/n_1 is between 1 and 5. If $n_2=5n_1$ the first maximum is equal to the second, and they occur at times $\dfrac{1}{n_1+n_2}$, $\dfrac{2}{n_1+n_2}$. If n_2/n_1 is between 5 and 9 the second maximum is the principal maximum, occurring at the time $\dfrac{2}{n_1+n_2}$. If $n_2=9n_1$ the second and third maxima are equal, and if n_2/n_1 is between 9 and 13 the third maximum is the principal maximum, and it occurs at $t=\dfrac{3}{n_1+n_2}$; and so on.

Consequently the principal maximum secondary potential is given by the equation

$$V_{2m}=2\pi L_{21}i_0\frac{n_1n_2}{n_2-n_1}.\sin\phi, \quad . \quad . \quad . \quad . \quad (8)$$

where

$\phi=\dfrac{2\pi n_1}{n_1+n_2}$ if $\dfrac{n_2}{n_1}$ is between 1 and 5,

" $\phi=\dfrac{4\pi n_1}{n_1+n_2}$ " " " 5 " 9,

" $\phi=\dfrac{6\pi n_1}{n_1+n_2}$ " " " 9 " 13,

. . . .

If n_2/n_1 has one of the values 3, 7, 11, . . . the maxima of the two oscillations occur simultaneously, the principal maximum occurring at the time $1/4n_1\left(\phi=\dfrac{\pi}{2}\right)$, and being equal to the sum of the amplitudes of the oscillations. These cases may be called the *coincidences*.

If the resistances of the circuits were taken into account the value of the maximum secondary potential would be considerably less than that given by (8), chiefly owing to the damping effect of the resistances*. In certain cases

* The full expression for V_2, with damping factors and phase-angles, was given in the Philosophical Magazine for April 1914, pp. 565, 574. Several examples of the (V_2, t) curve were given in the papers referred to above.

examined by the writer, in which an 18-inch coil was used, the damping was found to be sufficient to reduce the maximum secondary potential by about 25 per cent. It is, however, useful to consider the simpler theory in which the oscillations are regarded as undamped, since it enables us to trace with sufficient accuracy the general nature of the effect of varying one or more of the induction coefficients or capacities of the system. The other effects of the resistances, viz. on the frequencies, initial amplitudes, and phase relations of the oscillations, are generally small, and no serious error is introduced by neglecting them. Thus, while the value of the maximum secondary potential given by (8) is considerably in excess of the value found by experiment, the conditions in which it occurs do not differ greatly from those deduced from the simpler theory. For example, in three cases worked out in a former paper*, in which the damping and phase-angles were taken into account, the values of the angle $2\pi n_1t-\delta_1$ at which the maximum secondary potential occurred were 107°·4, 65°·8, and 74°·3 respectively. The values of ϕ for these cases, calculated as explained above, are 111°·3, 62°·8, and 71°·7.

The calculation of the most effective primary capacity.

One important problem connected with the induction-coil is that of determining the optimum primary capacity for a given coil, *i. e.* the capacity which, connected across the interruptor, allows the greatest secondary potential to be developed, when the induction coefficients of the circuits, the secondary capacity, and the primary current interrupted are all given.

In considering this problem, and other problems of this kind, it is convenient to express the sum of the amplitudes of the two oscillations in the secondary circuit in terms of $u\left(=\dfrac{L_1C_1}{L_2C_2}\right)$ and $k^2\left(=\dfrac{L_{12}L_{21}}{L_1L_2}\right)$. We have then for the principal maximum

$$V_{2m}=2\pi L_{21}i_0\frac{n_1n_2}{n_2-n_1}.\sin\phi$$

$$=\frac{L_{21}i_0}{\sqrt{L_2C_2}}\cdot U\sin\phi, \quad . \quad . \quad . \quad . \quad . \quad (9)$$

where

$$U^2=\frac{1}{1+u-2\sqrt{u(1-k^2)}}\dagger \quad . \quad . \quad . \quad . \quad (10)$$

* Phil. Mag. xxvii. pp. 572–577 (1914).

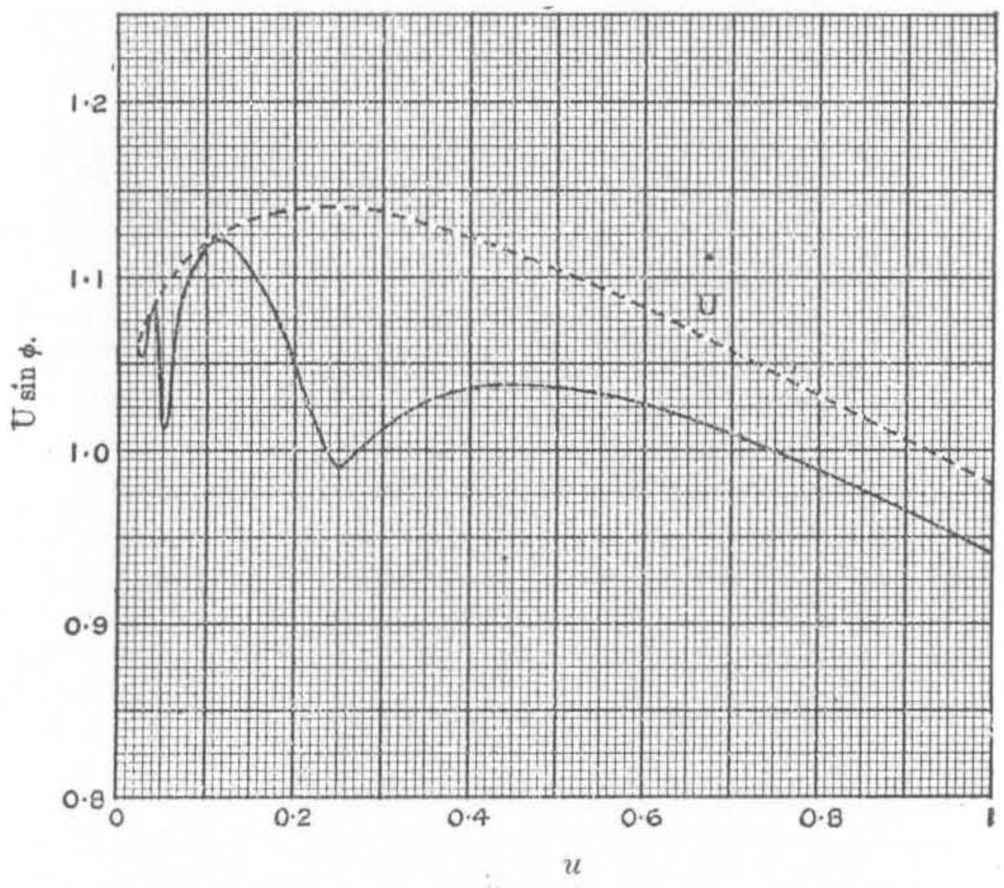
† Phil. Mag. xxvii. p. 584 (1914).

The angle ϕ can be calculated from the ratio of the frequencies, which is given by the equation

$$\frac{n_2^2}{n_1^2}=\frac{1+u+\sqrt{(1-u)^2+4k^2u}}{1+u-\sqrt{(1-u)^2+4k^2u}}. \quad . \quad . \quad . \quad (11)$$

In the present problem, in which the primary capacity C_1 alone is varied, we have to determine the conditions in which $U \sin \phi$ is a maximum, u varying while k is constant.

The function U has a maximum value of $1/k$ at $u=1-k^2$, and there is a series of values of k for which the maxima of U and $\sin \phi$ occur at the same value of u. If k has one of these values the optimum primary capacity is that which makes u equal to $1-k^2$. The necessary values of k may be calculated from (11) by putting in this equation $u=1-k^2$, and n_2/n_1 successively equal to 3, 7, 11, . . . The first four values of the series were given in a recent paper* by the writer, in which it was shown that this series of adjustments has the further property that in any one of them the system has unit efficiency, *i. e.* the maximum electrostatic energy in the secondary circuit is equal to the initial electrokinetic energy ($\frac{1}{2}L_1 i_0^2$) in the primary circuit, on the assumption of negligible resistances and perfect suddenness of the interruption of the primary current.



If k has not one of these special values the maximum value of $U \sin \phi$ does not occur when ϕ is exactly $\pi/2$, *i. e.* when the maxima of the two waves occur simultaneously. If, however, one of these coincidences occurs at a value of u not far from $1-k^2$, dU/du is small, and this coincidence determines very approximately a maximum of V_2. The *greatest maximum* secondary potential for any value of k^2 is then determined by that coincidence which comes nearest to the maximum value of U. The matter may be illustrated by the curves shown in figs. 1 and 2, in which the full line represents values of $U \sin \phi$, the broken line those of U, for various values of u. The full-line curve therefore shows how the principal maximum secondary potential changes when the primary capacity alone is varied. The points of contact of the two curves determine the coincidences, corresponding to $\phi=\pi/2$.

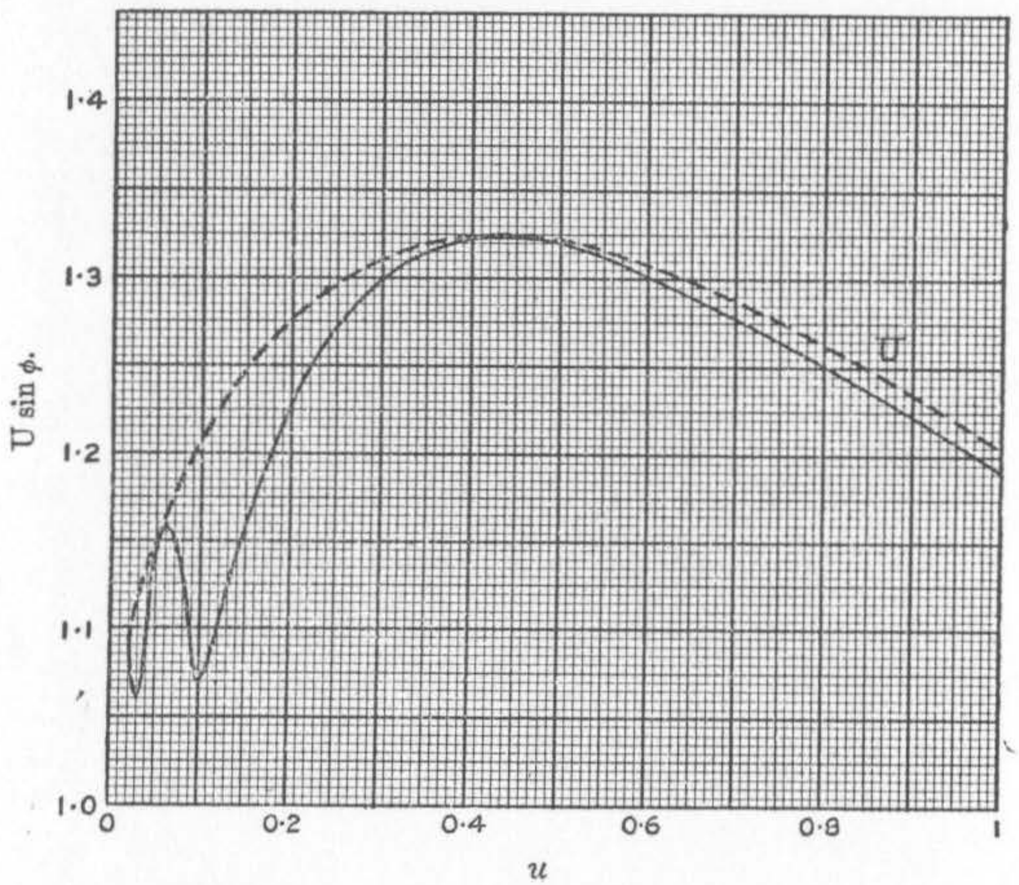
Fig. 1 refers to the case in which k^2, the square of the coupling coefficient, is equal to 0·768, the value for an 18-inch coil with which the writer has experimented. In this case the maximum value of U occurs at $u=0{\cdot}232$, and the greatest maximum of $U \sin \phi$ at $u=0{\cdot}11$ ($n_2/n_1=6{\cdot}801$), *i. e.* nearly

* Phil. Mag. xxix. p. 3 (1915).

at the 7/1 coincidence. As u diminishes from this value $U \sin \phi$ goes through a series of maxima and minima, the maxima corresponding approximately to the ratios $n_2/n_1=11, 15, 19, \ldots$ There is also another maximum of $U \sin \phi$ at about $u=0{\cdot}46$ ($n_2/n_1=4{\cdot}237$), and a marked minimum near $u=0{\cdot}25$ ($n_2/n_1=5$).

Fig. 1.

Curve showing the variation of maximum secondary potential of an induction-coil when the primary capacity is varied, k^2 being 0·768. The abscissa represents u ($=L_1C_1/L_2C_2$), the ordinate of the full-line curve $U \sin \phi$, of the broken-line curve U.



Some of the chief features of the $U \sin \phi$ curve may be traced experimentally by observing the spark-lengths obtained with various primary capacities. Thus, with the 18-inch coil, the greatest spark-length is found to occur near $u=0{\cdot}1$ ($C_1=0{\cdot}06$ mfd.*), there is a minimum spark-length when u is about 0·25 ($C_1=0{\cdot}15$ mfd.), and a second

* These spark-length measurements were described in a former paper (Phil. Mag. April 1914, pp. 582, 583), in which 0·05 mfd. was given as the optimum capacity. At that time I was not able to try 0·06 mfd., but I have since found that this represents more accurately the optimum.

(smaller) maximum near $u=0{\cdot}46$ ($C_1 \doteqdot 0{\cdot}28$ mfd.). The maxima corresponding to the higher ratios 11, 15, . . . are more difficult to demonstrate experimentally owing to the smallness of the primary capacities required and the consequent difficulty of obtaining good interruptions.

Fig. 2 shows the curves for the case $k^2=0{\cdot}571$, the first

Fig. 2.

Curve showing the variation of maximum secondary potential of an induction-coil when the primary capacity is varied, k^2 being 0·571.

of the unit-efficiency values. In this case the greatest maximum of U sin ϕ ($n_2/n_1=3$, $\phi=\pi/2$) agrees with the maximum of U, both occurring at $u=0{\cdot}429$. There is a minimum of U sin ϕ at $u=0{\cdot}1$, and a series of diminishing maxima at smaller values of u, the first of which occurs at $u=0{\cdot}06$, near the 7/1 coincidence. In this case also some of the main features of the U sin ϕ curve can be followed by observing spark-lengths. The coupling coefficient of the 18-inch coil being reduced, by the addition of series inductance to the primary circuit, so that $k^2=0{\cdot}571$, the greatest spark-length is found to be given by the primary capacity

which makes u equal to 0·429, a minimum occurs when $u=0{\cdot}1$, and a secondary maximum when u is about 0·06. At this last value of u, however, the primary capacity is only 0·025 mfd., and good interruptions are rare if the primary current is as great as 1 ampere.

For certain values of k^2 there are two equal greatest maxima of U sin ϕ, one corresponding to a value of u greater than, the other less than, $1-k^2$. This happens, for example, when k^2 is about 0·71, the two equally effective values of n_2/n_1 being in this case 3·767 and 6·595. It also happens when k^2 has the approximate values 0·87 and 0·92 (see Table I.). From the point of view of efficiency these adjustments are not so advantageous as those in which the maxima of U and sin ϕ occur together.

The values of u which give the greatest maxima of U sin ϕ have been calculated in the same way for other values of k^2 ranging from 0·92 to 0·5. The results of these calculations are given in Table I., in which the first column contains the

values of k^2, the second column the values of u required for the greatest maxima of U sin ϕ, the third column the corresponding values of the frequency-ratio n_2/n_1. The fourth and fifth columns contain the values of U and U sin ϕ, corresponding to these values of k^2 and u, and the last column gives the product $k^2U^2\sin^2\phi$, which is equal to the efficiency of the arrangement, *i. e.* the ratio of the greatest maximum electrostatic energy in the secondary circuit, $\frac{1}{2}C_2V_{2m}^2.\frac{L_{12}}{L_{21}}$, to the initial energy-supply $\frac{1}{2}L_1i_0^2$.

For any one of these values of k^2 the greatest maximum secondary potential is found (on the assumption of negligible resistances and perfect interruptions) by multiplying the corresponding value of U sin ϕ (fifth column) by the factor $L_{21}i_0/\sqrt{L_2C_2}$. If this factor is constant in all these adjustments the numbers in the fifth column are proportional to the greatest maximum secondary potential. This case is considered in the next section.

The greatest maxima of U sin ϕ are also shown in fig. 3 plotted as a curve, from which may be found the value corresponding to any degree of coupling within the same range.

It will be seen from the Table that for the higher values of k^2 the greatest maxima of U sin ϕ correspond very closely to coincidences ($\phi=\pi/2$), and that this applies with considerable accuracy down to the value 0·71 of k^2. Even at this degree of coupling the 7/1 coincidence value of U sin ϕ (approximately 1·134 at $u=0·078$) only differs by 4 parts in 1100 from the neighbouring maximum value (1·138) given in the Table. The rule, already stated in a former paper*, that the optimum primary capacity is that which determines the coincidence nearest to the maximum value of U, applies therefore with sufficient accuracy for all values of k^2 between 0·92 and 0·71.

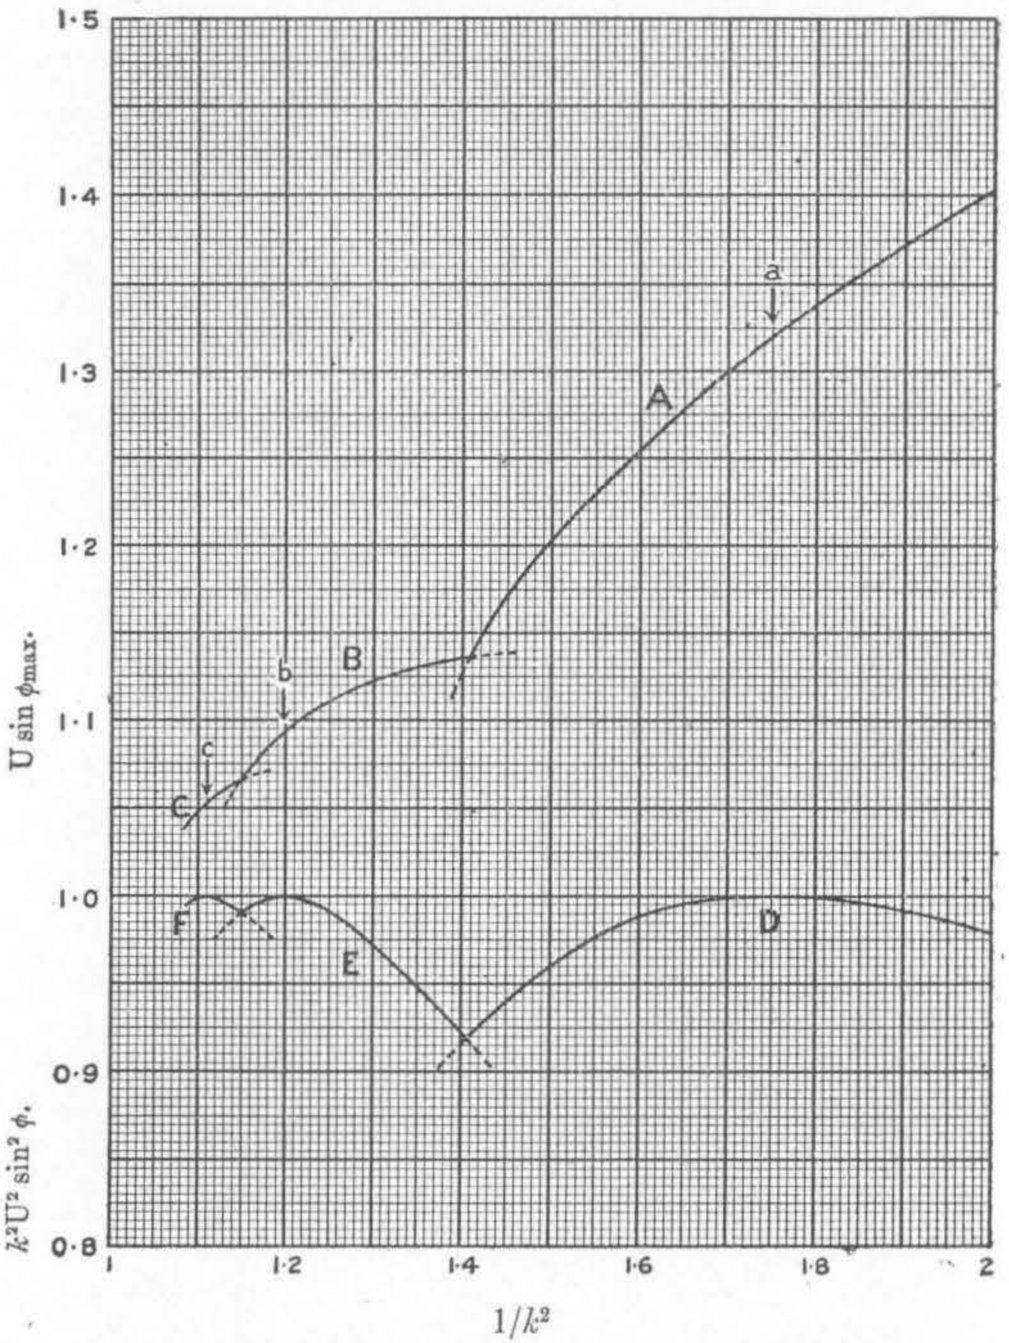
The more exact value of the optimum capacity, or rather of the optimum ratio L_1C_1/L_2C_2, for any value of k^2 within these limits may be found by plotting the (k^2, u) curve from the values given in the Table. This curve has two distinct segments, one covering the range $k^2=0·92$ to 0·87, the other running from 0·87 to 0·71. At those values of k^2 for which there are two equal greatest maxima of U sin ϕ, it is better in practice to choose the greater of the two values of u, since the larger capacity involved does not so readily allow troublesome sparking at the interruptor.

Over the lower range of values of k^2, viz. 0·71 to 0·5, the greatest maxima of U sin ϕ do not correspond so closely with the 3/1 coincidences, except near the value $k^2=0·571$. For this range, however, a simpler and more accurate rule may be stated. It will be noticed from Table I. that there is, within these limits, no great variation in the optimum value of u. It should also be noted that, for such values of k^2, U sin ϕ varies very slowly with u near the greatest maximum: these portions of the (u, U sin ϕ) curves are very flat-topped. We shall therefore make only a very slight error if we take u as constant and equal to the mean value

* Phil. Mag. xxvii. p. 584 (1914).

over this range. The values of U sin ϕ obtained in this way do not in fact differ by more than 1 in the third place of decimals from the maximum values given in the Table. Hence the rule may be stated:—If k^2 lies between 0·71 and 0·5 the optimum primary capacity is that which makes $L_1C_1=0·43\ L_2C_2$.

Of the adjustments specified in Table I. three give unit efficiency when the resistances are neglected, and the efficiency is least at $k^2=0·71$, one of the cases of equal greatest maxima. In this case rather over 8 per cent. of the initial energy $\frac{1}{2}L_1i_0^2$ appears as electrostatic energy in the primary condenser and electrokinetic energy in the primary circuit at the moment when the secondary potential reaches its greatest value. It can be shown that of this 8 per cent. about one quarter represents the energy of charge of the condenser, the remainder the energy of the primary current. How this percentage is affected in practice by the resistances may be considered on a future occasion.



On the use of Series Inductance in the Primary Circuit.

The series of adjustments given in Table I., or a portion of the series, may be effected with an induction-coil in various ways, among which the method of reducing k^2 by the addition of series self-inductance to the primary circuit is the most important if we keep in view the object of obtaining the greatest spark-length with a given current. In this process the quantities L_{21} and L_2C_2 are constant, so that the values of U sin ϕ in the fifth column of the Table are proportional to the maximum secondary potential attainable at the interruption of a given primary current. The optimum value of the ratio L_1C_1/L_2C_2 for any value of k^2 is given in the second column.

In fig. 3 the greatest maxima of U sin ϕ are plotted as a curve the abscissa of which represents $1/k^2$, this quantity being proportional to the total self-inductance of the primary circuit. The full-line curve, the ordinate of which is proportional to the greatest maximum secondary potential at each stage, consists of three portions A, B, C, corresponding to adjustments in which the frequency-ratio n_2/n_1 is near 3, 7, 11 respectively. The points at which these sections of the curve meet represent those cases in which there are two equal greatest maxima of V_2. The broken-line continuations of the curves at these points correspond to secondary maxima in the (u, U sin ϕ) curves. At each of these points of intersection also the efficiency is a minimum for "optimum" adjustments.

At the points marked a, b, c on the curve the frequency-ratio has the exact values 3, 7, 11, and the efficiency in these adjustments is a maximum. The efficiency curve is also shown in fig. 3, by the line DEF, the ordinate of which represents $k^2U^2 \sin^2\phi$.

Fig. 3.

Curve CBA shows the increase of maximum secondary potential accompanying the addition of series self-inductance to the primary circuit of an induction-coil. The abscissa $1/k^2$ is proportional to the total self-inductance of the primary circuit. The ordinate represents the greatest maximum of U sin ϕ (see figs. 1 and 2) at each stage. Curve FED shows the variation of efficiency.

The curve CBA shows how the maximum secondary potential for a given primary current may be increased by adding series inductance to the primary circuit, in the case of an ideal induction-coil with negligible resistances. In practice the curve is, owing to the damping effect of the resistances, considerably below the curve CBA of fig. 3. It may sometimes bend downwards near the point corresponding to a, as I found in some experiments described recently *. I was then under the impression that this is theoretically correct in all cases, but curve A shows that this view is erroneous ; and on repeating the experiments, using for the series inductance only air-core coils of low resistance, I found that the spark-length continued to increase when the self-inductance was increased beyond the value corresponding to the point a †. If suitable coils are used for the series inductance, and if the interruptions are good, the experimental results therefore conform in this respect with the theory as represented by the curve in fig. 3. The fact is that as the primary self-inductance is increased more energy is being put into the system, and, while the efficiency falls off from the point a, the maximum secondary potential continues to increase. This increase becomes, however, less and less rapid as L_1 is increased, and the facts that it is accompanied by loss of efficiency, that under less favourable circumstances it is converted into a diminution, and that a large increase of self-inductance gives rise to troublesome sparking at the interruptor, indicate that it is inadvisable to continue the process beyond the above-mentioned point.

In the *Annalen der Physik*, vol. v. p. 837 (1901), an induction-coil is described by Klingelfuss in which the primary and secondary coils are wound on a nearly closed magnetic circuit. The instrument is said to give a very long spark with a comparatively small number of turns in the secondary coil. The advantage of such an arrangement appears to arise from the low electrical resistance of the secondary coil and the low magnetic reluctance of the core. Since L_{21} is approximately proportional to the number of secondary turns, and L_2 to its square, the factor $L_{21}/\sqrt{L_2}$ of equation (9) is not changed by a reduction of the number of turns, but the lowering of secondary resistance, due both to the reduction of the length of wire and to the use of thicker wire for the secondary coil, diminishes the damping of the oscillations and thus tends to allow a higher secondary potential to be

* Phil. Mag. January 1915, p. 7.

† This effect was not found when coils with iron-wire or sheet-iron cores were used. Probably Maxwell's coil of maximum self-inductance for given length and diameter of wire is the best form for the purpose.

developed. Again, L_{21} and L_2 are inversely proportional to the magnetic reluctance of the core, and the factor $L_{21}/\sqrt{L_2}$ is therefore increased by closing, or nearly closing, the magnetic circuit of the core*.

On the other hand, the conditions do not seem so favourable from the point of view of the other factor of (9), viz. $U \sin\phi$. The values of the inductances and of the coupling coefficient are not stated, but from the description it would seem that the primary and secondary coils are very closely coupled. If this is the case $U \sin\phi$ cannot be large (see Table I. or fig. 3), and according to the present theory the instrument should give a longer spark for a given primary current, or the same spark-length at a smaller current, if suitable self-inductance were connected in series with the primary coil. If, for example, the instrument is so adjusted that $k^2=0{\cdot}835$ and $u=0{\cdot}165$ ($n_2/n_1=7$), and if L_1 and C_1 are increased, the former by 46 per cent. and the latter by 78 per cent., we should then have $k^2=0{\cdot}571$, $u=0{\cdot}429$, and the maximum secondary potential for a given primary current should—apart from any effect due to change in the logarithmic decrements of the oscillations—be increased by over 20 per cent. without loss of efficiency.

The Tesla Coil.

In the case of the Tesla coil the difference of potential v_2 of the terminals of the secondary coil, at time t after the beginning of the discharge in the primary circuit, is (neglecting resistances)

$$V_2=\frac{L_{21}C_1V_0}{\sqrt{(L_1C_1-L_2C_2)^2+4k^2L_1C_1L_2C_2}}(\cos 2\pi n_1t-\cos 2\pi n_2t), \quad . \ . \ . \quad (12)$$

where V_0 is the initial (discharge) potential of the primary condenser. The primary potential difference is given by

$$V_1=V_0\frac{n_1^2n_2^2}{n_2^2-n_1^2}\left[\frac{1-4\pi^2n_2^2L_1C_1}{n_2^2}\cos 2\pi n_1t-\frac{1-4\pi^2n_1^2L_1C_1}{n_1^2}\cos 2\pi n_2t\right]. \quad . \ . \ . \quad (13)$$

These results may be deduced from the solutions given in Fleming's 'Principles of Electric Wave Telegraphy and Telephony,' 2nd ed. p. 264. The full expression for V_2, in

* See du Bois, 'The Magnetic Circuit,' p. 276, 1896.

which the resistances are included, was given by Drude in a well-known paper*, but the above expressions will serve for the present purpose.

Drude considers the problem in which the secondary coil is given, and in which it is required to find what arrangement of the primary circuit gives the highest secondary potential†. After remarking (*l. c.* p. 539) that it is necessary to distinguish between the two cases in which (*a*) the capacity C_1 is varied, and (*b*) the self-inductance L_1 is the variable quantity, he apparently comes to the conclusion (p. 540) that in either case the highest secondary potential is attained when L_1C_1 is equal (or nearly equal) to L_2C_2, *i. e.* when the periods of the primary and secondary circuits, separated from each other, are equal. This is the case of so-called "resonance," and all the subsequent calculations and conclusions given by Drude, including the tables and curves (*l. c.* pp. 546–551), are based on the assumption that this condition ($L_1C_1=L_2C_2$) is satisfied. Drude finally arrives at the result that, if the damping of the oscillations is small, the secondary potential is greatest when the coupling coefficient is 0·6 and the primary capacity is so adjusted as to bring the primary circuit into "resonance" with the secondary, this adjustment of the system giving the frequency-ratio $n_2/n_1=2$.

The reasoning by which Drude arrives at the above result is, I think, not perfectly clear, and the result does not hold in case (*a*). Denoting the ratio L_2C_2/L_1C_1 by m, the expression (12) for V_2 becomes

$$V_2=\frac{L_{21}V_0}{L_1\sqrt{(1-m)^2+4k^2m}}(\cos 2\pi n_1t-\cos 2\pi n_2t). \quad . \quad (14)$$

If the primary capacity C_1 alone is varied (L_1, L_{21}, k^2, V_0, and L_2C_2 being constant), the denominator of this expression has a minimum value when

$$m=1-2k^2. \quad . \ . \ . \ . \ . \ . \ . \quad (15)$$

If also n_1 and n_2 are suitably related, the maxima of the two waves in the secondary coil will occur simultaneously, so that at time $1/2n_1$, $\cos 2\pi n_1t=-1$, $\cos 2\pi n_2t=1$. This happens, for example, when $k^2=0{\cdot}265$‡, $m=1-2k^2=0{\cdot}47$, which adjustment makes the frequency-ratio n_2/n_1 equal to 2.

It follows from (14) that if $k^2=0{\cdot}265$ the most effective primary capacity is that which makes $m=0{\cdot}47$, *i. e.* $L_1C_1=2{\cdot}128\ L_2C_2$. At this degree of coupling, therefore,

* P. Drude, *Ann. d. Physik*, xiii. p. 512 (1904).

† The primary sparking potential V_0 is also supposed to be given.

‡ More exactly $k^2=9/34$.

the optimum primary capacity should be more than twice as great as the value necessary for "resonance." The maximum value of V_2 in this case is numerically, by (14),

$$V_{2m}=2\cdot267\frac{L_{21}V_0}{L_1}*. \quad . \quad . \quad . \quad . \quad . \quad (16)$$

The adjustment recommended by Drude ($k^2=0\cdot36$, $L_1C_1=L_2C_2$) gives for the maximum secondary potential

$$V_{2m}=1\cdot667\frac{L_{21}V_0}{L_1}. \quad . \quad . \quad . \quad . \quad . \quad (17)$$

Even at this degree of coupling, however, a higher secondary potential may be obtained with a larger primary capacity. For example, the adjustment $k^2=0\cdot36$, $L_1C_1=2L_2C_2$, gives the frequency-ratio $n_2/n_1=2\cdot197$, and a maximum secondary potential, at time $t=0\cdot925/2n_1$, the value of which is

$$V_{2m}=1\cdot998\frac{L_{21}V_0}{L_1}. \quad . \quad . \quad . \quad . \quad . \quad (18)$$

From these examples it will be seen that Drude's rule does not in general give even approximately the correct value of the optimum primary capacity. The most effective capacity is generally greater than the "resonance" value.

In some preliminary experiments made by the writer last summer, it was found that in certain cases the best effect was obtained with a primary capacity considerably greater than that required to make the periods of the two circuits equal when separated, but a more extended series of experiments is in progress in the laboratory with the object of determining the best value of m for various values of k^2.

The conditions are very different if the primary capacity is kept constant and L_1 is varied, *e. g.* by means of variable series inductance in the primary circuit. In this case L_{21} is constant, k^2 is inversely proportional to L_1, and the coefficient of $(\cos 2\pi n_1 t-\cos 2\pi n_2 t)$ in (14) has a maximum value of $\frac{V_0}{2}\sqrt{\frac{L_{21}}{L_{12}}\cdot\frac{C_1}{C_2}}$ when $m=1$. If in addition $n_2=2n_1$ ($k^2=0\cdot36$) the numerical maximum of V_2 is given by

$$V_{2m}=V_0\sqrt{\frac{L_{21}}{L_{12}}\cdot\frac{C_1}{C_2}},$$

* The adjustment $k^2=0\cdot265$, $m=1$, gives approximately

$$V_{2m}=1\cdot88\,L_{21}V_0/L_1.$$

consequently

$$\tfrac{1}{2}C_2V_{2m}^2\cdot\frac{L_{12}}{L_{21}}=\tfrac{1}{2}C_1V_0^2,$$

i. e. the maximum electrostatic energy in the secondary coil is equal to the initial energy in the primary condenser.

In Drude's adjustment, therefore, the efficiency is unity if the resistances are negligible. This result may also be seen from the expression (13) for the primary potential, which reduces, if $\cos 2\pi n_1 t=-1$, $\cos 2\pi n_2 t=1$, to

$$V_1=V_0\frac{m-1}{\sqrt{(m-1)^2+4k^2m}},$$

and therefore vanishes when $m=1$. At the moment when the secondary potential reaches its maximum value, therefore, the primary condenser is uncharged, and, since $\frac{dV_1}{dt}=0$, $\frac{dV_2}{dt}=0$, there is no current in either circuit, so that the whole of the energy exists as electrostatic energy in the secondary coil.

In this kind of variation, in which L_1 alone is varied, the initial energy supplied to the system is constant, and the adjustment which gives maximum efficiency must also give the greatest secondary potential. But when the primary capacity is increased the energy supplied to the system becomes greater, and the secondary potential may be increased to a certain extent beyond the point corresponding to maximum efficiency.

Both forms of the problem may present themselves in practice. If, for example, the Tesla coil is given, and ample energy is available for charging the condenser, the capacity of the condenser may always be adjusted to the "optimum" value, whatever be the value of k^2. But if, on the other hand, the energy is limited and it is required to construct a Tesla coil which will make the fullest use of it in generating high secondary potential, the primary capacity is then constant, viz.: the greatest that can be charged to the required sparking potential with the energy available at each discharge of the induction-coil. In this case maximum efficiency and small secondary capacity should be the chief considerations borne in mind in the construction of the Tesla coil.

Bangor, May 1915.

TESLA VISIONS WIRELESS WONDERS

Declares They May Simplify National Defense and Solve Some of World's Greatest Problems

By Edward Marshall.

THOMAS A. EDISON, in one of these interviews, made a suggestion which will revolutionize the naval history of the United States. Already it has resulted in the appointment of a wonderful civilian consulting board.

Now comes Nikola Tesla with another plan which may revolutionize the nation's system of communication.

I went to him, the world's greatest expert, to learn what wireless had accomplished in this war and what of peculiar benefit to this country it might accomplish in the future. I was astonished by the richness of the field of thought into which the queries led.

He believes that wireless transmission might be adapted, without great expense so that it would decrease the outlay for our defense and, at the same time, immensely increase the efficiency of our means of protection against invasion.

He also holds that by the same network of Government-owned radio stations which would be required for this task we might so decrease the cost of the dissemination of useful information that every citizen of this country, resident no matter how remotely from the populated centres, could be kept continually in touch with the outer world occurrences, weather prospects, and all that helpful information which the Government already gathers, or might gather if it had at hand the means by which to make it public.

Indeed, he thinks that the impetus toward practical and rapid development which this war has given radio communication may result in the solution of some of the greatest problems confronting humanity, and announces as a fact that simple scientific application of the knowledge already at hand well may produce at slight cost electrical power wherever needed and for whatever purpose, from the electric operation of machines in factories to that of the farmers' plows.

"Is it not the fact that even in the present war the wireless telegraph has proved of immense value?" I asked the world-famous electrical inventor.

"This new and revolutionary method of flashing energy through space," he answered, "although, as yet, not much more than inaugurated, has profoundly modified methods of warfare, and, in both the constructive and destructive sense, has proved itself to be a factor of such potency that it must be reckoned with in all future naval and military operations.

"It has made surprises impossible, for instance, and that undoubtedly is one of the reasons why no decisive battle has been fought, so far, upon land or sea. To what degree this has been instrumental in saving human life, human effort and treasure, cannot be estimated."

"What are your ideas, in general, about government control of wireless?" I inquired.

"The mere fact that wonders can be achieved through the application of this subtle agent," Mr. Tesla answered, "makes some kind of governmental supervision of all wireless operations imperative, not only in this country, but throughout the world.

"In my opinion, however, governmental control should not be of a nature to hamper that legitimate commercial development which alone can lead to the ultimate perfection of the science.

"Systematic improvement and application of this new means of communication is, without doubt, imperative to our welfare as a nation.

"I cannot think of any one influence which would do more to aid our progress than a network of wireless stations, checker-boarding, as it were, the entire country. The expense of such a system would be relatively small and inestimable benefits would be derived therefrom.

"A high-power plant would cost less than $250,000 and its range would cover all of the United States.

"I am convinced that one year's service of such an installation would more than pay its first cost and the expense involved in its operation. There is scarcely any interest in all the nation which would not feel the benefit of a rightly planned and managed wireless service.

"Every Winter storms interrupt both telephonic and telegraphic transmission in many sections of the country. The sum total of any one year's damage would more than equal the original cost of the entire network of wireless plants which I suggest, and they would be beyond the reach of such destruction if constructed with reasonable care.

"Every one appreciates the value of our weather report service, but it is not as generally available as it would be if such a wireless network, under Government control, existed.

"Every year forest fires destroy millions upon millions worth of valuable property, which is a permanent loss. The existence of such wireless stations as I contemplate, operating in spite of obstacles, unaffected by rain, snow, wind, flood or fire, would constitute an incalculable gain.

"In this connection one of the most important advantages of the system would be the fact that the receiving apparatus would be so small and inexpensive that it could be placed anywhere and would be within the means of almost every one.

"For if we are to get the full benefits of a system of the sort, wireless telephonic transmission must be practically achieved, and when this is an accomplished fact the only apparatus necessary for the reception of perfectly intelligible, spoken messages, would be very inexpensive telephonic receivers.

"Imagine not only the value, but the comfort, which would accrue to dwellers in the isolated spots of the United States if, at certain hours each day, they knew that they could listen through such instruments to weather reports, crop advice, important general news, and, at stated intervals and times, through the same means could find relaxation.

"Operas, speeches, sermons — anything which can be made perceptible through the ear and is desirable—could be conveyed to them from the most remote centres of civilization and culture at a trifling cost.

"The educational effect of such service, alone, could not fail to bring about within a few years what would amount to an educational and psychological revolution in the rural districts of this country. This takes no account whatever of the immense commercial value and domestic convenience which, as a matter of course, would result from the use of such a system.

"And if a plan of this kind would do much for safety upon land, imagine what it would accomplish toward safety upon the oceans and the great lakes.

"We are now in a position to erect a plant which, when required, would emit peculiar waves, by means of which any navigator, no matter where his ship might be, could determine accurately his distance from and position in relation to any given point.

"The general installation and use of such devices on shore and at sea would enable seamen to exactly steer their courses, without dependence upon compasses or observations of the sun and stars.

"Once such a system is in operation it will be possible by law to closely define such navigation routes as will be certain to reduce to a minimum the dangers of marine adventure.

"There is one momentous desideratum which must especially appeal to every thinking human being at this particular time and would be brought infinitely nearer to consummation by the perfection of such a system.

"All these forces and influences inevitably must make for peace because, by annihilating distance they will bring men into intimate contact one with another. This will mean acquaintance, acquaintance will mean friendship, friendship will preclude misunderstandings and wars.

"Now, when all the rest of the world seems to be thinking in terms of destruction we of this republic should think in terms of construction.

"The first requisite of this is the perfection of our means of national self-preservation. There, again, the wireless would be of immense value if used as it easily might be.

"I have been always opposed to the manufacture of expensive war engines and implements of destruction, but the study of the awful spectacle which unfolds in Europe has taught me much.

"It is my present belief that no effort or expense should be spared which could help toward putting this country in a position not only to resist attack, but to make all the world respect those broad humanitarian principles for which the American people ever have been willing to fight."

This statement from the famous electrician astonished me. "How could this be done without incurring the same danger which has existed in Europe during many years, and which at last has culminated in the present calamity?" I asked.

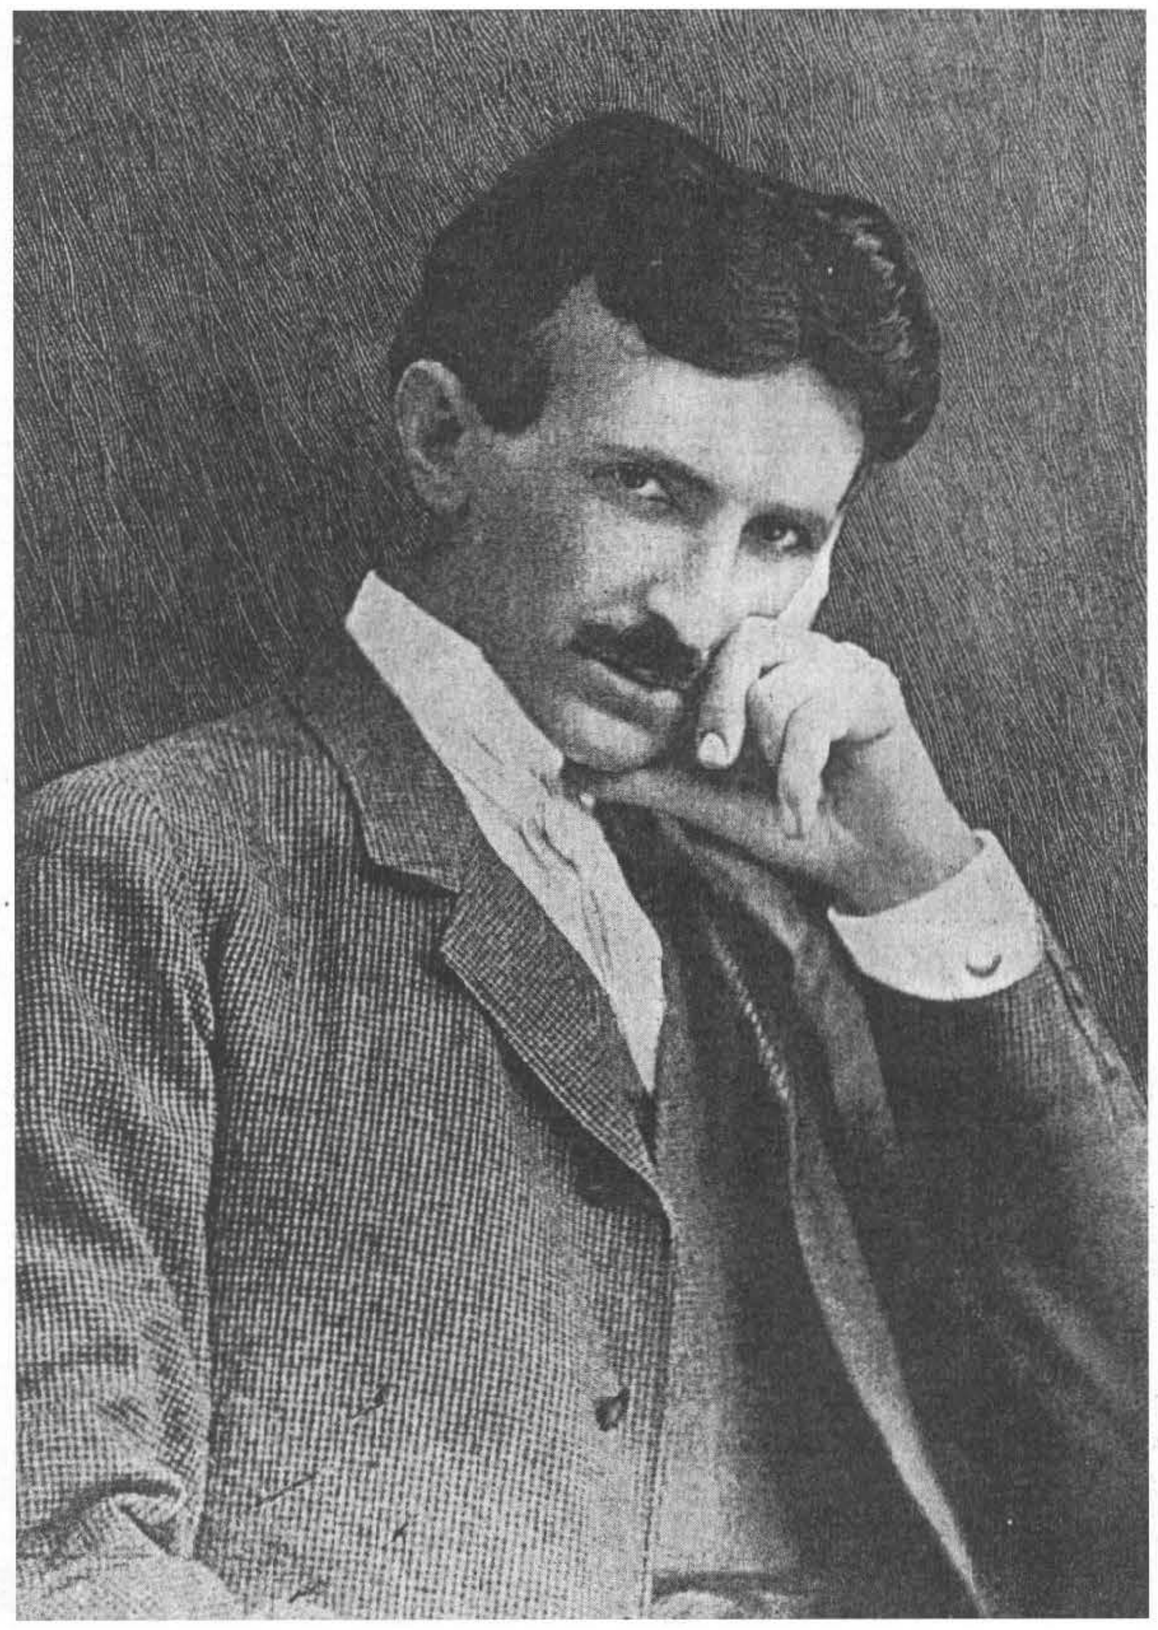
"We can maintain peace for ourselves and help to maintain it for the world only by adopting methods radically different from those which so signally have failed in Europe," he replied. "Hitherto it has been humanity's plan to preserve peace by creating forces for offense.

"But I am sure it is true that this country can do more toward promoting the world's progress and insuring its own tranquillity by making itself invulnerable than it could by making itself invincible.

"So, I believe that the United States, with every possible speed and energy, should attack the task of insuring its own safety by means more scientific and advanced than those which so lamentably have failed in Europe.

"This, I think, is rendered comparatively easy by our exceptionally favorable geographical position, and we already have means at hand, not merely theoretical but demonstrable and in a measure experimentally proved, which, if consequentially employed, would make it impossible for any hostile force to imperil our tranquillity.

"Even now, wireless control from the shore of crewless and therefore doubly offensive vessels is a possibility, though, with their automatic engines, automatic steering gear, and automatic weapons, they be well out at sea.



"It is my belief that we should install along both of our ocean coasts, upon proper strategic and elevated points, numerous wireless controlling plants under the command of competent officers, and that to each should be assigned a number of submarine, surface, and aerial craft.

"From the shore stations these vessels, of whatever character, could be perfectly controlled at any distance at which they remained visible through powerful telescopes.

"With proper refinements, all now well known to experts and fully developed, such operations could be put absolutely beyond the reach of interference, except such as might come through injury or destruction of the machinery.

"If we were properly equipped with such devices of defense, it is inconceivable that any battleship or other vessel of an enemy ever could get within the zone of action of these tel-automatic craft without incurring a risk of annihilation amounting almost to certainty.

"And such a danger never would be braved. In fact, the mere knowledge that such craft existed would determine all possible aggressors to give these peaceful shores of ours a wide berth."

Nikola Tesla.

The Invention Board --- Symbol of America's Future

This Is a Prophecy---That the Mobilization of the Inventive Genius of Industrial America Initiates a Period of Zest for Creating New Things That in Vision Is An American "Age of Pericles."

By George Henry Payne

NECESSITY, better known as the mother of invention, has called her sons as an aid to soothe the troubled world-mind.

The inventor works for peace—his greatest war triumphs have been Industry's greatest prizes.

America will find through her call to invention a Nation Spirit, as France found it in Art, and Germany has found it in Kultur. Peace and progress are but little half-sisters of Invention. They come after Invention, never before it.

"HUTCH," said the "Old Man,"—for so he is known through the antonomastic habit of those who work with him—"Hutch," and the light of assurance and prophecy came into Edison's eyes, "we're the biggest nation on earth, and I tell you we ought to have the biggest, damnedest navy in the world. There's no reason why we should be second to any nation. We don't want war, we want peace; but we ought to be in a position to see that no one interferes with our desire for peace."

And then the "Old Man," "Hutch" tells me, having uttered these sentiments, which to tender souls may seem very vigorous, turned abruptly and went back to his twenty-hour-a-day job of enabling America to produce her aniline dyes without regard to where war happens to raise its hoary head—a very practical kind of peace work.

"Hutch," in scientific and naval circles, in the patent office, the technical magazines, the government reports and even to the Queen of England, who once gave him a medal, is Miller Reese Hutchison, chief engineer of that city known as the Edison Manufacturing Plant and Laboratories, and personal representative of Thomas A. Edison. To "Hutch," this unassuming and modest scientist who is even less inclined to talk that Edison himself, the "Old Man" had relegated the task of setting forth his views as to what the new Board of Invention and Development that has been called to the aid of the Navy Department means.

In the first place, it is more or less essential to clear up certain misunderstandings about this innovation of having a board of inventors and civilian experts assist the regular navy authorities.

Such men as Colonel W. C. Church, the editor of "The Army and Navy Journal," have looked at the suggestion of the formation of this board with little favor, for they believe that the navy needs bolstering up in other and more important lines. Others have seen in it an invocation to the war spirit, through turning the attention of some of America's most conspicuous and able citizens to the manufacture and invention of weapons of destruction.

The Board of Invention will interfere with no other line of naval development, and it is the opinion of Edison himself that it will make more for peace and the inventions of peace than any other single movement.

As Mr. Edison's personal representative it was Mr. Hutchison himself who arranged the meeting between Secretary Daniels and the great inventor. A very modest man is this same Mr. Hutchison, refusing to speak at all of his own inventions or his refusal to go on the board himself, and even requesting that the naked facts of "Who's Who," with its long list of honors, be omitted in commenting on what he had to say.

"All over the country," said Mr. Hutchison, "men are working at inventions of all kinds. Necessarily, the main tendency of this feverish activity at present is to produce means of defence for the country. The Board of Invention will have to do simply with that division of the body politic, and will in no way interfere with the work or the plans of the navy.

"As I understand the matter of the proposed Board of Experts:

"First. When ideas are submitted by civilians or personnel of the navy, such communications will be addressed to the Secretary of the Navy.

"Second. The Secretary will turn these suggestions over to the Naval Board, consisting of an officer of rank, having a staff of experts selected from the personnel of the navy. This officer in charge will in turn turn the suggestions over to such of his aids as are competent to separate the chaff from the wheat, and who will make such recommendations to their chief as they see fit and proper.

"Third. If the staff is impressed with an idea as being logical and highly desirable, it will so advise their chief. He will then confer with such of them as are best qualified for expert opinion, or will communicate with such other officers of the navy as may be qualified to advise the naval head of the board.

"Fourth. If it is the consensus of opinion that the idea presented is of value, and if the Naval Board desires advice from any of the experts of the consulting board, such expert as is best qualified to pass on the feasibility of the idea, or give expert opinion regarding it, is communicated with by the head of the Naval Board.

"Fifth. When this expert, or these experts, receive a request from the head of the Naval Board for an opinion as to the feasibility of the idea and suggestions as to whether or not, in their estimation, it would pay to investigate the matter further experimentally, he or they will so advise the head of the board, without entering into any long-winded discussion as to the pros and cons. An affirmative answer from such an expert will then justify the Naval Board in turning the proposed invention over to the laboratory head, who will in turn assign such man or men as he may have on his corps of assistants to work the idea up with a view of embodying it for use by the navy into a concrete, practical apparatus.

"As I see it, the Board of Experts will not be a board at all, but simply a number of highly qualified specialists in their particular lines who, by reason of their intimate knowledge of the various arts and sciences, will give the government the benefit of the experience and knowledge gained by simply passing on and suggesting lines of research concerning new ideas presented. I do not see that this will entail very much work on the part of members of the board of consulting engineers (whichever they may be called). Neither do I think that they should be called upon to spend a great deal of time on each subject. They serve in the same capacity as a specialist in stomach troubles serves when called in for consultation.

"Before an invention is turned down by the Naval Board, unless it is a foolish suggestion and on the face of it a waste of time for further consideration, the Secretary of the Navy should be advised that same is being turned down and the reasons briefly stated. He will then be able to consult with such experts as he may deem qualified to give him a personal opinion. This to act as a check on the Naval Board.

"Similarly, when the Naval Board approves of and desires to further investigate, by experimentation, after the civilian board of experts has favorably passed on the proposition, the matter should be submitted to the Secretary, with the reasons briefly stated as to why the matter is to be investigated further.

"I therefore do not feel that the experts appointed by the engineering societies should be detail men at all. They should be men of very large calibre, with great breadth of vision and keen insight, rather than of accurate detail knowledge of and long actual working experience on given subjects. Naturally, a man who is fitted to go on such a board must have had long detailed experience with a subject regarding which he is supposed to be an expert, but he should have arrived at the point where he is no longer called upon to do detail work, but because of knowledge gained by such long experience and study he is qualified as an adviser.

"The plan is to have the present adequate and very able Naval Board look over every invention and when in doubt simply refer to a member of the consulting board.

Thomas Edison, the grand old dean of American inventive science talking ideas with Miller Reese Hutchison, his young "right arm

THE NEW NAVAL BOARD IN PROSPECTUS

Continued from first page.

"The need of such an experimental station is absolute. Even the little laboratory at Annapolis, with its sixty thousand dollars' appropriation, has saved the government hundreds of thousands of dollars. Here in Orange, in this very building, we spend four hundred thousand dollars a year on laboratory work. The United States government should have a laboratory and a laboratory appropriation befitting the nation and the people. Not only would that be a great benefit in developing a defence, but think of the industrial possibilities; for, after all, invention is a thing of peace and not of war, and almost every great invention that has been brought about in war times has been afterward developed in such a way as to bring about an industrial revolution.

"Take the case of the Monitor; that was supposed to be a purely warlike invention, born of the necessity to destroy the Merrimac, and yet the connection between the Monitor and Harveyized steel and the great development of the steel industry to-day is direct.

"With the war just a year old, there have already been many evidences of invention contributions to the industrial progress of the country. Mr. Edison is now manufacturing aniline oil from which dyes are made, not in large quantities, but up to a year ago nobody thought of this country doing it at all."

"I understand that you are also making carbolic acid, Mr. Hutchison; how about that?"

"That is a specific case in point," answered Mr. Hutchison, "and shows the value of developing the spirit of invention."

"When the war broke out we were notified from England and Germany that we would not be able to get any more carbolic acid. We had to have it for our records, and Mr. Edison went to work and in seventeen days he was producing carbolic acid, by a secret process, which had never before been manufactured commercially in this country. Inasmuch as the navy had to have carbolic acid also, we agreed to furnish them all they wanted, and have already contracted for four hundred thousand pounds at 56 cents a pound, which is the cost of manufacture. In the market those who had saved up some were asking the government a dollar a pound, but Mr. Edison's belief is that it is a citizen's duty in time of stress to stand by his country to the limit.

"It may be interesting to know that carbolic acid is extracted from coal-tar in England and Germany, but especially in England, where the coal tar in the gas mains is very rich in carbolic. It is also made from benzol. Benzol is absorbed from the coal smoke as a by-product of coke ovens. Now we are working not only to produce carbolic acid but benzol and toluol, which is found in benzol. Benzol is necessary for the production of perfumes and of pharmaceutical compounds, the production of saccharine, and in causing illuminating gas to give the white light, which otherwise would be a smoky yellow. It is also used as a substitute for gasolene for motor purposes, and mixed with toluol it produces a non-carbonizing fuel, and is non-freezing under ordinary circumstances.

"For years the Germans have been manufacturing carbolic acid out of benzol, and have had a law prohibiting the erection of a by-product coke oven without an absorber for taking over the benzol and toluol. That is the reason why Germany is now provided with munitions and fuel for submarines, etc. To-day you cannot buy a pound of coal in Germany. The coal is all used to produce benzol and toluol, and the by-product (coke) is now sold to the people instead of coal. All the German locomotives have been changed to coke burners.

"From this very same process, and these very same chemicals, Germany is able to hold her own in the production of explosives. Picric acid, the well known substance used in the manufacture of high explosives, is made from carbolic acid; and from toluol, tri-nitro toluol, a safer and better explosive, is made.

"When the war put a ban on the exportation of carbolic acid from England, and prevented its exportation from Germany, Mr. Edison was caught, as we used carbolic in quantity, as I have said, in the manufacture of our phonograph records. So Mr. Edison purchased all the benzol he could find in the market, about sixty thousand gallons, and invented a process to make carbolic acid, after finding it impossible to get any information on the subject, and in less than three weeks he had a plant installed and running and turning out two hundred and fifty pounds of pure crystal white carbolic per day. Its capacity has been greatly increased since then.

"But soon he ran out of benzol. Then he erected absorbers at several steel mills where they make coke for the manufacture of steel. To-day he is making all the carbolic we need and all the United States army and navy need.

"In the United States there are sixty-eight hundred by-product coke ovens that throw away annually twenty-nine million six hundred thousand gallons of benzol. The price of benzol per gallon has varied all the way from twelve cents to three dollars during the past thirty-five years, yet with a properly and comprehensively constructed absorption plant it should be absorbed and refined at a total cost of about six cents per gallon, including fixed charges, etc. It costs much more in our hastily constructed temporary absorbers.

"Coming to the aniline dyes, Mr. Edison, as soon as the war broke, was beset by the cloth manufacturers to produce aniline oil from which aniline dyes are made. He has finished a small plant and is about to put into operation a larger one on which he has been working. His point of view is that while he is interested more in other things, and has a great many calls on his time, it is his duty to work on these things, and that I think will be the spirit of the entire Board of Invention."

I went from Edison and Hutchison to Nicola Tesla.

These are days when the opinions of the foreign born citizens are of unusual interest and the foreign born inventor would seem to single himself out for conspicuous attention. Nicola Tesla was born in Austrian Croatia in 1857, and he speaks with the weight of the man who invented the modern principle of the rotary magnetic field, embodied in the transmission of power from Niagara Falls. Strangely, too, he speaks forcibly of the waste that awaits invention's magic wand to rise to useful life.

Thoughtful and hopeful he sat in the lounge room of the Waldorf the other night and talked:

"That America, the greatest inventive country in the world—in fact, when you look back, you can truthfully say the greatest inventive country in the history of the world—should have an official or semi-official inventive board, or board of inventors associated with the government, is one of the finest signs of the times and one of the most hopeful.

"It is not merely a matter of exploitation, although exploitation has many uses other than those that insure immediate and direct benefits. France's exploitation of her art, scientifically done, has other and finer uses than merely bringing to France millions of dollars every year. Switzerland, like a beautiful woman, living purely on the tourist tribute—without agriculture or industries—on the money of those who come from all over the world to see her marvellous beauty, has through the exploitation of her beauty given her people a solidarity.

"While before the world we saw France inharmonious and disjointed, the celerity with which the nation has settled into unanimity and furnished an army that is not second to even the German army in efficiency and oneness, is due to the fact that the race has had long and frequently recurring periods of what might be called psychological homogeneity.

"Invention is in the air in America, and while I am a very strong advocate of peace and abhor the idea of ever seeing this country become a militaristic nation, I am glad to see a movement inaugurated that will bring the civilian inventor in touch with the defence of the nation—that will bring him in touch with the government, which means all of the people, and thereby lead, I believe, to the development of a nation spirit, something in which we have been lacking, and which we need, especially in these times when there is such flux and counter-flux of political, social and economic ideas.

"Bismarck, who had many sides, and who is only thought of as the man of iron and blood, said that it would set the world back a thousand years if this country should ever become a military nation.

"It was not the size of this country that he was thinking of, nor yet of its millions of people, but of its resources. Russia, too, is a big nation, but there is no comparison, for this country, with its great resources and the character of its people, breathes invention. And because it is so big, because it has such wonderful possibilities and its character among nations is so vital to the peace and progress of the world, it must be made impregnable that it may be kept a peace nation and a power among nations for peace. Such a country is naturally a tempting prize, and what we think or believe must not stop us from making her secure.

"It is not inventions for warlike purposes alone that will be fostered by the creation of a board of inventions. The spirit of the government itself changes when it embarks on a move such as the one contemplated. Think of it—there are to-day in America over 250,000 amateur wireless operators, mostly young men, experimenting in their own way with a practical invention that only a short time ago was laughted at as an impossibility. There are a quarter of a million possible inventors. Who knows what may come out of that great self-educating school when they grow up or in the years to come?

"Take the matter of the automobile—it is not only a convenience and a pleasure, but it is a great school for millions of citizens. Men who would never think of learning the rudiments of electricity and mechanics are now, as part of their daily routine, called on to exercise judgment on what would once have been considered highly technical and difficult matters. The probable result will be that the next generation will consider it an essential part of education to be able to drive a motor and understand it, just as essential in fact as the ability to read and write.

"It isn't a war spirit that will dominate invention, but a peace spirit. We do not want war; but if we prepare for a defence we may seem to European nations to be following in their footsteps. But if the soul of our movement is the optimism of America, it will not be warlike. Instead of industry gaining through the by-products of warlike invention, it will gain directly because out of the encouragement of invention will come the cure of America's greatest evil—extravagance and waste.

"It is to do away with this great waste that I am turning my own mind just now. Think of it, the United States Steel Company alone loses fifty million dollars a year through waste; I am working on an invention now that will check this, and I believe that the young and inventive mind of America has no greater problem than the stoppage of waste, no more encouraging problem, for it is one to which the capitalist will give his aid. We all know, and I have had my own personal disappointing experiences, that the revolutionary invention that disturbs large investments has a hard row to hoe. But the stoppage of waste means encouragement from every one, capitalist and public alike."

The Boston Post August 1, 1915

"LET WIRELESS GUARD U. S."—TESLA

World-Famous Expert Outlines Plan of Crewless Warships

The wireless might become the savior of America in war time. This is the opinion of Nikola Tesla, our famous expert. He proposes a gridiron of stations covering both coasts, in an exclusive interview with Edward Marshall, the noted newspaper writer.

War and the Wireless

By Edward Marshall

Thomas A. Edison, in one of these interviews, made a suggestion which will revolutionize the naval history of the United States. Already it has resulted in the appointment of a wonderful civilian consulting board.

Now comes Nikola Tesla with another plan which may revolutionize the nation's system of communication.

I went to him, the world's greatest expert, to learn what wireless had accomplished in this war and what of peculiar benefit to this country it might accomplish in the future.

I was astonished by the richness of the field of thought into which the queries led.

He believes that wireless transmission might be adapted, without great expense, so that it would decrease the outlay for our defence and, at the same time, immensely increase the efficiency of our means of protection against invasion.

He also holds that by the same network of government owned radio stations which would be required for this task, we might so decrease the cost of the dissemination of useful information that every citizen of this country, resident no matter how remotely from the populated centres, could be kept continually in touch with the outer world occurrences, weather prospects and all that helpful information which the government already gathers, or might gather if it had at hand the means by which to make it public.

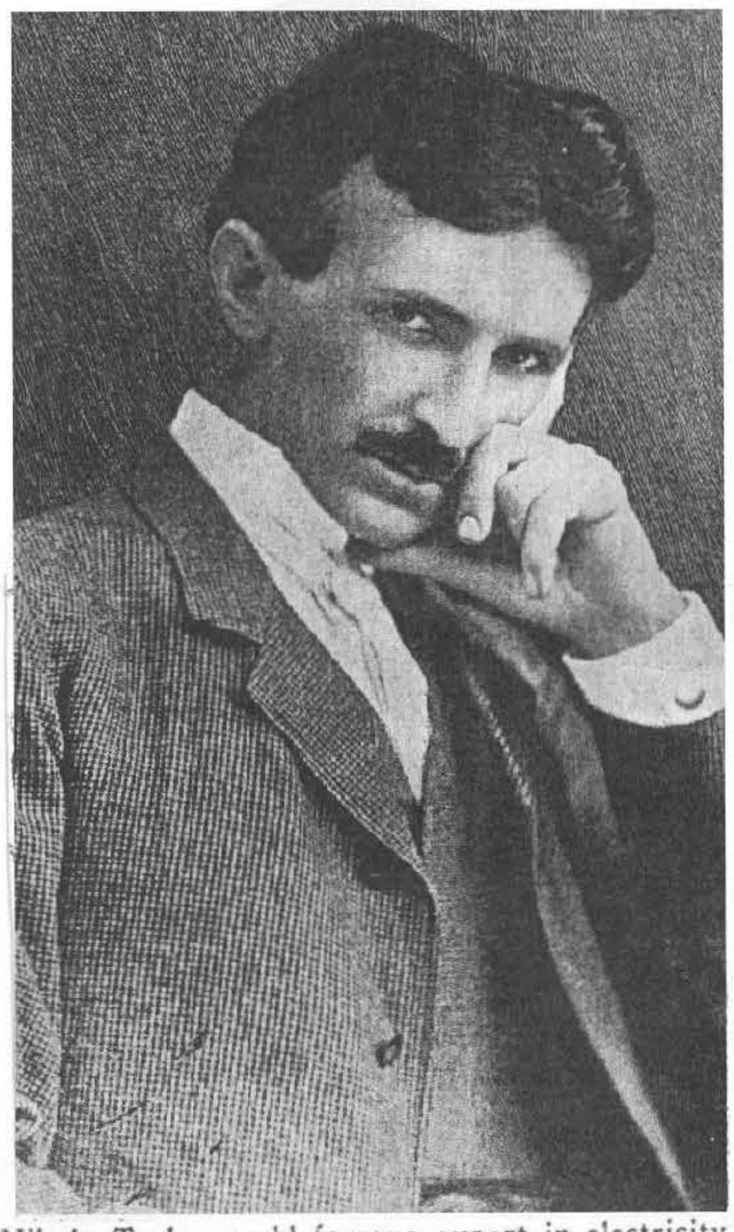
Indeed, he thinks that the impetus toward practical and rapid development which this war has given radio-communication may result in the solution of some of the greatest problems confronting humanity and announces as a fact that simple scientific application of the knowledge already at hand well may produce at slight cost electrical power wherever needed and for maturer purpose, from the electric operation of machines in factories to that of the farmers' plows.

"Is it not the fact that even in the present war the wireless telegraph has proved of immense value?" I asked the world famous electrical inventor.

"This new and revolutionary method of flashing energy through space," he answered, "although, as yet, not much more than inaugurated, has profoundly modified methods of warfare, and, in both the constructive and destructive sense, has proved itself to be a factor of such potency that it must be reckoned with in all future naval and military operations.

MADE SURPRISE NIL

"It has made surprises impossible, for instance, and that undoubtedly is one of the reasons why no decisive battle has been fought, so far, upon land or sea. To what degree this has been instrumental in saving human life, human effort and treasure, cannot be estimated."



I then asked Mr. Tesla to express himself concerning the importance to the fortunes of Germany in this war of the Sayville and Tuckerton wireless plants.

"The work of these two plants affords a striking example of the practical value of the wireless," he replied.

"Without them Germany would have been completely isolated from all the nations of the world except those which are at war with her.

"Under-sea cables are cut almost as easily as overhead wires can be, but it is impossible for an enemy to interrupt communication by this new method. Its medium is all pervading, invisible, intangible. It cannot be destroyed or even blocked, for it is space itself.

"The German stations which, possibly, thus have preserved from dire disaster the nation which claims them as its own, really are not more than one-tenth as powerful as some other existing plants and are scarcely a twentieth as powerful as others, although much has been printed about their enormous activity.

Nikola Tesla, world-famous expert in electricity, who says wireless may be salvation of the United States.

"In these stations, however, so far as I have seen, every detail has been scientifically developed with great skill, and it is because of this that through them communication between Germany and North America, across the 3000 and more miles of intervening sea, has been possible with the expenditure of energy amounting to no more than 30 kilowatts."

"Has not the lack of secrecy somewhat hampered their usefulness?" I inquired.

SECRECY HAS HAMPERED

"Undoubtedly. As messages now are transmitted by these and other wireless stations, there is no such thing as actual secret operation, for the reason that the system is dependent upon simple tuning of circuits.

"When this primitive method is used, any inquisitive outside expert, by quick manipulation of a wavemeter, can ascertain the rate of vibration and 'cut in' without the knowledge of either of the communicating operators.

"Not only this, but if he so desires and has at hand the necessary apparatus, he even can start, with his own instrument, a vibration similar to that of the other instruments and thus interfere with their successful operation.

"Thus, at present, the only possible guarantee of privacy at the German stations and others is the use of a code, which at best must be very inconvenient and time-consuming at both ends, for it entails codification at the sending and translation at the receiving station, with all the possibilities of error inseparable from both processes.

"This is a clumsy and unnecessary expedient. We in America have a well-developed means whereby we can render wireless messages absolutely safe against outside interruption.

"It completely protects them from meddlers of any sort, making them secret and inviolable. I have called this method the 'art of individualization.'

"I will try to illustrate for the lay reader the difference between the old 'tuning' as now practised and the 'individualizing' method which is coming into use.

"It is a matter of common understanding that an electric circuit, properly conducted, has a certain distinctive period of vibration, as has, for instance, a bell or tuning fork.

"If this particular vibration is emitted from a distant generator of oscillations, the circuit will readily respond and will absorb a relatively very great amount of energy.

"This wonderful phenomenon is called resonance, or resonant response, and its possibilities ages and ages ago captured man's imagination. Remember, for example, the trumpets which are credited with having 'crumbled the walls of Jericho.' If this actually occurred, it was a phenomenon of resonant response.

"The mechanical and electrical phenomena of response are entirely the same in general principle and obey identical laws—so much so that the mechanical engineer needs no special electrical knowledge in order to calculate accurately the effect of electrical resonant response.

"Lord Kelvin, England's great electrical genius, put this tersely when he said that a mechanical engineer can become an electrician within a month.

"Now to make the distinction clear it should be understood that while resonant response in tuned circuits is based upon a single feature or property of the same, in individualized circuits the dependence is not upon one, but upon numerous features or characteristics in combination.

"In this lies the tremendous difference between the old and imperfect method of wireless telegraphy permitting tapping and interference, and the new and absolutely safeguarded mode based on individualization.

"Unfortunately, the practice of this new art requires very skilful execution. This, and this alone, at present stands in the way of its general adoption.

"Here in the United States, where these improved methods and devices have been organized we should at once begin to protect our future by training many experts. The government, especially, should look to this."

"I cannot think of any one influence which would do more to aid our progress than a network of wireless stations, checker-boarding as it were, the entire country. The expense of such a system would be relatively small and inestimable benefits would be derived therefrom.

"A high-power plant would cost less than $250,000 and its range would cover all of the United States.

"I am convinced that one year's service of such an instalment would more than pay its first cost and the expense involved in its operation. There is scarcely any interest in all the nation which would not feel the benefit of a rightly planned and managed wireless service.

"Now, when all the rest of the world seems to be thinking in terms of destruction, we, of this republic, should think in terms of construction.

"It is my present belief that no effort or expense should be spared which could help toward putting this country in a position not only to resist attack, but to make all the world respect those broad humanitarian principles for which the American people ever have been willing to fight."

"Even now wireless control from the shore of crewless, and, therefore, doubly offensive vessels, is a possibility, though, with their automatic engines, automatic steering gear and automatic weapons they be well out at sea.

SHOULD PROTECT COAST

"It is my belief that we should install along both of our ocean coasts, upon proper strategic and elevated points, numerous wireless controlling plants under the command of competent officers and that to each should be assigned a number of submarine, surface and aerial craft.

"From the shore stations these vessels, of whatever character, could be perfectly controlled at any distance at which they remained visible through powerful telescopes. Thus they could be guided to any desired point and there made to perform such work as might be necessary.

"With proper refinements, all now well known to experts and fully developed, such operations could be put absolutely beyond the reach of interference, except such as might come through injury or destruction of the machinery.

"If we were properly equipped with such devices of defence it is inconceivable that any battleship or other vessel of an enemy ever could get within the zone of action of these tel- automatic craft without incurring a risk of annihilation amounting almost to certainty.

Tesla Sees Wireless Big Factor in Defense

Great Expert Proposes Gridiron of Stations

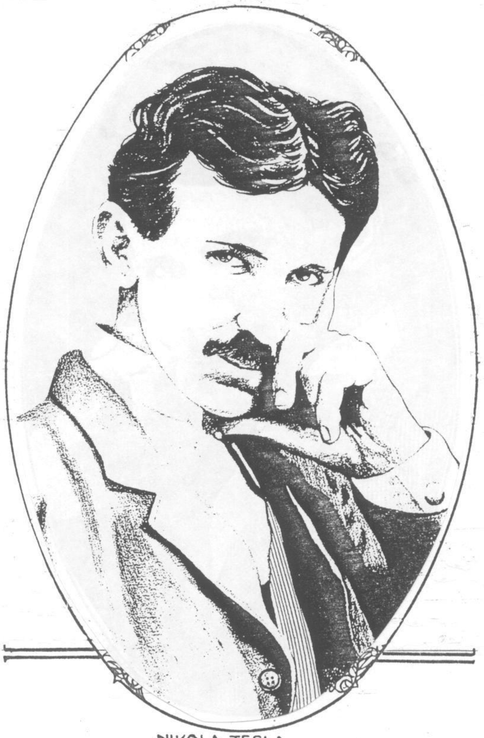
Predicts Cheap System for Communication

Says That It Is Possible to Control Crewless Warships and Fire Guns by Radio-Waves—Declares That Germany Without Wireless Would Have Been Nearly Helpless.

BY EDWARD MARSHALL.

THOMAS A. EDISON, in one of these interviews made a suggestion which will revolutionize the naval history of the United States. Already it has resulted in the appointment of a wonderful civilian consulting board.

Now comes Nikola Tesla with another gem which may revolutionize the nation's system of communication.



I went to him the world's greatest expert, to learn what wireless had accomplished in this war, and what of peculiar benefit to this country it might accomplish in the future.

He believes that wireless transmission might be adapted, without great expense, so that it would decrease the outlay for our defense, and at the same time immensely increase the efficiency of our means of protection against invasion.

"Is it not the fact that even in the present war the wireless telegraph has proved of immense value?" I asked the world-famous electrical inventor.

"This new and revolutionary method of flashing energy through space," he answered, "although as yet not much more than inaugurated, has profoundly modified methods of warfare and, in both the constructive and destructive sense, has proved itself to be a factor of such potency that it must be reckoned with in all future naval and military operations.

"It has made surprises impossible, for instance, and that undoubtedly is one of the reasons why no decisive battle has been fought so far upon land or sea. To what degree this has been instrumental in saving human life, human effort and treasure, cannot be estimated."

NIKOLA TESLA

In War Wireless Is Indispensible.

I then asked Mr. Tesla to express himself concerning the importance to the fortunes of Germany in this war of the Sayville and Tuckerton wireless plants.

"The work of these two plants affords a striking example of the practical value of the wireless, he replied.

"Without them Germany would have been completely isolated from all the nations of the world except those which are at war with her.

"Undersea cables are cut almost as easily as overhead wires can be, but it is impossible for an enemy to interrupt communication by this new method. Its medium is all pervading, invisible, intangible. It cannot be destroyed or even blocked, for it is space itself.

"The German stations which, possibly, thus have preserved from dire disaster the nation which claims them as its own, really are not more than one-tenth as powerful as some other existing plants and are scarcely a twentieth as powerful as others, although much has been printed about their enormous activity.

"In these stations, however, so far as I have seen, every detail has been scientifically developed with great skill, and it is because of this that through them communication between Germany and North America, across the 3,000 and more miles of intervening sea, has been possible with the expenditure of energy amounting to no more than 30 kilowatts."

"Has not the lack of secrecy somewhat hampered their usefulness?" I inquired.

"Undoubtedly. As messages now are transmitted by these and other wireless stations, there is no such thing as actual secret operation, for the reason that the system is dependent upon simple tuning of circuits.

"When this primitive method is used, any inquisitive outside expert, by quick manipulation of a wave meter, can ascertain the rate of vibration and 'cut in' without the knowledge of either of the communicating operators.

"Not only this, but if he so desires and has at hand the necessary apparatus, he can even start, with his own instrument, a vibration similar to that of the other instruments and thus interfere with their successful operation.

"Thus, at present, the only possible guarantee of privacy at the German stations and others, is the use of a code, which at best must be very inconvenient and time consuming at both ends, for it entails codification at the sending and translation at the receiving station, with all the possibilities of error inseparable from both processes.

U. S. Has Solved Problem of Secrecy.

"This is a clumsy and unnecessary expedient. We in America have a well-developed means whereby we can render wireless messages absolutely safe against outside interruption.

"What are your ideas, in general, about Government control of wireless?" I inquired.

"The mere fact that wonders can be achieved through the application of this subtle agent," Mr. Tesla answered, "makes some kind of governmental supervision of all wireless operations imperative, not only in this country, but throughout the world.

"In my opinion, however, governmental control should not be of a nature to hamper that legitimate commercial development which, alone, can lead to the ultimate perfection of the science.

"I cannot think of any one influence which would do more to aid our progress than a network of wireless stations, checker boarding, as it were, the entire country. The expense of such a system would be relatively small and inestimable benefits would be derived therefrom.

"A high-power plant would cost less than $250,000 and its range would cover all of the United States.

"I am convinced that one year's service of such an instalment would more than pay its first cost and the expense involved in its operation. There is scarcely any interest in all the nation which would not feel the benefit of a rightly planned and managed wireless service.

"Every winter storms interrupt both telephonic and telegraphic transmission in many sections of the country. The sum total of any one year's damage would more than equal the original cost of the entire network of wireless plants which I suggest, and they would be beyond the reach of such destruction if constructed with reasonable care.

"Everyone appreciates the value of our weather report service, but it is not as generally available as it would be if such a wireless network, under government control, existed.

"Every year forest fires destroy millions upon millions worth of valuable property, which is a permanent loss. The existence of such wireless stations as I contemplate, operating in spite of obstacles, unaffected by rain, snow, wind, flood, fire, would constitute an incalculable gain.

"In this connection one of the most important advantages of the system would be the fact that the receiving apparatus would be so small and inexpensive that it could be placed anywhere and would be within the means of almost everyone.

"For if we are to get the full benefits of a system of the sort, wireless telephonic transmission must be practically achieved, and when this is an accomplished fact the only apparatus necessary for the reception of perfectly intelligible, spoken messages, would be very inexpensive telephonic receivers.

"Imagine not only the value, but the comfort, which would accrue—to dwellers in the isolated spots of the United States, if, at certain hours each day, they knew that they could listen through such instruments to weather reports, crop advice important general news, and, at stated intervals and times, through the same means could find relaxation.

"Operas, speeches, sermons — anything which can be made perceptible through the ear and is desirable, could be conveyed to them from the most remote centers of civilization and culture at a trifling cost.

"The general installation and use of such devices on shore and at sea would enable seamen to exactly steer their courses, without dependence upon compasses or observations of the sun and stars.

Would Minimize Danger at Sea.

"Once such a system is in operation it will be possible by law to closely define such navigation routes as will be certain to reduce to a minimum the dangers of marine adventure.

"I have been always opposed to the manufacture or expensive war engines and implements of destruction, but the study of the awful spectacle which unfolds in Europe has taught me much.

"It is my present belief that no effort or expense should be spared which could help toward putting this country in a position not only to resist attack, but to make all the world respect those broad humanitarian principles for which the American people ever have been willing to fight."

"We can maintain peace for ourselves and help to maintain it for the world only by adopting methods radically different from those which so signally have failed in Europe," he replied. "Hitherto it has been humanity's plan to preserve peace by creating forces for offense.

"Had there been the slightest possibility of the success of this old method, Europe never would have known another war. Therefore, it is plain that this is the time and I am sure that we are the people, to cut loose from that traditional illusion.

"Other forces and implements different from those of war must be found for settlement of international disputes and he who finds these instrumentalities must first render himself invulnerable before he can force others to accept his suggestions.

"The task undoubtedly is ours.

"The underlying idea of war is fundamentally wrong, although it has been sanctioned by the theory of the survival of the fittest and, in earlier civilizations, may have been one of the necessities of advance.

Wireless Control of Vessels Possible.

"But I am sure it is true that this country can do more toward promoting the world's progress and insuring its own tranquility by making itself invulnerable than it could by making itself invincible.

"So I believe that the United States, with every possible speed and energy, should attack the task of insuring its own safety by means more scientific and advanced than those which so lamentably have failed in Europe.

"This, I think, is rendered comparatively easy by our exceptionally favorable geographical position, and we already have means at hand, not merely theoretical but demonstrative, and in a measure experimentally proved, which, if consequently employed, would make it impossible for any hostile force to imperil our tranquillity.

"Even now wireless control from the shore of crewless, and, therefore, doubly offensive vessels, is a possibility, though with their automatic engines, automatic steering gear and automatic weapons they be well but at sea.

"It is my belief that we should install along both of our ocean coasts, upon proper strategic and elevated points, numerous wireless controlling plants; under the command of competent officers and that to each should be assigned a number of submarine, surface and aerial craft.

"From the shore stations these vessels, of whatever character, could be perfectly controlled at any distance at which they remained visible through powerful telescopes. Thus they could be guided to any desired point and there made to perform such work as might be necessary.

"With proper refinements, all now well known to experts and fully developed, such operations could be put absolutely beyond the reach of interference, except such as might come through injury or destruction of the machinery.

"If we were properly equipped with such devices of defense it is inconceivable that any battleship or other vessel of an enemy ever could get within the zone of action of these tel-automatic craft without incurring a risk of annihilation amounting almost to certainty.

"And such a danger never would be braved. In fact the mere knowledge that such craft existed would determine all possible aggressors to give these peaceful shores of ours a wide and respectful berth.

TESLA SUES MARCONI ON WIRELESS PATENT

Alleges That Important Apparatus Infringes Prior Rights Granted to Him.

BASIC PRINCIPLES INVOLVED

Marconi Company Manager Claims Ownership of All Underlying Wireless Inventions.

A suit brought by Nikola Tesla against the Marconi Wireless Telegraph Company of America, seeking the annulment of one of the chief Marconi patents, will have its first public argument in the United States District Court tomorrow, when counsel for Mr. Tesla will seek to have the court strike out nine paragraphs in the Marconi Company's answer to Mr. Tesla's complaint. Simultaneously with the suit for the annulment Mr. Tesla has brought a suit against the Marconi Company for infringement of his patents.

This litigation is a new development in the Marconi Company's claim to ownership of all basic patent rights in the transmission of wireless messages. In a number of other wireless patent suits against companies and individuals the Marconi Company is the plaintiff, and, though a defendant in this latest litigation, Edward J. Nally, Vice President and General Manager of the Marconi Company, believes that Mr. Tesla's suit will serve as one of the mediums through which the Marconi Company hopes to establish the broad claim of its right to all basic wireless patents.

The dispute over patent rights between the Marconi Company and Mr. Tesla began in August, 1914, when the Marconi Company sued Fritz Lowenstein, a German engineer, alleging that certain wireless apparatus sold by him to the United States Navy was made in violation of Marconi patent 763,772. It was announced then that Mr. Tesla would testify for Mr. Lowenstein, alleging that the Lowenstein devices were developed from Tesla patents 645,576 and 649,621, which were granted prior to the Marconi patent.

In the present suit, Mr. Tesla bases his action on the allegation that his two patents were granted in 1900, and that the Marconi patent was not granted until 1904. The bill of complaint asks for a decree adjudging the Marconi patent null and void, and asserts that the Marconi patent covers the inventions and combinations of apparatus described and claimed in the Tesla patents.

The answer of the Marconi Company denies that the Marconi patent covers the inventions or combination of apparatus described by the Tesla patents, and also denies that it is guilty of any infringement. The company claims that its patent was granted to Guglielmo Marconi on the proof of independent invention by Mr. Marconi, not in any way due to or based on any invention of Mr. Tesla's. The paragraphs of the answer which Mr. Tesla seeks to have stricken out deal with details which, according to Mr. Tesla's counsel, "are not proper and are not defenses to a suit to annul a subsequent patent by a prior patentee."

Regarding the alleged infringement of his patents, Mr. Tesla said:

"My patents describe a new and original wireless system characterized by the employment of four circuits in perfect resonance, a condition essential to successful practice. Long after their grant to me Marconi filed an application and secured a patent which covers exactly the same fundamental arrangements. Such cases happen occasionally, as it is quite impossible for the examiners in the Patent Office to keep abreast with workers in new and special fields. A notable instance of this kind is my single phase induction motor, on which a celebrated inventor obtained a patent which was subsequently invalidated through my earlier application.

"In a recent suit in France, involving the same or corresponding patents, the highest court, acting on a statement submitted by me, decided against Marconi and recognized fully my priority of invention in all the important features."

Mr. Nally, however, said last night that he had no reason to fear the Tesla suit.

"The Marconi Company has a right to its patent," he said, "and can establish that right in the courts. Many individuals and companies have infringed the Marconi patents, and others have attempted to disprove the originality of our inventions, but when our present litigation shall have gone through the courts, I am confident that the leadership of the Marconi Company in the invention and development of wireless communication will be established."

In his suit for annulment of the Marconi patent, Mr. Tesla is represented by George H. D. Foster and Samuel E. Quigg of 32 Liberty Street. The Marconi Company is represented by Sheffield & Betts of 52 William Street.

The original papers in the annulment suit were filed on April 16, 1915, and the answer of the Marconi Company on May 25 following.

NIKOLA TESLA SUES MARCONI FOR FULL WIRELESS CONTROL

Serbian Inventor Claims to Have Patent Which Will Confine Any Amount of Electrical Energy Without Use of Insulation.

Nikola Tesla has appealed to the law to declare that he and not William Marconi is the inventor of wireless telegraphy. Many millions in money and world-wide control of the commercial use of the wireless transmission of energy are involved in the struggle.

The suit has been brought in the United States District Court here in the name of the Nicola Tesla Company, of which the Serbian inventor is the President, and to which he has transferred all of his fundamental patent rights in wireless telegraphy. The defendant in the action is the Marconi Wireless Telegraph Company of America.

Mr. Tesla announced last night, in connection with the suit, that he recently has been granted a patent by the United States Government which will supersede and revolutionize all present forms and applications of wireless telegraphy and will enable him and the financiers who are associated with him to obtain and keep a hold on commercial wireless telegraphy, no matter what may be the outcome of the litigation he has begun against the Marconi interests.

Mr. Tesla, when seen last night at the Waldorf-Astoria, appeared very confident as to the outcome of his suit to wrest the wireless patents from his Italian rival, and enthusiastic over the possibilities of his latest patent, by which he expects to send wireless messages with an intensity and to a distance impossible under any of the present systems.

"My earlier experiments in Colorado in 1899," he said last night, "demonstrated that I was on the right track, and with a transmitter of my invention of not more than thirty inches in diameter I succeeded in concentrating and applying an amount of electrical energy twice as strong as is contained in an ordinary stroke of lightning.

"Since then I have pursued my experiments with that one point in view, namely, the discovery of a way of concentrating and absolutely controlling electrical energy. This result has been attained under the workings of the apparatus for which the Government granted me a patent last December.

"I now claim that I can confine any amount of electrical energy,
