By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible to project a suitable chemical into any part of the body.

Since my above-mentioned discoveries I have made considerable progress, and can presently announce one more result of importance. I have lately obtained shadows by reflected rays only, thus demonstrating beyond doubt that the Roentgen rays possess this property. One of the experiments may be cited here. A thick copper tube, about a foot long, was taken and one of its ends tightly closed by the plate-holder containing a sensitive plate, protected by a fiber cover as usual. Near the open end of the copper tube was placed a thick plate glass at an angle of 45° to the axis of the tube. A single terminal bulb was then suspended above the glass plate at a distance of about eight inches, so that the bundle of rays fell upon the latter at an angle of 45°, and supposedly reflected rays passed along the axis of the copper tube. An exposure of forty-five minutes gave a clear and sharp shadow of a metallic object. This shadow was produced by the reflected rays, as the direct action was absolutely excluded, it having been demonstrated that, even under the severest tests with much stronger actions, no impression whatever could be produced upon the film through a thickness of copper equal to that of the tube. Concluding from the intensity of the action by comparison with an equivalent effect due to the direct rays, I find that approximately two per cent of the latter were reflected from the glass plate in this experiment.

TESLA'S ACHIEVEMENTS IN VACUUM TUBE LIGHTING.

The ELECTRICAL REVIEW has from the outset closely followed the promising work of Nikola Tesla. We had the privilege of announcing in 1886, for the first time, Tesla's investigations in a system of electric lighting. Early in 1888 we were the first to announce his epochal discovery of the multiphase system of power transmission, and since that time it has been our pleasant duty to keep our readers well informed on the various subjects of his important researches, of which we only mention his latest contributions to the great discoveries of Roentgen, which were exclusively published in our columns. It is, therefore, no small satisfaction for us to now first record another significant advance of this indefatigable worker. Ever since Tesla showed in his memorable lecture before the American Institute of Electrical Engineers, five years ago, the fascinating experiments with vacuum tubes, he has untiringly labored on, simplifying and improv- his methods, not for a moment diverted by other tasks—nor even discouraged by so great a calamity as the recent destruction of his laboratory—from the problem of producing an efficient and practical system of electrical illumination.

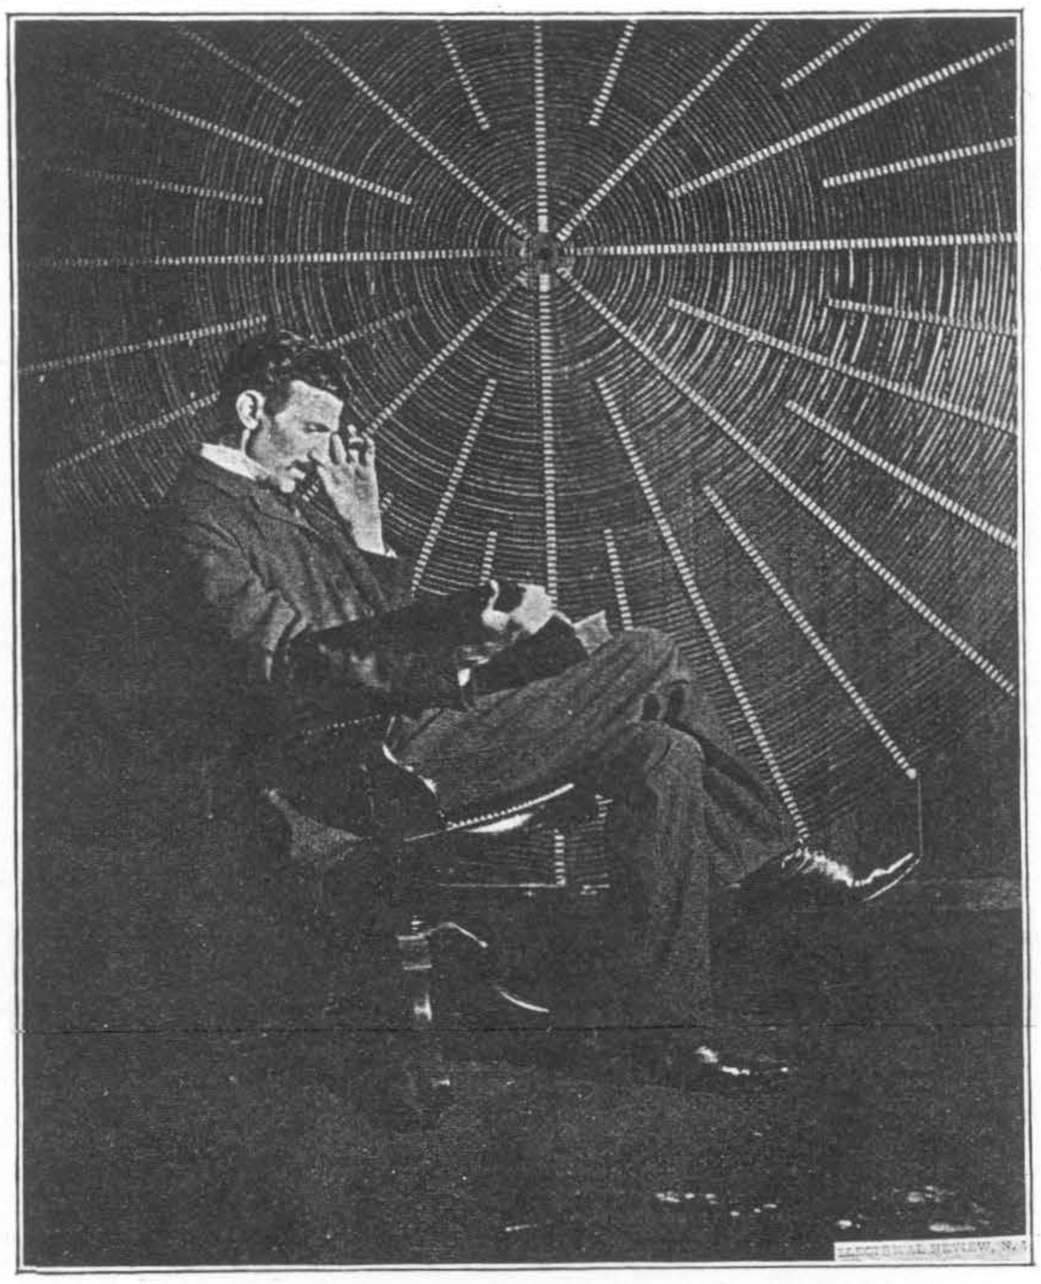
No more impressive result of Tesla's earnest efforts could be shown than that which is outlined in our present issue. The portrait of the great inventor, which, especially in view of the extraordinary way in which it was obtained will not fail to interest the scientific world, is a striking illustration of what he has done. Surely, since he has produced a vacuum tube which is capable of supplying any volume of light desired, even more than a powerful arc light, we can not hesitate to express our positive conviction that the introduction of a more perfect illuminant is near at hand.

TESLA'S IMPORTANT ADVANCES.

HIS REMARKABLE ACHIEVEMENTS IN VACUUM TUBE LIGHTING.

A representative of the ELECTRICAL REVIEW visited the laboratory of Mr. Tesla last week and found him engaged in putting the final touches to certain improvements in vacuum tube illumination. He was enthusiastic as to the results arrived at to such a degree that he expressed his positive confidence as to having made very important advances.

While reluctant to speak at present extensively on the subject of his most recent investigations, he authorized the statement to the effect that he has been most successful in several lines of work he has been following up for a long time, only temporarily interrupted by the lamented destruction of his laboratory by fire about a year ago.



When asked about his often-mentioned oscillator he said that a commercial machine is now being completed with which he expects to show the superiority of this mode of generating electricity.

He further stated with evident elation that in the study of the Roentgen phenomenon he has made great progress, so much so that he is now able to perceive through an Edison improved Roentgen-screen, recently purchased from Aylsworth & Jackson, of this city, the heart of an assistant so clearly as to note its expansions and contractions. In some instances he could locate evident defects in the lungs of a number of persons.

As to his continuous efforts to improve his system of lighting by vacuum tubes, with which he has been identified during a number of years, Tesla said that he has been more successful than he had ever dared to hope. His methods of conversion from ordinary to high-frequency currents are rendered simple in the extreme, the devices are thoroughly reliable and require no attention. Last, but most important of all, he has succeeded in increasing the candle-power of the tubes to practically any intensity desired.

A remarkable and most telling result of the advances he has made in the last direction is a portrait, which he has reluctantly allowed us to use, and which was obtained by *two seconds'* exposure to the light of a *single vacuum tube* of small dimensions. Tesla stated further that photographs obtained by the light of such powerful tubes show an amount of detail which no picture taken by the sun or flash light is capable of disclosing. This feature is only faintly shown in the reproduction on this page. The photograph was made by Tonnelé & Company, artists' photographers, who aided Mr. Tesla in his attempts to photograph by the light of phosphorescent tubes about two years ago.

When asked, Mr. Tesla said, in explanation of the picture, speaking with deep feeling, that the volume he was reading was one of the "Scientific Papers," of Maxwell, given to him as a token of friendship by Professor Dewar; the chair a gift of his warmest friend, Mr. E. D. Adams; and as to the queer coil to

TESLA IN HIS LABORATORY—PORTRAIT OBTAINED BY AN EXPOSURE OF TWO SECONDS TO THE LIGHT OF A SINGLE VACUUM TUBE WITHOUT ELECTRODES, HAVING A VOLUME OF ABOUT 90 CUBIC INCHES, GIVING APPROXIMATELY A LIGHT OF 250 CANDLE-POWER—PHOTOGRAPHED BY TONNELÉ & CO. COPYRIGHTED BY THE "ELECTRICAL REVIEW."

his left, Mr. Tesla hesitatingly remarked that it was the object "dearest of all in his laboratory," having been a most valuable instrument in his many-sided investigations.

Mr. Tesla added, good humoredly, that, had it not been for the extraordinary manner in which the photograph was taken, he would not have given this explanation even to such an important personage as the representative of the ELECTRICAL REVIEW.

The Apotheosis of Electricity.

THE latter half of the present century is to science what the Augustan age of Rome or the Elizabethan age of England was to literature. In our time the Muses have been superseded by the goddess of Electricity. Beside the name of a Shakespeare or a Virgil, that of an Edison or a Tesla is blazoned on the scroll of time; and as the words of the former are in all men's hearts and mouths, so the works of the latter are to-day in all men's minds and hands. Human genius, which in earlier days was esteemed bold to have lain a hand upon old ocean's mane, now has seized the cosmic currents of earth and sky, *givers of light and life*, yet swift and sure emissaries of death, and become the triumphant task-master of electricity—"that subtle and sublime agent of the Almighty, the most potent factor in the everlasting mystery of creation."

F. W. HAWLEY.

The National Electrical Exposition, held in conjunction with the nineteenth annual convention of the National Electric Light Association, puts this stupendous achievement, in all its bearings, before the eyes of the American public in the dazzling show which now occupies the Grand Central Palace in New York City. Governor Morton opened this unprecedented exposition by pressing a golden electrical key—the same which President Cleveland used in opening the world's fair at Chicago. The whole building blazed with light and vibrated with motion at this signal, which also, through telegraphic communication, fired simultaneously four guns, at the four sides of the country—namely, at Augusta, Maine, New Orleans, San Francisco, and St. Paul, Minnesota. And the electrical current thus turned on was generated at Niagara Falls by the power of the cataract, transmitted 462 miles over telegraph wires. This is by far the longest transmission of electricity for power or lighting purposes ever accomplished in the world, thus far.

The visitor saw around him at that moment, as he may see at the exposition any day until the end of the month, working machines and devices illustrating every conceivable application of electricity and electrical energy. Every kind of electric light invented up to date contributes to the general illumination there. Some idea of the magnitude of this branch alone may be obtained from the official statement that the delegates present at the convention represent nearly ten thousand electric-lighting plants in the United States, with an aggregate of capital amounting to seven hundred and fifty million dollars.

The vast space of the main floor in the "Palace" is taken up mostly with the countless exhibits of electrical mechanisms used in telegraphy and telephony, railway transportation, lighting, motors, and power. These fill about two hundred sections, occupied by leading companies and firms. In the middle of the hall is the popular *clou* of the show—the large working model of the Falls of Niagara, with the river above and below, the islands and Canadian shore, and a section of the city of Niagara, showing the power plant just completed there at an expense of six million dollars. Connected with this model are a number of telephone transmitters, in communication with receivers placed at Niagara above the great cataract itself. By this means it is possible to hear, at a distance of four hundred and sixty-two miles, the actual roar of the falls—which, however, is not a "roar" at all, but a deep, awesome diapason, pronounced by a musician to be "a perfectly constructed musical tone, or complete series of tones all in grand unison as in an organ." Near by is a forty-foot section of the Erie Canal, with real water, and model canal-boats run by the new electric bank haulage system, which is actually being put into operation on that ancient water-way. Another potent attraction, on the second floor, is the practical demonstration of the use of the Röntgen X rays, by means of Edison's fluoroscope.

Of course the exhibit of the Edison Electric Illuminating Company is a conspicuous feature. It includes a dynamo controlling section complete, with storage battery attached; and an almost infinite variety of electrical apparatus and inventions.

Although it is Nikola Tesla's alternating current motor which makes possible the long-distance transmission of energy over ordinary wires, as from Niagara in the present instance, yet there is comparatively little in this or in Tesla's other inventions and discoveries that could be made effective in a popular exhibit. Thus it happens that Tesla is practically unrepresented at the exposition, at this present writing. It is likely, however, that his "oscillator" and other mechanisms will be in place there by the time these notes are printed.

In connection with our illustrations of the exposition we give a portrait of Mr. Frank W. Hawley, chairman of the reception committee, and one of the most efficient workers for the success of the great show. Mr. Hawley has been prominently identified with the enterprise of applying electricity to the Erie Canal, and the elaborate model already mentioned was constructed at his special direction for the National Electrical Exposition.

HENRY TYRRELL.

The New York Herald May 21, 1896

TESLA'S LIGHT IS PERFECTED.

After Years of Endeavor He Declares Its Success to His Friends.

STEADY AS THE SUNLIGHT.

While the Incandescent Lamp Gives but Three Per Cent of Illumination His Produces Ten.

TO INCREASE IT TO FORTY.

No New Dynamos Necessary, the Current Used Being from the Street Circuit.

Nikola Tesla has solved the problem which he set before himself many years ago, and which may revolutionize the system of electric lighting. It is, electrical experts say, the nearest perfect adaptation of the great force of nature to the use of man.

In Mr. Tesla's laboratory, in Houston street, is a bulb not more than three inches in length, which when the current turns into it becomes a ball of light. The heat is almost imperceptible. With it a very large room is so lighted that it is possible to read in any corner. Yet this is done without films and without the attachments necessary in existing lights.

The rays are so strong that the sharpest photographs may be taken by them. No new dynamo is required to produce the current. The bulb is attached to a wire connected with the street current. There is no danger of harmful shock in its use.

Stories have come from time to time from Mr. Tesla's laboratory that he was experimenting on a light of this sort. Rumors of success and failure have followed each other and Mr. Tesla's friends were inclined to doubt that he would succeed. A half dozen times the discovery was at his finger tips, only to elude him. But now he has told his friends of his success.

TO SAVE MORE YET.

Mr. Tesla has been working for many years on his theory of the necessity and the practicability of the conservation of electrical energy. The present incandescent light gives only three per cent of illuminating power. The other ninety-seven per cent is wasted in heat.

In accordance with his theories, which have been already applied successfully to the economical transmission of the electric fluid, he applied himself to the saving of some of this wasted energy in electric lighting.

The bulb which he has perfected gives ten per cent of light and loses ninety per cent of energy. Mr. Tesla declares that he will, with the aid of a few more experiments, be able to produce forty per cent of light, so that the waste will be reduced to only sixty per cent, or thirty-seven per cent less than at present.

The principle of light is vibration. The illumination is secured by means of what Mr. Tesla terms a vibrator within a bulb, which holds the vibrating needle within a vacuum. The needle vibrates so rapidly that the figures per second sound imaginary, but it is this intensity of energy which gives the light its brilliancy and its apparent steadiness. The lights do not have to be renewed.

HIS PHOTOGRAPH TAKEN.

Friends who recently visited Mr. Tesla saw him photographed by means of his light. The exposure was but two seconds in the light of a single vacuum tube or bulb, without electrodes, having a volume of about ninety cubic inches. The light given was approximately 250 candle power. The photograph was as sharp in outlines as though it were taken in full sunlight.

Mr. Tesla has recently obtained many photographs in his study of the Roentgen ray. He has photographed the heart of one of his assistants so accurately as to note its expansions and its contractions, and he has also been able to locate defects in the lungs of several persons, the presence of tubercles being very evident.

The announcement of Mr. Tesla's discoveries created a genuine sensation at the Electrical Show last night and was the topic of conversation among the experts in the application of power. The light was commented upon also at the meeting of the American Institute of Electrical Engineers which was held in the exhibition building.

The New York Morning Journal May 22, 1896

EDISON AND TESLA RIVALS.

EACH HAS INVENTED A VACUUM ELECTRIC LIGHT OF WONDERFUL SOFTNESS AND ILLUMINATING POWER.

Nikola Tesla has devised a light as steady as the sun and more brilliant than any artificial light now in use. He is guarding the secret of its production jealously, but it is known that the light is created within a vacuum tube by an electric current passing through a wire that touches the tube, but does not enter it. As friends of Tesla, who have learned something of the system, a current of electricity passing close to the vacuum tube disturbs the remaining particles of air—for no tube can be made a complete vacuum—and the vibrations of these atoms creates the light. The effect can be had by touching the electric wire at any point with a vacuum tube, and as the tubes are easily made, it is claimed by Tesla's friends that the system will be a commercial success. The secret, which Tesla guards, is how to make the tubes, and the strength of the current that must be used.

One of the advantages in the system, it is claimed, is that whereas now only three per cent of illuminating power is obtained from the amount of energy expended, by Tesla's invention there will be ten per cent of illuminating power. In ordinary incandescent lights much of the energy is lost in heat. Tesla's tubes when in brilliancy are nearly cold. The light is white and is as pleasant to the eye as the moon's reflections.

Dr. Park Benjamin, a well known electrical expert, at the electrical show last night said:

"I don't know what Tesla has discovered, but I have faith in his ability, and I know he has been working hard to produce a successful vacuum tube light. The tubes are like the Crooke's tube, except that the air is not exhausted to the same degree. The molecules remaining are, of course, far apart and the electricity causes them to vibrate violently. All light is caused by vibration, so there is the secret of the whole thing. If the tube was not a vacuum, the air particles would be close together and there would not be the same effect. If the air was exhausted as in the Crooke's tube, there would not be enough of the molecules vibrating to cause the white light."

B. E. Green, a personal friend of Tesla's, said:

"In gas lighting less than 1 per cent of energy consumed produces light. In incandescent electric lighting about 3 per cent is available. We are able now to run about fifteen 16-candle power lights with one horse-power, and electricians have considered the possibilities to be about twenty 16-candle power lights to one horse-power. So it can be readily seen that any present form of illumination would be placed at serious disadvantage in competition with a system which could double or triple the efficiency."

In a few days the experts attending the electrical show will be given a view of a new vacuum tube light, the invention of Thomas A. Edison. Adjoining the black X ray booth is a smaller room for the use of the men who operate the apparatus producing the X ray.

Yesterday arrangements were made to drape this room in white. In this room will be given the first view to the persons outside of his laboratory of Mr. Edison's new light. The inventor has as yet made no announcement of his new light to the public, although a couple of months ago he stated that he had made a discovery in vacuum tube lighting in a paper written for an electrical journal.

When seen last night in regard to the great light claimed to have been made by Tesla, Mr. Edison said:

"The claim that Tesla has invented a lamp that gives ten per cent power may be correct. I have never seen it and consequently can not say that he has or has not. Fore sometime I have been experimenting with vacuum tubes and have a lamp that gives from twelve to fifteen per cent light. It is a white light and just what it is I will not state. I will, however, show it, and after it has been seen will tell what it is.

"One lamp will light a room in every corner, and you can take a photograph by it. But that means nothing, as a two-candle incandescent lamp raised to about six-candle power will take photographs. The vitascope pictures are printed by incandescent lamps. One of the new lamps will give as much light as all the Moore tubes scattered about the Electrical Exhibition.

"If Tesla has a light why don't he show it. He is in New York on Houston street, not so far away. Moore is showing his light and I will show mine. Let Tesla come along and show. What counts in the world is the man who produces not the man who talks. I found out a long time ago that if you talked about a thing it wasn't remembered, but if you produced it was remembered."

"Is the new light one that can be put on the market at a reasonable figure?" Mr. Edison was asked.

"Yes," he replied. "I think it is at the point right now. I believe it can be manufactured cheaply and quickly. Three are being made and I will show them; not to the public, but to the people interested in electric lighting. The booth will be draped in white and you can take all the photographs you want. The only thing I care to say about the lamp at present is that it gives a brilliant white light, that is 12 to 15 per cent light."

The New York Herald May 22, 1896

TESLA'S NEW ELECTRIC LIGHT.

Is Adapted to Private Houses and Cheaper Than Other Illuminants.

Nikola Tesla, whose new electric light was described in yesterday's HERALD, said yesterday he had little more to add to it. He said it was adapted for use in private houses and would be cheaper than any other method of illumination. There was no needle or wire within the bulb. The bulb was as near a vacuum as could be obtained, and the vibrations of electricity within caused the high white intensity of the light.

The fact was, he added, that the great power would have to be modified rather than increased—at present it was more than sufficient for ordinary purpses. Electricity, he said, could be taken from a trolley wire or any other conductor of electricity. He would not go into further details yesterday.

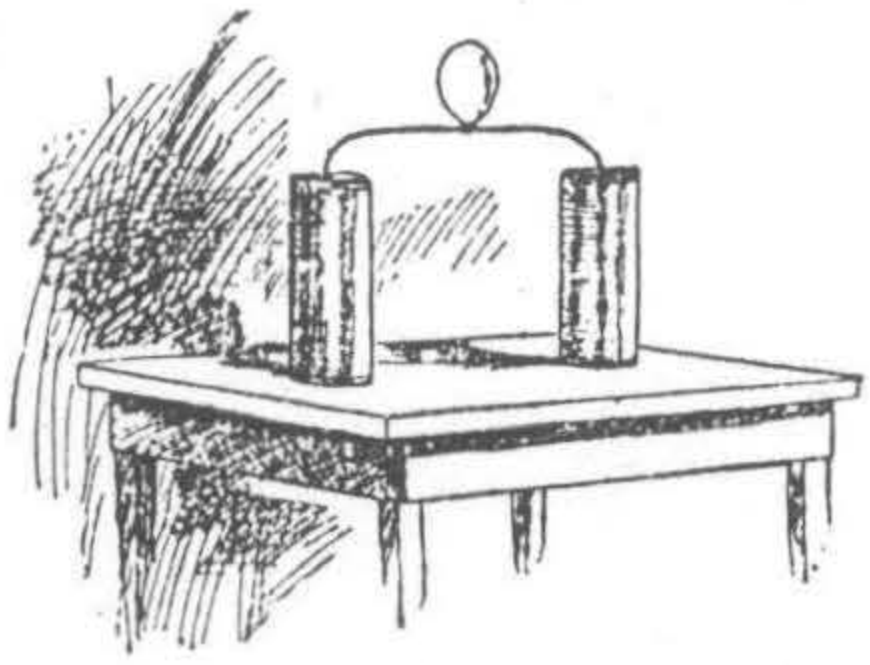
Mechanical Progress.

Tesla's New Electric Light.

A New York despatch says Nikola Tesla has solved the problem which he set before himself years ago, and which may revolutionize the system of electric lighting. It is thought to be the nearest perfect adaptation of the electric current for light uses. In his laboratory is a bulb three inches in length which, when the current is turned on, becomes a bulb of light. With it a large room is lighted so it is possible to read in any corner. This is done without the attachments necessary in existing lights. The rays are so strong that photographs may be taken by them. No new dynamo is required to produce the current. As compared with the incandescent light the Tesla bulb gives a greater per cent of light. The principle of the light is vibration. Illumination is secured by the means of what Tesla terms a vibrator within the bulb, which holds the vibrating needle within a vacuum. The needle vibrates so rapidly that the figures per second sound imaginary, but it is this intensity of energy which gives the light its brilliancy and its apparent steadiness.

TESLA'S BRIGHT LIGHT

Apparently Most Simple in Construction, Yet Its Penetrative Power Is Enormous.



HIS TRIBUTE TO MR. EDISON.

Will Not Make Public the Principles of His Light Until He Is Able to Save More Energy.

NOW HE LOSES NINETY PER CENT.

When He Has Reduced This to Sixty Per Cent He Will Give Away Chunks of the Sun.

How soon Nikola Tesla will consent to make public his new light and give its principles to the world he will not say. He declared yesterday that when it has reached the perfection which he believes it is capable of he will present his discovery before an electrical or other scientific society and demonstrate that not only is it the realization of a principle which he enunciated in St. Louis eight or ten years ago, and so set electricians experimenting along those lines, but that the light may be manufactured cheaper than any other form of electric lighting known. It will be to electric illumination what his oscillator is to the generation of the fluid. With the latter the expensive and elaborate conversion of power is saved and the energy developed almost directly from steam. So with the vacuum light. Without

TESLA'S LAMP.

filaments and without their attendant perishable quality, with nothing save a vacuum and an enormous vibratory power of electricity, light will be made as nature makes it, by the vibration of the molecules.

THE RETORT COURTEOUS.

Mr. Edison said yesterday that if Mr. Tesla had invented a light so wonderful, why not show it and demonstrate to the world by action rather than by words that the lamp was a reality and not a theory. Mr. Tesla was shown Mr. Edison's statement, and he smiled as he said:—

"I entirely agree with Mr. Edison that it is much better to act than to talk. I do, however, desire to say this:—Over the head of my bed in the Gilsey House hangs an incandescent lamp. I use it every night before I go to sleep, for I have the bad habit of reading after I have retired. I have never yet turned the current from this lamp without mentally expressing my gratitude to the man who made that method of lighting possible."

With this bucket of hot coals for Mr. Edison Mr. Tesla shut himself up in his workshop.

In that workshop is a little table, by the side of which is Mr. Tesla's place where he does most of his work, with plans for the development of his theories of electricity. On this table stands the wonderful lamp which, with the same number of cubic inches as a 16-candle power incandescent lamp and with the same voltage from the street current as the ordinary lamp has, is able to give forth a light of 250 candle power.

TESLA'S LAMP.

It is a very simple looking contrivance. Two brass cylinders, looking for all the world like the empty shells of shot for a rapid fire cannon, stand about six inches apart. A light wire extends between the two, which probably contain coils, but about them Mr. Tesla will not say a word. Directly in the centre of this thin wire is an ordinary electric light bulb used for incandescent lighting. The little point usually at the bottom of the bulb points upward. There is no filament in the vacuum. It appears merely as an ordinary bulb would appear if the carbon filament had been destroyed, but the interior has been exhausted of air many times more than the incandescent light bulb. When the current is turned into the electrodes and so into the bulb there is no foreign substance to burn. The electric molecules have the vacuum all to themselves. They move at the rate of from 3,000,000 to 4,000,000 vibrations a second. No one point gets bright and then seems to ignite the rest, as in the bulb usually seen. There comes a glow, just as there is a glow in the eastern sky at dawn, and then it becomes rapidly intenser, until the whole interior of the bulb sends out light, just as though a piece had been cut out of the edge of the sun and packed into the little glass receptacle.

WITH MORE ENERGY SAVED.

This is what the Tesla light does when it is used now when it loses ninety per cent of energy and only uses ten per cent in light. The difficulty which the inventor is experiencing in reducing the loss of energy to sixty per cent is the securing of a complete vacuum. This is the greatest problem perhaps which is set before him, but when it is understood that the vacuum which is secured in the Crookes tubes is many times greater than that used so far by Mr. Tesla it may be appreciated that he is not confronted with an insuperable difficulty. Of course the production of tubes or bulbs which are thin enough to permit of the full benefit of the light and are still strong enough to withstand the atmospheric pressure from without is at present very expensive. Mr. Edison, however, has produced a tube for his fluoroscope which is much cheaper and more effective than the Crookes tube. This, it is believed, demonstrates that the commercial difficulty may be readily overcome and Mr. Tesla's light, even with its vastly increased power, will be possible for any one to use. The increase in power, should he reduce the loss of energy to sixty per cent, will enable him to secure a light of nearly one thousand candle power in a bulb of the size of the ones which now give forth sixteen candle power.

SOMETHING LIKE IT ON SHOW.

Some idea may be formed of the Tesla light by an inspection of the tubes which are shown at the Electrical Exhibition by Mr. Farren Moore. They, too, give forth light as a result of the vibrations of electrical energy, but in them the rapidity of the vibrations only amounts to a few hundred a second, whereas in the Tesla bulb they number among the millions. Mr. Moore's lights burn with a bluish flame, which is not divisable with a prism. The Tesla light is as white as sunlight, and the prism shows upon a screen all the colors of a rainbow. It may be believed, therefore, that the Tesla light is the nearest approach yet to natural light, the definite markings of the divisions of the colors of the spectrum proving its clearness and intensity.

Mr. Moore has worked along the same lines as Mr. Tesla and is entitled, electricians say, to great credit in being able to demonstrate the practicability of Mr. Tesla's ideas of electric light production by means of vibrations, but the results of his experiments have not yet produced an illuminating power which is practicable in competition with the incandescent light, while Mr. Tesla's friends declare that his light far exceeds it.

PHOTOGRAPHING THE HEART.

The experiments which Mr. Tesla has been making with the Roentgen phenomena and which have been successful in permitting him to photograph tissues of varying density instead of bone, have been made possible by his adaptation of this principle of light generation, by means of vibration. The same principle applied to similar processes make the X rays so penetrating that the most delicate gradations are discernible. It is not outside of the bounds of probability that Mr. Tesla will be able to produce a photograph as the culmination of his efforts which will show the organs of the body and the entire structure of the frame as well. His present ability to see the contraction and expansion of the heart, and the imperfections of the lungs in a living body makes his hopes doubly assured.

WHAT EXPERTS SAY.

MacFarlane Moore Is Pessimistic When Discussing the Claims Put Forth by Mr. Tesla.

LIGHT FROM VACUUM TUBES.

The New Method May Become of Commercial Value, but Is Too Costly Now.

T. C. MARTIN HAS MUCH FAITH.

Max Osterberg Believes in the Possibilities of Success by Some Experimenter.

Nikola Tesla's claim that he has perfected a system of lighting by means of excited vacuum tubes has aroused great interest in the electrical world, and provoked no end of discussion. The matter is the one leading topic of conversation at the Electrical Exposition, in the Grand Central Palace, where experts in electricity and men versed in the mysteries of vacuum tubes are to be found day and night.

One of these is Mr. D. MacFarlane Moore, who has invented a system of lighting by means of vacuum tubes, and who calls the light thus produced "etheric light." When I spoke to him about Tesla's light he said:—

"Tesla five years ago made a few experiments and prophesied a great deal, but, judging from reports that were published comparatively recently, he found the 'nut a hard one to crack,' and has made but little headway beyond what has been known for almost two hundred years. I think I made a gigantic stride in lighting a whole lecture hall, a photograph of which, by the vacuum tube light, is better than one by daylight.

"I then lighted the stage in a lecture before an audience of more than one thousand persons. After this a portion of my apparatus was moved to the Electrical Exposition and it immdiately became one of the leading attractions at the great show, not excluding Edison and the Roentgen rays. My light led everything else when Governor Morton opened the exposition, and again when Chauncey Depew's famous telegram had started and arrived. Tesla and Edison are stirred up, and now announce that they have not given up the race, but have also made advances and can now produce a bright light. But the proof of the pudding is in the eating. They do not show their light.

STILL DOUBTFUL.

"The high rate of vibration Tesla now claims is nothing new, because he claimed the same thing several years ago. It is now claimed that he can make a light 250 candle power. This is a vague statement, and needs confirmation. He claims it has ten per cent efficiency, therefore the rest of the energy must be heat, and his small bulb must get impracticably hot. These are vital shortcomings, because the new light must properly resemble daylight—that is an intense light in a small bulb is most decidedly not wanted, and cold light is not only wanted, but must be attained, or the system will be very costly to operate.

"Again, the proper current is of as much value as the proper light. Tesla's current is of such a high voltage that it can never be handled in a practical manner, and besides is dangerous; and this high rate of vibration prevents it being sent over a wire, which again makes it impracticable. The voltage of my current is low, and it can be sent over any reasonable length of wire.

COMPLICATED AND COSTLY APPARATUS.

"Again, Tesla's aparatus is large, complicated and costs many thousands of dollars; mine is very small and inexpensive. My methods were discussed on Wednesday morning before that intensely critical scientific body, the American Institute of Electrical Engineers. During the discussion I stated that the efficiency of my apparatus was 11,000,000 per cent better than that used by Tesla in one of his lectures. This statement was met by violent opposition from several of the leading college professors present. In fact they flatly denied that such could be the case. I replied by inviting them to make the test themselves. They accepted the invitation and made their test the same evening, and reported that I had not actually done myself justice—that the apparatus was even better than I had claimed.

"For several years Edison has fought the idea of a new light, but lately he got much interested. He visited my booth at the show last Saturday; to-day he claims to be able to produce a brighter light than either Tesla or myself, and says he will not do as Tesla does, but will show his light at the exposition. It is obvious to everybody that the ultimate in artificial light production will not be reached until we have imitated day.

"Edison, like Tesla, is trying to make units of light. The light Edison will show will consist of a small bulb containing the same material he has used on his kind of fluoroscope. The Edison bulb will be excited by the old Ruhpkorff induction coil, in a manner that has been known of for many years, but as a wofully insufficient piece of apparatus. The only difference will be that Edison will use a new chemical with the bulb to be fluoresced, but nevertheless it will last but for a short time, while my tubes, being empty, have unlimited life."

VACUUM LIGHTING NEXT.

I also approached Mr. T. C. Martin, the editor of the Electrical Engineer, on the subject, and he said:—

"It is thought by many that the next advance in electrical illumination must come in the direction of vacuum lighting. If it does not it is difficult to know just what is to be aimed at. And when such far sighted men as Tesla say it is worth going for—and he has been insisting on it for years past—you may depend upon it there is something in it."

"But what is the difference between the old methods and this new one?"

"Well, in the arc lamp you have the light produced by the jumping of the current from one stick of carbon to the other. The feeding of the carbons toward each other has to be regulated carefully, as they are rapidly consumed in the heat of the arc, which is next to the sun in its fierceness. In the incandescent lamp you have a small filament of carbon shut up in a small glass globe. The friction or resistance of that filament to the current flowing in the circuit causes the carbon to glow and give light, but as the air has no access to the filament it is not consumed, in the ordinary sense, although after a time it is used up. In the new method there are no carbon points to burn up, no filaments to break down or sealed globes to dim. There is simply a glass bulb, more or less exhausted of air. When in that condition if electricity be applied to what is left—rarified air, ether or what not—the bulb gives forth a luminiscence or phosphorescence that is bluish white in color and powerfully actinic. Some of these bulbs have had short wires leading into them, some have had phosphorescent materials placed in them, but the vacuum tube, as generally understood, means just the plain bulb of glass. Such tubes have been lit up simply by waving them in highly electrified air, but the current is usually led to them by caps or cups of tinfoil slipped on the outside ends. Methods differ in this respect, as do those for getting the bulb into such an electrically agitated condition as to give the best results."

"When do you expect the new method to become commercial?"

"Any time. It can be used now for spectacular and decorative effects. It will have a large place in the arts when ripe, with the best lamps invented and the best methods approved by experience. But the other methods will in all probability long remain in vogue. They have an enormous sphere of usefulness, and will doubtless grow for many years yet, while the new will also win a big realm for itself."

BELIEVES IT IS POSSIBLE.

Max Osterberg, E. E., who is in charge of Professor Pupin's exhibit at the Electrical Show, said:—

"The very fact that a number of our most prominent men have of late devoted their time and energy to vacuum tube lighting is sufficient reason to believe in the possibility. The idea itself, of course, is quite old, but the methods are new and there are about as many methods an investigators. Among the prominent experimenters, one may possibly develop into a practical inventor and produce a commercial result. One line of investigators believes in high frequency, high pressure, alternating current; another uses a direct current with a vibrator in a vacuum; a third produces luminosity of the tubes by resonance effects, and still others are at work on the perfection of the lamp, which seems to be the vital part of the entire problem. The demonstrations thus far made in vacuum tube lighting suffice to show its adaptability to special uses, although its field may be unfitted for general illumination."

How To Make and Use a Tesla High-Frequency Coil.

TO THE EDITOR OF ELECTRICAL REVIEW:

In hopes to aid your correspondent "F. P. L." * in the matter of a Tesla high-frequency coil, I beg to offer my experience, gained after long search.

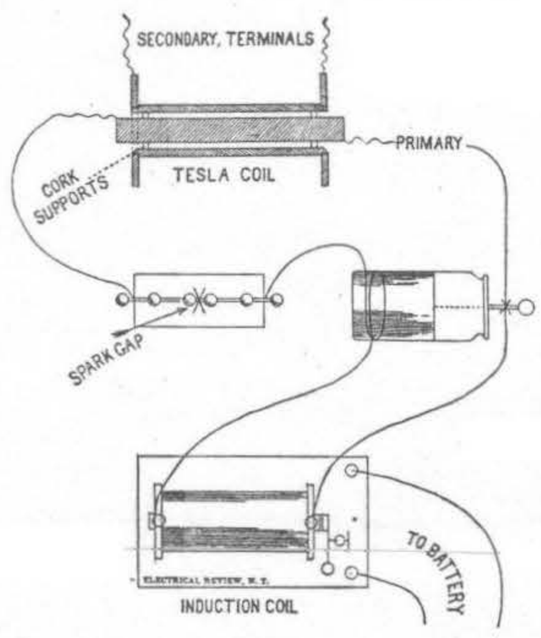

FIG. 1.—SECTIONAL VIEW OF TESLA COIL.

Go to some reliable wood turner and have a spool turned of three and one-half inches, outside diameter, with the interior turned out two and one-half inches diameter. Have a solid piece turned on which to wind your primary, two inches diameter and 14 inches long. The length of the first hollow spool should be 12 inches. It would be well to have the first spool one-half inch longer at each end, or 13 over all, but turned down one-quarter inch deep and of a width of one-quarter inch, so that a check block can be turned to slip on the end of the outer spool for appearance sake, and to which the terminals of the secondary wire can be led. The rough sketch herewith, Fig. 1, will give you the proper idea.

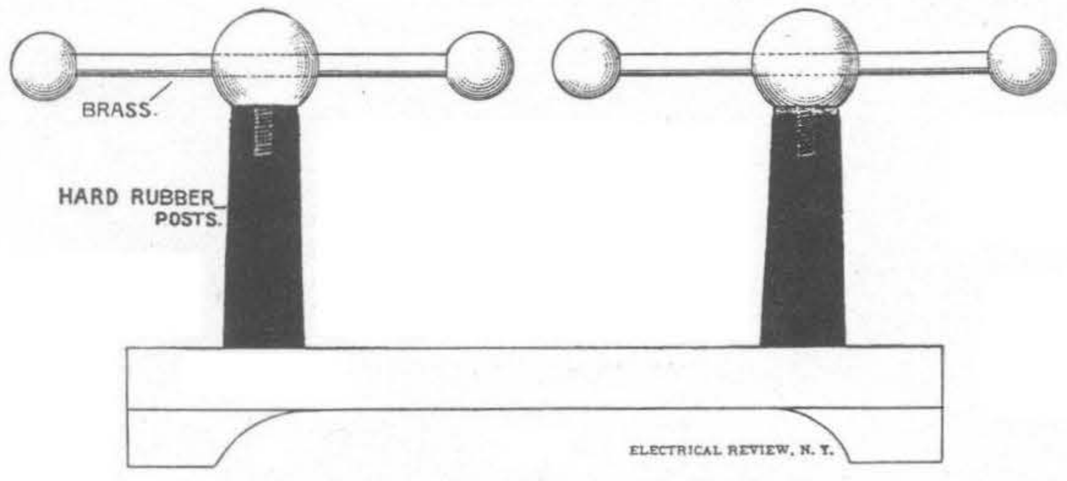

FIG. 2.—DISCHARGER USED WITH TESLA COIL.

For the primary, wound on the solid core, use No. 18 double cotton-covered wire wound in a single layer, with the ends being fastened to the core and left with plenty of projecting wire. For the secondary, use No. 36 double silk-covered wire carefully and compactly wound across the outer spool in a single layer. After winding, both the inner coil and the outer should be carefully shellaced; and it would be well, as I have done, to boil all wood pieces in paraffine before winding.

Such a coil can be operated for high-frequency effects by an ordinary spark coil giving at least two-and-one-half-inch spark. To do this you will require a Leyden jar ordinarily known as a half-gallon jar. The discharge of the jar must be made through the primary circuit of the Tesla coil and care must be taken to arrange the wires so that you will not short-circuit the induction coil. I have endeavored to sketch you the ordinary form of discharger (Fig. 2), with well polished balls which must be drawn apart to the limit of the sparking distance of your Leyden jar. Another way would be to keep the discharging balls tolerably near together and use an air blast across the gap when the coil is in operation. The effects by this latter method are much greater.

To give the Tesla effects, the Tesla coil should be placed in an oil-tight wooden box and covered with oil; otherwise the streams formed will pass through the coil sectionally and occasion a great loss of energy.

A Crookes bulb, which I can not operate with my three-inch spark coil *alone*, fluoresces readily when the Tesla coil is operated by the same induction coil. Yours truly,

ELLIOTT WOODS.

Washington, D. C., May 14.

NOTES.

Nikola Tesla.—Mr. Tesla, a few days ago, announced the discovery of a method of inducing millions of etheric vibrations per second within a vacuum tube without using any direct electrical connection. An ordinary 16-candle bulb gives by this method, it is said, a light equal to 250 candles, which is sufficient to light very pleasantly a large room. It enables rapid and perfect photographs to be taken. Its commercial efficiency is claimed to be three times as great as that of the prevailing system, and it provides an ample margin for further improvement. *Voilà tout.*

Niagara Power Transmission, the Electrical Exposition and Mr. Johnston's Libel Suit.

It is to be regretted that the holding of the National Electrical Exposition at New York and the remarkable demonstration of the transmission and application of electricity from Niagara Falls to the exhibition were attended by an unpleasant incident which cannot fail to detract from the general good feeling that has prevailed up to the present time. An eastern publication, the *Electric Railway Gazette*, published an editorial under the title "Transmission of Power Extraordinary," in which it pronounced the exhibition of the model of the Niagara Falls power plant operated by current from the Falls a "fake" and seriously reflected upon the gentlemen who were identified with the project. The article had the effect of creating a sensation and brought the hitherto obscure publication into prominence. The management of the exposition was naturally indignant at the outrageous charges, and the gentlemen who had planned and executed the project issued statements in which they flatly denied the accusation. Their personal and professional reputation alone should have protected them from even an insinuation of trickery or fraud. T. C. Martin, with whom the scheme originated, made the following statement:

For nearly a year past I had believed it possible to deliver Niagara energy over wire at the exposition, and some months ago set out to do it by securing a small model of the Niagara power plant to begin with, then permission from the Niagara Falls Power company to connect with the power house, Tesla apparatus from the Westinghouse Electric & Manufacturing company for the transmission to the model, two wires from the Western Union Telegraph company, and wires from the American Telegraph & Telephone company (long-distance telephone) to transmit the roar also to the model. The plan has been, to my positive knowledge, carried out, as I have personally watched the accomplishment of my plan. The electrical engineers coöperating have been A. S. Brown of the Western Union company, Nikola Tesla, L. B. Stillwell of the Westinghouse company, assisted by Messrs. Maclaren and Zimmerman and F. A. Pickernell of the Long Distance Telephone company. I would add that as the Western Union wires are available only in the evening, I carried out the suggestion of A. S. Brown of sending storage batteries to Niagara to be charged, so that the model could also be run in that way for the benefit of daytime visitors, who might otherwise be disappointed. This difference of method in daytime and at night has been carefully explained in labels and printed statements, so that there could be no doubt or misapprehension as to the facts. The Niagara transmission over Western Union wires has been a great success, doing far more than was expected. In fact, failure was freely predicted by many.

In addition to the foregoing statement a card was prepared by L. B. Stillwell of the Westinghouse company, in which that gentleman said:

The power used to operate the small Tesla motor at the electrical exposition comes from Niagara. During the evening it is transmitted over a circuit consisting of three conductors. Two of these are wires ordinarily used for telegraphic purposes by the Western Union Telegraph company. The third is the earth. In technical language, it is a case of tri-phase alternating current transmission. For a time direct or continuous current was used. When the alternating current is in use the potential as measured across any two conductors at the Niagara end of the line is approximately 500 volts. The currents are delivered to the exposition building at a potential approximating 250 volts. The gentlemen in charge of this undertaking have accomplished precisely what they undertook to accomplish, and the transmission is an unqualified success.

The following announcement was officially made by the exposition management:

The National Electrical Exposition company, through its counsel, J. G. Wells, on Saturday, May 23d, brought suit in the Supreme Court against the W. J. Johnston company, publisher of the *Electric Railway Gazette* and the *Electrical World*, for $50,000 damages for libel, the suit being based upon an article in the last issue of the first named paper, charging that the exhibition of Niagara power transmission at the electric show is in the nature of a "fake" and "gigantic fraud" upon the public. The officers of the National Electrical Exposition company are: H. J. Smith, general superintendent of the Edison Illuminating company of New York; W. F. Weiss, vice-president of the New York Steam Heating company; George F. Porter, secretary of the National Electric Light association; C. O. Baker, Jr., of the Baker Platinum Refining company; R. B. Corey, General Incandescent Arc Light company; H. L. Lufkin, Crocker-Wheeler Electric company, and E. F. Peck of the Peck Electric company.

A letter was also issued, signed by "W. J. Johnston, editor *Electric Railway Gazette*," of which the following is a copy:

In the *Electric Railway Gazette* of May 10th appeared an item, written immediately after the opening of the electrical exposition, saying that the success of the experiment in the transmission of electric power from Niagara to New York savors strongly of "fake." The author of the paragraph believed at the time that he had grounds for making the assertion. He has since made a thorough examination of the circumstances, however, and satisfied himself that he was entirely mistaken in what he said, and a correction will be made in the next issue of the *Gazette*, dated May 25th. I need not add that both the author of the item and I regret the appearance in an electrical journal of anything that might be construed as a reflection upon the good faith of the well-known companies and gentlemen to whose efforts are due the success of the Niagara transmission.

Pittsburgh Dispatch May 31, 1896

TESLA AT THE TOP

After a Bitter Struggle He Is Now the King of Inventors.

FOUGHT HARD FOR RECOGNITION.

An Interesting Interview Secured in His New York Laboratory.

HE TAKES PICTURES WITH A NEW LIGHT

[WRITTEN FOR THE DISPATCH.]

It is now generally agreed among electrical men that Nicola Tesla is the greatest electrical inventor of the age. In all his works he has conclusively shown himself to be far ahead of anyone else in originality of thought, in his conception of the wonderful possibilities of electricity and in their development.

More than ten years ago, even before he was working in Pittsburg, his mind was quite positive that, in his invention of the now well known Tesla motor, and the equally important Polyphase system of long distance power transmission, he had opened to the electrical industry a new and most important field of exploitation. Then, however, he could find few people who believed in him, and many looked upon his schemes and plans as grand and wonderful imaginations of a theorist, but whose ideas would never stand the test of practicability.

Nevertheless, Mr. Tesla was not discouraged by the criticisms passed upon his work. He was convinced that he was right, and he continued his researches, his experiments and his labors undaunted, knowing that his time to smile would come at last. And it did.

When the gigantic power of the falls of Niagara began to operate the large generators, ready to distribute electrical energy of 5,000 horse power, it was a great triumph for Tesla. Since then, of course, everybody has come to the conclusion that Mr. Tesla's ideas were correct on that matter, and those who were once known as the most pronounced skeptics are now his staunchest admirers and believers.

Startled London Scientists.

It was long before the triumph at Niagara, however, that Tesla astounded the whole civilized world in another direction, and that was in 1892, when he, a comparative youth, appeared before the Institution of Electrical Engineers of London, England, and showed to some of the most renowned men in electrical science, experiments and phenomenon which they had never dreamed of. He exhibited a motor running on one wire, and also without any connection whatever with the generator, demonstrating the possibility of running motors without wires altogether. He created a sensation when he handled electrical currents of the enormous pressure of 250,000 volts, and his audience was amazed as they viewed his demonstrations of phosphorescent lighting.

Mr. Tesla repeated that lecture before all the learned societies of Europe, and wherever he went he was received with the greatest distinction. Honors were showered upon him by the crowned heads of the old world. Since then the name of this great electrical inventor has become familiar throughout the world, and he is considered the greatest electrical genius of the age.

These wonderful triumphs of the young electrician are always gloried in by people in Pittsburg, because it was here he practically commenced to develop the wonders which have startled the world of late years.

The Dispatch Brought Him Out.

The Dispatch especially takes a great interest in the career of Tesla, because it was through this paper he first uttered to the world the marvelous ideas

The original was obtained by two seconds' exposure to the light of a single vacuum tube of very small dimensions.

Speaking about this photograph Mr. Tesla remarked that pictures taken by the light of such tubes show an amount of detail which no picture taken by the sun on flashlight is capable of disclosing.

MATOR.

THE INVENTIONS OF NIKOLA TESLA.

While everybody knows that Nikola Tesla is one of the greatest—perhaps the greatest—living discoverer in the field of electricity, not every one knows just what Mr. Tesla has done. It may be said, to start with, that to talk about Tesla's inventions leads one into a maze of electrical terms that defy the understanding of the mind not educated in electricity and anything like a description of the technicalities of his work, his discoveries, and his inventions here would be about as valuable as a column of Hebrew jargon. Hence, all that will be attempted is to tell what he has accomplished. First, take the transmission of power.

When Tesla came into the field in America little was known of the alternating current. The single alternating current was used, but for the purpose of lighting only. The continuous current was used almost exclusively.

The continuous current system is very good for short line work, but with it energy cannot be delivered successfully at any great distance at high pressure. To deliver the continuous current at high pressure at a distance would require the use of wires so heavy that they would be cumbersome and entirely impracticable for use. Tesla made an alternating current motor that permitted the transmission of energy long distances at high pressure over thin wires, the delivery being made at the same pressure or at a lower or a higher pressure, whichever was desired, by means of a transformer. Thus the bridling of the power in Niagara was made possible, and natural forces everywhere can be similarly harnessed and made to do the work that has heretofore been done at great cost by other forms of force and energy. A great many smaller inventions are included in this great one. Its possibilities are just now beginning to be realized. Tesla's discoveries in connection with this motor, it is said, were the prime cause of the recent consolidation of the Edison and the Westinghouse Electric Companies.

In this motor two wires were used for the transmission of the current. Tesla believed that the extra wire was a useless expense; that all the work could be done with one, and no return circuit was necessary. So he set himself about the work of finding a way to accomplish this. He did accomplish it,

and now it is possible through his invention to transmit the energy with the aid of only one wire. This invention, however, has not been of the same practical use as the other. It is merely a step in the direction of accomplishing the third thing that Tesla is aiming at. That is the transmission of power and intelligence without any wires, by means of the earth itself. If such a thing can be accomplished the human mind can hardly conceive of the possibilities. Tesla believes that it can be accomplished. The fact that he believes it is proved by the ten years of work he has devoted to experimenting on that line.

Next in order is the perfection of an apparatus for the production of electrical vibrations. Electrostatics is the science of electricity at rest. Tesla demonstrated that for the production of light waves, primarily, electrostatic effects must be brought into play, and he formed the opinion that all electrical and magnetic effects may be referred to electrostatic molecular forces. In a glass bulb filled with electrostatically charged molecules he found that by agitating them, causing them to vibrate, to strike against each other, brilliant light was produced. No carbon was required, such as is used in the ordinary incandescent light. There was nothing but the glass bulb. Tesla's accomplishment was the making of apparatus to stir up the molecules which don't cost anything and are ever present, while the carbon heretofore needed is expensive. This apparatus is nearing perfection now, and lamps which furnish light without carbon are in sight. The saving in the cost of electric lighting will be tremendous, and, as measured by Tesla, 200 times the light can be produced with the same energy that is now used in the production of the ordinary incandescent lights. This will mean more light with less power and less expense, because there will be no expensive carbons required.

Last on Tesla's list is the oscillator, now perfected and ready to be put on the market. It is estimated that nine-tenths of all the dynamos in the world are operated by steam power. Every step in the production of electricity by steam power is attended with waste and loss of force and energy. The problem Tesla set out to solve was the saving of the 95 per cent. of energy that was wasted. Actual tests showed that only 5 per cent. of the energy used in making incandescent lights manifested itself as light. The 95 per cent. was lost. There was loss in every step from the putting of the coal into the furnace to the delivery of the electricity. Tesla has combined an engine and a dynamo. Steam is forced into the engine at high pressure, which produces an extremely rapid vibration of a steel rod, and this rod or piston is so adapted to a set of magnets that the mechanical energy of the vibration is converted into electricity. Fly wheels and governing balls and eccentrics and valves and all the rest of the complicated mechanism required for the purpose of control or regulation are done away with.

The steam cylinder with its piston is the only thing that does the work about a steam engine. All the rest take energy, but produce nothing; so if they can be done away with, the energy that it takes to run them is saved. Tesla's oscillator does away with them. The oscillator converts the energy of steam into electricity directly. It would appear that this invention, if it does all that it promises, will revolutionize all business that requires energy in the form of steam or electric force to operate it. The machine doesn't take up one-tenth of the room needed by an ordinary engine and dynamo.

Probably the oscillator and the new system of lighting would both have been in use long ago had it not been for the destruction of Tesla's laboratory last year. He had these and other inventions very near completion. He had in his workshop the result of years of work. He had many models of machinery that he could not replace. All the work that had been done in making these things had to be done over again. He said himself at the time that a million dollars could not repay the loss.

Regarding the future he has said:

"I expect to live to be able to set a machine in the middle of this room and move it by the energy of no other agency than the medium in motion around us."—*N. Y. Sun.*

Tesla and Edison Apparatus.

To the Editor of Electrical Review:

You deserve the hearty thanks of all who are interested in the progress of the Roentgen-ray researches for the many excellent articles which have appeared in your journal upon the subject, but especially for those emanating from Mr. Tesla. Nothing has been done which promises more for the aid of medicine and surgery than these experiments of Mr. Tesla, for his appliances appear to have developed more penetrating power and greater definition of the tissues of the body than those of any other experimenter.

You would confer a great favor upon those who are attempting to follow in the wake of these able investigators, if you would take pains to present in your columns a detailed description of the apparatus that is employed by them. It would be very interesting to a large number of your readers, I am sure, if you would have a competent member of your staff describe in detail the apparatus employed both by Mr. Edison and Mr. Tesla. The structure of the coils they make use of, the manner of getting the interruptions in the circuit, the frequency of interruptions and the electro-motive force employed; also the source of, amount and electro-motive force of the current used to excite the primary coil. These are bits of information which all persons need who are attempting to secure equally good results with those that have been reported from the laboratories of these two able investigators. Would it be presumption on my part to ask you to furnish this information through the columns of your journal?

Very truly yours,

W. J. Herdman.

University of Michigan, Ann Arbor, May 26.

General Electric.—Westinghouse Electric & Manufacturing.—The board of control is reported to have completed the work of settling all the patent suits in which the two companies had engaged, numbering more than three hundred. W. D. Updegraff, private secretary to George Westinghouse, Jr., says that under the new arrangement the board of control, consisting of C. A. Coffin, President of the General Electric; F. D. Fish, its General Counsel; George Westinghouse, Jr.; P. D. Cravath, of New York, counsel for the Westinghouse Co., and F. B. Thomas, of New York, will enter suits and prosecute for both companies. The agreement as to common use of patents it is understood went into effect June 1.—V. 62, p. 689, 780.

THE WESTERN ELECTRICIAN'S first special electric light convention number (dated May 9th) contained 7,576 square inches of advertising. For the same week the *Electrical World* contained 7,326, the *Electrical Engineer* 3,687 and the *Electrical Review* 3,375 square inches of advertising.

The WESTERN ELECTRICIAN'S advertising, therefore, exceeded that of the *Electrical World* by **250** inches, that of the *Engineer* by **3,889** inches and that of the *Review* by **4,201** inches. It exceeded the combined advertising of the *Review* and *Engineer* by **514** inches.

The steady advancement of special convention advertising in the WESTERN ELECTRICIAN can be shown by a little table well worthy of attention:

Issue.	Number of Advertising Pages.	Total Number of Pages.	Square Inches of Paid Advertising Matter.
March 3, 1894....	40	56	4,145
February 23, 1895.	52	68	5,593
May 9, 1896.....	72	88	7,576

These figures are carefully and accurately compiled. They illustrate more forcibly than words a steady and vigorous growth during the hard times. It is to be remembered, also, that, in computing the square inches of advertising, all announcements of the WESTERN ELECTRICIAN or the Electrician Publishing company are rigorously excluded, so that the result shows net, *bona fide*, paid advertising. The figures show a growth of 2,000 square inches in a year. They are eloquent and may be left to speak for themselves.

THERE has been a good deal of talk of late about what Edison and Tesla are about to do in the way of astonishing the world with their discoveries in electric lighting, but thus far there have been no practical results made public. However, we are encouraged in the belief that each of the gentlemen named has something up his sleeve which, after the manner of Herrmann, he proposes to flash upon the public at a propitious moment. With owl-like wisdom an eastern contemporary sagely remarks: "We cannot hesitate to express our positive conviction that the introduction of a more perfect illuminant is near at hand." Well, well! How very definite, to be sure!

In the meantime, while Edison and Tesla are talking about their plans, or rather their friends are talking for them, D. MacFarlan Moore is going ahead and trying to accomplish something in the way of commercial utilization of the vacuum tube light with which Tesla has been experimenting so long. There are many prominent engineers who agree with the views expressed by Mr. Wessels in his communication on this subject, which appears elsewhere in this issue. One cannot read this contribution without feeling that there is cause for criticism of the policy pursued in attaching so much importance to the vague promises that are said to emanate from the "wizard" and the "magician" of the profession, but which many are disposed to consider the product of the lively imagination possessed by a newspaper writer who furnishes popular electrical stories to metropolitan dailies.

COMMUNICATION.

Claims of Moore, Tesla and Edison.

To the Editor of the WESTERN ELECTRICIAN:

In some of the New York papers I recently noticed articles headed "Tesla's Achievements," which would be amusing were they not misleading.

Stripped of ambiguity, they stated Mr. Tesla will, "with the aid of a few more experiments, be able to produce 40 per cent. of light and his perfected (?) bulb gives 10 per cent. of light." We need not concern ourselves with what Mr. Tesla is "going to do," as the outcome of the "few more experiments" is purely speculative.

Five years ago Mr. Tesla announced he would revolutionize the lighting field. The public saw some faint electrical pyrotechnics, then nothing was seen or heard. No wonder the *Mail and Express* of May 22, 1896, concluded: "There is nothing new in Mr. Tesla's work. His light is the same as he showed to the Society of Electrical Engineers five years ago."

In the *Electrical Engineer*, November 13, 1895, I pointed out the constant tendency of the press to credit Mr. Tesla with the achievements of other inventors! No one will begrudge him credit, if any, due for original work actually demonstrated before reliable witnesses; but the articles I am criticizing are misleading in that they credit to Mr. Tesla, Mr. Moore's achievements. If Moore is substituted for Tesla, the articles will be fairly accurate, if all reference to what is "going to be" is omitted.

The absence of filaments in the tubes is mentioned. The fact cannot be disproved that the first tube-lighted room in this world's history was lighted by Mr. Moore's vibrator and vacuum tubes. Neither Mr. Edison nor Mr. Tesla has shown a room lighted by vacuum tubes up to this time. It was Mr. Moore who first demonstrated commercial etheric lighting. He lighted a room with his tubes over a year ago, as the signed laboratory register and photographs witness. Long before that he lighted the laboratory with lamps and by them obtained clear photographs, along side of which the Tesla pictures published in the April, 1895, *Century* are very obscure. Before the *Century* article appeared, I showed Mr. Moore's photographs to prominent electrical engineers.

Mr. Moore alone is entitled to the credit of having discovered new fundamental principles and made them operative. In this credit neither Mr. Edison nor Mr. Tesla is justly entitled to share. Yet the dailies are devoting much space to what is "going to be" and ignoring what is. They head articles "Edison and Tesla Rivals" and shut their eyes to the fact that Mr. Moore is the only one who has shown a tube-lighted room. They print accounts of what "will be," but Mr. Moore demonstrates nightly what is.

The unfounded advertising Mr. Tesla is getting is based upon the *Electrical Review* article of May 20, 1896. That article says that the *Review's* representative saw Tesla's tube. Did others see it? It is proper to inquire—

First—Was the representative (name not given) a qualified electrical engineer, capable of judging, or merely a non-technical journalist?

Second—Who made the test of power said to be consumed?

Third—How was the illuminating capacity of the tube measured?

Fourth—Was the light diffused for any length of time, or evanescent?

Fifth—Did the light work on alternating and direct circuits, or only on one of them?

Sixth—How much power was used?

Seventh—Is the system practical? It is well known that in Mr. Tesla's experiments five years ago such enormous voltages were used as made them absolutely useless for any but laboratory use. Moreover (discarding the factor of danger), the cost of insulation would be ruinous, even if, as was not the case, commercial results had been obtained.

Assuming, however, that all the articles stated was true, why has Mr. Tesla not publicly shown his tube? Why is he not present at the electrical show? If prevented from coming, why does he not send a representative with the tube? He never had a better chance than the show affords. As Mr. Edison said, "Moore is showing his light and I will show mine. Let Tesla come along and show his. What counts in the world is the man who produces, not the man who talks."

Against Mr. Tesla's statement of what he is "going to

do," the discriminating electrical public will place what Mr. Moore actually did and is doing. Mr. Tesla lectured in 1891 and has shown absolutely nothing since. Mr. Moore's record follows:

1891.	Mr. Moore claimed he could produce better results than Mr. Tesla showed in his lecture.
1893, Sept. 20.	Mr. Moore read his paper before the American Institute of Electrical Engineers on "A New Method for the Control of Electric Energy." Discussion followed, and the paper was printed in the Institute's *Transactions*,
1894, April 1.	Mr. Moore showed fine photographs from unretouched negatives taken by his lamps.
1894, July.	Mr. Moore's article on "The Light of the Future" appeared in *Cassier's Magazine*, nine months ahead of the Tesla (*Century*) article.
1895, May.	Mr. Moore lighted a room in his laboratory with vacuum tubes for the first time in history.
1895, December.	Mr. Moore was photographed by his tubes and a full-page reproduction appeared in the *Electrical Engineer*, New York, the *Electrical Review*, London, and elsewhere.
1896, April 22.	Mr. Moore lectured before the American Institute of Electrical Engineers on "Recent Developments in Vacuum Tube Lighting," and showed many forms of lamps and tubes, closing by lighting the hall with 27 vacuum tubes. The photograph of the hall, taken by those tubes after a five-minute exposure, from an unretouched negative, appeared in the *Electrical Engineer* on May 5, 1896.
1896, May 4.	Mr. Moore lighted up Governor Morton by a frame of seven feet six inch tubes as he opened the electrical exposition, and showed the signs "N. E. L. A." and "Let There Be Light" above Governor's Morton's head.
1896, May 6.	Mr. Moore lectured under the auspices of the National Electric Light association (President Wilmerding presiding) and lighted the stage with his vacuum tubes.
1896, May 16.	Mr. Moore lighted his tubes in the form of flying arrows, and kept them lighted while Dr. Depew made his speech.
1896, May 20.	Mr. Moore participated in the American Institute of Electrical Engineers' discussion of his paper, and, by exhibiting his apparatus and tubes, more than proved his claims. He scored a great victory, and the parties who, before making the tests, had denied his claims, admitted Mr. Moore was right and they were wrong.
1896, May 4 and every week-day to date.	Mr. Moore's chamber of light has been visited by thousands, who have seen and wondered at his artificial daylight. They make an unimpeachable crowd of witnesses to the great simplicity and inexpensiveness of his apparatus and its low voltage.

Is it not singular (to say the least) that only after Mr. Moore made this unimpeachable record did newspaper articles appear, stating what Messrs. Edison and Tesla were "going to do."

Yet many of the dailies are silent about Mr. Moore, and even the lecture he delivered at the request of the National Electric Light association was only referred to by one of the electrical journals, although the hall was filled with a thousand delegates and others. President Wilmerding held one of the tubes and showed the induction effects when Mr. Moore lighted the stage.

Mr. Moore's demonstrations have greater historic value than press effusions, and these demonstrations cannot be ignored.

Mr. Moore is most willing to continue his public demonstrations after the electrical show closes. Will Mr. Tesla show his tubes at the same time? Let instruments be used by competent electrical experts. Then let the results of the competitive test be published authoritatively. The public will always prefer actual achievements to speculative theories.

The Goebel litigation showed conclusively the unwisdom of allowing incorrect statements to go unrefuted when made. This is one of my reasons for writing this letter. If further argument be needed to demonstrate that Mr. Moore was absolutely first in the vacuum tube lighting field (ahead of Messrs. Edison and Tesla) it will be found in the fact that he secured in the last three years some 20 patents for his inventions in vacuum tube lighting, and further, that a number of his applications are awaiting action in the Patent Office. At no time were there any "references" to Edison or Tesla, and the patents were only issued after Mr. Moore had gone to Washington, set up a miniature laboratory in the United States Patent Office, and proved to the examiners that they were wrong when they originally wrote "each of the claims therefore must be denied on the ground of inoperativeness." Although the examiners said his system would not work by any known law, Mr. Moore proved that it did work, came off a victor at all points and received his patents.

The editor of the *Electrical Review* saw Mr. Moore's laboratory lighted by vacuum tubes in 1894 and was photographed at that time by the light of the tubes. On the day the *Review* published the Tesla article, Mr. Moore appeared before the American Institute of Electrical Engineers and submitted his apparatus for tests. The result of the tests made by such men as Prof. W. A. Anthony, Prof. Nichols of Cornell, Nelson W. Perry and others proved that Mr. Moore had understated rather than overstated, his claims. Let Mr. Tesla produce his tube, face the same searchlight, and if he passes muster, he will get all the credit really due him.

No matter what Mr. Edison, Mr. Tesla or anyone else may produce, the fact remains that to D. MacFarlan Moore alone belongs the credit of first having produced commercial light by means of vacuum tubes.

It is largely to put this fact indisputably on record that I have written this letter.

EDWARD J. WESSELS,
President Moore Electrical company.

Newark, N. J., May 25, 1896.

Tesla and Marriage.—Our sprightly contemporary, the *Electrical Journal*, takes issue with Mr. Nikola Tesla as to the undesirability of marriage for inventors, and after disproving his statement that few great inventions have been made by married men, proceeds as follows: "We are great admirers of Mr. Tesla and his work. We give him credit for mighty good hard sense. We do not think he is like the Frenchman who excused his bachelorhood on the ground that he was "one butterfly, zat fly from ze flower to ze flower and sip ze honey." We know, too, that Mr. Tesla's nature is a very intense one, but we have just faith enough in women—especially American women—to make Mr. Tesla a straight-out offer to find a girl for him who will not only match his intensity in all respects, but who will tax his inventive genius to the utmost—and hence encourage it—trying to explain where he was at 2 A. M. some night when she had gone to his laboratory to bring him home and found it dark, although he had told her he was going to have to "stay down town to work to-night." Then again, if Mr. Tesla were to have ordinary Benedict luck and half a score of little Teslas, his inventive genius would be kept up to a white heat, hustling for the wherewithal to supply their wants. Mr. Tesla knows that "necessity is the mother of invention." Fie, Mr. Tesla, fie, we say. Get married. You'll get strong, be happy, sleep o'nights; and if you leave an invention or two less to posterity, you will leave a more material and fully as necessary a legacy in another shape. Besides, they try to steal inventions from a man; they don't steal his children, seldom his wife, and never the pleasures that a married man falls heir to."

EDITORIAL.

All of these experimenters have obtained in their laboratories wonderfully interesting results and they have been enabled to produce startling effects of great brilliancy which have drawn to their preliminary experiments the attention of reporters from the daily press, the result being that where a more thorough knowledge of the problem is lacking, one is almost inclined to believe that we are on the verge of a great revolution in both the manner and efficiency of illumination. Indeed, it may be that we are soon to see the solution of the problem of economical illumination, but if this is true it will be through the agency of some discovery not less startling than the recently announced Roentgen phenomenon.

The problem is not, as the daily papers would have us believe, bounded by the production of an economical lamp along lines which have been experimentally developed in the laboratory, but is one that has not yet been attempted, that of the economical generation and distribution of high frequency currents. Until this problem shall have been attacked and a practical solution proposed, the lighting effects already obtained must be confined to the sphere of laboratory experiments, and however great may be their beauty and whatever theoretical efficiency we may calculate for the system of illumination, we can only expect to see their application many years in the future.

HIGH FREQUENCY EXPERIMENTS

One evening after Tesla had been exhibiting some of the wonderful phenomena produced by his high frequency currents and displaying vacuum tubes without electrodes illuminated by induction from the current flowing in a neighboring wire, he was asked if it would be possible to so insulate the leads in this system of lighting as to prevent unauthorized use of the current, and he replied that a covering of hard rubber one foot thick would do the insulating very nicely, provided that the dielectric would not succumb to the heat generated in it. Though this remark was made more than four years ago, and though Tesla, Edison and McFarlane Moore have all made advances in the field of illumination with high frequency currents, there has been no means of distributing such remains to-day, as it has since the beginning of this line remains today, as it has since the beginning of this line of experimentation, without practical solution. Judging from the papers that have been published, Moore expects to employ current from an ordinary lighting system and to generate his high frequency currents at the points where they are used by the means of a specially devised interrupter. Tesla's plans have frequently been stated to embody the use of the oscillator generator requiring a distribution of high pressure steam and sometimes to embody the Tesla transformer with a spark gap interrupter. So far as is known at the present time, Edison has not attacked the problem of distribution, but has only concerned himself with the production of high frequency lamps.

ELECTRIC "L" CARS.

Tesla's Discovery of the Rotating Magnetic Field Has Solved the Problem of Motive Power.

TEST FOR THE MANHATTAN.

Officials Will Watch an Early Application of the System at the Westinghouse Works.

GREAT PROMISES ARE MADE.

Speed, Safety and Economy Result, It Is Claimed, from Tesla's Latest Find.

THAT electricity will be the motive power on the New York elevated railways is quite well assured, and promises to be certain within a few days. The trial trip of a new motor is to be made at Pittsburg by the Westinghouse Electric Company so soon as arrangements are made with the elevated railway people to witness it.

"The trial trip will likely be made within ten days, though it may be longer," said Mr. George Westinghouse, two days ago, when I saw him in his office. "We are now almost ready, and will notify the elevated people according to the understanding between us. The experiments and severest tests have produced the most satisfactory results. In fact, the new motor is away beyond our expectations. It is Tesla's greatest discovery, and solves the problem of rapid transit motive power. It cannot help being the power to be used."

ROTATING MAGNETIC FIELD.

Nikola Tesla was found in his laboratory, in East Houston street, surrounded by the mysterious appliances of his science, and quite ready to give information of interest to the public.

"This polyphase alternating current as used in the new motor to be soon put on its trial trip in Pittsburg is sure to furnish the motive power for our elevated roads," he said. "It cannot be avoided, simply because it will do the work surely, safely and economically. Then it is so easily managed, and without the constant danger of requiring an expert electrician to care for it.

"Now, the whole secret lies in my discovery of what is known as the rotating magnetic field. What it is I cannot explain, neither is it explainable. I can only give the facts which have been discovered through experiment. The discovery of these scientific facts has done entirely away with the commutator, which has heretofore been used on all electric motors. This commutator, with its close adjustment, delicate and intricate parts, has been the cause of all of the trouble. It is that complicated piece of machinery which shows the scores of pieces of brass arranged fan like, only making an entire circle. A slight injury to this commutator, which may arise from the presence of even a drop of water, may destroy the whole machine. The danger is now all done away with by discarding the commutator entirely.

"This result is accomplished by utilizing the rotating magnetic field, which simply means that if a circular metal disk is placed on an axle and brought near the electric coil it will revolve. The disk touches nothing but its own bearings, yet it revolves and thus produces power. This power is what is used in the new motor."

PREPARING FOR THE TRIAL.

In the yards of the Westinghouse Electric Company, at East Pittsburg, a new combination electric locomotive engine and passenger car is now being equipped with these new motors, and in a few days will be ready for the trial trip. When all is in readiness the motor car will be coupled to five passenger coaches, and the special test for the benefit of the Manhattan Elevated Railway officials will be given. An actual demonstration of results now known will follow, and the gas and smoke producing engine will disappear from the streets of New York.

The new locomotive, which was in place last week, is forty-six feet long on the outside and thirty-eight feet inside. There are seats on both sides running lengthwise and exactly like "L" coaches. The motorman will stand at one end of the car. There will be a controller or lever at either end, and it will not be necessary to turn the locomotive. A pilot will be at either end to brush obstructions from the track.

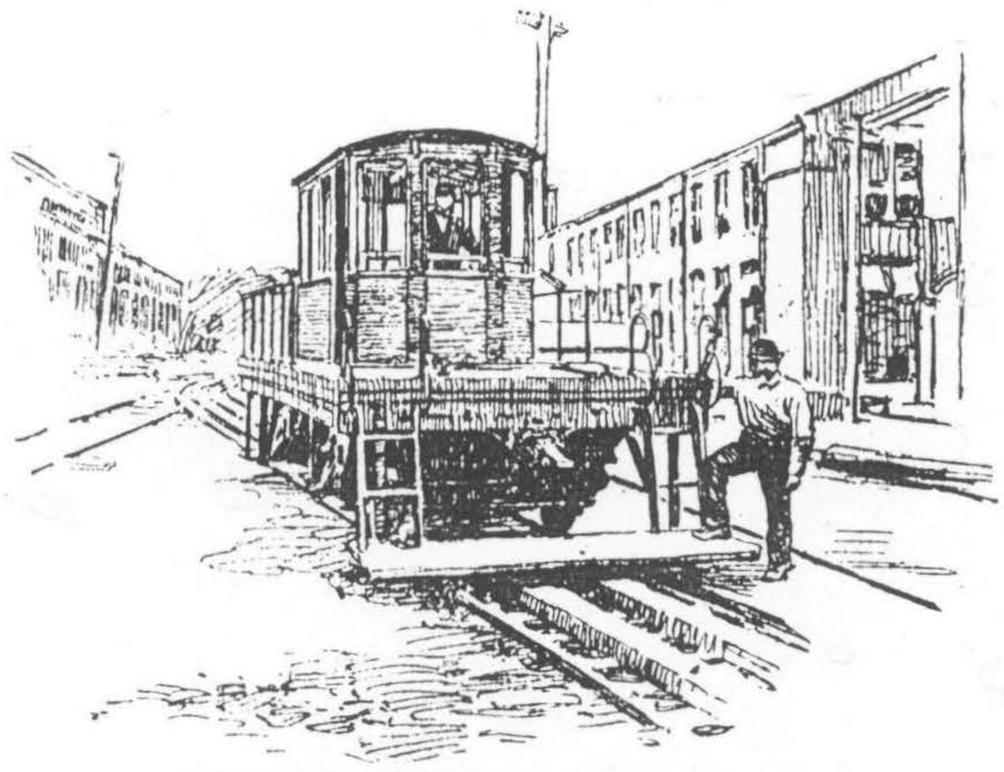
There will be no fireman on the new locomotive, which will be equipped with air as well as hand brakes. It has a cast iron bottom to give it adhesion and weight. On the heavy axles are four motors of 100 horse power each, and the hauling capacity will be equal to that of 400 horses. The motors have been tested and were found equal to the task of hauling six or seven "L" passenger coaches in addition to the locomotive at a maximum speed of twenty-eight miles per hour. The average that would be maintained on the Manhattan system, it is claimed, would be from sixteen to eighteen miles per hour.

The new locomotive is entirely different from the first electric locomotive equipped at the Westinghouse works, and by which it was intended to make the "L" test. This machine is now used exclusively in shifting freight cars in and about the Westinghouse yards. Then a second one, which was an improvement on the first, was equipped. It in turn gave way to the Suburban electric locomotive, which contains all the improvements known to date. This is what has delayed the test.

This will be the first time the Tesla system will be used for railway work, and it is expected to revolutionize the present trolley and steam railroads. The cars are standard gauge and the test will take place on the tracks of the Turtle Creek branch of the Pennsylvania Railway. The line has been wired, the double trolley system being used, and the tracks reballasted, so that the highest speed can be attained. The test track, which is about three miles long, has been divided with posts set in the ground every quarter of a mile. These posts are numbered from one up, and represent the "L" stations. At these posts the train will be stopped and started as if running on the elevated tracks in New York. With stop watches the time of stopping and starting will be taken. In a preliminary test with the direct current a speed of ten miles per hour within a distance of sixty feet was acquired.

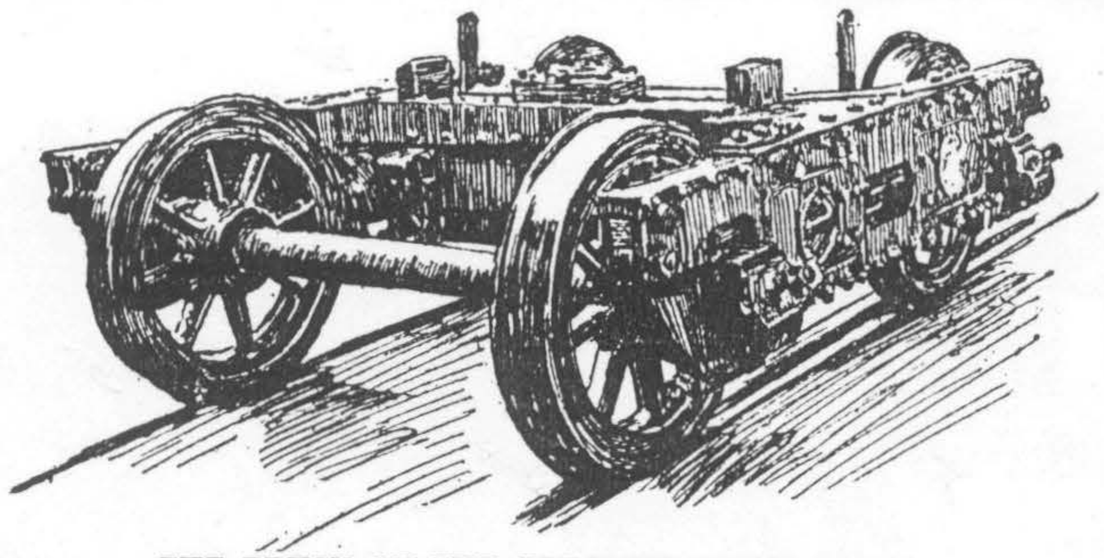
The train will be exactly the same weight as an "L" train, and everything will be arranged so that the test will be as if it occurred in New York.

SOME OF THE ADVANTAGES.



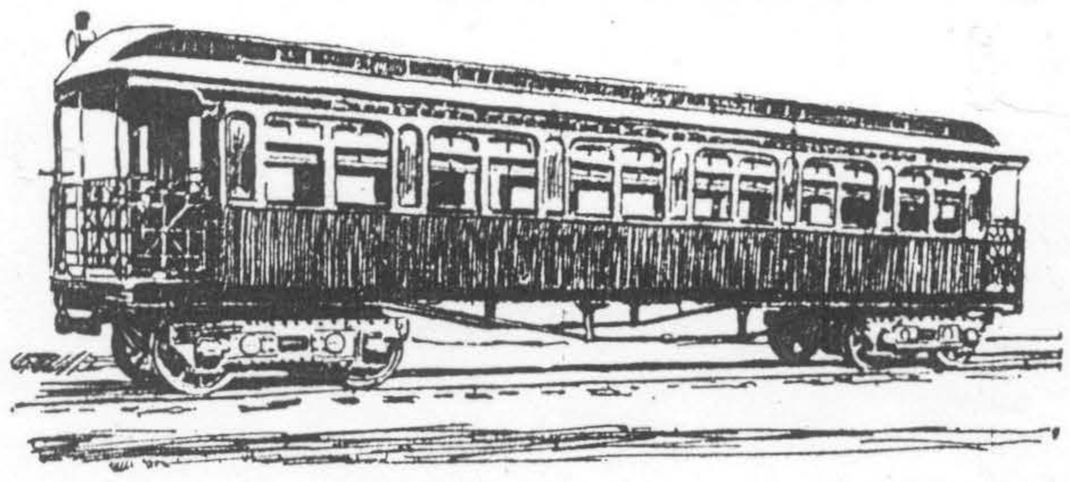
One advantage claimed for the new system, and one that will be appreciated in New York, is that the current used to run and light the trains could also be utilized to light the stations and operate a passenger elevator service.

The great advantage of the alternating system is that it saves lives in case a person takes hold of a live wire. Using the direct current 500 volts are necessary for ordinary street car work. This must be transmitted over expensive copper wire. By the invention of Tesla the current can be transmitted long distances over ordinary iron telegraph or telephone wires. The voltage can be so reduced that a person might take hold of a live wire with safety. He would be shocked, but would not be killed. With the general introduction of the new system it is claimed that electrocutions from the trolley will be rare.



In the direct current motor the commutator, which gathers the electricity from the armature and carries it to the brush, and the brush itself, are expensive and necessary features. They are continually breaking, wearing out and needing repairs, and add largely to the maintenance and operative cost of the system.

With the Tesla polyphase motor, these difficulties are obviated. The heavy copper feed wires, which are always dangerous by reason of having to carry at least 500 volts, will be replaced by lighter wires having a voltage of about 210. No commutators or brushes are needed, the armature playing in a field. The power plant can be located many miles away from the road if found necessary. If the new system is adopted in New York one power plant in Westchester could furnish sufficient power to operate all the "L" lines and surface roads in the city. This would do away with the expense of having to erect power houses where land is valuable, and where the smoke would prove a nuisance.



When the great revolution in street railway motive power will be completed it is difficult to say, for both sides have moved slowly and been conservative. The street railway people have been slow to decide on changes that would involve expense and perhaps prove experimental, and the men who are furnishing the capital for the great plants that are making the tests have been equally conservative. But within a few weeks there has been a great change, and both sides appear to think that they stand on safe ground, that the problem has been solved and that the great change is about to be entered upon. The questions of speed, safety, durability, convenience and economy appear to have been settled, and now only a formal acceptance of the inevitable is necessary. It means much for a great railway company to revolutionize its motive power, but the Manhattan Elevated people have admitted for some time that a change would come, and they have only delayed to be certain that the new system embodied all of the requisites. Now, all sides appear satisfied that the trial being arranged for at Pittsburg will be satisfactory, pronounce the fate of steam in cities and establish electricity as the great motive power.

TESLA DESCRIBES AN INTERESTING FEATURE OF THE X-RAY RADIATIONS.

TO THE EDITOR OF ELECTRICAL REVIEW:

The following observations, made with bulbs emitting Roentgen radiations, may be of value in throwing additional light upon the nature of these radiations, as well as illustrating better properties already known. In the main these observations agree with the views which have forced themselves upon my mind from the outset, namely, that the rays consist of streams of minute material particles projected with great velocity. In numerous experiments I have found that the matter which, by impact within the bulb, causes the formation of the rays, may come from either of the electrodes. Inasmuch as the latter are by continued use disintegrated to a marked degree, it seems more plausible to assume that the projected matter consists of parts of the electrodes themselves rather than of the residual gas. However, other observations, upon which I can not dwell at present, lead to this conclusion. The lumps of projected matter are by impact further disintegrated into particles so minute as to be able to pass through the walls of the bulb, or else they tear off such particles from the walls, or generally bodies, against which they are projected. At any rate, an impact and consequent shattering seems absolutely necessary for the production of Roentgen rays. The vibration, if there be any, is only that which is impressed by the apparatus, and the vibrations can only be longitudinal.

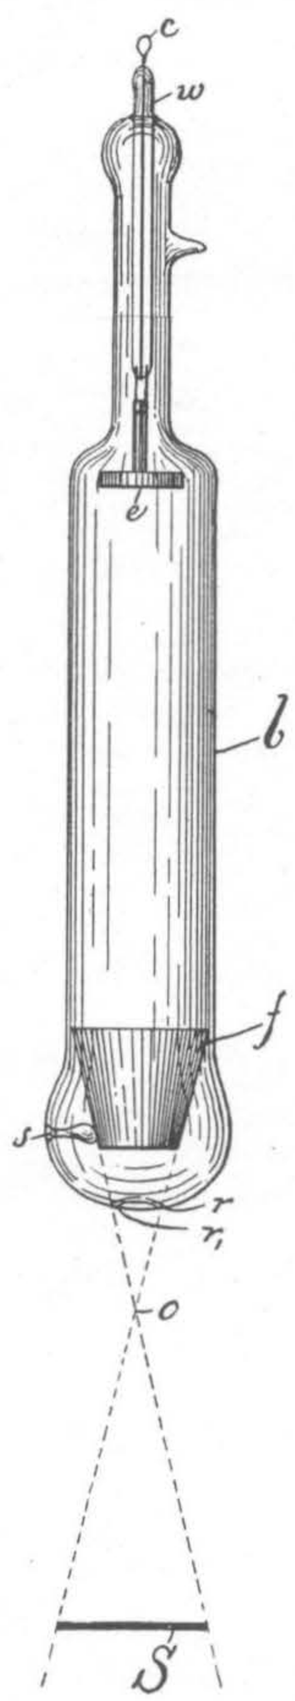

DIAGRAM ILLUSTRATING TESLA'S EXPERIMENT.

The principal source of the rays is invariably the place of first impact within the bulb, whether it be the anode, as in some forms of tube, or an inclosed insulated body, or the glass wall. When the matter thrown off from an electrode, after striking against an obstacle, is thrown against another body, as the wall of the bulb, for instance, the place of second impact is a very feeble source of the rays.

These and other facts will be better appreciated by referring to the annexed figure, in which a form of tube is shown used in a number of my experiments. The general form is that described on previous occasions. A single electrode *e*, consisting of a massive aluminium plate, is mounted on a conductor *c*, provided with a glass wrapping *w* as usual, and sealed in one of the ends of a straight tube *b*, about five centimetres in diameter and 30 centimetres long. The other end of the tube is blown out into a thin bulb of a slightly larger diameter, and near this end is supported on a

glass stem *s* a funnel *f* of thin platinum sheet. In such bulbs I have used a number of different metals for impact with a view of increasing the intensity of the rays and also for the purpose of reflecting and concentrating them. Since, however, in a later contribution, Professor Roentgen has pointed out that platinum gives the most intense rays, I have used chiefly this metal, finding a marked increase in the effect upon the screen or sensitive plate. The particular object of the presently described construction was to ascertain whether the rays generated at the inner surface of the platinum funnel *f* would be brought to a focus outside of the bulb, and further, whether they would proceed in straight lines from that point. For this purpose the apex of the platinum cone was arranged to be about two centimetres outside of the bulb at *o*.

When the bulb was properly exhausted and set in action, the glass wall below the funnel *f* became strongly phosphorescent, but not uniformly, as there was a narrow ring *r r* on the periphery brighter than the rest, this ring being evidently due to the rays reflected from the platinum sheet.

Placing a fluorescent screen in contact or quite close to the glass wall below the funnel, the portion of the screen in the immediate neighborhood of the phosphorescent patch was brightly illuminated, the outlines being entirely indistinct. Receding now with the screen from the bulb, the strongly illuminated spot became smaller and the outlines sharper, until, when the point *o* was reached, the luminous part had dwindled down to a small point. Moving the screen a few millimetres beyond *o* caused a small dark spot to appear, which widened into a circle and became larger and larger in the same measure as the distance from the bulb was increased (see S), until, at a sufficiently large distance, the dark circle covered the entire screen. This experiment illustrated in a beautiful way the propagation in straight lines, which Roentgen originally proved by pinhole photographs. But, besides this, an important point was noted; namely, that the fluorescent glass wall emitted practically no rays, whereas, had the platinum not been present, it would have been, under similar conditions, an efficient source of the rays, for the glass, even by weak excitation of the bulb, was strongly heated. I can only explain the absence of the radiation from the glass by assuming that the matter proceeding from the surface of the platinum sheet was already in a finely divided state when it reached the glass wall. A remarkable fact is, also, that, at least by a weak excitation of the bulb, the edges of the dark circle were very sharp, which speaks strongly against diffusion. By exciting the bulb very strongly, the background became brighter and the shadow S fainter, though it continued to be plainly visible even then.

From the preceding it is evident that, by a suitable construction of the bulb, the rays emanating from the latter may be concentrated upon any small area at some distance, and a practical advantage may be taken of this fact when producing impressions upon a plate or examining bodies by means of a fluorescent screen.

N. TESLA.

New York, July 1, 1896.

Tesla Transformers for Röntgen Photography.—Fig. 1 shows a complete Tesla apparatus, being patented by Mr. L. Miller, for obtaining high tension oscillating discharges from the street electric light mains, where the current is alternating. The illustration is taken from a set of apparatus supplied to St. Bartholomew's Hospital for obtaining photographs of injured limbs, &c., by means of Röntgen rays. Messrs. Miller & Woods supply a standard

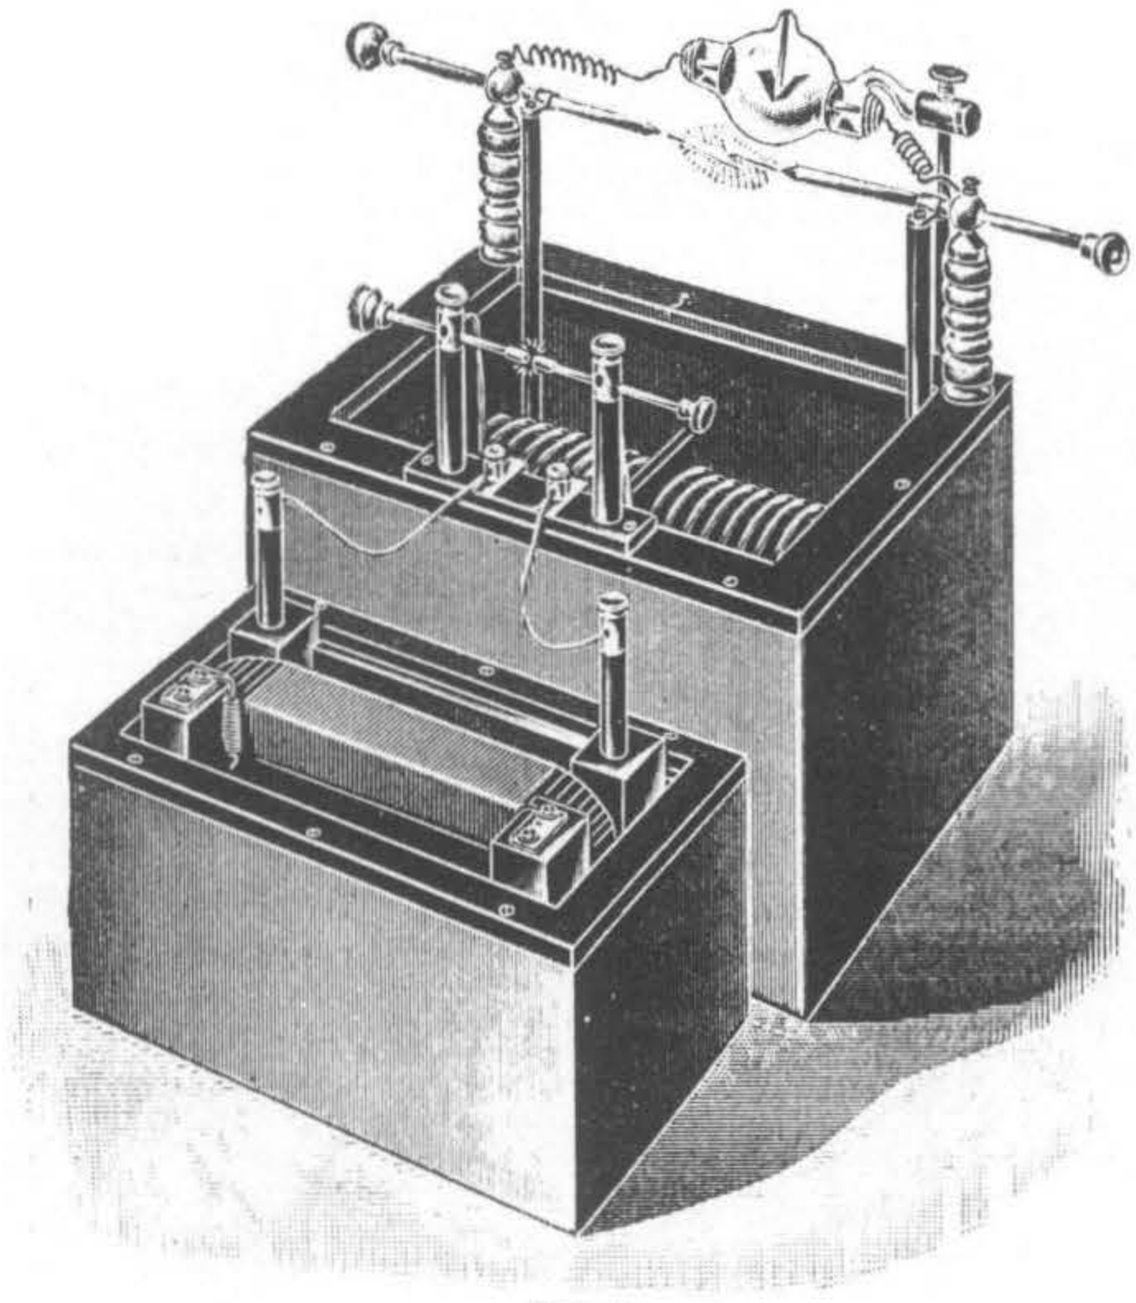

FIG. 1.

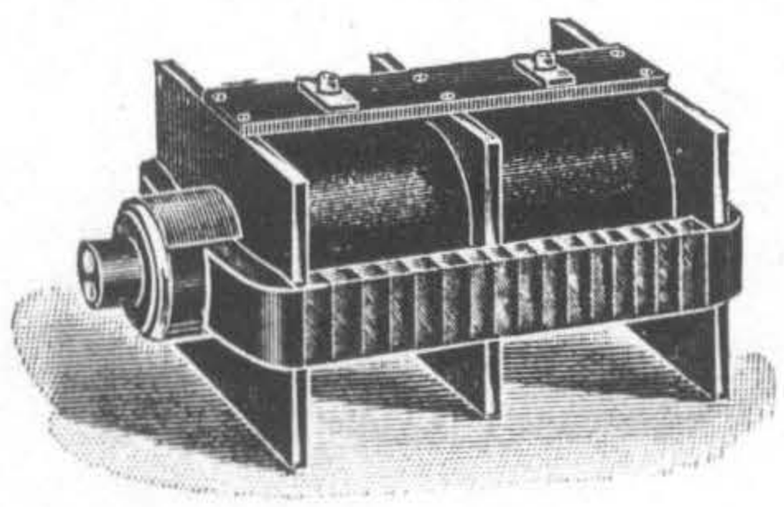
set which gives a stream of sparks over more than a 6-inch air gap. The set consists of a step up transformer (fig. 1) from 100 volts to about 6,000 volts, and taking the same current as two lamps of 16 candle-power each; a condenser; and a Tesla transformer to about 70,000 volts. The condenser discharges by rapid oscillations of current across the spark gap (shown in figure) through the primary thick wire winding of the Tesla coil. Induced currents are then set up in the inner thin wire secondary winding of the Tesla coil.



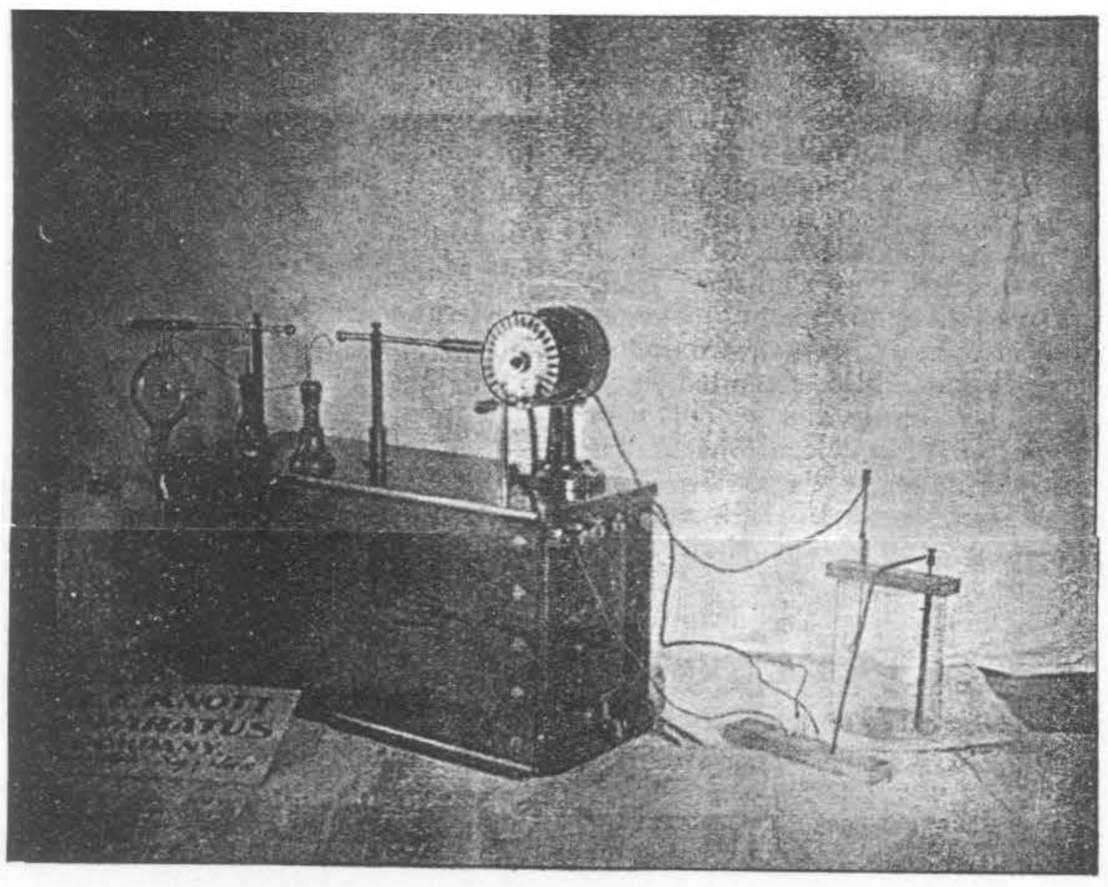


FIG. 2.

These are led to the discharge rods and can be used to excite Röntgen rays in a single or double focus tube as shown, or demonstrate the Tesla experiments. The boxes in which the above are contained are filled with mineral oil. Fig. 2 shows a high tension transformer which can be used up to about 4,000 volts without oil. It is said to be a neat compact form of transformer for exciting vacuum tubes, ozone generators, &c., and can readily be connected to the electric mains by means of a lampholder attached to a piece of flexible cord.

New Tesla Coil for X-Ray Work.

During the last few months the subject of exciting Crookes tubes has received much attention from electricians and scientists in general. It is not surprising, therefore, that enterprising experimenters have placed upon the market various devices which they believe to be an improvement over the old methods of exciting these tubes. The difficulties in the way were not easy to surmount. First of all it was found there must be an exceedingly rapid discharge of the current through the tube. Second, this discharge must be of sufficiently high potential to make it vigorous. Third, the amperage must be so low as to produce little or no heat in the tube itself. This last point was a subject of great moment, as in one form of the tube where the cathode rays focus upon the glass itself it was found that if a large amount of current was used the glass became heated and the tube collapsed.

Many experiments have been performed showing the adaptability of

A New Tesla Coil for X-Ray Work.

the Holtz machine to this work. At present, however, no satisfactory device has been hit upon by which a Holtz machine can be made to give sufficiently rapid discharges combined with durability and readiness to work under all climatic conditions. Any one of these points seems to have been attained, but to our knowledge no similar machine has yet been able to meet them all.

The induction coil seems to have been productive of better results in that it can be relied upon under all atmospheric conditions, and with proper care is not so liable to get out of order. The difficulty, however, of making a complete break of sufficient rapidity in the primary current, has rendered this apparatus of little practical value for hospital work. Furthermore, the problem of adjusting the ratio between the primary and secondary coil has not yet been settled, so that many of the induction coils placed upon the market have been found to be exceedingly destructive to the Crookes tubes. This deterioration of the tubes, when used on these coils, has been from overheating either the aluminum or platinum electrode. In either event the degree of vacuum would be changed, and hence the efficiency of the tube greatly interfered with.

The wonderful and startling results produced by Nikola Tesla during the early stages of this work lead many to believe that much was to be hoped for in the development of the form of apparatus used by him. A coil known as the modified Tesla coil has been placed upon the market by the L. E. Knott Apparatus Company, of 14 Ashburton Place, Boston, Mass. This coil contains many new features entirely different from anything before seen in the practical electrical field. They have employed a new form of transformer, which lifts the current from 52 to about 35,000 volts. The principle of this transformer does not differ materially from that of the induction coil, except the ratio of the core to the primary and secondary is so adjusted that the principle of the regular alternating current transformer applies. Also, by a new method of insulation, the secondary coil is so wound that each layer is surrounded by an oil of high insulating properties. A new feature also has been introduced in the condenser since not only the transformer and oscillator, but also the condenser itself, is immersed in oil. Great improvement has been made here in the condensing surface since the old method of using tinfoil has been discarded and a much more permanent copper plate substituted. By an arrangement of the primary of the transformer, also, either a 52 or 104-volt current can be used equally well. If the former, the machine will take six amperes. If the latter, about three. When working on the number of watts here indicated, a steady discharge of something over eight inches is obtained. The frequency is so high that striking Tesla effects are also produced. Many of the experiments that are so ably discussed in Tesla's little book can be shown with great satisfaction with the coil here described.

It is not thought that the problem of running a high-frequency coil on a direct current has ever before been successfully solved. Wonderfully successful work, it is said, has been done by this coil so excited.

The great improvement, however, on this coil is the mechanical spark gap which renders the discharge of the condenser absolutely uniform and the rapidity of the discharge under the control of the operator. As the manufacturers of these coils are in the physical and chemical apparatus business, and dealing with hospitals, it is but natural that they should endeavor to place a coil on the market which is especially adapted to this kind of work. We are pleased to know of their success and to know that the instruments have so far been developed that surgeons find them of great practical value. The manufacturers of these coils have recently issued an eight-page pamphlet on the use of the X rays, and are soon to issue a new edition containing their recent improvements. The amount of energy they have shown is surely commendable.

SCIENCE.

TESLA'S NEW X-RAY EXPERIMENTS.

AMONG all scientific men of recognized authority Nikola Tesla has stood practically alone in his views of the constitution of the Röntgen rays, in that he has been inclined to regard them not as vibrations but as actual streams of fine particles passing directly through the pores of material bodies. The objections to such a hypothesis are evident, and it is therefore interesting to see that Tesla adheres to it and now brings forward some special experiments that seem to strengthen it considerably. We quote part of a description of these experiments contributed by the experimenter himself to *The Electrical Review* (July 8). Says Mr. Tesla:

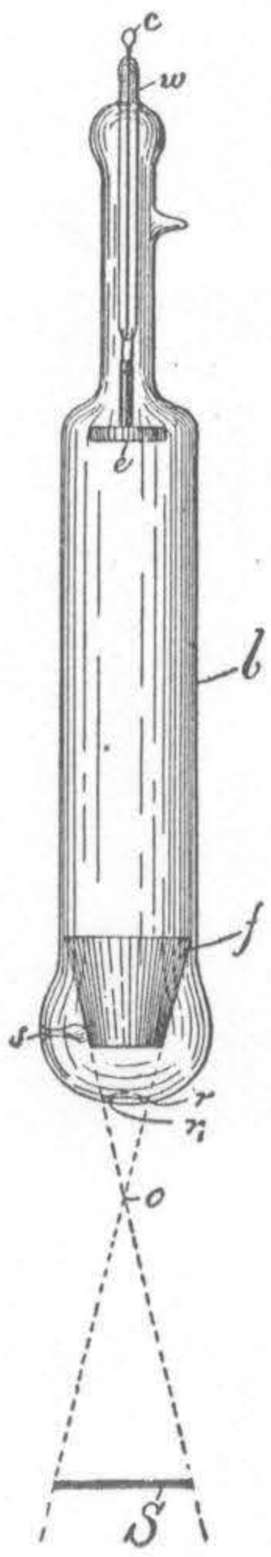

DIAGRAM ILLUSTRATING TESLA'S EXPERIMENT.

"In the main these observations agree with the views which have forced themselves upon my mind from the outset, namely, that the rays consist of streams of minute material particles projected with great velocity. In numerous experiments I have found that the matter which, by impact within the bulb, causes the formation of the rays, may come from either of the electrodes. Inasmuch as the latter are by continued use disintegrated to a marked degree, it seems more plausible to assume that the projected matter consists of parts of the electrodes themselves rather than of the residual gas. However, other observations, upon which I can not dwell at present, lead to this conclusion. The lumps of projected matter are by impact further disintegrated into particles so minute as to be able to pass through the walls of the bulb, or else they tear off such particles from the walls, or generally bodies against which they are projected. At any rate, an impact and consequent shattering seems absolutely necessary for the production of Röntgen rays. The vibration, if there be any, is only that which is impressed by the apparatus, and the vibrations can only be longitudinal.

"The principal source of the rays is invariably the place of first impact within the bulb, whether it be the anode, as in some forms of tube, or an enclosed insulated body, or the glass wall. When the matter thrown off from an electrode, after striking against an obstacle, is thrown against another body, as the wall of the bulb, for instance, the place of second impact is a very feeble source of the rays.

"These and other facts will be better appreciated by referring to the annexed figure, in which a form of tube is shown used in a number of my experiments. The general form is that described on previous occasions. A single electrode *e*, consisting of a massive aluminum plate, is mounted on a conductor *c*, provided with a glass-wrapping *w* as usual, and sealed in one of the ends of a straight tube *b*, about 5 cm. in diameter and 30 cm. long. The other end of the tube is blown out into a thin bulb of a slightly larger diameter, and near this end is supported on a glass stem *s* a funnel *f* of thin platinum sheet. . . . The particular object of the presently described construction was to ascertain whether the rays generated at the inner surface of the platinum funnel *f* would be brought to a focus outside of the bulb, and further, whether they would proceed in straight lines from that point. For this purpose the apex of the platinum cone was arranged to be about 2 cm. outside of the bulb at *o*.

"When the bulb was properly exhausted and set in action, the glass wall below the funnel *f* became strongly phosphorescent, but not uniformly, as there was a narrow ring *r r* on the periphery brighter than the rest, this ring being evidently due to the rays reflected from the platinum sheet."

By holding a phosphorescent screen outside the bulb and shifting it to and fro, Mr. Tesla showed that the rays focus at *o*. He goes on to say:

"This experiment illustrated in a beautiful way the propagation in straight lines, which Röntgen originally proved by pinhole photographs. But, besides this, an important point was noted, namely, that the fluorescent glass wall emitted practically no rays, whereas, had the platinum not been present, it would have been, under similar conditions, an efficient source of the rays, for the glass, even by weak excitation of the bulb, was strongly heated. I can only explain the absence of the radiation from the glass by assuming that the matter proceeding from the surface of the platinum sheet was already in a finely divided state when it reached the glass wall. . . .

"From the preceding it is evident that, by a suitable construction of the bulb, the rays emanating from the latter may be concentrated upon any small area at some distance, and a practical advantage may be taken of this fact when producing impressions upon a plate or examining bodies by means of a fluorescent screen."

The New York Herald July 25, 1896

TESLA ON X RAYS.

Believes Them To Be Moving Material Particles That Affect Tissue and Organs.

WILL APPLY CRUCIAL TESTS.

Radiations from the Bulb That Have an Effect, Sometimes Harmful, on Human Brain.

MAY INJURE HAIR AND EYES.

On Other Hand, Roentgen's Discovery May Possibly Be Used to Destroy Bacilli.

That Roentgen rays are moving material particles, having an appreciable effect on human tissues and organs, and that they may likely be used as a means to destroy disease bicilli, are conclusions that Nicola Tesla has arrived at as the result of his experiments during the past six months; but he awaits crucial tests before positively announcing his clusions as scientific facts.

Mr. Tesla was found in his laboratory. He was very busy, but he found time to answer the several vital questions put to him as to the effect of X rays on physical health and bacilli life.

MOVING MATERIAL PARTICLES.

"In my attempts to contribute my humble share to further knowledge of the properties of the Roentgen rays," Mr. Tesla said, "I am finding more and more evidence in support of the theory of moving material particles. It is not my intention, however, to advance just now any view as to the bearing of such a fact upon the present theory of light, but I merely seek to establish the fact of the existence of such material streams in so far as the isolated effects are concerned. I have already a great many indications of a 'bombardment' occurring outside of the bulb from which the rays emanate, and I am arranging some crucial tests, which I hope will be successful, and which will prove whether or not I am right in my conclusions.

"Now, if these material streams are impinging themselves against substances toward which they are directed it is natural that some effect should follow the contact. It is not unreasonable to say that organs and tissues may be affected. We often read in reports made by experimentalists that human hair has fallen out from the effect of frequent use of the rays, and I have myself noted that effect in my experiments.

"I have also noticed that, when working with highly strained bulbs, I frequently experience a sudden, and sometimes even painful, shock in the eye. Such shocks may occur so often that the eye gets inflamed, and one canno' be considered overcautious if he abstains from watching the bulb too closely. These shocks are to me further evidence of larger particles being thrown off from the bulb.

"If these conclusions, which seem to be forced on me by the experience coming from experiment, are correct, then it may be that the rays have an effect on bacilli. Indeed, Professor Roentgen himself has announced it as his firm belief that bacilli can be destroyed by the rays, and his experiments warrant his conclusion. Yet we must wait patiently to hear from those who are investigating in this direction before formulating scientific conclusions.

EFFECTS ON THE BRAIN.

"The theory of material particles," continued Mr. Tesla, "and the theory that the rays affect the human system are borne out by my own further experience in the laboratory here. By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep, and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of my head. An assistant experienced identically the same sensations as myself.

"Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body."

Discharge of an Electrified Body by Means of the Tesla Spark.

IT has been shown that a body charged with electricity may be discharged by means of the rays from a Röntgen bulb. I find, also, that an electrified body is rapidly discharged by the influence of a high-frequency spark, such as that produced by the Tesla apparatus. The discharging action was shown in this way. A high-frequency spark was produced between two rather blunt points, one inch apart in air, no bulb being used. A gold-leaf electroscope, placed far away from the influence of the spark, was used to test the electrical condition of the charged bodies—viz. a stick of sealing-wax and a rod of glass. The sealing-wax was rubbed, and the electroscope indicated that it was well charged. It was again rubbed, and then brought to within a foot of the points, and by means of a key in the battery circuit the Tesla coil was thrown into action for an instant. On testing the sealing-wax rod with the electroscope, it was found to be entirely discharged. A similar experiment was next made with a glass rod; the glass rod was entirely discharged by the Tesla spark. From a previous experiment, it was seen that the electrification of the rods was dissimilar. The influence, then, of the high-frequency spark is to discharge electricity of either sign.

FREDERICK J. SMITH.

Oxford, July 17.

CONSTRUCTION OF A TESLA-THOMSON HIGH FREQUENCY COIL.

BY PROF. A. F. MCKISSICK.

The following is a description of the construction of a Tesla-Thomson high frequency coil, large enough to give a five-inch spark and excite Röntgen ray tubes.

To excite the Tesla-Thomson coil, a high

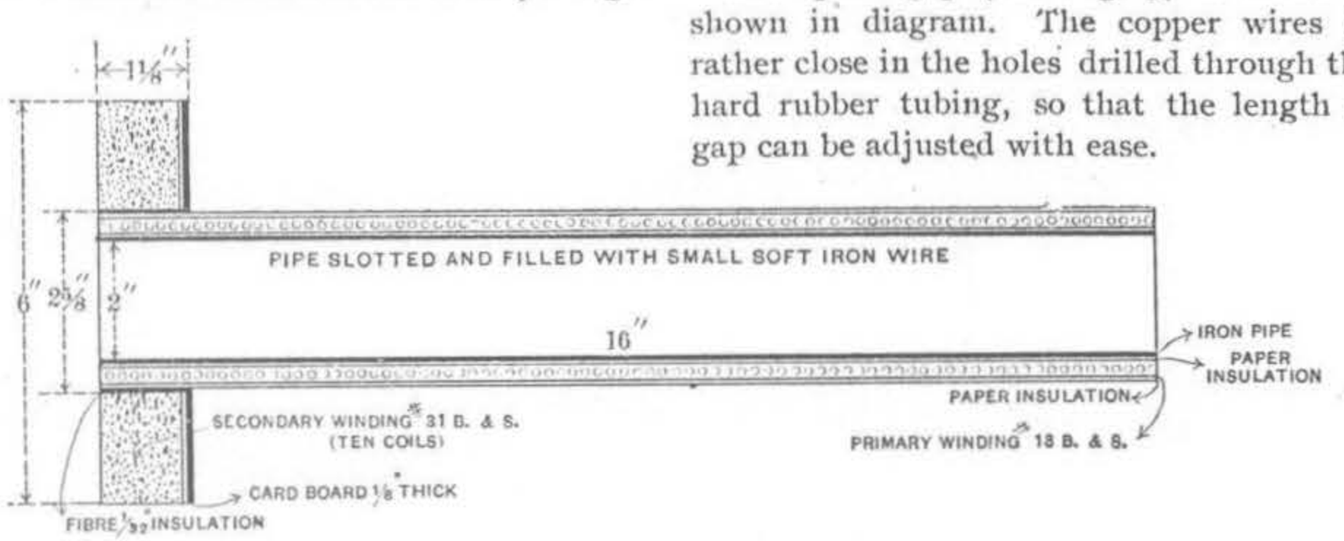

FIG. 1.—HIGH TENSION TRANSFORMER.

potential transformer of from 10,000 to 15,000 is necessary. The construction of this transformer will be first given. Fig. 1 gives a partial cross-section of the trans-

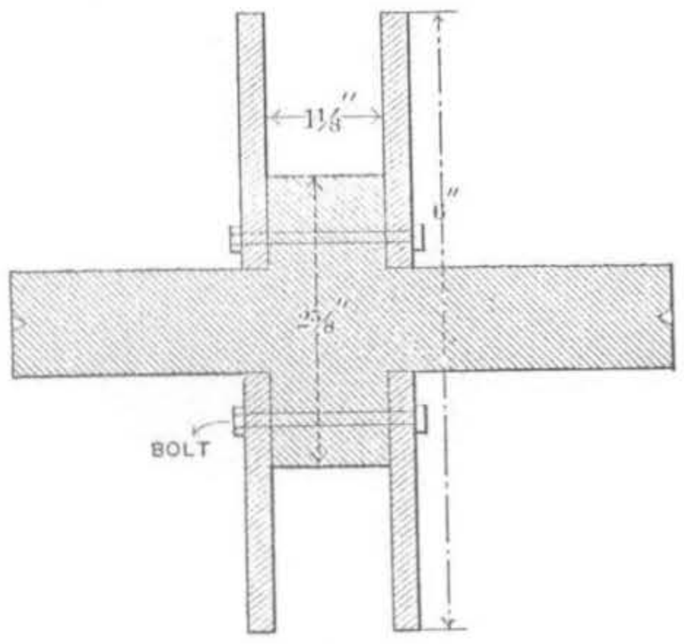

FIG. 2.—FORM FOR WINDING COILS.

former, which is made as follows: A two-inch iron pipe, sixteen inches long is slotted the whole length, either in a milling machine, planer or shaper. This slot need not be more than 1/16 in. in width. The pipe is then insulated with ordinary wrapping paper to an outside diameter of 2⅛ ins., shellac being freely used, and is then wound with No. 13 B. & S. double cotton-covered wire for its whole length (one layer). It is then covered with paper and shellaced until the outside diameter is 2⅝ ins.

The next step is to fill the pipe with soft iron wires, No. 16 B. & S., each wire being cut eighteen inches long. This completes the primary winding of the high tension transformer.

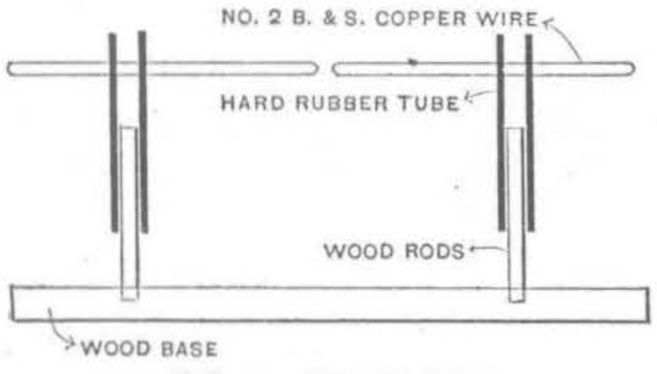

FIG. 3.—SPARK GAP.

The secondary winding of this transformer consists of ten coils wound in a form and thoroughly taped and insulated. This form is shown in Fig. 2, and can be easily made of wood. The wire is wound in this form, shellaced, removed, taped and baked. These coils are then slipped over the primary winding, between each coil being placed a disk of cardboard ⅛ in. thick, care being taken to connect the coils so that none will be in opposition.

The spark gap (see Fig. 3) is made as shown in diagram. The copper wires fit rather close in the holes drilled through the hard rubber tubing, so that the length of gap can be adjusted with ease.

The condenser is made of ordinary 10 in. × 12 in. window glass. A sheet of tin foil 8 ins. × 10 ins. is pasted on one side of the glass with shellac, leaving a margin of one inch.

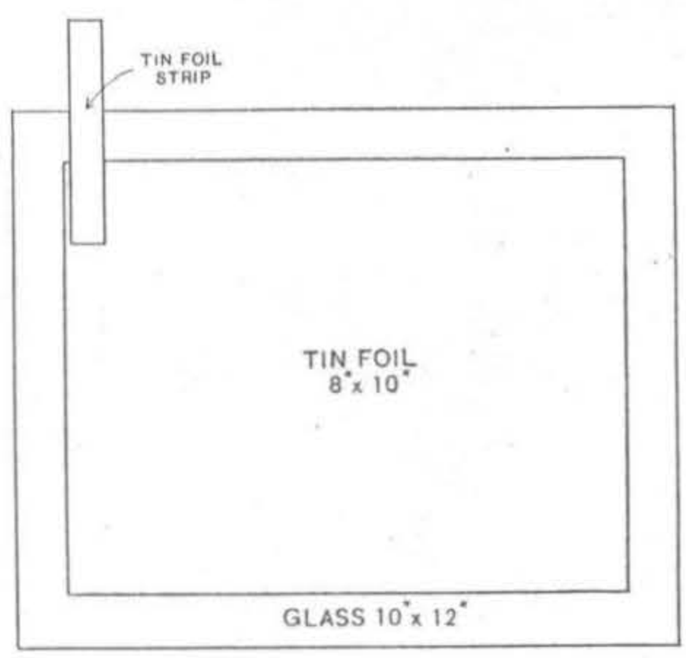

FIG. 4.—CONDENSER PLATE.

(See Fig. 4.) A strip of tin foil two inches wide is placed across one corner, this strip being placed alternately on each side. For each side of this condenser there should be fifteen plates.

To build this condenser proceed as follows: Place on a smooth surface a condenser plate with the connecting strip projecting on the right. On top of this plate place another piece of glass, 10 ins × 12 ins., that has no tin foil on it at all. Then place a condenser plate with the strip projecting on the left. Then a piece of glass without tin foil, and on top of this a condenser plate with the strip projecting on the right, and so on. This construction gives two thicknesses of glass between each sheet of tin foil, which is absolutely necessary.

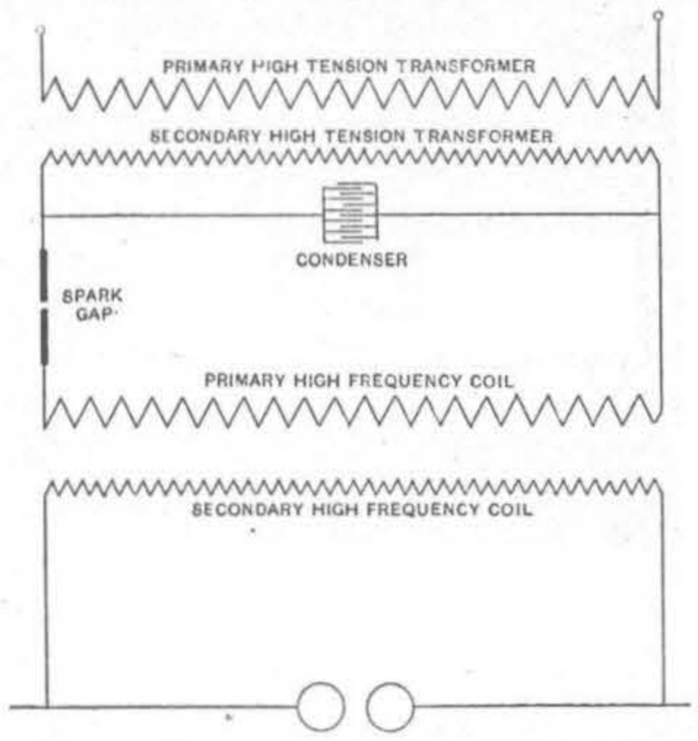

FIG. 6.—DIAGRAM OF CONNECTIONS.

The high frequency coil is made as follows: Wind an eight-inch paper cylinder eighteen inches long with No. 31 B. & S. double cotton-covered wire (or larger), leaving a margin at each end of about one inch. This is the secondary winding. The primary winding is placed on a twelve-inch paper cylinder eighteen inches long and consists of fourteen turns of four No. 8 B. & S. double cotton-covered wires in parallel. Each of these No. 8 wires is wound on separately, then the four ends at the beginning and ending are soldered together. Between wires of different polarity, as an extra precaution, two turns of cord are wound. The primary and secondary coils are then shellaced and baked. After being baked, the secondary coil is placed concentrically (see Fig. 5) inside the primary and the connections as shown in Fig. 6 then made.

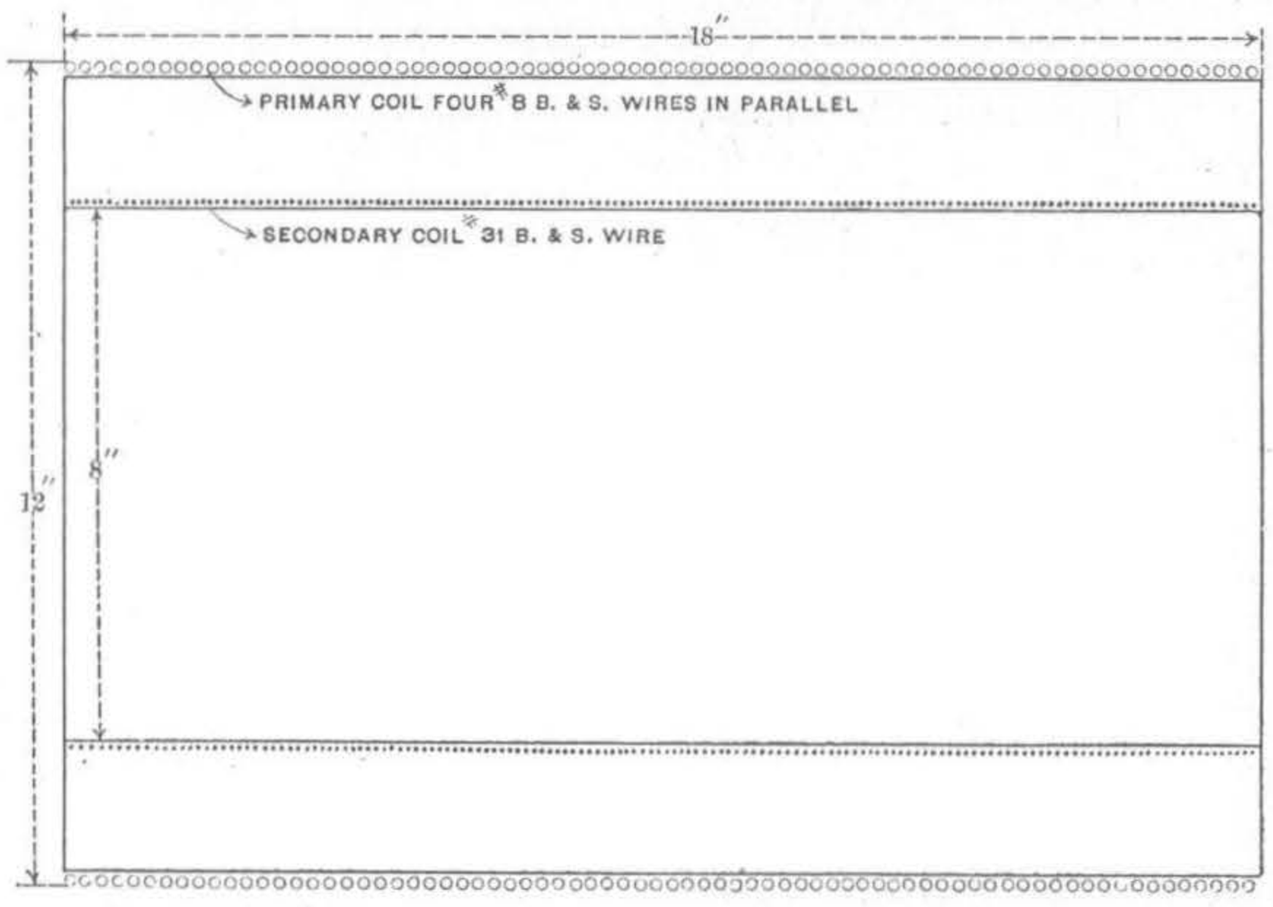

FIG. 5.—PRIMARY AND SECONDARY COILS OF HIGH FREQUENCY TRANSFORMER.

The primary of the high tension transformer must be excited with an alternating current. With a frequency of 60 cycles per second 50 volts will suffice, and for 125 cycles per second 100 volts. The length of the spark from the secondary of the high frequency coil will depend on the width of the "spark gap," consequently, in exciting a tube it is best to start with the "spark gap" very short, then gradually increase until the tube is properly excited. When the terminals of the secondary high frequency coil are separated farther than five inches, a spark will pass from the secondary to the primary of the high frequency coil. By the use of a good insulating oil a much longer spark can be obtained from the high frequency coil, but for exciting Röntgen ray tubes a five-inch spark will be sufficient.

AN interesting account of the first visit of Tesla to the plant of the Niagara Falls Power company is furnished by a special correspondent of the WESTERN ELECTRICIAN on another page in this issue. It is worthy careful perusal, and must of necessity attract much attention among the friends and admirers of the great investigator, as it presents his impressions of the greatest electric power equipment of the world. It was the first opportunity the visitor had of seeing in practical operation the special apparatus which he designed for the great generating station which put into practice the theories he had developed after years of careful study and experiment. It would be impossible to describe the sensation which such an impressionable mind as Tesla's must have experienced on first beholding in operation the system of development and transformation of the power of the great waterfall into electrical energy with which he had so much to do. That must be left to the reader's imagination. Our correspondent declares that Tesla was delighted with the manner in which his discoveries had been adapted to practical use by the engineers, and that he was particularly pleased with the successful operation of the transformers upon which he had spent so much time and thought and labor. He looks for still greater accomplishments in the electrical field. At present, he said, he was devoting all of his attention to the transmission problem, and he added that he would continue his study and experimental work in this direction until he had obtained results that would be satisfactory to him. Speaking of the project for transmitting power to Buffalo from the Niagara plant, Tesla said of the undertaking: "Its success is certain." Of the commercial feature of the question, he said that the power company could sell current in Buffalo at a much lower price than the present cost of power in that city. Altogether the visit was eminently satisfactory to the great inventor. He inspected the power plant "from top to bottom," as he expressed it, and pronounced it "the greatest and the best, the most thoroughly equipped in the world." He said that it came up to his expectations; in fact, surpassed them. "It is one of the wonders of this century!" he exclaimed. This view will find general acceptance. The world is greatly indebted to Nikola Tesla for his share in bringing about this accomplishment.

Nikola Tesla at Niagara Falls.

By Orrin E. Dunlap.

Nikola Tesla paid his first visit to the great electrical power plant of the Niagara Falls Power company on Sunday, July 19th. In the party with Tesla were George Westinghouse, Jr., president of the Westinghouse Electric & Manufacturing company of Pittsburg, and his son, H. H. Westinghouse; Thomas N. Ely of Philadelphia, superintendent of motive power of the Pennsylvania railroad, Commodore George W. Melville of Washington, chief engineer of the United States Navy; Edward D. Adams, president of the Cataract Construction company, and William B. Rankins, secretary of the company; Paul D. Cravath, counsel for the Westinghouse company, and George Urban, Jr., of Buffalo, president of the Cataract Power & Construction company of Buffalo, which company was organized recently to distribute the electric power in Buffalo.

Quite naturally, the event of Tesla's visit was one of importance, for never before had his eyes rested on this greatest of power plants. For four years he had refused to leave his work and visit the Falls, preferring to work out his theories and await the proper time to see them put into practical use and operation. Tesla was delighted with the manner in which his discoveries had been adapted to practical use by the engineers, and he unhesitatingly declared that there was no doubt of the success of the gigantic undertaking and that power would be transmitted to Buffalo without the least semblance of failure in any important detail. He was greatly interested in the working of the transformers invented by him, and the great electrician declared that they solved one of the most difficult and important problems in electrical science.

It is a well known fact that Tesla does not like to speak of himself. He will talk freely about electrical discoveries or inventions, but when his own are broached he modestly says that he prefers to say little about them.

"I do not like to speak of what I am doing or what I hope to do," said he. "It is enough to let others do that when what I have done is before the world. I am content to be in my workshop and to work day and night to discover something which we are looking for and which will assist the development of electricity as a great and universal power. The time will come when steam will not be used for commercial purposes. I am working to bring that about." This, then, is the present great ambition. He desires to see electricity fully occupy the power field.

"I came to Niagara Falls," said he, "to inspect the great power plant and because I thought the change would bring me needed rest. I have been for some time in poor health, almost worn out, and I am now trying to get away from my work for a brief spell and at the same time see the great results of electrical development within the last half dozen years. Those results have been wonderful, have far surpassed the expectations of the people generally, but they are what those who have made electricity their study for years and their life work have expected and have labored so hard to bring about. Yet scientists are not content and great wonders in the future development of electric power for many purposes are anticipated and are confidently expected by the great men in all countries who are trying to discover nature's secrets and to develop the things which God has placed within the reach of those who will seek that they may find."

"What do you think of the Niagara power plant, Mr. Tesla? Is it fully up to your ideas and expectations?"

It was this question that aroused the great electrician's enthusiasm. "Yes," said he; "it is all and more than I anticipated it would be. It is fully all that was promised. It is one of the wonders of this century. The power-producing plant of the Cataract Construction company is a marvel in its completeness and in its superiority of construction. When it shall be in full operation the results in many ways will be wonderful; will be surprising to those who have doubted that such things could be accomplished. In its entirety, in connection with the possibilities of the future, the plant and the prospect of future development in electrical science, and the more ordinary uses of electricity, are my ideals. They are what I have long anticipated and have labored, in an insignificant way, to contribute toward bringing about."

"What, in your judgment, will be the effect on Niagara Falls?"

"The first effects naturally will be to the advantage of Niagara Falls, and the falls will be the greatest reaper of benefits. The result of this great development of electric power will be that the falls and Buffalo will reach out their arms and will join each other and become one great city. United they will form the greatest city in the world."

"This is your first visit to the plant?"

"Yes, I came purposely to see it. I am somewhat interested in the working of some of the machinery. But, and it is a curious thing about me, I cannot stay about big machinery a great while. It affects me very much. The jar of the machinery curiously affects my spine and I cannot stand the strain."

"It is Mr. Tesla's two-phase system which is used," put in Secretary Rankine, who was standing by. "It is the new and great system of the two-phase alternating currents."

"What do you think of the transmission of electric power to Buffalo? Is it an assured undertaking?" Tesla was asked.

"Its success is certain. The transmission of electricity is one of the simplest of propositions. It is but the application of pronounced and accepted rules which are as firmly established as the air itself."

"Do you think the cost of electric power in Buffalo will be half, or lower, than the present cost of steam?"

"I do not know what is the cost of steam power in Buffalo."

"About $60 to $70," said Mr. Rankine.

"Well," continued Mr. Tesla, "the cost certainly will be much less than the cost of steam. The beauty of using electricity for industrial purposes is that you can use it without any loss. When you get done with your work you just shut it off until you want it again; therefore there is no appreciable percentage of loss except that in transmission. On the other hand you cannot use steam without loss. Steam must be kept up. That involves a loss of 20 per cent. at the start, which is continuous and must be counted as a fixed loss. No matter if steam were cheaper than electricity there would be a great saving in favor of electricity because of its adaptability, its freedom from smoke and dust and the fact that it may be shut off when it is not needed."

At this point Secretary Rankine advanced a piece of news. "Buffalo," said he, "will have its first installment of electric power by November. You may say that without fear of making any mistake. The first delivery will be about 1,000 horse power, all that we can give this fall. It will be the initial installment of the 10,000 horse power which we must furnish under our franchise within the ensuing year. The contract for the construction of the pole line will soon be let. The work will be pushed rapidly and Buffalo will find that the company will be faithful to all of its agreements."

In regard to the transmission of power Tesla continued: "It is cheaper to transmit electricity in large quantities than in small. The larger the force the less the loss in transmission. The loss in transmission of power to Buffalo, for instance, will be comparatively small because of the large quantity which Buffalo will receive."

Tesla was averse to speaking of his recent investigations of the vacuum electric lamp and telegraphy without the use of wires.

"I am not prepared to say anything now about those little schemes of mine," said Mr. Tesla. "They must stand aside for awhile. Just now I am devoting my time to the study and development of the transmission and insulation of electricity. Until I get these matters well worked out and obtain satisfactory results I shall do little else. I shall return to my laboratory in New York and continue my work, I am delighted with my trip to the Falls. I have been from top to bottom of the power plant. You may say it is the greatest and the best, the most thoroughly equipped in the world."

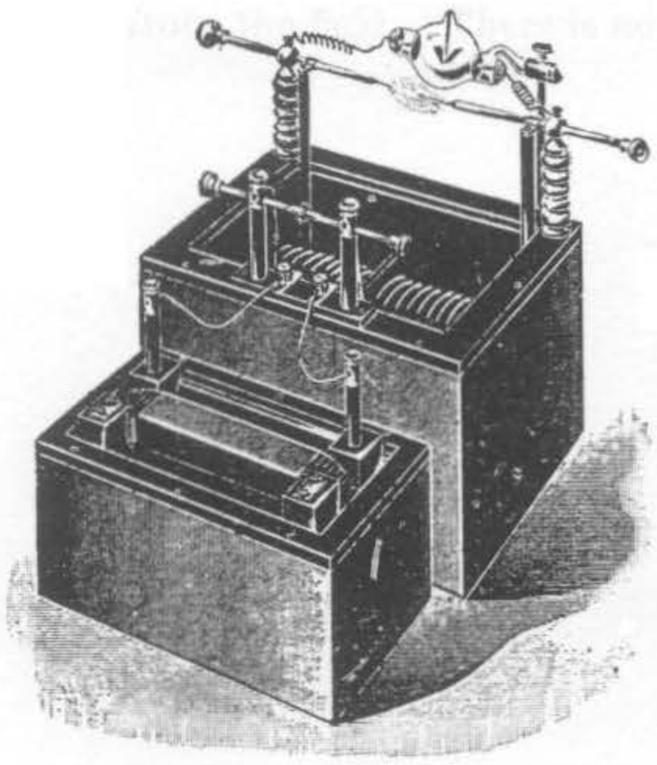

FIG. 1.—AN ENGLISH FORM OF TESLA APPARATUS.

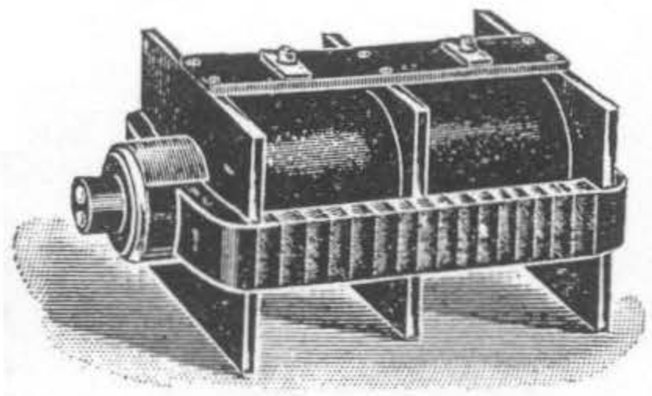

FIG. 2.—HIGH-TENSION TRANSFORMER.

An English Form of Tesla Apparatus for Radiography.

The accompanying illustrations show a form of Tesla apparatus which is being made by an English firm. The London *Electrical Review* describes this apparatus as follows:

Fig. 1 shows a complete Tesla apparatus, being patented by Mr. L. Miller, for obtaining high-tension oscillating discharges from the street electric light mains, where the current is alternating. The illustration is taken from a set of apparatus supplied to St. Bartholomew's Hospital for obtaining photographs of injured limbs, etc., by means of Roentgen rays. Messrs. Miller & Woods supply a standard set which gives a stream of sparks over more than a six-inch air gap. The set consists of a step-up transformer, Fig. 1, from 100 volts to about 6,000 volts, and taking the same current as two lamps of 16-candle-power each; a condenser, and a Tesla transformer to about 70,000 volts. The condenser discharges by rapid oscillations of current across the spark gap (shown in figure) through the primary thick wire winding of the Tesla coil. Induced currents are then set up in the inner thin wire secondary winding of the Tesla coil. These are led to the discharge rods and can be used to excite Roentgen rays in a single or double-focus tube as shown, or demonstrate the Tesla experiments. The boxes in which the above are contained are filled with mineral oil. Fig. 2 shows a high-tension transformer which can be used up to about 4,000 volts without oil. It is said to be a neat, compact form of transformer for exciting vacuum tubes, ozone generators, etc., and can readily be connected to the electric mains by means of a lamp-holder attached to a piece of flexible cord.

NICOLA TESLA, electrical expert and engineer, was recently shown a published statement which was telegraphed from Buffalo to the effect that he had discovered a method for successfully transmitting electricity long distances, and when asked as to the truth of it, replied: "Yes; I did state that electricity can be transmitted long distances upon a commercial basis over a distance of at least 500 miles. I will stake my reputation and my life upon it. I only qualify it by adding that the amount of power transmitted must be quite considerable."

TESLA ON THE NATURE OF THE ROENTGEN RAYS.

In our present issue we publish another important communication from Mr. Tesla in regard to the Roentgen rays. Mr. Tesla has worked ceaselessly, and in his articles, exclusively published in our columns, he has made most valuable contributions to the knowledge of this fascinating subject. His opinions carry the greater weight as they are supported by a mass of experimental evidence, and as his insight into many phenomena has proved to be true. What services has he not rendered to science and industry merely by his demonstrations of the action of air or gases in condensers and high-tension transformers! His present contribution is, in part, a summing up of the observations already made by him, and is particularly important in this, that it substantiates the ideas originally expressed by Professor Roentgen.

Mr. Tesla brings forward many convincing arguments to show that these rays consist of streams of matter in some primary condition, which is, to a certain extent, equivalent to saying that they are streams of ether into which the matter is dissolved by the violent impact.

There is thus opened up a wonderful possibility of transformation of matter into its primary constituents, never before contemplated or thought possible, and it is safe to say that a more absorbing subject for study and investigation could not be found in physical science.

DELETERIOUS EFFECTS OF X RAYS ON THE HUMAN BODY.

It seems that the wonderful effects of X rays have not all been learned. One of the newest of these takes the form of a physical effect upon the person who uses powerful X-ray apparatus for comparatively long periods at a time. Mr. H. D. Hawks, a graduate in the class of 1896, of Columbia College, has for the past few weeks been giving exhibitions in the vicinity of New York with an unusually powerful X-ray outfit. Mr. Hawks, during the afternoon and evening of each day for four days, was working around his apparatus for from two to three hours at a time. At the end of four days he was compelled to cease active work, owing to the physical effects of the X rays upon his body. The first thing Mr. Hawks noticed was a drying of the skin, to which he paid no attention, but after awhile it became so painful it was necessary to stop all operations. The hands began to swell and assumed the appearance of having a very deep sunburn. At the end of two weeks the skin all came off the hands. The knuckles were especially affected, they being the sorest part of the hand. Among other effects were the following: The growth of the finger nails was stopped and the hair on the skin that was exposed to the rays all dropped out, especially on the face and sides of the head. The hair at the temples has entirely disappeared, owing to the fact of Mr. Hawks having placed his head in close proximity to the tube to enable spectators to see the bones of the jaw. The eyes were quite bloodshot and the vision was considerably impaired. The eyelashes began to fall out and the lids to swell. The chest was also burned through the clothing, the burn resembling sunburn. Mr. Hawks's disabilities were such that he was compelled to suspend work for two weeks. He consulted physicians, who treated the case as one of parboiling.

To overcome these effects of the X rays, Mr. Hawks first tried covering his hand with vaseline and then putting a glove on, but the hand was at once burned again, the glove affording no protection whatever. The hand was finally protected by covering it with tin foil. Mr. Hawks coincides with Tesla's belief that X rays are practically minute material particles thrown off from the walls of the tube. The apparatus used was a 10-inch induction coil, manufactured by Ritchie & Son, of Brookline, Mass. The primary circuit was opened and closed by means of a rotary brake mounted on the shaft of a motor, there being 120 breaks a second. The tube used was a focusing tube, made by Emil Greiner, of New York.

Mr. Hawks has made a careful study of his case and has reached the conclusion that no other cause than his exposure to the X rays is responsible for his condition. His personal appearance certainly bears out his statement. The ELECTRICAL REVIEW will be glad to hear from any of its readers who have experienced similar effects, even in a lesser degree.

Roentgen Rays or Streams.

To the Editor of the Electrical Review:

In the original report of his epochal discoveries, Roentgen expressed his conviction that the phenomena he observed were due to certain novel disturbances in the ether. This opinion deserves to be considered the more as it was probably formed in the first enthusiasm over the revelations, when the mind of the discoverer was capable of a much deeper insight into the nature of things.

It was known since long ago that certain dark radiations, capable of penetrating opaque bodies, existed, and when the rectilinear propagation, the action on a fluorescent screen and on a sensitive film was noted, an obvious and unavoidable inference was that the new radiations were transverse vibrations, similar to those known as light. On the other hand, it was difficult to resist certain arguments in favor of the less popular theory of material particles, especially as, since the researches of Lennard, it has become very probable that material streams, resembling the cathodic, existed in free air. Furthermore, I myself have brought to notice the fact that similar material streams —which were subsequently, upon Roentgen's announcement, found capable of producing impressions on a sensitive film—were obtainable in free air, even without the employment of a vacuum bulb, simply by the use of very high potentials, suitable for imparting to the molecules of the air or other particles a sufficiently high velocity. In reality, such puffs or jets of particles are formed in the vicinity of every highly charged conductor, the potential of which is rapidly varying, and I have shown that, unless they are prevented, they are fatal to every condenser or high-potential transformer, no matter how thick the insulation. They also render practically valueless any estimate of the period of vibration of an electro-magnetic system by the usual mode of calculation or measurement in a static condition in all cases in which the potential is very high and the frequency excessive.

It is significant that, with these and other facts before him, Roentgen inclined to the conviction that the rays he discovered were longitudinal waves of ether.

After a long and careful investigation, with apparatus excellently suited for the purpose, capable of producing impressions at great distances, and after examining the results pointed out by other experimenters, I have come to the conclusion which I have already intimated in my former contributions to your esteemed journal, and which I now find courage to pronounce without hesitation, that the original hypothesis of Roentgen will be confirmed in two particulars: first, in regard to the longitudinal character of the disturbances; second, in regard to the medium concerned in their propagation. The present expression of my views is made solely for the purpose of preserving a faithful record of what, to my mind, appears to be the true interpretation of these new and important manifestations of energy.

Recent observations of some dark radiations from novel sources by Becquerel and others, and certain deductions of Helmholtz, seemingly applicable to the explanation of the peculiarities of the Roentgen rays, have given additional weight to the arguments on behalf of the theory of transverse vibrations, and accordingly this interpretation of the phenomena is held in favor. But this view is still of a purely speculative character, being, as it is at present, unsupported by any conclusive experiment. Contrarily, there is considerable experimental evidence that some matter is projected with great velocity from the bulbs, this matter being in all probability the only cause of the actions discovered by Roentgen.

There is but little doubt at present that a cathodic stream within a bulb is composed of small particles of matter, thrown off with great velocity from the electrode. The velocity probably attained is estimable, and fully accountable for the mechanical and heating effects produced by the impact against the wall or obstacle within the bulb. It is, furthermore, an accepted view that the projected lumps of matter act as inelastic bodies, similarly to ever so many small lead bullets. It can be easily shown that the velocity of the stream may be as much as 100 kilometers a second, or even more, at least in bulbs with a single electrode, in which the practicable vacua and potentials are much higher than in the ordinary bulbs with two electrodes. But, now, matter moving with such great velocity must surely penetrate great thicknesses of the obstruction in its path, if the laws of mechanical impact are at all applicable to a cathodic stream. I have presently so much familiarized myself with this view that, if I had no experimental evidence, I would not question the fact that some matter is projected through the thin wall of a vacuum tube. The exit from the latter is, however, the more likely to occur, as the lumps of matter must be shattered into still much smaller particles by the impact. From my experiments on reflection of the Roentgen rays, before reported, which, with powerful radiations, may be shown to exist under all angles of incidence, it appears that the lumps or molecules are indeed shattered into fragments or constituents so small as to make them lose entirely some physical properties possessed before the impact. Thus, the material composing the electrode, the wall of the bulb or obstruction of any kind placed within the latter, are of absolutely no consequence, except in so far as the intensity of the radiations is concerned. It also appears, as I have pointed out, that no further disintegration of the lumps is attendant upon a second impact. The matter composing the cathodic stream is, to all evidence, reduced to matter of some primary form, heretofore not known, as such velocities and such violent impacts have probably never been studied or even attained before these extraordinary manifestations were observed. Is it not possible that the very ether vortexes which, according to Lord Kelvin's ideal theory, compose the lumps, are dissolved, and that in the Roentgen phenomena we may witness a transformation of ordinary matter into ether? It is in this sense that, I think, Roentgen's first hypothesis will be confirmed. In such case there can be, of course, no question of waves other than the longitudinal assumed by him, only, in my opinion, the frequency must be very small—that of the electro-magnetic vibrating system—generally not more than a few millions a second. If such process of transformation does take place, it will be difficult, if not impossible, to determine the amount of energy represented in the radiations, and the statement that this amount is very small should be received with some caution.

As to the rays exhaustively studied by Lennard, which have proved to be the nucleus of these great realizations, I hold them to be true cathodic streams, projected through the wall of the tube. Their deflectibility by a magnet shows to my mind simply that they differ but little from those within the bulb. The lumps of matter are probably large and the velocity small as compared with that of the Roentgen rays. They should, however be capable in a minor degree of all the actions of the latter. These actions I consider to be purely mechanical and obtainable by other means. So, for instance, I think that if a gun loaded with mercury were fired through a thin board, the projected mercury vapor would cast a shadow of an object upon a film made especially sensitive to mechanical impact, or upon a screen of material capable of being rendered fluorescent by such impact.

The following observations made by myself and others speak more or less for the existence of the streams of matter.

I—PHENOMENA OF EXHAUSTION.

On this subject I have expressed myself on another occasion. It is only necessary to once more point out that the effect observed by me should not be confounded with that noted by Spottiswoode and Crookes. I explain the latter phenomenon as follows: The first fluorescence appearing when the current is turned on, is due to some organic matter almost always introduced in the bulb in the process of manufacture. A minute layer of such matter on the wall produces invariably this first fluorescence, and the latter never takes place when the bulb has been exhausted under application of a high degree of heat or when the organic matter is otherwise destroyed. Upon the disappearance of the first fluorescence the rarefaction increases slowly, this being a necessary result of particles being projected from the electrode and fastening themselves upon the wall. These particles absorb a large portion of the residual gas. The latter can be again freed by the application of heat to the bulb or otherwise. So much of the effects observed by these investigators. In the instance observed by myself, there must be actual expulsion of matter, and for this speak following facts: (a) the exhaustion is quicker when the glass is thin; (b) when the potential is higher; (c) when the discharges are more sudden; (d) when there is no obstruction within the bulb; (e) the exhaustion takes place quickest with an aluminum or platinum electrode, the former metal giving particles moving with greatest velocity, the latter particles of greatest weight; (f) the glass wall, when softened by the heat, does not collapse, but bulges outwardly; (g) the exhaustion takes place, in some cases, even if a small perceptible hole is pierced through the glass; (h) all causes tending to impart a greater velocity to the particles hasten the process of exhaustion.

II—RELATION BETWEEN OPACITY AND DENSITY.

The important fact pointed out early by Roentgen and confirmed by subsequent research, namely, that a body is the more opaque to the rays the denser it is, can not be explained as satisfactorily under any other assumption as that of the rays being streams of matter, in which case such simple relation between opacity and density would necessarily exist. This relation is the more important in its bearing upon the nature of the rays, as it does not at all exist in light-giving vibrations, and should consequently not be found to so marked a degree and under *all conditions with vibrations*, presumably similar to and approximating in frequency the light vibrations.

III—DEFINITION OF SHADOWS ON SCREEN OR PLATE.

When taking impressions or observing shadows while varying the intensity of the radiations, but maintaining all other conditions as nearly as possible alike, it is found that the employment of more intense radiations secures little, if any, advantage, as regards the definition of the details. At first it was thought that all there was needed was to produce very powerful rays. But the experience was disappointing, for, while I succeeded in producing rays capable of impressing a plate at distances of certainly not less than 30 metres, I obtained but slightly better results. There was one advantage in using such intense rays, and this was that the plate could be further removed from the source, and consequently a better shadow was obtained. But otherwise nothing to speak of was gained. The screen in the dark box would be at times rendered so bright as to allow reading at some distance plainly, but the shadow was not more distinct for all that. In fact, often a very strong radiation gave a poorer impression than a weak one. Now, a fact which I have repeatedly observed and to which I attach great importance in this connection, is the following: When taking impressions at a small distance with a tube giving very intense rays, no shadow, unless a scarcely perceptible one, is obtained. Thus, for instance, the flesh and bones of the hand appear equally transparent. Increasing presently gradually the distance, it is found that the bones cast a shadow, while the flesh leaves no impression. The distance still increased, the shadow of the flesh appears, while that of the bones grows deeper, and in this neighborhood a place can be found at which the definition of the shadow is clearest. If the distance is still further continually increased, the detail is lost, and finally only a vague shadow is perceptible, showing apparently the outlines of the hand.

This often-noted fact disagrees entirely with any theory of transverse vibrations, but can be easily explained on the assumption of material streams. When the hand is near and the velocity of the stream of particles very great, both bone and flesh are easily penetrated, and the effect due to the difference in the retardation of the particles passing through the heterogeneous parts can not be observed. The screen can fluoresce only up to a certain limited intensity, and the film can be affected only to a certain small degree. When the distance is increased, or, what is equivalent, when the intensity of the radiation is reduced, the more resisting bones begin to throw the shadow first. Upon a further increase of the distance the flesh begins likewise to stop enough of the particles to leave a trace on the screen. But in all cases, at a certain distance, manifestly that which under the conditions of the experiment gives the greatest difference in the trajectories of the particles within *the range perceptible on the screen or film,* the clearest shadow is secured.

IV—THE RAYS ARE ALL OF ONE KIND.

The preceding explains the apparent existence of rays of different kind; that is, of different rates of vibration, as it is asserted. In my opinion, the velocity and possibly the size of the particles both are different, and this fully accounts for the discordant results obtained in regard to the transparency of various bodies to these rays. I found, for example, in many cases that aluminum was less transparent than glass, and in some instances brass appeared to be very transparent as compared with other metallic bodies. Such observations showed that it was necessary, in making the comparison, to take rigorously equal thicknesses of the bodies and

(Concluded on page 83.)

ROENTGEN RAYS OR STREAMS.

(*Concluded from page 79.*)

place them as closely together as possible. They also showed the fallacy of comparing results obtained with different bulbs.

V—ACTION ON THE FILMS.

Many experiments with films of different thicknesses show that decidedly more detail is obtainable with a thick film than with a thin one. This appears to me to be a further evidence in support of the above views, as the result can be easily explained when considering the preceding remarks.

VI — THE BEHAVIOR OF VARIOUS BODIES IN REFLECTING THE RAYS,

on which I have previously dwelt, will, if verified by other experimenters, leave no room for a doubt that the radiations are streams of some matter, or possibly of ether, as before observed.

VII—THE ENTIRE ABSENCE OF REFRACTION

and other features possessed by the light waves has, since Roentgen's announcement, not yet been satisfactorily explained. A trace at least of such an effect would be found if the rays were transverse vibrations.

VIII—THE DISCHARGE OF CONDUCTORS

by the rays shows, in so far as I have been able to follow the researches of others, that the electrical charge is taken off by the bodily carriers. It is also found that the opacity plays an important part, and the observations are mostly in accord with the above views.

IX—THE SOURCE OF THE RAYS

is, I find, always the place of the first impact of the cathodic stream, a second impact producing little or no rays. This fact would be difficult to account for unless streams of matter are assumed to exist.

X—SHADOWS IN SPACE OUTSIDE OF THE BULB.

An almost crucial test of the existence of material streams is afforded by the formation of shadows in space at a distance from the bulb, to which I have called attention quite recently. I will presently refer to my preceding communication on this subject, and will only point out that such shadows could not be formed under the conditions described, except by streams of matter.

XI—ALL BODIES ARE TRANSPARENT TO VERY STRONG RAYS.

Experiments establish this fact beyond any doubt. With very intense radiations, I obtain, easily, impressions through what may be considered a great thickness of any metal. It is impossible to explain this on any theory of transverse vibrations. We can show how one or other body might allow the rays to pass through, but such explanations are not applicable to *all* bodies without exception. On the contrary, assuming material streams, such a result is unavoidable.

A great many other observations and facts might be added to the above, as further evidence in support of the above views. I have noted certain peculiarities of bodies obstructing a cathodic stream within the bulb. I have observed that the same rays are produced at all degrees of exhaustion and using bodies of vastly different physical properties, and have found a number of features in regard to the pressure, the vacuum, the residual gas, the material of the electrode, etc., all of which observations are more or less in accord with what I have stated before. I hope, however, that there is enough in the present lines to enlist the attention of others.

NIKOLA TESLA.

New York, August 11, 1896.

ROENTGEN RAYS ARE MATERIAL.

So Says Nikola Tesla After an Investigation That Confirms His Long Standing Belief.

THE MATTER CAN BE FELT.

Particles Bombard the Tube and Act as Inelastic Bodies Similar to Small Lead Bullets.

MOVE AT GREAT VELOCITY.

The Roentgen rays—the wonderful X rays, as commonly called—which have astonished the world by bringing light out of dark places, even illuminating the human body, are now declared to be material particles by no less an authority than Nikola Tesla.

Mr. Tesla has been led to take this view for some time from the results of experiments which he has been conducting in his laboratory, as told by the HERALD after an interview with him. But now he comes forward without hesitation and says that the electrical conditions within the tube from which the rays issue produce absolute particles. They are material as cannon balls; infinitesimal and attenuated, it is true, but actual material which bombard the glass and any object which may come in line with their motion. And this motion is no insignificant thing, and would make the most rapid moving cannon ball appear to stand still, for Mr. Tesla says his experiments show them to move at a velocity of not less than sixty-two miles a second. In the measurements he uses he calls it "100 kilometres a second."

Mr. Tesla further says he can feel the effects of these particles striking against his eye, and has noted the sensation produced when they come in contact with his brain.

MR. TESLA'S DECLARATION.

Mr. Tesla makes public his conclusions in relation to the Roentgen rays in a letter to the Electrical Review of this week, in which—after referring to Professor Roentgen's theory that the rays were longitudinal waves of ether—he says:—

"After a long and careful investigation with apparatus excellently suited for the purpose, capable of producing impressions at great distances, and after examining the results pointed out by other experimenters, I have come to the conclusion, which I now find courage to pronounce without hesitation, that the original hypothesis of Roentgen will be confirmed in two particulars—first, in regard to the longitudinal character of the disturbances; second, in regard to the medium concerned in their propagation.

"There is but little doubt at present that a cathodic stream within a bulb is composed of small particles of matter, thrown off with great velocity from the electrode. The velocity probably attained is estimable, and fully accountable for the mechanical and heating effects produced by the impact against the wall or obstacle within the bulb. It is, furthermore, an accepted view that the projected lumps of matter act as inelastic bodies, similarly to ever so many small lead bullets. It can be easily shown that the velocity of the stream may be as much as one hundred kilometres a second, or even more.

SHATTERED INTO FRAGMENTS.

"But, now, matter moving with such great velocity must surely penetrate great thicknesses of the obstruction in its path, if the laws of mechanical impact are at all applicable to a cathodic stream. I have presently so much familiarized myself with this view that, if I had no experimental evidence, I would not question the fact that some matter is projected through the thin wall of a vacuum tube. The exit from the latter is, however, the more likely to occur, as the lumps of matter must be shattered into still much smaller particles by the impact.

"From my experiments it appears that the lumps or molecules are indeed shattered into fragments or constituents so small as to make them lose entirely some physical properties possessed before the impact.

MATTER TURNED TO ETHER.

"The matter composing the cathode stream is," continues Mr. Tesla in his letter, "to all evidence, reduced to matter of some primary form, heretofore not known, as such velocities and such violent impacts have probably never been studied or even attained before these extraordinary manifestations were observed. Is it not possible that the very ether vortexes which, according to Lord Kelvin's ideal theory, compose the lumps, are dissolved, and that in the Roentgen phenomena we may witness a transformation of ordinary matter into ether? It is in this sense that, I think, Roentgen's first hypothesis will be confirmed.

"The important fact pointed out early by Roentgen and confirmed by subsequent research—namely, that a body is the more apoque to the rays the denser it is—cannot be explained as satisfactorily under any other assumption as that of the rays being streams of matter, in which case such simple relation between opacity and density would necessarily exist. This relation is the more important in its bearing upon the nature of the rays, as it does not at all exist in lightgiving vibrations, and should consequently not be found to so marked a degree and under all conditions with vibrations, presumably similar to and approximating in frequency the light vibrations.

"An almost crucial test of the existence of material streams is afforded by the formation of shadows in space at a distance from the bulb. Such shadows could not be formed under the conditions described, except by streams of matter."

Nikola Tesla and Matrimony.

Those who are acquainted with the History of Socrates must have read how, upon his making a discourse concerning Love, he pressed his point with so much success that all the bachelors in his audience took the opportunity of getting married on the first occasion, and all the married men immediately took horse and galloped home to their wives. We think that it is rather a pity that Mr. Tesla did not hear Socrates on this subject for his own good, though for the good of science in general we much prefer that he should be reminded of it a score of centuries or so later. According to a New York daily paper, Nikola Tesla is a disciple of the Baconian theory, that the man who marries gives hostages to fortune. "I do not believe," he says, "that an inventor should marry, because he has so intense a nature and so much in it of wild passionate qualities that in giving himself to a woman he might love, he would give everything, and so take everything from his chosen field." It can readily be imagined with what reluctance Mr. Tesla would allow his views on this important question to be heralded broadcast to the world, but in doing so he is doubtless actuated by a sense of duty to his fellow inventors, and "simple duty hath no place for fear." Those of us who had the pleasure, a short time ago, of meeting this gentle, unassuming and clever man, can hardly reconcile our views of him as a woman-hater; rather we would interpret this information concerning him as representing him to be not a woman-hater so much as a devotee of science. If he were the former we should feel disposed to remind him that it is very usual for those who have been severe upon marriage in some part or other of their lives, to enter into the Fraternity of Benedicts which they have ridiculed, and to see their raillery return upon their own heads. Marriage, which is a blessing to another man falls upon such an one as a judgment. Congreve's "Old Bachelor" is a literary example of this kind, and Hymen takes his revenge in kind on those who turn his mysteries into ridicule. Mr. Tesla is yet a young man, and doubtless he will be the first to admit that he has much to learn. Possibly his immersion in the deep seas of pure science have so far flooded out from his experience, that emotional life, which, after all, is the only part of life which is worth living. We are not going to take up the cudgels on behalf of matrimony, neither are we going to enlist the resources of our memory in discovering great inventors who caught inspiration and obtained zest for their work, and encouragement to persevere unto the end by associating their lives with women whom they really loved. The history of scientific development is full of such instances, and, if Mr. Tesla is unaware of them, it is only another illustration of the tremendous concentration which he brings to the matters he may have on hand to the entire exclusion of everything else which is interesting in the world. To turn from pathos to bathos, one would have thought that the material advantages, which to many orders of mind is associated with the idea of wife, would have appealed to him when he received, in the course of one of his experiments, a shock of three and a half million volts. It is said that this shock, entering his body above the shoulder, signalised its departure by leaving a hole in his sock. Being a bachelor, it may be presumed that he did not have anyone to mend it, but if he had been of a practically reflective turn of mind, it ought to have occurred to him that matrimony did present some material advantages. Of course Mr. Tesla may be quite invulnerable to Cupid's shafts, but somehow or other we doubt it. We are great admirers of him and his work, and we give him credit for good hard sense, and we do not think he is like the Frenchman who excused his bachelorhood on the grounds that he was "one butterfly zat fly from flower to flower and sip ze honey;" the very fact of his being such a devotee to his science proves that his nature is a very intense one. We have faith enough in women to believe that his fate will come, and that some one will be found who is not only a match for his intensity in all respects, but who will tax his inventive genius to the utmost; for example, in trying to explain where he was at 2 o'clock some night when she had gone to his laboratory to bring him home, and found it dark, although he had told her he was going to "stay down town to work to-night." We are afraid that Mr. Tesla has been studying *Punch*, whose well-known advice about getting married is a household word. Or possibly he may remember Æsop's Fables: the frogs there were extremely wise; they had a mind for some water, but they knew they would have to go down a deep well for it, from which it would be impossible to get out, and so they elected to hop round the edge of the well and contemplate it without committing themselves. Or again, Mr. Tesla may remember that old saying that "he who marries a wife may possibly take an eel by the tail." Whatever may be the cause of the abnormal emotional condition in which this distinguished scientist finds himself, we hope that it will soon be removed, for we are convinced that science in general, and Mr. Tesla in particular, will be all the richer when he gets married.

DISCHARGE OF AN ELECTRIFIED BODY BY MEANS OF THE TESLA SPARK.

In a communication to "Nature" Mr. Frederic J. Smith states that it has been shown that a body charged with electricity may be discharged by means of the rays from a Röntgen bulb. "I find, also, that an electrified body is rapidly discharged by the influence of a high-frequency spark, such as that produced by the Tesla apparatus. The discharging action was shown in this way. A high-frequency spark was produced between two rather blunt points, one inch apart in air, no bulb being used. A gold-leaf electroscope, placed far away from the influence of the spark, was used to test the electrical condition of the charged bodies—viz., a stick of sealing-wax and a rod of glass. The sealing-wax was rubbed, and the electroscope indicated that it was well charged. It was again rubbed, and then brought to within a foot of the points, and by means of a key in the battery circuit the Tesla coil was thrown into action for an instant. On testing the sealing-wax rod with the electroscope, it was found to be entirely discharged. A similar experiment was next made with a glass rod; the glass rod was entirely discharged by the Tesla spark. From a previous experiment, it was seen that the electrification of the rods was dissimilar. The influence, then, of the high-frequency spark is to discharge electricity of either sign."

NIKOLA TESLA AT NIAGARA FALLS.

Mr. Orrin E. Dunlap, in the *Western Electrician*, says that Nikola Tesla paid his first visit to the great electrical power plant of the Niagara Falls Power Company on Sunday, July 19th. In the party with Tesla were George Westinghouse, jun., president of the Westinghouse Electric and Manufacturing Company, of Pittsburg, and his son, H. H. Westinghouse; Thomas N. Ely, of Philadelphia, superintendent of motive power of the Pennsylvania Railroad; Commodore George W. Melville, of Washington, chief engineer of the United States Navy; Edward D. Adams, president of the Cataract Construction Company, and William B. Rankine, secretary of the company; Paul D. Cravath, counsel for the Westinghouse Company; and George Urban, jun., of Buffalo, president of the Cataract Power and Construction Company, of Buffalo, which company was organised recently to distribute the electric power in Buffalo.

Quite naturally, the event of Tesla's visit was one of importance, for never before had his eyes rested on this greatest of power plants. For four years he had refused to leave his work and visit the Falls, preferring to work out his theories and await the proper time to see them put into practical use and operation. Tesla was delighted with the manner in which his discoveries had been adapted to practical use by the engineers, and he unhesitatingly declared that there was no doubt of the success of the gigantic undertaking, and that power would be transmitted to Buffalo without the least semblance of failure in any important detail. He was greatly interested in the working of the transformers invented by

him, and the great electrician declared that they solved one of the most difficult and important problems in electrical science.

It is a well known fact that Tesla does not like to speak of himself. He will talk freely about electrical discoveries or inventions, but when his own are broached he modestly says that he prefers to say little about them.

"I do not like to speak of what I am doing or what I hope to do," said he. "It is enough to let others do that when what I have done is before the world. I am content to be in my workshop and to work day and night to discover something which we are looking for, and which will assist the development of electricity as a great and universal power. The time will come when steam will not be used for commercial purposes. I am working to bring that about." This, then, is the present great ambition. He desires to see electricity fully occupy the power field.

"I came to Niagara Falls," said he, "to inspect the great power plant, and because I thought the change would bring me needed rest. I have been for some time in poor health, almost worn out, and I am now trying to get away from my work for a brief spell, and at the same time see the great results of electrical development within the last half dozen years. Those results have been wonderful, have far surpassed the expectations of the people generally, but they are what those who have made electricity their study for years and their life work have expected, and have laboured so hard to bring about. Yet scientists are not content, and great wonders in the future development of electric power for many purposes are anticipated, and are confidently expected, by the great men in all countries who are trying to discover Nature's secrets, and to develop the things which God has placed within the reach of those who will seek that they may find."

"What do you think of the Niagara power plant, Mr. Tesla? Is it fully up to your ideas and expectations?"

It was this question that aroused the great electrician's enthusiasm. "Yes," said he; "it is all and more than I anticipated it would be. It is fully all that was promised. It is one of the wonders of this century. The power-producing plant of the Cataract Construction Company is a marvel in its completeness and in its superiority of construction. When it shall be in full operation the results, in many ways, will be wonderful; will be surprising to those who have doubted that such things could be accomplished. In its entirety, in connection with the possibilities of the future, the plant, and the prospect of future development in electrical science, and the more ordinary uses of electricity, are my ideals. They are what I have long anticipated, and have laboured, in an insignificant way, to contribute toward bringing about."

"What, in your judgment, will be the effect on Niagara Falls?"

"The first effects naturally will be to the advantage of Niagara Falls, and the falls will be the greatest reaper of benefits. The result of this great development of electric power will be that the Falls and Buffalo will reach out their arms, and will join each other, and become one great city. United, they will form the greatest city in the world."

"This is your first visit to the plant?"

"Yes; I came purposely to see it. I am somewhat interested in the working of some of the machinery. But, and it is a curious thing about me, I cannot stay about big machinery a great while. It affects me very much. The jar of the machinery curiously affects my spine, and I cannot stand the strain."

"It is Mr. Tesla's two-phase system which is used," put in Secretary Rankine, who was standing by. "It is the new and great system of the two-phase alternating currents."

"What do you think of the transmission of electric power to Buffalo? Is it an assured undertaking?" Tesla was asked.

"Its success is certain. The transmission of electricity is one of the simplest of propositions. It is but the application of pronounced and accepted rules which are as firmly established as the air itself."

"Do you think the cost of electric power in Buffalo will be half, or lower than the present cost of steam?"

"I do not know what is the cost of steam power in Buffalo."

"About $60 to $70," said Mr. Rankine.

"Well," continued Mr. Tesla, "the cost certainly will be much less than the cost of steam. The beauty of using electricity for industrial purposes is that you can use it without any loss. When you get done with your work, you just shut it off until you want it again; therefore there is no appreciable percentage of loss, except that in transmission. On the other hand, you cannot use steam without loss. Steam must be kept up. That involves a loss of 20 per cent. at the start, which is continuous, and must be counted as a fixed loss. No matter if steam were cheaper than electricity, there would be a great saving in favour of electricity, because of its adaptability, its freedom from smoke and dust, and the fact that it may be shut off when it is not needed."

At this point Secretary Rankine advanced a piece of news. "Buffalo," said he, "will have its first instalment of electric power by November. You may say that without fear of making any mistake. The first delivery will be about 1,000 horse power, all that we can give this fall. It will be the initial instalment of the 10,000 horse power which we must furnish under our franchise within the ensuing year. The contract for the construction of the pole line will soon be let. The work will be pushed rapidly, and Buffalo will find that the company will be faithful to all of its agreements."

In regard to the transmission of power, Tesla continued: "It is cheaper to transmit electricity in large quantities than in small. The larger the force the less the loss in transmission. The loss in transmission of power to Buffalo, for instance, will be comparatively small becau e of the large quantity which Buffalo will receive."

Tesla was averse to speaking of his recent investigations of the vacuum electric lamp and telegraphy without the use of wires.

"I am not prepared to say anything now about those little schemes of mine," said Mr. Tesla. "They must stand aside for awhile. Just now I am devoting my time to the study and development of the transmission and insulation of electricity. Until I get these matters well worked out, and obtain satisfactory results, I shall do little else. I shall return to my laboratory in New York and continue my work. I am delighted with my trip to the Falls. I have been from top to bottom of the power plant. You may say it is the greatest and the best, the most thoroughly equipped in the world."

NICOLA TESLA ON FAR SEEING.

The Inventor Talks Interestingly on the Transmission of Sight by Wire.

HAS A PRACTICABLE SCHEME.

Will Not Tell Exactly What It Is, Lest Ill Be Caused by False Impressions.

DIFFICULT AND FASCINATING.

He Draws a Captivating Picture of the Pleasures of the Imagination.

THERE is a subject which has exercised the imagination, excited the ambition and damped over and over again the ardor of the genius of invention for hundreds of years.

It is that of "seeing beyond the limits of sight."

Long distance speaking and long distance hearing have been accomplished long ago, and are to-day the common property of all. But to be able to see the person in Chicago, San Francisco, London or Hong Kong, with whom one speaks—that has not yet been made possible. Many scientists have declared the feat possible. Many scientists have tried to solve the problem. Not one has yet succeeded. All agree that when the solution is arrived at it will mean a revolution in the world's conditions.

I found Mr. Nicola Tesla in his laboratory yesterday, and propounded to him that difficult question about photography by electricity. He was, for once, in a communicative condition of mind; for, be it well understood, these inventors are generally so absorbed in their projects that, forsooth, they have not even time to speak to a newspaper man! But yesterday I was fortunate, and here is what Tesla said:—

Mr. Tesla's Views.

"This problem of transmitting sight by wires or otherwise to any distance is as difficult as it is fascinating. It must not be compared as to its technical difficulties with the transmission of pictures or even colors by such means. These are comparatively easy tasks.

"The solution of this problem has been attempted very many times, and more recently a further stimulus to research in this direction has been given by the magnificent inventions of Alexander Graham Bell, of the telephone and photophone. As soon as it became possible to transmit the strains of an entire opera over a wire the mind jumped immediately to the conclusion that seeing by similar methods will also soon become an accomplished fact. This appeared the more reasonable, as Bell succeeded in transmitting speech through the medium of no more than a ray of light. The activity in this direction has not abated, but, on the contrary, has increased, especially since we have learned more about the nature of light through the discoveries of Heinrich Hertz.

"Notwithstanding this, I have not found a single idea or experiment recorded which, in my estimation, would have even the faintest chance of success. The old fact, known to the ancients, that one can see through a hollow wire, has been more firmly established—that's all. This may appear to be a strong statement, but so far as actual accomplishment is concerned it is true. Many schemes have been proposed, but it was mostly a case of a hollow wire or a hollow project. Still, the task is not to be considered hopeless. On the contrary, in all probability individual investigators have found more or less rational solutions of the problem, only the difficulties to be overcome are enormous and the realization is still far, far off.

"I could hardly name two, or perhaps three, other problems or lines of investigation which have taxed my own powers of thinking as much as this. And yet, while in these other lines I have considerably realized, as regards this problem of transmitting sight I am still very far from positive demonstration by experiment. You should not infer from this that all my efforts to find a solution have been futile. Only experience has made me more exacting, and even pessimistic, as to the final carrying out of my ideas, while, I am happy to say, I have remained as optimistic as I ever was in their first conception. Very often during the day I conceive ideas which give me pleasure and hope, but in the calm retirement of the night, when things appear to me more as they are, my practical sense deals mercilessly with the projects I have formed.

"As a rule, all is rejected, and I realize with sorrow that the day has been spent in vain. But the next day the imagination starts off again, nothing the worse for the punishment. After going on for many years this constant effort of building and again destroying no doubt cripples the powers of execution, but it develops very much the analytical and critical faculties. You may tire yourself out repeatedly by overcoming an imaginary danger, but you become more expert in finding means of escape and prepared to meet any calamity. So, in investigation, one becomes distrustful of the beauties of the ideas as they first present themselves, and particularly apprehensive of error.

Importance of Certitude.

"It is one of the most important considerations for every worker to render himself continuously an account of the degree of certitude, when, either going from known facts, he systematically seeks to attain some novel result, or when, conversely, beginning from an abstract idea, he endeavors to reach its realization. Perhaps it is useful to give an illustration to this effect. There is:—

"First—The absolute certitude or truth which we always strive for, but never can reach.

"Second—There is the certitude of physical facts which we arrive at through our senses and which depends on the precision of the latter.

"Third—There is the experimental demonstration, less certain than the existence of the physical facts themselves, as it contains elements of uncertainty in the features of the experiment.

"Fourth—There is the logical inference or conclusion from physical facts, less certain than the experiment, as it lacks the tangible evidence of the latter.

"Fifth—There is mathematical demonstration, less certain, again, than mere logical conclusion, as it carries with itself possible errors or mistakes in methods and symbols.

"Sixth—There is the accurate estimate from some positive facts by experiment, logical conclusion, or calculation.

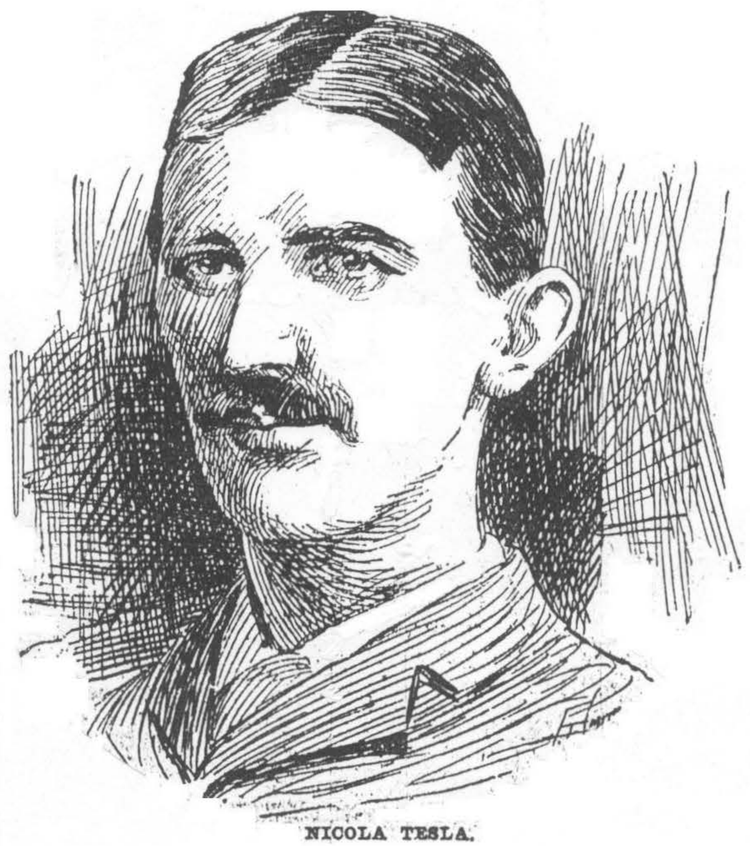
"Seventh—There is the approximate estimate from few precise, but insufficient facts by the same methods.

"Eighth—There is the probable estimate, when no precise facts are available.

"Ninth—There is the consideration of mere practicability.

"Tenth—There is the consideration of mere possibility, with no practicability, and eleventh, there is the entirely impossible, that which is against all the positive facts observed, or logical deductions, or mathematical demonstrations based on them. There is where, as Mr. Dana might say, the 129-cent dollars are located.

'I am now able to indicate, in a general way, how far I have gone toward the solution of the problem. After many fruitless efforts I have conceived an idea. I have for a long time scrutinized it and found it agreed with all the established facts I knew, hence, as far as I was capable to decide, it is possible. Next I have examined the difficulties which I had to overcome in carrying the idea into practice and have found that they were not insuperable; hence my scheme is practicable. Then I have searched for means of carrying it out, and close analysis of these has led me to the conviction that my idea will probably be carried out.



"Finally, after a long study, mostly experimental, of all the means and conditions, I have arrived at a few precise facts, enough to make an approximate estimate of all the elements involved in a practical demonstration, and—here I am sticking, sticking since three years.

Mr. Tesla's Idea.

"I say that I conceived an idea. In reality I have conceived many, but for the benfit of my fellow men and myself they will never be known. They were either fallacious or impracticable, products of a heated inventor's imagination. But this particular idea is of a different kind.

"It withstood my critical examination for weeks, months, and years. Now, when through so long a time no flaw in an idea can be found, when through all stages of excitation and subsequent relaxation it maintains its firm hold upon reason; when, as the knowledge of the subject increases and the desire to accomplish grows more intense by approach to realization, it returns after each period of exhaustion with increased force, then this idea is a truth. That is, it is a truth so far as the individual observer is concerned, for there is still the superior scrutiny of many which may disclose errors which he was incapable of perceiving.

"Naturally, you expect me to tell you all about my scheme. This I cannot do. You may think it is a question of a patent. Nothing could be further from my mind than this. Many scientific men think that an idea should be given to the world as soon as conceived, thinking that nothing would be lost in this way, and arguing also that even an erroneous idea may reveal some truth to others. This may be so, but we must consider that error breeds error, and that inestimable ill can be caused by wrongly impressing the younger generation. Now, while I have convinced myself that my scheme is fundamentally correct, there are still details in its execution in which I may be mistaken. I can, therefore, only give a general outline of what I have recognized as absolutely necessary for a practical realization.

NICOLA TESLA.

"But before I do this let me ask you, have you ever considered what vision means to you, have you ever thought how much enjoyment you are deriving from the magnificent panorama which is daily unfolding before your eyes? Have you ever abandoned yourself to the raptures of contemplation of a world you yourself create? You want a palace, and there it stands, built by architects finer than Michael Angelo—aye, even finer than my friends McKim, Mead & White. You fill it with marvellous paintings, and statuary and all kinds of objects of art. You summon fairies if you are fond of them. Now, perhaps, you want to sit on a throne, and there is your throne, greater than that of Great Britain! And all your subjects are around you—countless subjects. No fellows to run after you with a pistol, as fellows do after illustrious personages, like William and Nicholas or Li Hung Chang. And if they would, what do you care? You stop their bullets in midair.

"Now you walk out in the streets of a wonderful city. Perchance it is one of my cities. Then you may see that all the streets and halls are lighted by my beautiful phosphorescent tubes, that all the elevated railroads are propelled by my motors, that all the traction companies' trolleys are under ground and supplied by my system, and that all the currents are supplied by my oscillators, or else that my friends of the Cataract Construction Company are transmitting all the power by my system from a far-off Niagara. And now, perhaps, you meet a tramp in the street, and you reach in your pocket and give him something. Five cents, you think. No, sir; you give him not less than $5,000,000.

"Strangely, though, instead of collapsing at your generosity, he looks at you in an insolent way and turns the money in his hand and says, contemptuously:—'Take it back; you mean skinflint.' And then you throw down your royal insignia and you begin to grapple with him. You are endowed with giant strength, and he is no fellow to fool with, either. At any rate, the issue is uncertain. He may be stronger, and then, well—then you wake up, saved, but badly used up. If you defeat him, then you recompense him royally by giving him your insignia and your throne, and you continue your adventurous voyage peacefully and contented.

"Suddenly you throw yourself in the roar of a battle, you cut and slash, and a whole army of noble knights flees before you. And now something rattles in the bushes, and you, who know no fear, you run away. Then you may witness a terribly impressive scene of years gone by. You witness the death of your father or your mother, and you go through all the agonies again. You realize the immense gulf that separates you from them. Then overwhelming desire takes hold of you to be with them again. You know it is impossible to get them back; but never mind, you will invent something, you will discover some force which will reunite those separated molecules and make them form those lovely shapes so dear to you.

"And now suddenly there comes a revulsion, and you are throwing a stick at a cat in a backyard. You miss it, too, aggravating circumstance. But years afterward you can tell the exact spot on the wall, you can tell every mark of the stick, and you see exactly how the cat's fur was brushed one or the other way. So your imagination leads you on, from sorrow to joy, from work to play, and all this world is ever present, ever ready for your pleasure and enlightenment, and at your wish and command. All this world, real or imaginary, it matters little, you want to be able to see through some such thing as a wire, for if you succeed in transmitting sight you will see it all.

Difficulty of the Task.

"You may appreciate in a general way the difficulty of the task, but if you have not studied it as closely as I did you will not know the real difficulty. You will, of course, ask how is it that I can transmit the enchanting notes of a Paderewski concert all over one line. There are innumerable intonations, there are color and volume. But you must remember that this whole is brought about only by variation of pitch and intensity of the notes. This you can all reproduce at a distance by means of a wire. You may go even further than that. You may transmit all colors over three channels or even one channel. Technically this problem is incomparably more difficult, because you have still to find a medium for transmission, as the vibrations are inconceivably rapid. But when you come to the transmission of shapes there the difficulty begins!

"The most wonderful thing about the eye is its capability of conveying to the mind the idea of tridimensional extension. Although a result of touch, change of place or generally previous experience, it nevertheless is possible only through the medium of the eye. And such conception can be conveyed to the mind only by countless points of action. To illustrate:—I have in this room, say, fifty coils, each of which has its own rate of vibration. I send a composite vibration through the room and I am able to make any one of these coils respond.

"Now, imagine that I had a contrivance in the middle of this room and I had provided it with as many coils, each of which would be controlling the motion of the mechanism in a different direction. I can then cause the motion of this contrivance in as many different directions as the combination will permit. But the number of these motions is limited, and to accomplish a motion in any direction imaginable I must have an infinite number of such coils.

"Now, this is precisely what the optic nerve does. Your body is a mechanism which converts the energy of the food into other forms of energy. You are surrounded by influences which primarily affect your eye and so direct your motions. This may seem a bold statement, but I have so far convinced myself of its truth that I can think of no subject, I can conceive no idea of anything without being able to locate the first visual impression which started the train of thought.

"To give an example, rather unusual, I dream of a ship struck by a tidal wave. A few days later reports reach me that an Atlantic steamer has been struck by such a wave. I now search for the primary image which caused my dream. I search a long time and in vain, but finally, after weeks of fruitless effort, I find a picture in a show window, which I recognize as having given me the original impression. You may think of a friend you have not seen since many years, and you may turn around the corner and he stands before you.

"If you are not an experienced observer you actually think you have not seen him; but you are wrong, for you have seen him, only unconsciously. When you have familiarized yourself with such facts, you begin to look at the eye as a mechanical contrivance, and you are led to think how to imitate it, and then you are on the right track. In order to transmit shape, you recognize the necessity of hundreds, thousands or more channels of transmission, each independent, each capable of transmitting impressions of any intensity.

"Now, however difficult the task of transmitting sight to a distance in this sense may be, some results, possibly valuable, can be easily accomplished by primitive means. So, for instance, I have for many years believed that we may provide a building with a system of tubes, and by mirrors placed in them enable persons to see each other in distant parts of the building. It may even be possible to witness in this manner a performance on a stage, and for many practical purposes such a result would have a permanent value. If the mirrors be simply placed in a tube the transmission could not be effected to a considerable distance, because of the loss in the successive reflections, but I have overcome this by supplying additional light from another source, and at small distances I believe the project to be entirely feasible.

As to the Roentgen Ray.

"There still exists much confusion in regard to the possibilities offered by the Roentgen rays. By means of them we can discern the contours of an object—even its interior, to a certain extent—at distances of twenty or thirty feet or more. Perhaps we may be able to project rays through a mountain and locate lumps of mineral therein; but that is a remote possibility.

"However, through their agency, nothing be done toward the solution of the great problem in question. Nor can we hope to arrive at a practical result by a conversion of light waves into longer waves and their reconversion into the original form, as has been suggested.

"The chief difficulty, as before stated, only lies in providing countless independent channels between properly constructed receiving and transmitting instruments. It is in this direction that I have thought and worked. With what success I hope eventually to show."

my friends McKim, Mead & White. You fill it with marvelous paintings and statuary and all kinds of objects of art. You summon fairies if you are fond of them. Now, perhaps, you want to sit on a throne, and there is your throne, greater than that of Great Britain! And all your subjects are around you—countless subjects. No fellows to run after you with a pistol, as fellows do after illustrious personages, like William and Nicholas or Li Hung Chang. And if they would, what do you care? You stop their bullets in midair. Now you walk out in the streets of a wonderful city. Perchance it is one of my cities. Then you may see that all the streets and halls are lighted by my beautiful phosphorescent tubes, that all the elevated railroads are propelled by my motors, that all the traction companies' trolleys are under ground and supplied by my system, and that all the currents are supplied by my oscillators, or else that my friends of the Cataract Construction Company are transmitting all the power by my system from a far-off Niagara. And now, perhaps, you meet a tramp in the street, and you reach in your pocket and give him something. Five cents, you think. No, sir; you give him not less than $5,000,000.

"Strangely, though, instead of collapsing at your generosity, he looks at you in an insolent way and turns the money in his hand and says, contemptuously:—'Take it back you mean skinflint.' And then you throw down your royal insignia and you begin to grapple with him. You are endowed with giant strength, and he is no fellow to fool with, either. At any rate, the issue is uncertain. He may be stronger, and then, well—then you wake up, saved, but badly used up. If you defeat him, then you recompense him royally by giving him your insignia and your throne, and you continue your adventurous voyage peacefully and contented.

"Suddenly you throw yourself in the roar of a battle, you cut and slash, and a whole army of noble knights flees before you. And now something rattles in the bushes, and you, who know no fear, you run away. Then you may witness a terribly impressive scene of years gone by. You witness the death of your father or your mother, and you go through all the agonies again. You realize the immense gulf that separates you from them. Then overwhelming desire takes hold of you to be with them again. You know it is impossible to get them back; but never mind, you will invent something, you will discover some force which will reunite those separated molecules and make them form those lovely shapes so dear to you.

"And now suddenly there comes a revulsion, and you are throwing a stick at a cat in a backyard. You miss it, too—aggravating circumstance. But years afterwards you can tell the exact spot on the wall, you can tell every mark of the stick, and you see exactly how the cat's fur was brushed one or the other way. So your imagination leads you on, from sorrow to joy, from work to play, and all this world is ever present, ever ready for your pleasure and enlightenment, and at your wish and command. All this world, real or imaginary, it matters little, you want to be able to see through some such thing as a wire, for if you succeed in transmitting sight you will see it all."

Tesla as a Seer.—The following curious extract is from an interview by a New York *Herald* reporter with Mr. Nikola Tesla, the subject of the interview being "the transmission of sight by wires or otherwise." After stating that he had arrived at a few precise facts bearing on that problem, but yet enough to make an approximate estimate of all the elements involved in a practical demonstration, Mr. Tesla says "Have you ever abandoned yourself to the raptures of the contemplation of a world you yourself create? You want a palace, and there it stands, built by architects finer than Michael Angelo—aye, even finer than if by

The New York Tribune September 13, 1896

TESLA'S ELECTRIC OSCILLATOR.

IMPROVED APPARATUS FOR EXCITING WAVES OF HIGH FREQUENCY.

It is now four or five years since Nikola Tesla startled the electricians of the world by allowing a current of 200,000 volts to pass through his body. And it was nearly or quite as long ago that he produced a beautiful effulgence in a sealed glass tube by electrical means, yet without connecting the tube with a wire. These and other wonderful achievements of that eminent investigator have been the outgrowth of his study of "high frequency" and "high potential" currents. In fact, his most brilliant and original experiments for several years have been conducted in this, his favorite, department of research, and he has contributed greatly to the general stock of knowledge on this subject.

Every schoolboy, nowadays, knows the difference between a direct and an alternating current; and the practical electrician, if not the schoolboy, is aware that an alternating current may have oscillations of almost any frequency. The waves may number only twenty-five to the second, as in the great Niagara dynamos, or they may occur several thousand times as frequently. It is only the low-frequency current that is used commercially at present; but Mr. Tesla has repeatedly expressed his belief that practical results of great importance ought to be developed out of the use of high-frequency currents.

Few readers of The Tribune need to be reminded of the difference between the volume and the pressure or potential of an electric current. The one is expressed in "amperes," and the other in "volts." When, for any reason, you transform a current so as to raise the voltage, you correspondingly reduce the amperage. You cannot by any such operation increase the total energy, which is calculated by multiplying the number of volts by the number of amperes.

Reference is here made to these elementary principles of electrical science in order to render more intelligible the announcement that Mr. Tesla has nearly perfected a new piece of apparatus, which is designed to transform both the frequency and the potential of an alternating current, and do so very economically. It frequently happens that pioneers in scientific investigation find it necessary to make a special tool before they can manufacture the article they have in view. Perhaps that tool is a new mathematical formula or a novel chemical process, or a bit of electrical apparatus. In any case, it is a means to an end. This latest invention, or improvement on old devices, with which Mr. Tesla is to be credited, is to be regarded in the same light. His goal is the production of cheap, cold light in vacuum tubes; and the new instrument is designed to help him and others in attaining that object. Mr. Tesla has imitators, and there are people audacious enough to think of themselves as his rivals. But, after all, the great number and broad scope of his experiments and their character place him distinctly at the front in this magnificent field of inquiry. The public grows impatient at times because Mr. Tesla does not occasionally "report progress," like a Congressional committee; but, as The Tribune has often remarked, it is the privilege of genius to take its own time and work in its own way.

Already Mr. Tesla has given to science many useful hints and suggestions as to the arrangement of well-known pieces of apparatus in electrical work. His famous "disruptive discharge coil," designed to excite subordinate waves of enormous frequency (millions to the second) in an electric circuit, may be cited by way of illustration. The instance also serves to show that the new apparatus is not the first of its kind which he has originated for the same purpose. As yet Mr. Tesla does not want to furnish details regarding his latest advance in this direction. But it seems probable that it will replace the costly "induction coils" now extensively used in much laboratory work. Such coils costs hundreds, even thousands, of dollars. In Röntgen-ray photography, as well as the production of "the light of the future," the new apparatus is likely to prove exceedingly useful. The author of it calls it an "electrical oscillator," but is careful to explain that it is a very different sort of a contrivance from his well-known "mechanical oscillator," which exercises the functions of a steam engine and a dynamo combined.

CONSTRUCTION OF A TESLA-THOMSON HIGH FREQUENCY COIL.

By Prof. A. F. McKISSICK.

THE following is a description, from the *American Electrician*, of the construction of a Tesla-Thomson high frequency coil, large enough to give a 5-inch spark and excite Röntgen ray tubes.

To excite the Tesla-Thomson coil, a high potential transformer of from 10,000 to 15,000 volts is necessary. The construction of this transformer will be first given. Fig. 1

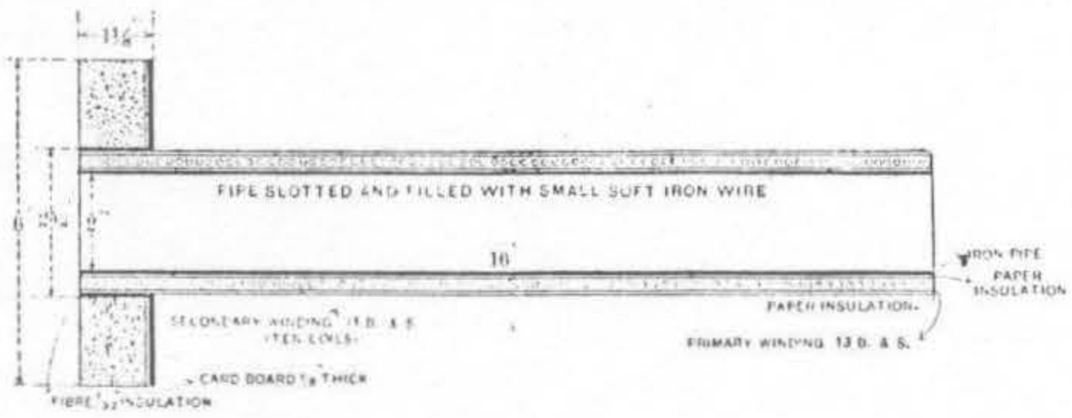


FIG. 1.

gives a partial cross-section of the transformer, which is made as follows:—A 2-inch iron pipe, 16 inches long, is slotted the whole length, either in a milling machine, planer or shaper. This slot need not be more than $\frac{1}{16}$th inch in width. The pipe is then insulated with ordinary wrapping paper to an outside diameter of $2\frac{1}{8}$ inches, shellac being freely used, and is then wound with No. 13 B. & S. double cotton-covered wire for its whole length (one layer). It is then covered with paper and shellaced until the outside diameter is $2\frac{5}{8}$ inches.

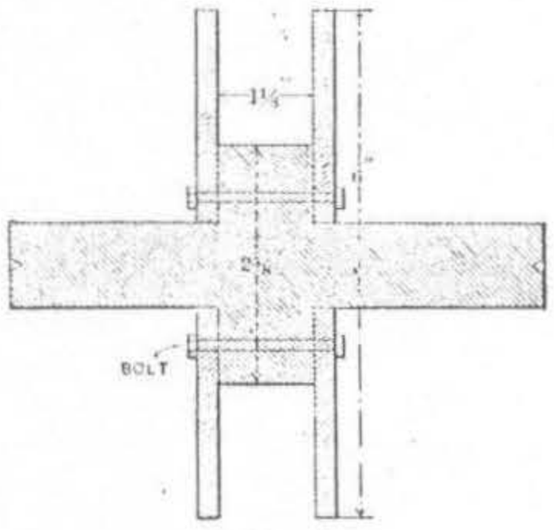

FIG. 2.

The next step is to fill the pipe with soft iron wires, No. 16 B. & S., each wire being cut 18 inches long. This completes the primary winding of the high tension transformer.

The secondary winding of this transformer consists of 10 coils wound in a form and thoroughly taped and insulated. This form is shown in fig. 2, and can be easily made of wood. The wire is wound in this form, shellaced, removed, taped and baked. These coils are then slipped over the primary winding, between each coil being placed a disc of cardboard $\frac{1}{8}$th inch thick, care being taken to connect the coils so that none will be in opposition.

The spark gap (see fig. 3) is made as shown in diagram.

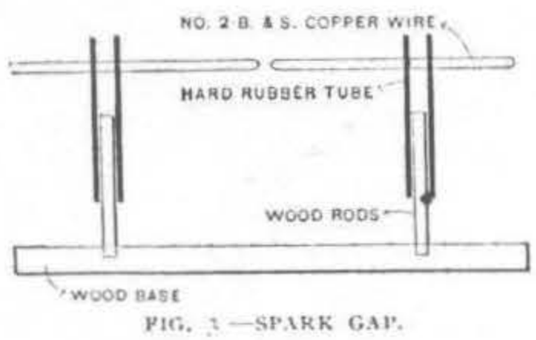

FIG. 3.—SPARK GAP.

FIG. 3.

The copper wires fit rather close in the holes drilled through the hard rubber tubing, so that the length of gap can be adjusted with ease.

The condenser is made of ordinary 10-inch × 12-inch window glass. A sheet of tin foil 8 inches × 10 inches is pasted on one side of the glass with shellac, leaving a margin

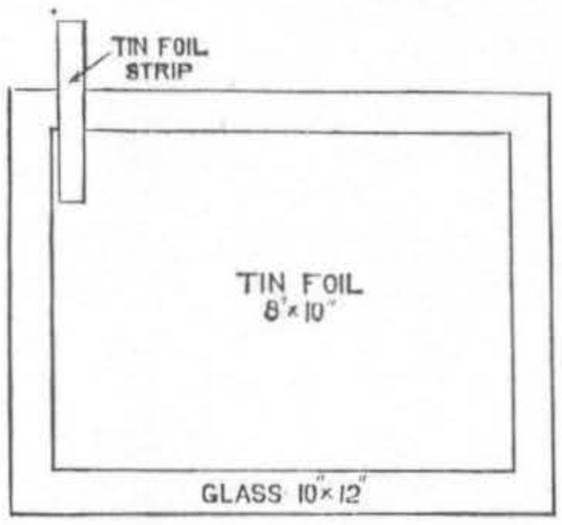

FIG. 4.

of 1 inch. (See fig. 4.) A strip of tin foil 2 inches wide is placed across one corner, this strip being placed alternately on each side. For each side of this condenser there should be 15 plates.

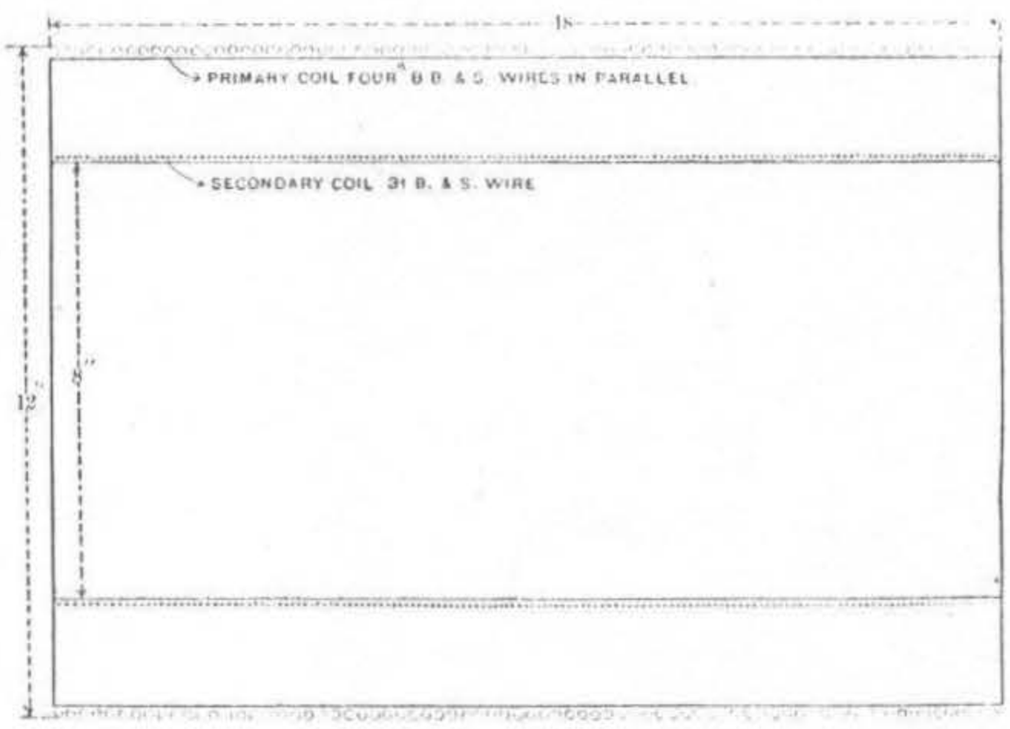

FIG. 5.

To build this condenser proceed as follows:—Place on a smooth surface a condenser plate with the connecting strip projecting on the right. On top of this plate place another piece of glass, 10 inches × 12 inches, that has no tin foil on it at all. Then place a condenser plate with the strip projecting on the left. Then a piece of glass without tin foil, and on top of this a condenser plate with the strip projecting on the right, and so on. This construction gives two thicknesses of glass between each sheet of tin foil, which is absolutely necessary.

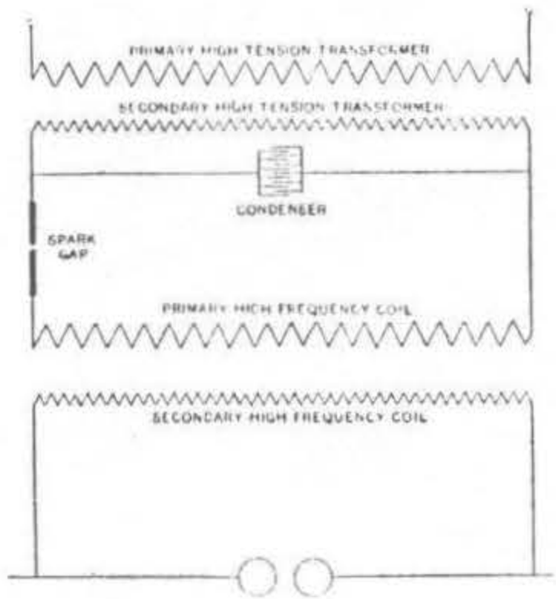

FIG. 6.

The high frequency coil is made as follows :—Wind an 8-inch paper cylinder 18 inches long with No. 31 B. & S. double cotton-covered wire (or larger), leaving a margin at each end of about 1 inch. This is the secondary winding. The primary winding is placed on a 12-inch paper cylinder 18 inches long, and consists of 14 turns of four No. 8 B. & S. double cotton-covered wires in parallel. Each of these No. 8 wires is wound on separately, then the four ends at the beginning and ending are soldered together. Between wires of different polarity, as an extra precaution, two turns of cord are wound. The primary and secondary coils are then shellaced and baked. After being baked, the secondary coil is placed concentrically (see fig. 5) inside the primary and the connections as shown in fig. 6 then made.

M. TESLA ON THE ROENTGEN RAYS.

ACCORDING to statements recently published, the Röntgen rays are now declared, by M. Nikola Tesla, to be material particles. M. Tesla states that the electrical conditions within the tube from which the rays issue produce absolute particles. He further says he can feel the effects of these particles striking against his eye, and has noted the sensation produced when they come in contact with his brain. He says: There is little doubt now that a cathodic stream within a bulb is composed of small particles of matter thrown off at great velocity from the electrode. The velocity probably obtained can be estimated, and fully accounts for the mechanical and heating effects produced by the impact against the wall or obstacle opposed to the bulb. It is furthermore an accepted view that the projected lumps of matter act as inelastic bodies, like innumerable infinitesimal bullets. It can be shown that the velocity of the stream may be as much as 100 kilos. a second, or even more. But matter moving with such great velocity must surely penetrate great thicknesses of the obstruction in its path, if the laws of mechanical impact are at all applicable to a cathodic stream. I have so much familiarised myself with this view that, if I had no experimental evidence, I would not doubt that some matter is projected through the thin wall of a vacuum tube. The exit from the latter is, however, the more likely to occur, as the lumps of matter

must be shattered into still much smaller particles by the impact. From my experiments it appears that the lumps or molecules are indeed shattered into fragments or constituents so small as to make them lose entirely some physical properties possessed before the impact. The matter composing the cathode stream is, continues M. Tesla in his letter, reduced to matter of some primary form heretofore not known, as such velocities and such violent impacts have probably never been studied or even attained before these extraordinary manifestations were observed. The important fact pointed out early by Röntgen and confirmed by subsequent researches, namely, that a body is the more opaque to the rays the denser it is, cannot be explained as satisfactorily by any other assumption than that of the rays being streams of matter, in which case such simple relation between opacity and density would necessarily exist. This relation is the more important in its bearing upon the nature of the rays, as it does not at all exist in light-giving vibrations, and should consequently not be found to so marked a degree and under all conditions with vibrations presumably similar to and approximating in frequency the light vibrations. An almost crucial test of the existence of material streams is afforded by the formation of shadows in space at a distance from the bulb. Such shadows could not be formed under the conditions described except by streams of matter.

THE TESLA ELECTRICAL CONDENSER.

In this week's issue of the ELECTRICAL REVIEW we take pleasure in recording again an important advance made by Mr. Tesla. In a patent issued last week he describes a novel form of electrical condenser, especially adapted for high frequency currents.

It will be remembered by all those who have followed his work that a few years ago Mr. Tesla demonstrated the hurtful action of the air in ordinary condensers, and showed the necessity of completely excluding gaseous matter from the condenser in order to secure efficiency. His demonstrations applied not only to condensers proper, but to all sorts of induction apparatus. In his lectures Mr. Tesla described, as a convenient means for exclusion of the gas, the employment of a vacuum for forcing the dielectric between the conducting armatures.

The improvement, now described, implies the exclusion of the gas and the employment of condenser armatures, consisting of a fluid conductor, such as an electrolyte. Mr. Tesla informs us that condensers of this type have been in use in his laboratory for the past few years, and that they show absolutely no increase of temperature by constant use. Many of the remarkable experiments with which he has delighted a few privileged visitors to his laboratory would have been impossible without these well-nigh perfect instruments.

We feel sure that all those who have occasion to use such appliances, as, for instance, in the Roentgen experiments, will be amazed at the performance of this form of condenser. As Mr. Tesla points out repeatedly in his writings, it is of the utmost importance to exclude the air from the active surfaces, as by a layer of oil on the top, otherwise the mere employment of an electrolyte would not overcome the inherent defects in the condenser of the usual form.

Tesla's Electrical Condenser.

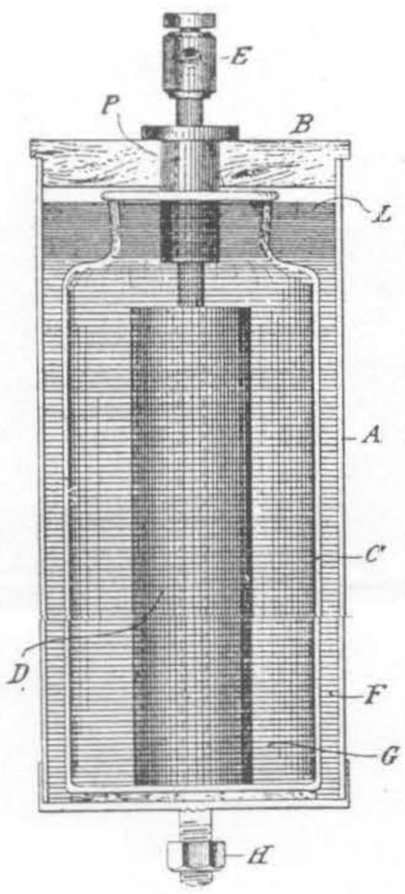
The following is the inventor's own description of his electrical condenser, for which patent was issued September 15, 1896:

Be it known that I, Nikola Tesla, a citizen of the United States, residing at New York, in the County and State of New York, have invented certain new and useful improvements in electrical condensers, of which the following is a specification, reference being had to the drawings accompanying and forming a part of the same.

It has heretofore been announced and demonstrated by me that, under ordinary conditions, the efficiency of an electrical condenser is greatly increased by the exclusion of air or gaseous matter in general from the dielectric. In a patent granted to me December 8, 1891, No. 464,667, I have shown and described a convenient and practicable means of accomplishing this result by immersing the conducting plates or armatures of the condenser in an insulating fluid, such as oil.

My present invention, while based upon this important feature of the practically complete exclusion of air or gas from the dielectric, is an improvement on the forms of condenser heretofore described and used by me.

Fig. 1



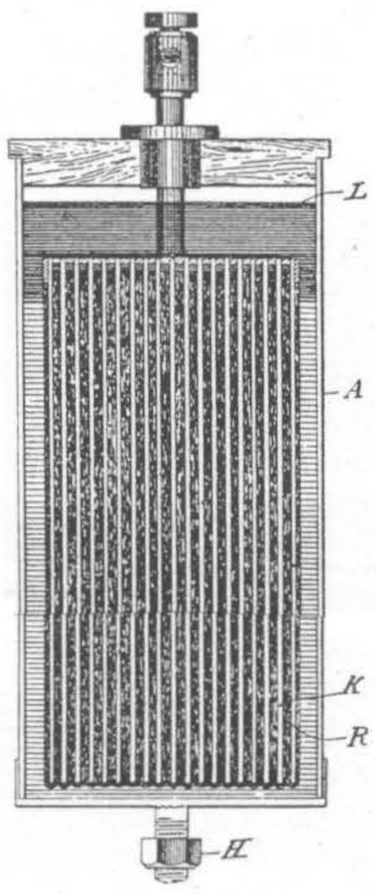


Fig. 2

SECTIONAL VIEW OF THE TESLA CONDENSER.

According to my present invention, I employ an electrolyte, or, in general, a conducting liquid in lieu of a solid, as the material for the armatures of the condenser, under conditions more fully hereinafter described, whereby air or gas will be practically prevented from exercising upon the condenser or the more active portions of the same, the detrimental effects present in such devices as heretofore made. Such condensers are especially advantageous when used with circuits of great rates of electrical vibration, because of the high conducting capacity of such fluids for currents of this character. There is, however, a general advantage derived from the fact that the conducting fluids have a high specific heat, so that the temperature remains constant, a condition in many cases highly advantageous, and not met with in condensers of ordinary construction.

In the accompanying drawings, annexed in illustration of the manner in which my improvement is or may be carried into practice, Fig. 1 is a view partly in vertical section of a condenser constructed in accordance with the invention.

Fig. 2 is a part vertical section of a modified form of such condenser.

A designates a jar or receptacle partly or wholly of conducting material, and provided with a closely fitting cap or cover B, preferably of insulating material.

Within this receptacle is a smaller jar or vessel C, of insulating material, containing a conducting electrode D, supported by the cover B, through which passes a suitable terminal E, which may be incased in an insulating plug P.

The spaces within the jars or receptacles are nearly filled with a conducting liquid F, G, such as a saline solution, the two bodies of such liquid, in the inner and outer receptacles, constituting the condenser armatures.

Above the conducting solution in each of the receptacles is poured a layer of oil or other insulating liquid, which serves to prevent access of air to the highly charged armatures.

The terminals for the two armatures may be provided in various ways, but in such forms of condenser as that illustrated, I prefer to utilize the conducting portion of the outer receptacle as one terminal, securing a binding post to the same as at H, and to employ an electrode D of suitably extended surface immersed in the liquid of the inner receptacle and in electrical connection with the binding post E.

It is desirable in some cases to modify the construction of the condenser, as when a larger capacity is required. In such instances, in order to secure the substantial benefits of the improvement above described, I construct the instrument as shown in Fig. 2.

In this case I employ a jar or receptacle A, which is preferably used also as one terminal, and filled with a conducting liquid, as before. Into the latter extends a series of connected conductors K, inclosed and fully insulated from the liquid by a coating of such material as gutta-percha R. These conductors are electrically joined to a terminal E, which extends up through the cover B, and constitute one of the armatures of the condensers.

On the surface of the electrolyte or conducting liquid is poured a quantity of oil L, for the purpose above stated.

While I have illustrated the invention in its preferred form for general practical purposes, it will be understood that, without departure from the invention, its construction may be greatly varied and modified.

What I claim is:

1. In an electric condenser constructed or provided with means for the exclusion of air and gas, an armature composed of a conducting liquid, as herein set forth.

2. A condenser comprising as armatures two bodies of conducting liquid electrically insulated, and contained in a receptacle from which air and gas are excluded.

3. A condenser comprising two bodies of conducting liquid electrically insulated and contained in a receptacle, and a seal of insulating liquid on the surfaces of the liquid, as set forth.

In testimony whereof, I have hereunto set my hand this 15th day of June, 1896.

[88960.]—**Tesla Apparatus for X-Ray Work.**—See my reply (88810) in "ENGLISH MECH." for Sept. 11, 1896. The only difference you need make will be to wind the secondary with about ten layers of No. 36 instead of No. 32, using thin red vulcanised fibre ($\frac{1}{64}$in. thick) between each layer of wire. Of course, you must use a resistance in circuit with the primary, so as to limit the current to about six ampères; otherwise you may heat the wire injuriously.

S. BOTTONE.

TESLA'S ELECTRICAL OSCILLATORS.

The important researches and experiments which Nikola Tesla has been carrying on for years, and which have created such a widespread interest in the scientific world, have culminated in the production of thoroughly practical and efficient electrical oscillators or transformers for the conversion of ordinary direct or alternating currents into electrical vibrations of any desired frequency. In five patents, granted to him September 22, 1896, he shows typical forms of his apparatus as adapted to any of the usual sources of supply. The remarkably clear and simple description of the features involved makes it perfectly easy for any one to understand the operation of these most valuable appliances.

The numerous uses to which these high-frequency transformers can be put will, we believe, cause their rapid and extensive introduction, and it is difficult to estimate the benefit which will result to science and industry from their applications. For lighting with phosphorescent bulbs or tubes, for the production of Roentgen phenomena, for the manufacture of ozone, argon and such bodies, for electro-therapeutic employment, and many uses for which induction coils are suitable, they afford ideal instruments. New applications will no doubt be found, but it is very probable that their chief employment will be for purposes of lighting by high-frequency currents, in which Tesla is the recognized pioneer.

We quote the exact language of the inventor in describing a few forms of his appliances for high-frequency phenomena:

The object of my present improvements is to provide a simple, compact and effective apparatus for producing these effects, but adapted more particularly for direct application to and use with existing circuits carrying direct currents, such as the ordinary municipal incandescent lighting circuits. The way in which I accomplish this, so as to meet the requirements of practical and economical operation under the conditions present, will be understood from a general description of the apparatus which I have devised. In any given circuit, which for present purposes may be considered as conveying direct currents or those of substantially the character of direct or continuous currents, and which, for general purposes of illustration, may be assumed to be a branch or derived circuit across the mains from any ordinary source, I interpose a device, or devices, in the nature of a choking coil, in order to give to the circuit a high self-induction. I also provide a circuit controller of any proper character that may be operated to make and break said circuit. Around the break, or point of interruption, I place a condenser, or condensers, to store the energy of the discharge current, and in a local circuit, and in series with such condenser, I place the primary of a transformer, the secondary of which then becomes the source of the currents of high frequency. It will be apparent from a consideration of the conditions involved that, were the condenser to be directly charged by the current from the source, and then discharged into the working circuit, a very large capacity would ordinarily be required, but by the above arrangement the current of high electro-motive force, which is induced at each break of the main circuit, furnishes the proper current for charging the condenser, which may, therefore, be small and inexpensive. Moreover, it will be observed that, since the self-induction of the circuit through which the condenser discharges, as well as the capacity of the condenser itself, may be given practically any desired value, the frequency of the discharge current may be adjusted at will.

Fig. 1 is a diagrammatic illustration of the apparatus, and Fig. 2 a modification of the same.

Referring to Fig. 1, A designates any source of direct current. In any branch of the circuit from said source, such, for example, as would be formed by the conductors A″ A″ from the mains A′ and the conductors K K, are placed self-induction or choking coils B B and a circuit controller C. This latter may be an ordinary metallic disk or cylinder with teeth or separated segments D D, E E, of which one or more pairs, as E E, diametrically opposite, are integral or in electrical contact with the body of the cylinder, so that when the controller is in the position in which the two brushes F F bear upon two of said segments E E, the circuit through the choking coils B will be closed. The segments D D are insulated, and while shown in the drawings as of substantially the same length of arc as the segments E E, this latter relation may be varied at will to regulate the periods of charging and discharging.

The controller C is designed to be rotated by any proper device, such, for example, as an electro-magnetic motor, as shown in Fig. 2, receiving current either from the main source or elsewhere. Around the controller C, or, in general, in parallel therewith, is a condenser H, and in series with the latter the primary K of a transformer, the secondary L of which constitutes the source of the currents of high frequency which may be applied to many useful purposes, as for electric illumination, the operation of Crookes tubes, or the production of high vacua.

L′ indicates the circuit from the secondary, which may be regarded as the working circuit.

A more convenient and simplified arrangement of the apparatus is shown in Fig. 2. In this case the small motor G, which drives the controller, has its field coils in derivation to the main circuit, and the controller C and condenser H are in parallel in the field circuit between the two coils. In such case the field coils M take the place of the choking coils B. In this arrangement, and, in fact, generally, it is preferable to use two condensers, or a condenser in two parts, and to arrange the primary coil of the transformer between them. The interruptions of the field circuit of the motor should be so rapid as to permit only a partial demagnetization of the cores. These latter, however, should in this specific arrangement be laminated.

In a modified arrangement the coils operating the interrupter are placed in series with a coil of large self-induction, or the latter is dispensed with by giving to the coils a suitable self-induction. Quoting the inventor, "this apparatus may be constructed and combined in very compact form and small compass. Its operation involves but a small expenditure of energy, while it requires practically no care or attention for the continued

production of ozone in unlimited amount."

Dwelling specifically upon the conversion of alternating or undulating currents, Mr. Tesla says:

When the potential of the source periodically rises and falls, whether with reversals or not is immaterial, it is essential to economical operation that the intervals of interruption of the charging current should bear a definite time relation to the period of the current, in order that the effective potential of the impulses charging the condenser may be as high as possible. I therefore provide, in case an alternating or equivalent electro-motive force be employed as the source of supply, a circuit controller which will interrupt the charging circuit at instants predetermined with reference to the variations of potential therein. The most practicable means for accomplishing this, of which I am aware, is to employ a synchronous motor connected with the source of supply and operating a circuit controller which interrupts the charging current at or about the instant of highest potential of each wave, and permits the condenser to discharge the energy stored in it through its appropriate circuit. This apparatus, which may be considered as typical of the means employed for carrying out the invention, I have illustrated in the accompanying drawings.

Referring to Fig. 3, A designates any source of alternating or equivalent current, from which lead off mains A′ A″. At any point where it is desired to produce the high-frequency currents, a branch circuit B is taken off from the mains, and, in order to raise the potential of the current, a transformer is employed, represented by the primary C and secondary D. The circuit of the secondary includes the energizing coils of a synchronous motor E and a circuit controller, which, in the present instance, in Fig. 3, is shown as composed of a metal disk F with insulated segments F′ in its periphery and fixed to the shaft of the motor. An insulating arm G, stationary with respect to the motor shaft and adjustable with reference to the poles of the fixed magnets, carries two brushes H H, which bear upon the periphery of the disk. With the parts thus arranged, the secondary circuit is completed through the coils of the motor whenever the two brushes rest upon the uninsulated segments of the disk and interrupted through the motor at other times. Such a motor, if properly constructed, in well understood ways, maintains very exact synchronism with the alterations of the source, and the arm G may, therefore, be adjusted to interrupt the current at any determined point in its waves. It will be understood that by the proper relations of insulated and conducting segments and the motor poles, the current may be interrupted twice in each complete wave at or about the points of highest potential. The self-induction of the circuit containing the motor and controller should be high, and the motor itself will usually be constructed in such manner that no other self-induction device will be needed. The energy stored in this circuit is utilized at each break therein to charge a condenser K. With this object the terminals of the condenser are connected to the two brushes H H or to points of the circuit adjacent thereto, so that when the circuit through the motor is interrupted, the terminals of the motor circuit will be connected with the condenser, whereby the latter will receive the high-potential inductive discharge from the motor or secondary circuit.

The condenser discharges into a circuit of low self-induction, one terminal of which is connected directly to a condenser terminal and the other to the brush H opposite to that connected with the other condenser terminal, so that the discharge circuit of the condenser will be completed simultaneously with the motor circuit and interrupted while the motor circuit is broken and the condenser being charged.

The discharge circuit contains a primary M of a few turns, and this induces in a secondary N impulses of high potential, which, by reason of their great frequency, are available for the operation of vacuum tubes P, single terminal lamps R, and other novel and useful purposes.

It is obvious that the supply current need not be alternating, provided it be converted or transformed into

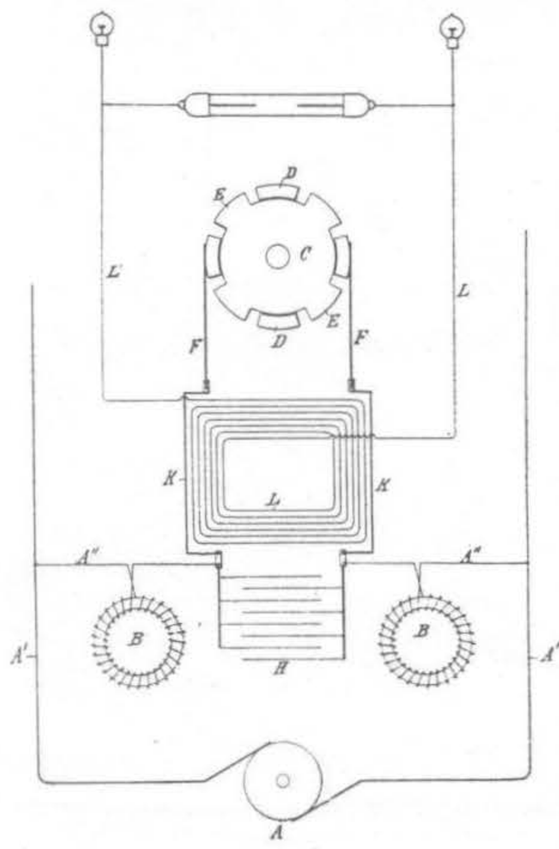

FIG. 1.—TESLA'S ELECTRICAL OSCILLATOR—DIAGRAM ILLUSTRATING CONNECTIONS OF OSCILLATOR AS ADAPTED TO AN ORDINARY MUNICIPAL LIGHTING CIRCUIT.

an alternating current before reaching the controller. For example, the present improvements are applicable to various forms of rotary transformers, as is illustrated in Fig. 4.

E′ designates a continuous-current

With such arrangement it is evident that any two adjacent segments *c c* become the terminals of an alternating current source, so that if two brushes H H be applied to the periphery of the cylinder, they will take off current during such portion of the wave as the width of segment and position of the brushes may determine. By adjusting the position of the brushes relatively to the cylinder, therefore, the alternating current delivered to the segments *c c* may be interrupted at any point in its waves.

While the brushes H H are on the conducting segments, the current which they collect stores energy in a circuit of high self-induction formed

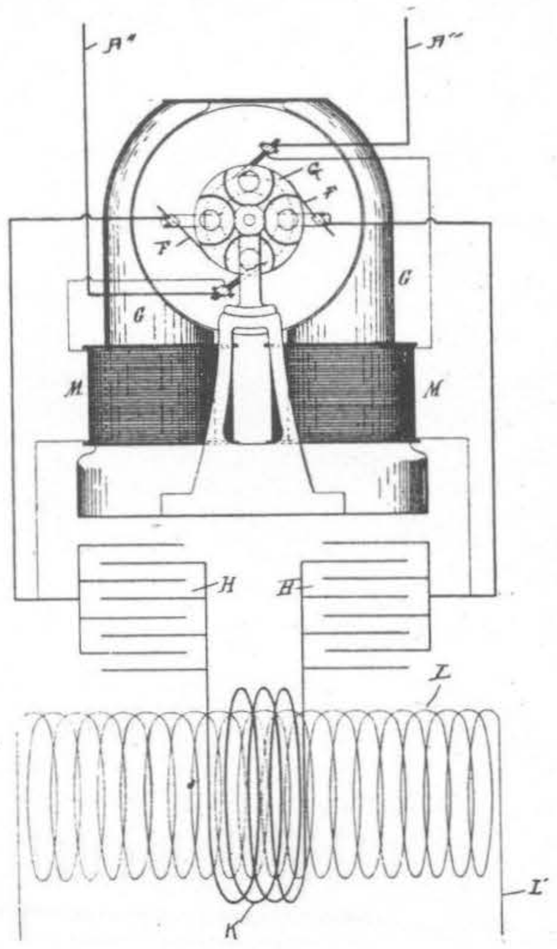

FIG. 2.—TESLA'S ELECTRICAL OSCILLATOR—DRAWING ILLUSTRATING A SIMPLIFIED FORM OF OSCILLATOR AND CONNECTIONS.

by the wires *f f*, self-induction coils S S, the conductors B B, the brushes and commutator. When this circuit is interrupted by the brushes H H passing on to the insulating segments of the controller, the high-potential discharge of this circuit charges the condensers K K, which then discharge through the circuit of low self-induction containing the primary M. The secondary circuit N contains any devices, as P R, for utilizing the current.

In other arrangements, circuit controllers of special construction are shown mounted on the shaft of a generator, and a transformer is employed in connection to raise the tension of the supply current.

In regard to the regulation of his system Tesla says:

It is well known that every electric circuit, provided its ohmic resistance does not exceed certain definite limits, has a period of vibration of its own analogous to the period of vibration of a weighted spring. In order to alternately charge a given circuit of this character by periodic impulses impressed upon it and to discharge it most effectively, the frequency of the impressed impulses should bear a definite relation to the frequency of vibration possessed by the circuit itself. Moreover, for like reasons the period or vibration of the discharge circuit should bear a similar relation to the impressed impulses or the period of the charging circuit. When the conditions are such that the general law of harmonic vibrations is followed, the circuits are said to be in resonance or in electro-magnetic synchronism, and this condition I have found in my system to be highly advantageous. Hence in practice I adjust the electrical constants of the circuits so that in normal operation this condition of resonance is approximately attained. To accomplish this, the number of impulses of current directed into the charging circuit per unit time is made equal to the period of the charging circuit itself, or, generally, to a harmonic thereof, and the same relations are maintained between the charging and discharge circuit. Any departure from this condition will result in a decreased output, and this fact I take advantage of in regulating such output by varying the frequencies of the impulses or vibrations in the several circuits.

Inasmuch as the period of any given circuit depends upon the relations of its resistance, self-induction, and capacity, a variation of any one or more of these may result in a variation in its period. There are, therefore, various ways in which the frequencies of vibration of the several circuits in the system referred to may be varied, but the most practicable and efficient ways of accomplishing the desired result are the following: (*a*) Varying the rate of the impressed impulses of current, or those which are directed from the source of supply into

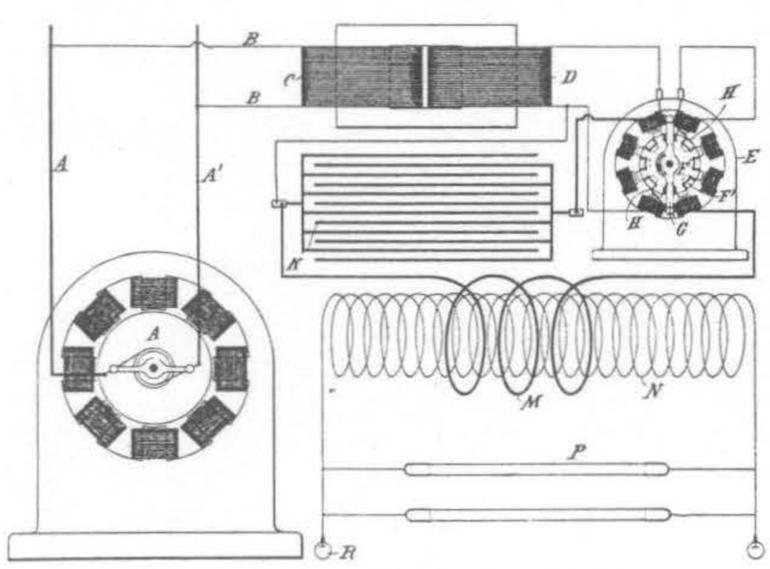

FIG. 3.—TESLA'S ELECTRICAL OSCILLATOR—DIAGRAM ILLUSTRATING APPARATUS AND CONNECTIONS AS ADAPTED TO A MUNICIPAL ALTERNATING CURRENT OF SUPPLY.

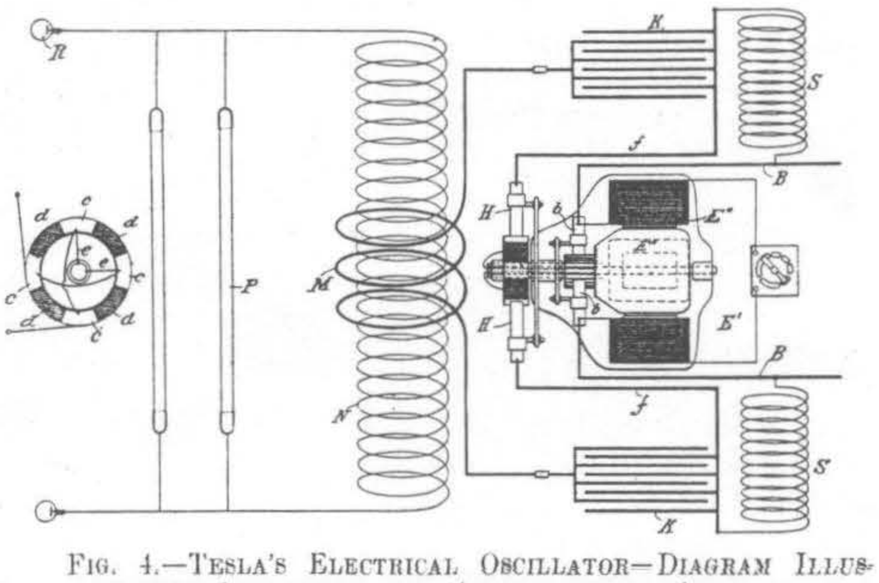

FIG. 4.—TESLA'S ELECTRICAL OSCILLATOR—DIAGRAM ILLUSTRATING APPARATUS AND CONNECTIONS AS ADAPTED TO A FORM OF ROTATING TRANSFORMER OPERATED FROM A MUNICIPAL LIGHTING CIRCUIT.

motor, here represented as having four field poles wound with coils E″ in shunt to the armature. The line wires B B connect with the brushes *b b* bearing on the usual commutator.

On an extension of the motor shaft is a circuit controller composed of a cylinder, the surface of which is divided into four conducting segments *c* and four insulating segments *d*, the former being diametrically connected in pairs, as shown in detail in Fig. 4.

Through the shaft run two insulated conductors *e e* from any two commutator segments 90 degrees apart, and these connect with the two pairs of segments *c*, respectively.

the charging circuit, as by varying the speed of the commutator or other circuit controller; (*b*) varying the self-induction of the charging circuit; (*c*) varying the self-induction or capacity of the discharge circuit.

To regulate the output of a single circuit which has no vibration of its own by merely varying its period would evidently require, for any extended range of regulation, a very wide range of variation of period; but in the system described, a very wide range of regulation of the output may be obtained by a very slight change of the frequency of one of the circuits when the above mentioned rules are observed.

TESLA'S ELECTRICAL OSCILLATORS.

Those who have followed the development of electrical industry in recent years, and more particularly the application of alternating currents for industrial purposes, will be able to justly appreciate the great services which Mr. Nikola Tesla has rendered to the world in this field of endeavor by his discovery of the rotating magnetic field, recorded in this journal early in 1888. They will remember that a few years after this publication, Tesla startled the scientific world through his brilliant lectures here and abroad, in which he disclosed entirely novel phenomena, produced by high-frequency currents. In these lectures he showed for the first time the possibility of lighting by means of phosphorescent bulbs and tubes. The currents he obtained either by specially constructed machines or by means of a new form of induction coil, now commonly known as the Tesla coil, or transformer.

Since his original announcement in this later field, Tesla has incessantly labored to simplify and improve his methods and apparatus, and as an evidence of his progress we only need recall to our readers his valuable contributions to the Roentgen phenomena, which he was able to so exhaustively investigate by the help of his perfected coils, or "oscillators." We also recorded, a few months ago, the remarkable results he obtained in the production of light of high candle-power by vacuum tubes.

Mr. Tesla now comes forward with perfected and extremely simple transformers, or oscillators, adapted to every-day use with ordinary sources of current supply. We believe that the importance of the advent of these new implements for the development of science and industry can not be overestimated. That high-frequency currents are destined to play an important part in the practical applications of electricity there can be no doubt, and with the introduction of efficient high-frequency transformers adapted to ordinary circuits their numerous uses are sure to come at once. The old and familiar form of induction coil, with its multitude of uses, can not possibly survive when a new inductive apparatus is at hand fully as simple, but far more economical, and requiring only a minute fraction of the wire needed in the old form.

Tesla has been working arduously for a number of years to bring about these results, as evidenced by the publication of his always original researches, and it is most unfortunate that his progress was delayed by the destruction of his laboratory a year and a half ago.

We heartily congratulate him on his practical success, as placed on record in the patents granted to him last week, on which we dwell on another page in this issue.

The New York Herald September 30, 1896

TESLA'S LATEST DISCOVERY.

Makes Practicable the Lighting of Vacuum Glass Bulbs Without the Usual Filaments.

The last issue of the Electrical Review describes the latest electrical invention of Nikola Tesla. He has succeeded, it says, in perfecting his so called electrical oscillators, or machines for the economical production of rapid electrical vibrations. By means of the oscillators he is confident that his lighting by glass bulbs, without the usual filament of the incandescent lamp, will become practicable.

They are, besides, capable of developing far more powerful Roentgen rays than was heretofore possible with the old apparatus, and they lend themselves to numerous other uses, such as photography, the production of ozone and other chemical combinations, and to electro-therapeutic treatment. Tesla's work has always attracted great attention among electrical workers, but it is probable that these latest contributions of his will prove more fruitful and far reaching than his previous achievements.

In an editorial the Electrical Review says:—

"We recorded a few months ago the remarkable results he obtained in the production of light of high candle power by vacuum tubes. Mr. Tesla now comes forward with perfected and extremely simple transformers, or oscillators, adapted to every day use, with ordinary sources of current supply. We believe that the importance of the advent of these new implements for the development of science and industry can not be overestimated.

"That high-frequency currents are destined to play an important part in the practical application of electricity there can be no doubt, and with the introduction of efficient high-frequency transformers adapted to ordinary circuits their numerous uses are sure to come at once.

"The old and familiar form of induction coil, with its multitude of uses, cannot possibly survive when a new inductive apparatus is at hand, fully as simple but far more economical and requiring only a minute fraction of the wire needed in the old form."

The New York Tribune September 30, 1896

TESLA'S LATEST DISCOVERY.

HE SUCCEEDS IN PERFECTING MACHINES FOR THE ECONOMICAL PRODUCTION OF RAPID ELECTRICAL VIBRATIONS.

Nikola Tesla has succeeded in perfecting his electrical oscillators or machines for the economical production of rapid electrical vibrations. By means of these he is confident that his lighting by glass bulbs, without the usual filament of the incandescent lamp, will become practicable. They are, besides, capable of developing far more powerful Röntgen rays than was heretofore possible with the old apparatus, and they lend themselves to numerous other uses, such as photography, the production of ozone and other chemical combinations, and to electro-therapeutic treatment.

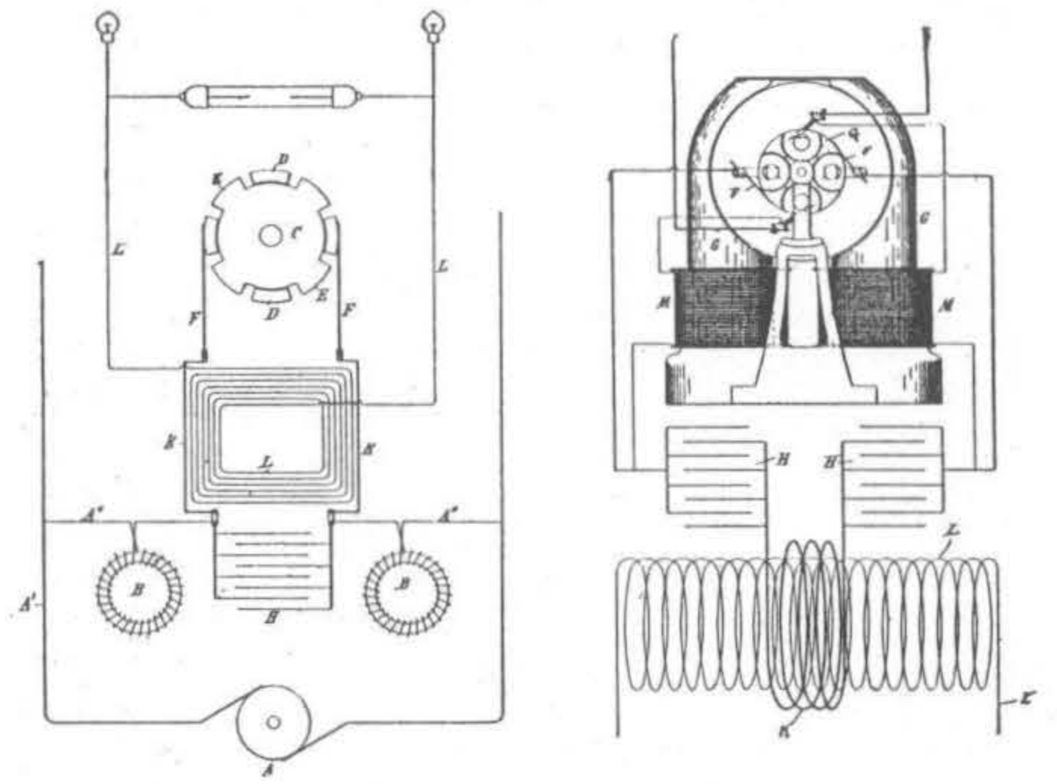
"The Electrical Review," which to-day announces the inventor's success, says of his latest work: "Tesla, since he startled the scientific world by showing for the first time the possibility of lighting by means of phosphorescent bulbs and tubes, has incessantly labored to simplify and improve his methods and apparatus, and now comes forward with perfected and extremely simple transformers, or oscillators, adapted to every-day use with ordinary sources of current supply.

"That high-frequency currents are destined to play an important part in the practical applications of electricity there can be no doubt. The old and familiar form of induction coil, with its multitude of uses, cannot possibly survive when a new inductive apparatus is at hand fully as simple, but far more economical, and requiring only a minute fraction of the wire needed in the old form."

[88998.]—**Roentgen-Ray Work.**—No: I believe I am right in saying that with a coil the Tesla gives absolutely no increase in length of spark; rather the other way. The radiographic effects from coil direct are at least quite as good as when used in conjunction with the Tesla. S. Bottone.

[89000.]—**Tesla Effects** are due to increased frequency and high potential. The increased frequency depends on the oscillatory nature of the Leyden jar discharge. The lighting up of the incandescent lamp is probably a discharge through the vacuum and through the outer glass of tube, and will probably end in the fracture of the lamp. Roughly, the voltage of a 3in. spark is 150,000 volts.
S. Bottone.

Tesla's Oscillator.



Nikola Tesla was used to distinguish himself by a closer attention to business than to publicity, and the more was hoped for from him for that reason. Of late he has occasionally allowed enthusiasm and hope to run away with speech, and he has told too freely what he was going to do. It is always wiser to do a thing before talking about it. It saves chagrin, accusation and misunderstanding. There is little doubt that Tesla is the foremost electrician in the country, if not in the world. Mr. Edison has perfected more than he has invented. Mr. Tesla has fallen upon or has reasoned out devices that promise to revolutionize the systems of power and lighting that so recently revolutionized the methods of steam, water and other forces. The oscillator, which he was to have shown last winter he has now succeeded in perfecting, according to the Electrical Review, and he offers it in so concise and economical a form that the prevalent machinery of lighting would seem to be doomed to speedy abolition. It gives some idea of the tremendous velocity and force of the subtle fluid of which we still know so little, when we learn that the new machine can produce 100,000,000 vibrations in a second. Granted that it does but a thousandth part of that and the wonder is little less. By interrupting the current every sixty-millionth part of a second a vivid light is induced in vacuum tubes which appear to be disconnected with the apparatus. The new process also yields the Roentgen ray, can be employed in the separation of the new element argon and likewise the production of ozone, and may prove to be of value in electrical therapeutics. The advantage of the light over that of incandescent and arc lamps is that while it is brighter it is also softer and more diffused. so that the observer is not dazzled or blinded. Probably it is also steadier. The usual and existing appliance for breaking the current is entirely mechanical in its operation and only a few hundred vibrations, at the most, can be induced in a second. The high vibrations of the Tesla machine make the light practically if not mathematically constant. We live in an age of progress and wonders, but they multiply so fast that our grandchildren may look upon us as fogies.

TESLA HIGH FREQUENCY APPARATUS OPERATED FROM LOW POTENTIAL DIRECT CURRENT CIRCUITS.

THE brilliant experiments in high frequency and high potential currents made by Mr. Tesla have been carried out by the aid of initial alternating currents raised from low to high potential. But in order to simplify the methods of work in this field, Mr. Tesla has devised a type of apparatus noted in our Patent Record last week, which enables currents of the desired high potential to be obtained from ordinary low potential continuous current circuits. In carrying out this scheme, Mr. Tesla employs a circuit breaker, around the contacts of which a condenser is connected, to store the energy of the discharge current; and in a local circuit and in series with the condenser he places the primary of a transformer, the secondary of which then becomes the source of the high frequency currents.

The accompanying diagram, Fig. 1, shows one form of the apparatus. The choking coils, B B, and circuit breaker, C, are placed in circuit with the continuous current mains, A. The circuit breaker is rotated by a continuous current motor. In parallel with the circuit breaker is the condenser, H, and in series with the latter the primary, K, of a transformer,, the secondary, L, of which is the source of the high frequency currents.

Another, more convenient form of the apparatus is the arrangement shown in Fig. 2. In this case the motor, G, which

FIGS. 1 AND 2.—TESLA'S SIMPLIFIED HIGH FREQUENCY APPARATUS.

drives the circuit breaker, has its field coils in derivation to the main circuit, and the controller, C, and condenser, H, are in parallel in the field circuit between the two coils; the field coils, M, taking the place of the choking coils, B.

In this arrangement, and in fact generally, according to Mr. Tesla, it is better to use two condensers or a condenser in two parts and to arrange the primary of the transformer between them. The breaks of the field circuit should be so rapid as to permit only of partial demagnetization of the cores which should be laminated.

It will be apparent from a consideration of the conditions involved that were the condenser to be directly charged by the current from the source and then discharged into the working circuit a very large capacity would ordinarily be required, but by the above arrangement the current of high electromotive force which is induced at each break of the main circuit furnishes the proper current for charging the condenser, which may therefore be small and inexpensive. Moreover, it will be observed that since the self-induction of the circuit through which the condenser discharges, as well as the capacity of the condenser itself, may be given practically any de-

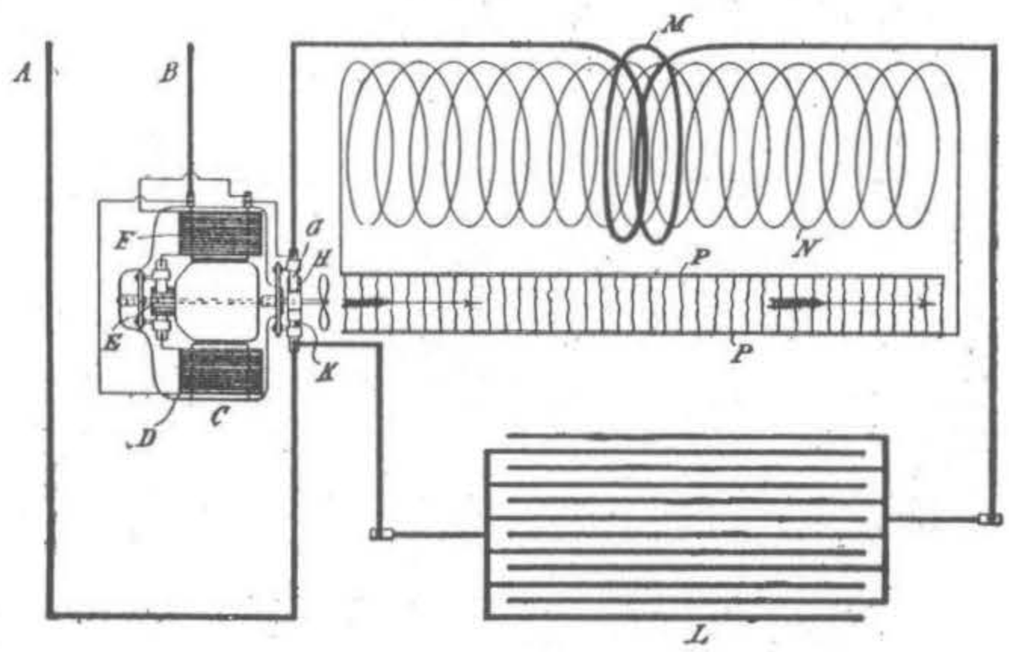


FIG. 3.—TESLA'S OZONE GENERATOR.

sired value, the frequency of the discharge-current may be adjusted at will.

Mr. Tesla has also devised a number of other methods for accomplishing the same object, which form the subject matter for a number of patents just issued to him.

Among the uses to which Mr. Tesla proposes to put the new arrangement is the generation of ozone in large quantities. The engraving, Fig. 3, shows the simple method employed for

this purpose. The high frequency brush discharge takes place between the metal plates, P P, and a current of air is forced between the latter by the fan blower attached to the motor that drives the circuit breaker.

LETTERS TO THE EDITOR.

A Note on the Tesla Sparkand X-Ray Photography.

A CROOKES' radiometer was supported by its stem about four inches above the hand, which was placed upon a photographic plate enclosed in two light-tight cases. The terminals of a Tesla coil were placed about half an inch from the bulb on either side of it, inclined to one another at an angle of 120°, the vertex of the angle being in the axis of the radiometer. The Tesla discharge was allowed to bombard the bulb for four minutes. On development a clear picture of the bones in the hand appeared. The experiment shows that the X-ray photo can be produced when an exhausted bulb is used having no terminals.

I failed entirely to get any X-ray results when only the usual induction sparks bombarded the bulb, these sparks often destroying the vacuum. My Tesla apparatus gives a spark three inches long in air at normal pressure. The mica radiometer vanes after many experiments lost nearly all the black substance with which they were coated; it appeared in the form of a deposit on the inside of the bulb, and it was deposited in the form of concentric circles, the centres of which were situated exactly opposite to the ends of the pointed conductors attached to the Tesla coil.

Thinking that the mica vanes in the Crookes' radiometer might have played a considerable part in producing the X-ray photograph, I replaced the radiometer by a well-exhausted bulb 4 c.m. diameter, made of soda glass; the bulb was placed with respect to the conductors from the Tesla coil in the same position as the radiometer in the former experiment. I found that with the same exposure and distance, a good X-ray photograph of the bones in the hand was produced. During the experiment the bulb was lit up with a bright and yellowish green glow. Since the Tesla discharge rapidly produces ozonised air which is irritating to the nose, throat and lungs, it is best to place the terminals in a draught of air moving away from the operator.

Oxford, October 17. FREDERICK J. SMITH.

PART TWO.

THE SUNDAY TIMES-HE

The Sunday Chicago Times Herald CHICAGO, OCTOBER 25, 1896.—FORTY-FOUR PAGES.

FINDS NATURE'S SECRET

Has Mrs. Benedict Solved Tesla's Great Problem?

ATOMIC SHEATH BROKEN.

Research Reveals the Force Long Sought by Scientists.

VIBRATION'S POWER FREED.

Claim That Electricity May Be Supplanted.

EFFECT ON AERIAL NAVIGATION.

Discoverer Believes That Human Life Will Be Prolonged Through Its Agency.

DETROIT, Mich., Oct. 24. Nikola Tesla:—I have discovered the hiding place of universal force, of that most vital and terrible thing, the fountain of pure electrical fluid.

Universal force is in the inter-atomic atmosphere and cannot be brought into open demonstration except by disrupting the atomic sheath, which has never been accomplished, except under veiled conditions, and then unwittingly and without recognition.

The phenomenon of the dynamite explosion when it takes place in open air apparently disrupts or disentangles or destroys every vestige of material substance included within a certain radius, from the apex of its prime energy, but I understand the methods by which these disruptions may be produced both in the air and upon the earth.

If the great master, Nikola Tesla, may think what I have said worth his attention I would be pleased to give him my plans.

With such power released and under control. I can see no reason why aerial navigation is not within easy reach, or why, with this most intense of all motor concept, the free activity of fluid electricity in its primal strength and vitality may not be applied to human life in its greatest complex and most extreme and minute extremities, why human life may be not only freed from depleted fiber and tissue, but prolonged for great periods of time. I give these suggestions, fully realizing what I say, and also understanding methods by which far more can be accomplished. I know there are countless discreet movements in the human body merging their energies into the complex and continuous. Also that they lose energy or that the atomic piston rods fall or move with much less rapidity from lack of the supply of pure electric energy.

Nikola Tesla has seen the inconceivable rapidity of the atomic movements in the human body, the fierce flames and vibration giving and receiving the lectric atomic energies and vitalities in every most minute viscera of every structure, and I am also conscious that he understands far more than I am able to express of this motor power of the universe alike in atom or whole, and of the infinite possibilities yet to be revealed to the world.

I am a woman past the meridan of physical years, but I have given all the best energy of the years I have had searching for the unseen, and at last I have been rewarded. I have just returned to Detroit from a four years' sojourn on the deserts of Colorado, away from books and papers, and I have known but very little of what has been done in the world during that time. Since my return it has been suggested that I write to you, giving my theories.

I believe I outlined my discovery and have given some suggestion of the magnitude of its possibilities, if such a discovery is developed.

That I am a woman does not exclude me from understanding so great a wonder.

Hoping I may hear from you, I subscribe myself, respectfully,

MRS. RENEW BENEDICT, Detroit, Mich.

This is a copy of a letter which Mrs. Renew Benedict, a lineal descendent of Benjamin Franklin, has written to Nikola Tesla, the great electrician. Tesla has been seeking for years to discover the solution of the problem Mrs. Benedict claims that she has solved. Mrs. Benedict had determined to mail the letter to Tesla, but finally changed her intentions, believing that if the announcement was made through THE TIMES-HERALD Mr. Tesla would be certain to see it, and would consider her discoveries more carefully than if he first learned of them through an unknown source.

If anyone should have been predestined to make a discovery which would revolutionize electrical science no better person could be found than Mrs. Benedict. She is a lineal descendant of Benjamin Franklin, the philosopher who discovered the identity of lightning and electricity. When less than a day old she was carried by her mother to the roof in deference to an old-time custom, and there above the flooded valleys of the keystone state was told to look up and be "high-minded."

As if to verify the custom, the child began life as a seer of visions and a dreamer of dreams. Before she could speak strange and marvelous revelations came to her which so impressed themselves on her infant mind that her first spoken syllables were themes of a world unknown, and on subjects since revealed through the interpretation of science.

When grown to womanhood Renew Daniels became a teacher in the romantic community of New Bergon, that ideal wild of Pennsylvania over which Ole Bull presided, a dreamer at the feet of the master and a teacher in a log schoolhouse, whence the strains of the magic violin had power to lure every pupil, leaving the youthful instructor free to close the temple of learning and follow the vagaries of genius.

These scenes passed like a dream, and Renew Daniels became Renew Benedict and was lost sight of in the retirement of domestic life. After that season of blessedness came widowhood, and years of sorrow and research. The strange doctrine of theosophy attracted her, and she studied it until she became an adept, reaching the highest circles, a member of the "king's chamber."

It was then that an inspiration seized Renew Benedict to go into the desert and learn the law of vibration. She purchased a ranch at Colorado Junction, and for the past four years has labored with pick and shovel on a fruit farm planted by her own hands. Suddenly she believed that she was enlightened and found herself on the verge of a great discovery, which even the latest disciple of science, Nikola Tesla, has not as fully fully developed, although working on the same lines.

Scientific men not only Nikola Tesla but others in America as well as German and French physicists, have been struggling with the problem of force. Electricity as known to-day is unknown. Although it has been made the servant of man, no man knows its nature. But slight advance has been made in the real knowledge of it since Franklin, Mrs. Benedict's ancestor, discovered its positive and negative conditions. For some time it was regarded as imponderable, as a tangible thing, an indivisible mass, but with the light shed by the latter experiments of science, the conclusion has been reached that it is a composition of something else as yet unknown. This may be what Mrs. Benedict has discovered.

The theory that light and heat was imponderable was held for years, as it has been held that electricity was an imponderable. But the world of science now believes that "imponderable" is only a word employed to mask ignorance of causes. Science discovered that light was a vibratory motion in the ether, while heat was a vibratory motion of atoms and molecules. This has engendered various theories as to the nature of electricity, and by some it has been thought to be due to rotations of matter.

Vibratory motion has been guessed to be the cause of electricity. Scientists have held that theory, but none have been able to prove it conclusively. Vibratory motion is the cause of the great phenomena of natural science, light, heat and electricity. Mrs. Benedict believes she has found a new force, perhaps akin to electricity, for which the scientists have been blindly groping, and which, like light and heat and what we call electricity, is due to vibrations.

Empty space is a perfect nonconductor of electricity. Tesla and Bell have proved this. It has been discovered that an electric spark would not pass through a vacuum, but that it would jump three feet in the air rather than bridge the eighth of an inch where there was no conducting material. It is therefore apparent that electricity or the force imperfectly known by that name exists in the air.

As the electro-magnetic theory is now well established, it implies that ether waves, either long or short, have their origin in the movements of matter of one size or another. The forces in electricity are the result of two effects. As light is an effect of forces in ether, and heat is an effect of forces in matters, so electricity, as it is known, is the result of an effect in matter and an effect in ether, the second being caused by the first.

Scientists have made sure of one thing. This is that electricity never manifests itself, except when there is some mechanical disturbance, which is termed vibration, in ordinary matter, and every exhibition of electricity may always be traced back to a mass of matter. Some of the electricians have confined themselves to a study of that which takes place in matter, others to that which takes place in ether. The confusion of scientists has been due to this divided experimental condition.

On the other hand, it has been the belief of Tesla and his followers, as well as scientists in France and Germany, that there is some latent force as yet unknown at work behind this, and they have believed that if the energy stored in each individual atom of matter could be released it would result in the securing of tremendous force with little waste.

Tesla believes that this can be secured by rapid vibrations. His theory is that all manifestations of energy are but the different tangible or apparent evidences of one force, and he has set himself to discover that force. All energy, whatever its form or manifestation, is, according to him, simply molecular agitation of greater or less degree. If that be true, then heat and light are merely the results of molecular agitation, and could this agitation be set up by purely mechanical means, heat or light would result. Then all forces would be found to be one.

It is the bold idea of Tesla that by causing matter to pass to the stage of luminous vibration, without remaining, for any appreciable time, in the stage of heat vibration, he could produce light without heat, and he has come very near success, thus proving the kinship of the phenomena.

Tesla started with the idea of setting matter into vibration at a rate approximating that of light, which is at the rate of 2,500,000 vibrations a second. He expected that under such violent agitation it would emit light. But he has not succeeded in producing so great a vibration, although wonderful luminous effects produced at a lower rate foretell his success. His discoveries have astonished the scientific world, and have paved the way for Mrs. Benedict's discovery.

The vibratory theory of a universal force is not new. It was surmised by ancient philosophers, and Pythagoras taught his pupils that the same forces underlaid both the harmonies of music, which are the result to vibrations, and the motion of the heavenly bodies. Leucippus believed, as Tesla has believed, and as Mrs. Benedict has discovered, that atoms possess within themselves a principle of energy. This belief extended so far as to enter upon the range of natural theology, and the theory of Democritus was that the soul's construction approached the hypotheses of vibratory physics. The mystics believed that matter is latent force, and force free matter. To liberate the force contained in the matter was their aim, but this was abandoned as impossible by the scientists of a century ago, although the realization of the ideas of the ancients now seems at hand.

Sound, the result of vibration of the waves of the air, enters into Mrs. Benedict's ideas. The explosion of dynamite or electricity in a vacuum would not be audible to our imperfect sense of hearing, and no man can see an atom, yet it is believed that it is there and that the laws governing nature's world may be revealed, as the telescope and microscope have daily revealed the existence of things hitherto unknown.

No man can see an atom. It is the indivisible substance of which everything is composed, innumerable atoms being required to make the mass. Electricity is the result of atomic friction, light and heat are have been found to be due to the same causes. Natural forces of heat, light and electricity are due to a disturbance of harmony, caused by the effort of each atom to assert its power over its neighbor—to separate itself from the average harmony of the mass and become independent. The individual atoms are each sustained by life, or in other words, the vibrations. The atoms independently separate from the light rays, and restored to the average harmony of the mass after absorbing vibration of the mass is the new condition of energy called electricity.

"I do not believe," says Edison, "that matter is inert; to me it seems that every atom is possessed of a certain amount of intelligence."

Mrs. Benedict, the descendant of Franklin, seems to have succeeded in releasing the atom from its sheath, giving it the ability to accomplish almost everything that is now done by other forces, while its possibilities for the future surpass the dreams of the wildest romancers.

Mrs. Benedict is now in Detroit. She is not a woman of fashion, for she has lived out of the world and has not even heard of balloon sleeves. In answer to a leading question she said:

"Yes, I believe that I have discovered the hiding place of universal force, of that most terrible and subtle thing, the fountain of pure electric fluid, not a highly impregnated substance in which electricity may be engendered or collected, but the fountain of the eternal and endless force itself. I believe that I have not only discovered its hiding place, but a means by which it can be liberated."

"Are you willing to give it to the world?"

"I am willing to give suggestive propositions to the world through the press of what this force is and where it can be found, and how it may be seized upon and brought into submission, but my actual method must remain my secret in the cause of science until I am fully prepared to demonstrate it to scientists. My secret is the disruption of the atomic sheath. I know Tesla is working on the same lines, but he has not accomplished that result. I believe that I have solved the problem, and when this great power is released and conserved in the interests of mankind, I can see no reason why aerial navigation will not be a result. Human life can also be indefinitely prolonged by the renewal of the vital functions, by use of the energizing power now wasted. This elixir of life will be produced when the vibratory force is released from its atomic sheath."

"Will you explain the method?"

"Yes. When dynamite explosions take place in the open air, they apparently disrupt or destroy every vestige of material substance included within a certain radius from the apex of its prime energy. But the power of the explosion is not contained within the dynamite, but the force generated by the gunpowder explosion is held in concentric waves, by its compact in the etheric glycerin envelope, which compact so intensifies the blow struck upon the air as to cause the air to retrovert upon itself with such intense vibration as to disrupt the atomic sheath and liberate the terrible force secreted within."

"Why has this never been discovered before?"

"The world has not been ready for a discovery of such godlike proportions. The atomic world is waiting for a Columbus—a liberator. It has never been compelled to yield its

[89000.]—**Tesla Effects.**—The cause of the innocuousness of these seems not to have been determined with certainty. If the impulses alternate at the rate of a million per second, it can easily be imagined that one of these would not have time in $\frac{1}{1000100}$th of a second to produce a destructive effect on the tissues, and at the expiry of that minute interval an impulse operating in the opposite direction, and therefore tending to counteract the first, would follow, while its destructive tendency would, in turn, be neutralised by the third impulse, and so on. Analogous results occur in hearing, where, as the pitch of a note is gradually increased, it becomes more and more shrill till it reaches a certain rapidity of vibration which varies with individual hearers, and then the sensation of sound ceases entirely. On the other hand, it was lately maintained in a leading medical journal that the great potential, and not the high frequency, is the operating cause. As the potential is increased the quantity of electricity is diminished, and may at last become so small as to be too weak to injure the human frame. Mr. Harcourt will find much interesting information bearing on the lighting-up of an incandescent lamp on short circuit in Tesla's lecture on "Light and other High Frequency Phenomena," delivered before the Franklin Institute, Philadelphia, February, 1893, and before the National Electric Light Association, St. Louis, March, 1893.

A. T.

[89311.]—**Tesla Coil.**—Provided you do not use a higher battery-power on your coil itself than you have usually employed, the presence of the Tesla transformer will not affect your coil in the slightest degree.

S. BOTTONE.

[89311.]—**Tesla Coil.**—Since your coil has the secondary wound in two sections only, it will be as well to be careful with it. If you mean to make it a part of a Tesla apparatus, you are almost certain to spoil it.

F. C. ALLSOP.

[39398.]—**Tesla Coil.**—No, to both queries. If your coil works badly, the Tesla will do worse. With a good steady running coil, the Tesla, as it increases the voltage, and also the oscillation frequency, enables a given coil to light up tubes which, owing to their high resistance, would be unworkable by the coil alone. But I am very doubtful whether, beyond this, any real advantage is gained—in other words, whether better radiographs are not to be obtained from a given coil by using a tube suitable to it, rather than by attempting to raise the voltage of the coil by the use of a Tesla to suit a higher voltage tube. S. Bottone.

TESLA'S LATEST CONTRIBUTION TO THE ROENTGEN-RAY PHENOMENA.

In this issue of the ELECTRICAL REVIEW we have the pleasure to bring to the attention of our readers another contribution on the subject of the Roentgen rays from the pen of Mr. Tesla, which, like all previous articles, conveys much useful and interesting information.

Mr. Tesla dwells on the nature of the rays, and brings out in strong relief some ideas and results which he has already recorded in our columns, and at the same time advances new observations and conclusions that can not fail to attract the attention of all workers in this new and fruitful field of investigation. We believe the possibilities pointed out of producing nitrogen compounds will prove of the greatest value.

The medical profession must indeed be indebted to Mr. Tesla for the valuable hints he gives for the application of Roentgen's discoveries to surgery.

His announcement of the real causes of the deleterious effects on the skin noted by a number of experimenters will be a welcome and timely revelation.

Mr. Tesla touches on the recently brought out and sensational subject of "making the blind see" by means of the Roentgen rays, presenting arguments and regretfully showing the hopelessness of such a task.

This latest communication will particularly interest the readers of the ELECTRICAL REVIEW by the wealth of the suggestions and important information it conveys.

TESLA ON THE ROENTGEN STREAMS.

To the Editor of Electrical Review:

The following lines may contain some useful information for physicists and physicians. Those who, in the exercise of their professional duties, are applying the discoveries of Roentgen to the relief of the suffering by determining the position of foreign objects or ascertaining the condition of local troubles or malformations in the organism, are apt to be disappointed in many instances. While it is perfectly easy to find the position of a foreign object in the head, neck and all soft tissues of the body, and detect some far gone trouble in the lungs, often the location of even such a large and opaque object as a bullet, when imbedded in certain bony parts of the trunk of the patient, may be attended with difficulties. Success will be invariably attained if the suggestions which are given below, and which are the outcome of a number of observations of such cases, are strictly followed.

In order to make the present statements self-contained and more useful, I deem it of advantage to say a few words in regard to the Roentgen rays. According to all evidences so far obtained by me, I entertain the view, which I have expressed on other occasions, that these rays are formed by streams of some matter projected with great velocity, and generally intermittently, from the walls of the tube. The intermittent character is only due to this feature of the apparatus usually employed for the production of the rays; but the oscillatory or intermittent discharge is not absolutely necessary, as I have produced unidirectional currents of high tension which are likewise capable of generating strong rays, and as a static machine may be used with a like result. The mode of formation of these rays or streams is, for the present purposes, of little importance. The small particles within the bulb, which are the original cause, may be ions, formed by a process of electrolysis, or they may be comparatively larger particles of the electrode, or perhaps molecules of the residual gas. At any rate, it is probable that the particles are very minute, and that, therefore, the velocities of the cathodic streams within the vessel are such and the impacts so violent as to cause a further disintegration of the cathodic matter to a state probably never before studied by physicists. We may have to deal, as I have already suggested, with an actual breaking up of the ether-vortexes, which, according to Lord Kelvin's theory, compose the material particles, or we may be confronted with a dissolution of matter into some unknown primary form, the Akasa of the old Vedas. Experiments show that this matter is reflected, sometimes very well, sometimes poorly; but in all cases the various metals behave in a curious manner, which I have studied, and the results obtained, though probably not free of error, because of the great difficulties in getting an exact estimate in such an investigation, were, nevertheless, sufficiently positive as to lead me to the conviction that the same medium or element which is concerned in the setting up of the electro-motive tension between metals in contact is present in the streams of Roentgen. It might have been proper to say, in the spirit of more modern views on contact electricity, that these streams are formed by ether, but I have preferred to use the term "primary matter;" for, although the expression "ether" conveys a perfectly definite idea to the scientific mind, there exists, nevertheless, much vagueness as to the structure of this medium. The matter projected is not revealed by spectral analysis, and it does not seem to produce any appreciable mechanical nor even heating effects, nor is it deflected by a magnet, all of which facts tend to show that it can not be composed of *molecules* of any known substance. The streams exercise a powerful action upon a photographic plate or fluorescent screen, but I look upon these results as obvious consequences of the energetic impact.

Of the various more or less plausible views in regard to the formation of these streams outside of the vessel, the simplest, to my mind, is to assume an actual projection through the walls of the bulb of the disintegrated cathodic matter. Granted that there are particles sufficiently small within the bulb, then all velocities, up to many thousands of kilometers per second, are not only possible, but also probable; and, even if the particles would not be further disintegrated by the impact against the wall or other comparatively opaque body within the bulb, they surely would penetrate through great thicknesses of most substances. My experiments in this direction have shown that all the disintegration is practically accomplished in the first impact against the more or less impenetrable obstacle within the bulb, the second impact having seemingly little effect, as might be inferred from well established mechanical principles. I have also found that the place of first and most energetic impact, be it the anode, cathode or wall of the vessel, is invariably the principal source of the rays or streams. Again, quite in accordance with mechanical principles, the penetrative power of the streams is the greater the more complete the disintegration. Thus, for instance, rays which have traversed thick opaque objects, and are presumably further disintegrated, pass more freely through dense substances. An observation to this effect has likewise been made by Professor Wright, who was the first to publish definite results in the United States. I find that bulbs with thick walls give rays of greater penetrating power. It should be, of course, understood that I do not mean by this a greater outward effect. It is principally the above fact which makes it appear more probable that the matter projected is not a *homogeneous stream*, but consists of particles of varied magnitude moving with different velocities, for, were the former the case, the penetrative power would depend chiefly on the velocity. In the practical use of the Roentgen streams it would, therefore, seem very important to find a method of filtering and rendering them homogeneous, for only by such a method can we hope to obtain exact results in their investigation. Streams of perfectly uniform velocity and character, if produced, would no doubt be more suitable for the purposes of research.

Since the disintegration of the electrodes, especially if they are of aluminum, is so slow that no appreciable diminution of the weight results even after long use; it follows that the matter conveyed by the Roentgen streams is so minute as to escape detection. Some bulbs, which I have used for a number of months, showed that the bombarded spot of the glass was entirely permeated with particles of the aluminum electrode, but it would probably require years of constant use to accumulate any appreciable amount of matter outside. Referring to a tube with an electrode of aluminum, it is a noteworthy fact that, if properly managed, it does not impair in quality, but, on the contrary, seems to improve; whereas, when a platinum electrode is used, the life of the bulb is very short, owing to the conductor being deposited on the walls, which deposit, as I have explained on another occasion, renders difficult the passage of the discharge. Namely, as soon as some of the projected particles strike the conducting layer, they impart a similar electrification to the latter, and a repulsion is exerted upon the particles following. The result is an apparent increase in the resistance of the tube. The above defect of the platinum electrode, despite of its effectiveness, must, in my opinion, lead to its abandonment.

It has been suggested that the Roentgen rays may be due simply to a propagation of electro-static stress; but, on this assumption, it is difficult to conceive how rays could be produced in instances when the glass wall is at a high temperature and consequently conducting, or when the impact plate or inclosure is of metal and connected to the ground. Stokes has recently considered the possibility that the impact of the cathodic stream on one side of a partition might give rise to a molecular motion on the other side without necessarily there being a transit through the partition. According to this view, which I have likewise considered some time ago, it would appear that the material streams might start on the outer side of the wall of the tube, in which case only the air would be responsible for the effects, and the futility of a spectral analysis test would be in a certain measure accounted for. But is it not more probable to assume an actual passage and shattering of matter, as all evidences point in this direction? Assuming that, as Professor Stokes now thinks it probable, the disturbance is non-periodic and still capable of producing effects characteristic of transverse vibrations of extremely high frequency, it seems to me a serious question whether the old Newtonian views on light should not be reconsidered rather than the conclusion drawn that the novel manifestations observed by Roentgen are due to transverse vibrations, when there is no experimental evidence to this effect, nor even a satisfactory explanation found how the cathodic impact might give rise to waves of a higher frequency than those of light.

Being, as I am, firmly convinced of the existence of material streams, I look upon the unsuccess of the attempts of demonstrating an actual transit of matter as being due to either the minuteness of the amount or else to the state of the matter, but rather to the former cause, as all peculiarities of the streams point in this direction. In my opinion, no experimenter need be deterred from carrying on an investigation of the Roentgen rays for fear of poisonous or generally deleterious action, for it seems reasonable to conclude that it would take centuries to accumulate enough of such matter as to interfere seriously with the process of life of a person. But I look confidently to the demonstration of actions of a purely qualitative nature. For instance, despite of the danger of such an assertion by encouragement which might be given to quacks, I would say that I expect with the utmost confidence the demonstration of a germicidal action. In addition to the physiological effects, to which I have early drawn attention, I have more recently observed with powerful tubes that a sensation of pain is produced in the forehead above the eyes just as soon as the current is turned on. This sensation is very similar to that one frequently experiences when stepping from a dark room into the glare of bright sunlight, or when walking for some time over fields of fresh-fallen snow.

As to the hurtful actions on the skin, which have been variously reported, I note that they are misinterpreted. These effects have been known to me for some time, but I have been unable, on account of pressing matters, to dwell on the subject. They are not due to the Roentgen rays, but merely to the ozone generated in contact with the skin. Nitrous acid may also be responsible, to a small extent. The ozone, when abundantly produced, attacks the skin and many organic substances most energetically, the action being no doubt heightened by the heat and moisture of the skin. After exposing the hand, for instance, for some time, the skin loses its elasticity, which causes a tension and pain, and subsequently an inflammation and blistering. This occurs mostly only at short range, but may be produced by a single terminal bulb, or generally by a very highly exhausted bulb, in which the terminals act independently, at greater distance. Owing to this, I have always taken the precaution, when getting impressions with the rays, to guard the person by a screen made of aluminum wires which is connected to the ground, preferably through a condenser. The radical means, however, of preventing such actions is to make impossible the access of the air to the skin while exposing, as, for instance, by immersing in oil. As this would be inconvenient in most cases, a metallic screen should be resorted to. The action of the ozone on some substances, when placed near the bulb in such a way that the gas is generated on their surfaces, is so powerful that the substances are practically destroyed in a few minutes. When a wire heavily insulated with rubber is connected to the terminal of a high-frequency coil, sometimes an exposure of barely a minute is sufficient to completely wreck the rubber insulation. There are certain commercial insulating compounds which are even more quickly destroyed, but which I will not enumerate, because of a possible disadvantage to the manufacturers. Gutta-percha, beeswax and paraffine stand the attack very well, and such

(Continued on page X.)

TESLA ON ROENTGEN STREAMS.

(Continued from page 277.)

wires should be used with high-frequency coils. This powerful action of the ozone was observed by me first about two years ago, when performing an experiment which was shown to many persons in my laboratory. The experiment consisted of charging a person, standing on an insulated stand, with a potential approximating one and one-half million volts, which was alternated several hundred thousand times a second. Under such conditions luminous streams break out on all parts of the body, especially abundantly on the feet, hands, hair, nose and ears. I subjected myself a number of times to this experiment, which seemed to offer no other danger except the possible rupture of a blood vessel, if the skin was very dry and non-conducting. I then noted on myself and others after effects resembling much those attributed to the Roentgen rays. With currents produced by perfected electrical oscillators, such as were described in one of your recent issues, [See ELECTRICAL REVIEW, September 30, 1896.—ED.] the production of the ozone is so abundant that it is sufficient to merely turn on the current for a few seconds and ozonize strongly the atmosphere of a large hall. These currents are also capable of bringing about chemical combinations, of which the chief is that of the nitrogen with the oxygen of the atmosphere, and an immense possibility, which I have been following up for a long time, is opened up; namely, the combination of the nitrogen of the atmosphere on an industrial scale by practically no other means than mechanical power. If merely fertilizers of the soil would be manufactured in this manner, the benefits to humanity derived therefrom would be incalculable. From the above-named action of the ozone, it follows that the experimenter should use the indicated precaution, for, while ozone in small quantities is a most beneficial disinfectant, when generated in large quantities it is not free of danger.

It is an unpleasant duty to say on this occasion a few words on the subject of "making the blind see" by means of the Roentgen rays. This sensational topic has been given a wide circulation in the journals. Is it not cruel to raise such hopes when there is so little ground for it? For, first of all, the rays are not demonstrated to be transverse vibrations. If they were, we would have to find means for refracting them to make possible the projection of a sufficiently small image upon the retina. As it is, only a shadow of a very small object can be projected. What possible good can result from the application of these rays to such purposes? The shape of the small object might eventually be recognized by impressing the retina, but the sense of touch is more than sufficient to convey such impressions. Luminous sensations are well known to be excited in two ways; namely, by mechanical shock and electrical transmission. Both of these, I think, are present in the Roentgen streams, and hence such an effect on the optic nerve might be expected. I may say, however, that I can not confirm some of the experiments reported. For instance, when a hand is put before the closed eyes it is easy to distinguish the shadow, much the same as before the light of a candle; but when the tube is inclosed, and all light from the same excluded, I fail to get such an impression. The latter is, therefore, chiefly due to ordinary light, or else my tubes act differently from those experimented with by others. It may be proper to recall here that in ordinary bright sunlight, especially in the southern climates, it is easy to distinguish the shadow of objects, and even their rough outlines, with the eyes shut.

Proceeding on the assumption that we have in reality to deal with material streams, it is important to inquire which are the best conditions to be maintained when taking impressions with the sensitive screen or plate. First, the experimenter will easily observe that there are two causes which, with a given bulb and coil, tend to increase the intensity of the impressions. One of these may be said to lie in the bulb, the other in the coil. The latter, being most generally made of many turns of fine wire, is very sensitive to changes in the capacity of bodies attached to its terminals. The capacity of these bodies, therefore, in such a coil largely determines the difference of potential. At a certain degree of exhaustion this capacity assumes such a value that the pressure rises to a maximum, this tending to give the highest velocity to the cathodic stream, and, consequently, to give rise to the most intense rays. But at that degree of exhaustion it may happen, and usually does happen, that the cathodic streams are not most abundant. To produce the best result it is necessary that both of these causes should be made to cooperate by a careful proportioning of the dimensions of the bulb, which, in practice, is very difficult, inasmuch as the experimenter has to avail himself of commercial bulbs which may or may not be best suitable for his coil. This simple consideration shows the great advantage of the use of a coil which contains no fine wire and is capable of giving a heavy current through the secondary far in excess of what even the largest bulb requires.

Assuming the physician has learned how to manipulate his apparatus to best advantage, he will next notice that, to secure the clearest definition, he will have to maintain a certain pressure on the terminals of the tube, dependent chiefly on the distance and degree of opacity of the object investigated. It goes without saying that the definition is the better the smaller the spot from which the rays are emanating, but this is true only when impressions are taken at very small distances. When the distances are large, it is a disadvantage to use a too small radiating surface, as then the density is diminished to such a degree that the action is too weak. Discarding this consideration, it is clear that, if the rays are intense, the more opaque portions of the body are likewise penetrated and much detail is lost, whereas, when the rays are less intense, the impression might be altogether too weak to bring out sufficient detail.

To illustrate in a popular manner the best way to proceed, I shall avail myself of a simple illustration. Suppose that there would be imbedded between two panels of cloth a foreign object, such as a coin, and it is desired to locate it. We may accomplish this by placing behind the cloth a cardboard, for instance, and then firing from a certain distance a load of fine shot through the cloth in the region where the coin is supposed to be located. The shot will penetrate the cloth on all points except on the place where the coin is located, and on the cardboard behind, this place will be plainly indicated by the absence of the marks. Exactly in this way we proceed in applying the Roentgen rays to the location of such a body. Roentgen gave us a gun to fire—a wonderful gun, indeed, projecting missiles of a thousandfold greater penetrative power than that of a cannon ball, and carrying them probably to distances of many miles, with velocities not producible in any other way we know of. These missiles are so small that we may fire them through our tissues for days, weeks, months and years, apparently, without any hurtful consequence. Instead of the cardboard to indicate the path of the missiles, he gave us what is properly called a Roentgen screen, which becomes luminous on all places where it is hit by the missiles. Where the latter are prevented from hitting the screen by the intervention of the opaque body, the screen does not glow and we observe the shadow of the object. It is simple enough to project the shadow of an object in this way, but when it is required to show the finer detail of the structure of the object, the difficulty begins. It will at once appear that, to produce such a result to best advantage, two conditions will have to be more or less realized. Firstly, the screen should be composed of such material that it is capable of becoming luminous by the *faintest impact;* and, secondly, the missiles should all be of uniform size, and should move with uniform velocity. Neither of these two conditions has so far been realized in practice, for all the bodies we know require a violent impact to become luminous, and no way has been found as yet to produce a uniformity in velocity and magnitude of the supposed projectiles. But a little thought leads immediately to the conclusion that there will be a certain velocity of the missiles which will give, under all conditions, the best definition. This velocity is easily ascertained by trial. Evidently the definition will be best when the bullets which pass through the densest parts of the body strike the screen so feebly as to not make it light up, whereas, those passing through portions of slightly smaller density hit it sufficiently strong as to make it light up feebly. The more sensitive the screen to impact, that is, the weaker an impact is required to make the screen light up, the more detail will be revealed. It therefore follows that, in the application of the Roentgen rays, not the body which fluoresces strongest, but the one which is most sensitive, is best suited for finer work.

The above considerations have led me to adopt the following procedure, which, in practice, has proved very successful. The Roentgen screen is first applied to the body to be investigated, the pressure at the terminals of the tube being very much reduced. The pressure is then slowly and gradually raised. It will be presently observed that, at a certain pressure, the shadow of the object examined is clearest. But as the vacuum is increasing, the pressure generally rises, and the image gets blurred in spite of the screen getting much brighter. Just as soon as the clearness is slightly diminished, the experimenter should for a few moments reverse the current, lowering a little the vacuum in this manner. The current being again given the direction it had at first, namely, that which causes a slow and steady increase of the vacuum, the shadow gets again clear, and by such easy manipulation the best result may be secured. An additional advantage, however, is gained, because the frequent reversals produce a brighter phosphorescence of the screen. When taking a photograph, the bulb should be watched through the screen and the switches manipulated in the above manner.

To give a practical example of the effectiveness of this procedure, I need only mention one of the instances which have come to my notice. A few months ago I investigated the case of Mr. Cornelius Mack, of Watertown, Mass. Mr. Mack, while performing his duties many years ago, was struck by a bullet which lodged somewhere in the chest and could not be located. I applied the screen vainly a number of times; for although the streams penetrated the body with such ease as to make the screen behind appear bluish white, and reveal all the bones of the body, I could not observe the missile. I then resorted to the above indicated means, and immediately and easily the exact location of the projectile, between the shoulder blade and one of the ribs, was ascertained and the bullet successfully extracted. NIKOLA TESLA.

New York, November 30.

The New York Herald December 2, 1896

X RAYS ON THE BLIND.

Nikola Tesla Deprecates the Holding Out of Hope to the Sightless and Says Facts Do Not Warrant It.

The Electrical Review will publish to-day an exhaustive communication from Nikola Tesla on his latest experiment with the X ray. Tesla states that the sunburn effects noted by many experimenters are not due directly to the rays, but to the ozone generated by the rays in contact with the skin.

In referring to the recently widely heralded experiment for making the blind see by means of the Roentgen rays, he regretfully remarks:—

"Is it not cruel to raise such hopes when there is so little ground for it? For, first of all, the rays are not demonstrated to be transverse vibrations. If they were, we would have to find means for refracting them to make possible the projection of a sufficiently small image upon the retina. As it is, only a shadow of a very small object can be projected. What possible good can result from the application of these rays to such purposes?

"I cannot confirm some of the experiments reported. For instance, when a hand is put before the closed eyes it is easy to distinguish the shadow, much the same as before the light of a candle; but when the tube is enclosed and all the light from the same excluded, I fail to get such an impression. The latter is, therefore, chiefly due to ordinary light."

Tesla then points out a possible method of manufacturing fertilizers by electricity. "With currents produced by perfected electrical oscillators it is possible to combine the nitrogen of the atmosphere. If merely fertilizers of the soil would be manufactured in this manner the benefits to humanity derived therefrom would be incalculable."

He concludes with an interesting description of an improvement in the method of taking X ray impressions in surgical cases.

The New York Tribune December 2, 1896

TESLA'S EXPERIMENTS WITH X RAYS.

"The Electrical Review" will publish to-day a communication by Nikola Tesla concerning his recent experiments with X rays. He says that the sunburn effects observed in the use of the rays are not due directly to the rays, but to the ozone generated by the rays, and adds: "The ozone, when abundantly produced, attacks the skin and many organic substances most energetically." By the use of perfected oscillators, he asserts, "the production of ozone is so abundant that it is sufficient merely to turn on the current for a few seconds to strongly ozonize the atmosphere of a large hall." He hints at the possible manufacture of fertilizers by the use of the electrical current, and goes on: "If merely fertilizers of the soil could be manufactured in this manner, the benefits to humanity derived therefrom would be incalculable."

The inventor does not think it is possible to make the blind see by means of the X rays, because by means of the rays only the shadow of a small object can be projected. He declares that he cannot confirm some of the experiments reported, and remarks: "When a hand is put before the closed eyes it is easy to distinguish the shadow, much the same as before the light of a candle, but when the tube is inclosed, and all the light from the same excluded, I fail to get such an impression. The latter is, therefore, chiefly due to ordinary light."

NEWS AND NOTES.

MR. TESLA ON THERMO ELECTRICITY.

In a letter to the editor of the Buffalo Enquirer, Mr. Nikola Tesla replies as follows in regard to an inquiry on the subject of the future of electricity:

"The transmission of power has interested me not only as a technical problem, but far more in its bearing upon the welfare of mankind. In this sense I have expressed myself in a lecture, delivered some time ago.

"Since electrical transmission of energy is a process much more economical than any other we know of, it necessarily must play an important part in the future, no matter how the primary energy is derived from the sun. Of all the ways the utilization of a waterfall seems to be the simplest and least wasteful. Even if we could, by combining carbon in a battery, convert the work of the chemical combination into electrical energy with very high economy, such mode of obtaining power would, in my opinion, be no more than a mere makeshift, bound to be replaced sooner or later by a more perfect method, which implies no consumption of any material whatever.

THE WONDERFUL EXPANSION IN THE USE OF ELECTRIC POWER.

By Louis Bell.

THE transmission and distribution of energy is the latest of the great electrical arts. To be sure, in the almost prehistoric days before the invention of the dynamo, there were electric motors, as there were electric locomotives and electric lights, electric heaters and electric boats; but the ingenuity of Henry, Jacobi, Davidson, and Page led to no useful end. Their machines were relegated to the scrap-heap or the cabinet shelf by the same grim logic of economy that, in the fullness of time, has forced the modern motor into the front rank of industrial improvement.

When, just a quarter of a century ago, Gramme and Siemens gave the dynamo substantially its present form, every kind of electrical work received a sudden and powerful impetus. The subsequent half-dozen years were crowded with developments. In 1873 the first motor of modern type was put into operation at the Vienna Exposition by Fontaine and Breguet, the motor working a little pump through a mile or so of cable. In the next few years motors were occasionally exhibited or put to temporary use, but it was not until the autumn of 1878 that experiments and demonstrations culminated in commercial operation.

The time was propitious; the growth of electro-plating and electrotyping had given the dynamo-builders encouragement and occupation; the arc lamp had outgrown the laboratory and the lecture-room, and was becoming a practical illuminant. It was whispered, too, that, if the experiments then in progress on incandescent lamps were successful on a commercial scale, the problem of general electric lighting was to be at last accounted as solved.

More than this, some convenient and economical means of transmitting and distributing mechanical power had long been badly needed, and men were ready to turn hopefully to the potent force that had already achieved so much. Power transmission by wire ropes and by compressed air had already been weighed in the uncompromising balance of experience, and had been found wanting,— the former in flexibility, the latter in efficiency.

In the latter part of 1878 MM. Chrétien and Félix installed in the beet-sugar works at Sermaige the first commercial electric motor, operating a little hoist used in unloading the beets from the boats in

which they were brought down the river. During the succeeding winter four thousand tons of beets were thus unloaded, and the cost was found to be about forty per cent. less than unloading by hand The appearance of this historical motor is shown in Fig. 1. It developed only two or three horse power, and received its energy from a similar generator about twenty rods away. From this beginning has sprung the prodigious growth of to-day.

The next summer the first electric railway was put into operation at the Berlin Exhibition,—a single car, capable of carrying fifteen or twenty passengers, and running over fifty rods of track. The trans-

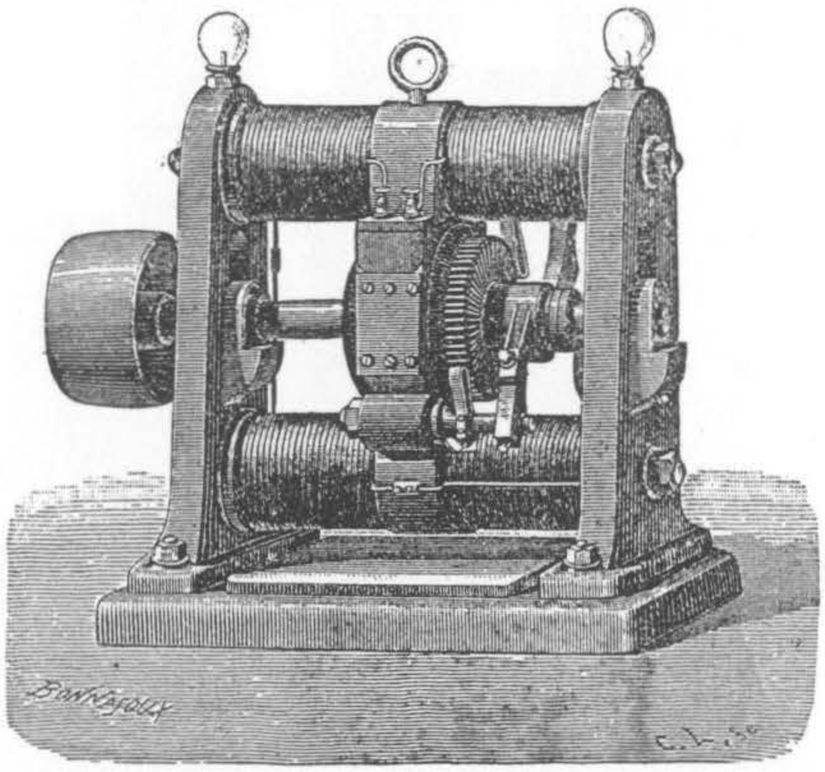

FIG. 1. ONE OF THE FIRST COMMERCIAL MOTORS.

mission of energy to both stationary and moving motors was quickly taken up in this country. S. D. Field and Edison were pioneers in the work; in fact, the former was actively experimenting when the foreign work was made known; and presently scores of inventors were busy, with true Yankee push, in working out the manifold applications of electrical motive power.

At first the only available sources of current were the recently-established arc-light circuits. Upon these small motors began to appear soon after 1880, and with increasing frequency in the next succeeding years. Soon Edison lighting-stations became available, and during 1882 and 1883 small motors began to go into service in con-

nection with them. By the fall of 1884, when the Philadelphia Electrical Exhibition was in progress, the electric motor was firmly established as a machine commercially available, and its valuable properties were well understood. In fact, the Electrical Expositions of 1881 in Paris and 1882 in Munich had shown the capabilities of motor service, and at the latter had been shown the first experiment in long-distance power transmission,—an experiment more daring and revolutionary even than the famous one at Lauffen-Frankfort nine years later.

This work was done by Marcel Deprez, and consisted in the transmission of power from Miesbach to Munich, — thirty-seven miles, a distance longer than is spanned by any commercial plant in operation to-day. The line was of common telegraph wire, and the energy delivered was less than half a horse power, which was employed in driving a centrifugal pump. The voltage of the dynamo was about 1350, and both generator and motor were specially-wound Gramme machines. The station at Miesbach, the first power-transmission plant in the world, is shown above in Fig. 2.

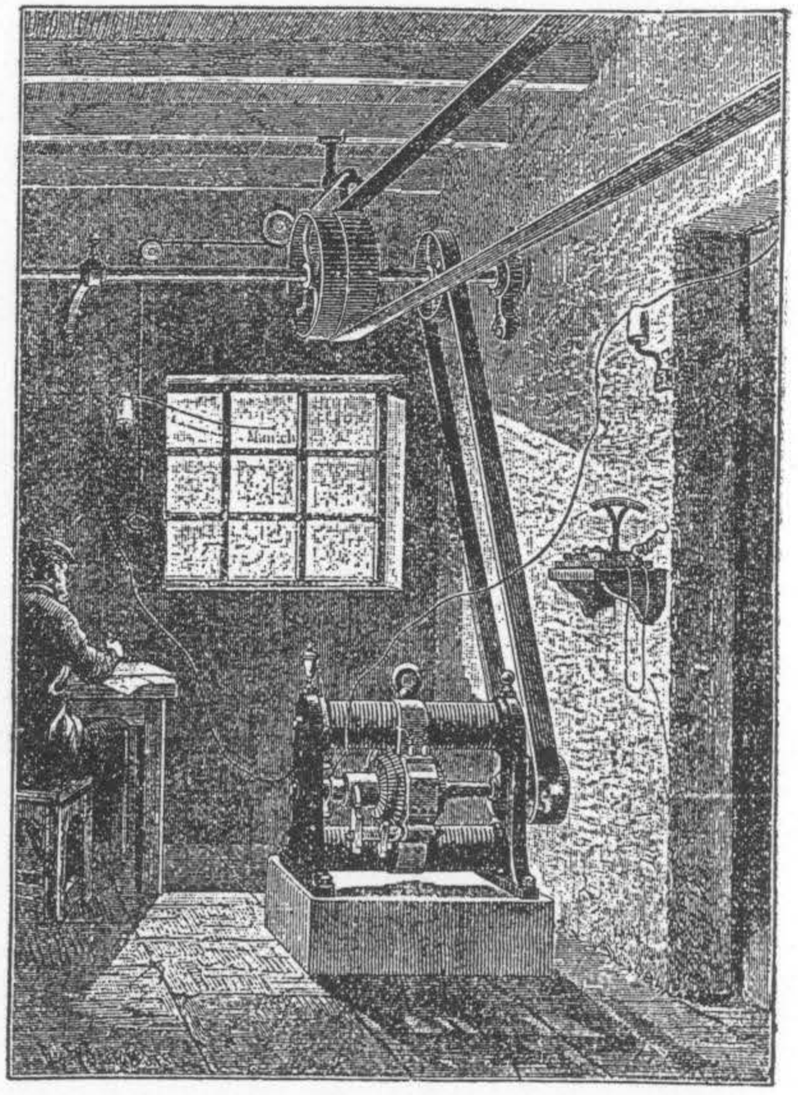

FIG. 2. THE MIESBACH POWER STATION.

From 1884 the development of the motor, following up the growth of electric lighting, was increasingly rapid, and by the autumn of 1886

it was estimated that there were no less than five thousand electric motors in use in the United States.

At the same period there were nine electric railways in operation, running fifty-eight motor cars and aggregating thirty-five and one-half miles of track. Many battery motors are included in this estimate, and the arc circuit was still an important source of power.

Thereafter the growth of the art was mainly in the direction of railway service, though the incandescent lighting stations soon began to take on motor service in considerable amounts.

In 1888 came the Tesla motor that has since played so important a part in the development of electric power, particularly in the past few years. As electric railways became more and more common, and engineers became more familiar with the construction and management of dynamos for fairly high voltages, motor work began to assume larger proportions and to reach out over greater distances. A few special motor circuits were installed at 220 and 500 volts, and a successful series motor distribution was started in San Francisco. But more experience was needed, and the time was not yet ripe, so that it was not until 1890 that power transmission as such began to gather headway. From 1890 dates the real period of industrial development.

By this time it was well ascertained that the electric motor was a thoroughly efficient and reliable machine, capable of being trusted with important work and fully able to compete with steam power under conditions that could often be realized. With power derived from ordinary central stations the motor was often far more economical in its operation than small steam engines with their attendant inconvenience and care; and it was obvious enough that no known means of transmitting power was so efficient or convenient for general purposes. Given a cheap source of power, the problem of its economical distribution was at last solved.

It was but natural that the mining regions of the far west, where coal was very expensive and water power plenty, should have been the scene of the first attempts at the electrical transmission of power. About the beginning of 1890 several transmission plants were put in operation, employing for the most part 500-volt railway generator and distributing power for mills, pumps, and hoists. This was only a useful makeshift, and it was necessary to break away from ordinary voltages before power transmission could assume the industrial importance that is its due. The step was not an easy one, for high voltage was a dreadful bug-a-boo in 1890; but taken it was, both with continuous and with alternating currents, and early in the next season two notable plants went into operation: one at the Dalmatia Mine, Califor-

nia, transmitting 100 h. p. at 1,800 volts 1½ miles; the other at Telluride, Col., delivering a similar amount of power 2½ miles away by means of a monophase alternating current at an effective pressure of 3,000 volts. A single synchronous motor was used, brought up to speed by a Tesla split-phase starting motor. At the Dalmatia Mine Brush continuous-current machines were used, one at each end of the line.

The polyphase systems were as yet undeveloped, as shown by the use of monophase current instead; but the Tesla motor had already been in use, for in the summer of 1890 several Hercules mining machines had been equipped with them and put into regular service near Pittsburg. One of these pioneer machines—the first commercial polyphase induction motor—is shown in Fig. 3. Then, in the summer of 1891, came the Frankfort Electrical Exhibition, which gave to electric power development the final impulse needed. Since then the transmission work in this country has been, with a few trivial exceptions, entirely polyphase. The next year saw much experimentation, much growth of ordinary motor service, but no power-transmission plants, save a small monophase synchronous one at Walla Walla, Washington, and another, closely similar to the Telluride plant, but of double the capacity, and working over a line 12½ miles long, at Bodie, Cal. A notable step was taken, however, in the establishment of a long-distance lighting plant, delivering energy from the generating plant in San Antonio Cañon to the towns of Pomona and San Bernar-

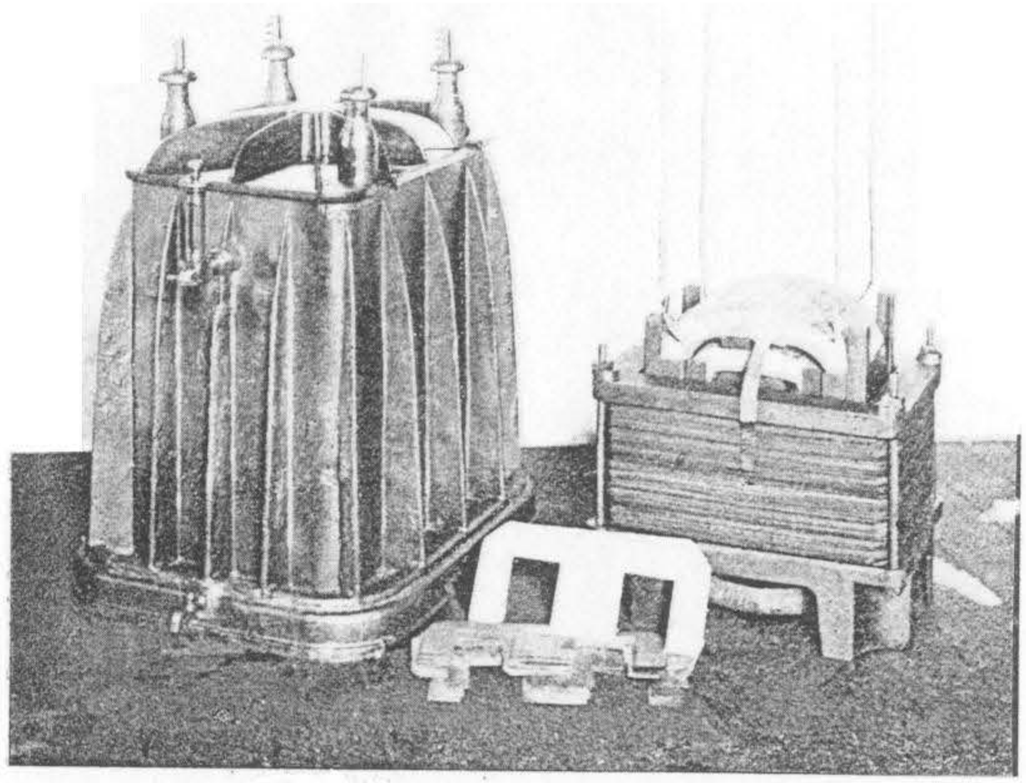

FIG. 4. POMONA TYPE TRANSFORMER.

dino, Cal., distant respectively 13¾ and 28¾ miles. An ordinary alternating generator was used, but the voltage was raised to 10,000 volts by a bank of twenty step-up transformers in series. It was the first commercial use of so high a pressure, and the extreme distance of transmission has been exceeded only within the past year. One of these historical raising transformers is shown in Fig. 4.

The hard times were now drawing near, but the good work went along, and 1893 saw marked and substantial progress in the use of electric motive power. Not only was there steady increase in the installation of motors for every purpose, but the Columbian Exposition was rich in transmission apparatus, and before the end of the year three polyphase plants had gone into service, and—what was worthy of special note—the final steps had been taken to furnish the great Niagara plant with generators of American design and manufacture.

During the times of dire financial stress in 1893 and 1894, when many industries were completely prostrated, the electrical distribution of power grew as it had never grown before. Business men saw an opportunity of reducing operating expenses by securing cheap power, and grasped it. Aside from all the motors sold for factories

and work-shops, contracts were made by the leading electrical companies for more than a score of polyphase transmission plants.

Notable among these were two great cotton mills at Columbia and Pelzer, S. C., equipped throughout with polyphase motors, for the most part applied directly to groups of machines, dispensing with the costly and complicated systems of belting and shafting heretofore used in such factories. Fig. 5 shows the generating plant at Pelzer, with its three 750-kilowatt three-phase generators, directly coupled to turbines, delivering current at 3,300 volts to the mills 3½ miles away.

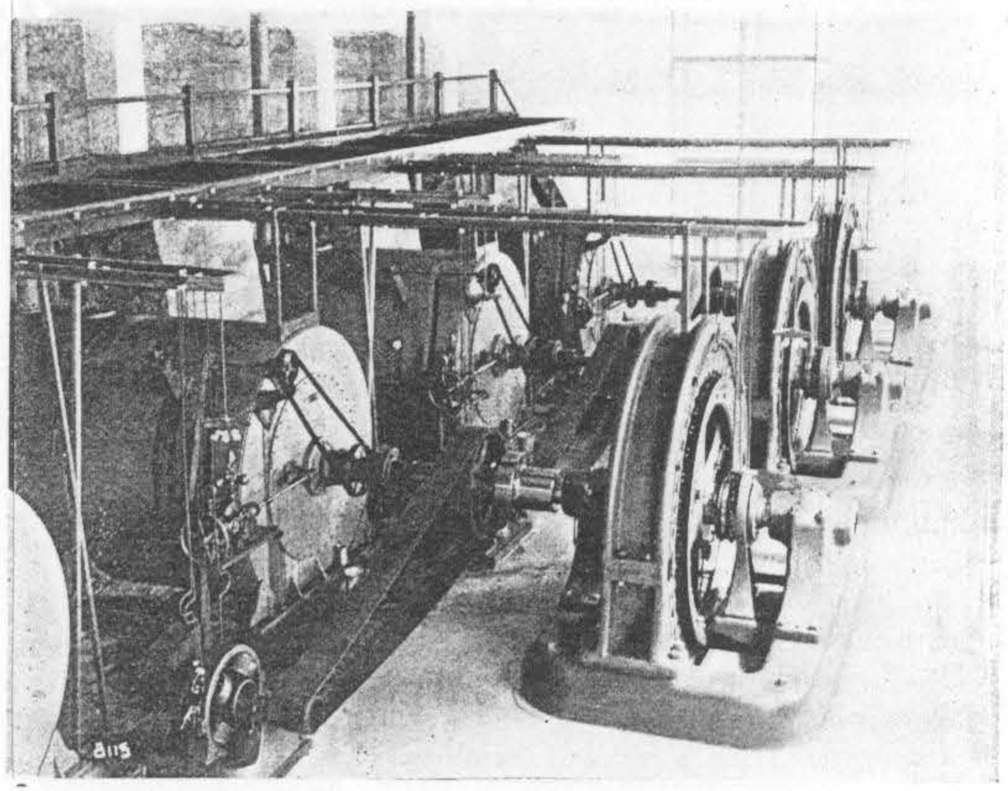

FIG. 5 THE PELZER DYNAMO ROOM.

The next year saw increased activity and epoch-making work. In the early summer the Folsom-Sacramento three-phase plant went into operation, of 3,000 kilowatts capacity, furnishing all the power and light used in Sacramento 23 miles away,—the longest commercial transmission that had yet been installed. A little later the huge Niagara plant went into operation with its 5,000-h. p. generators,—an installation that for size and startling engineering features will stand unique for many a year to come. Fig. 6 shows the present appearance of this immense station, of which so much has been heard of late that further description is needless.

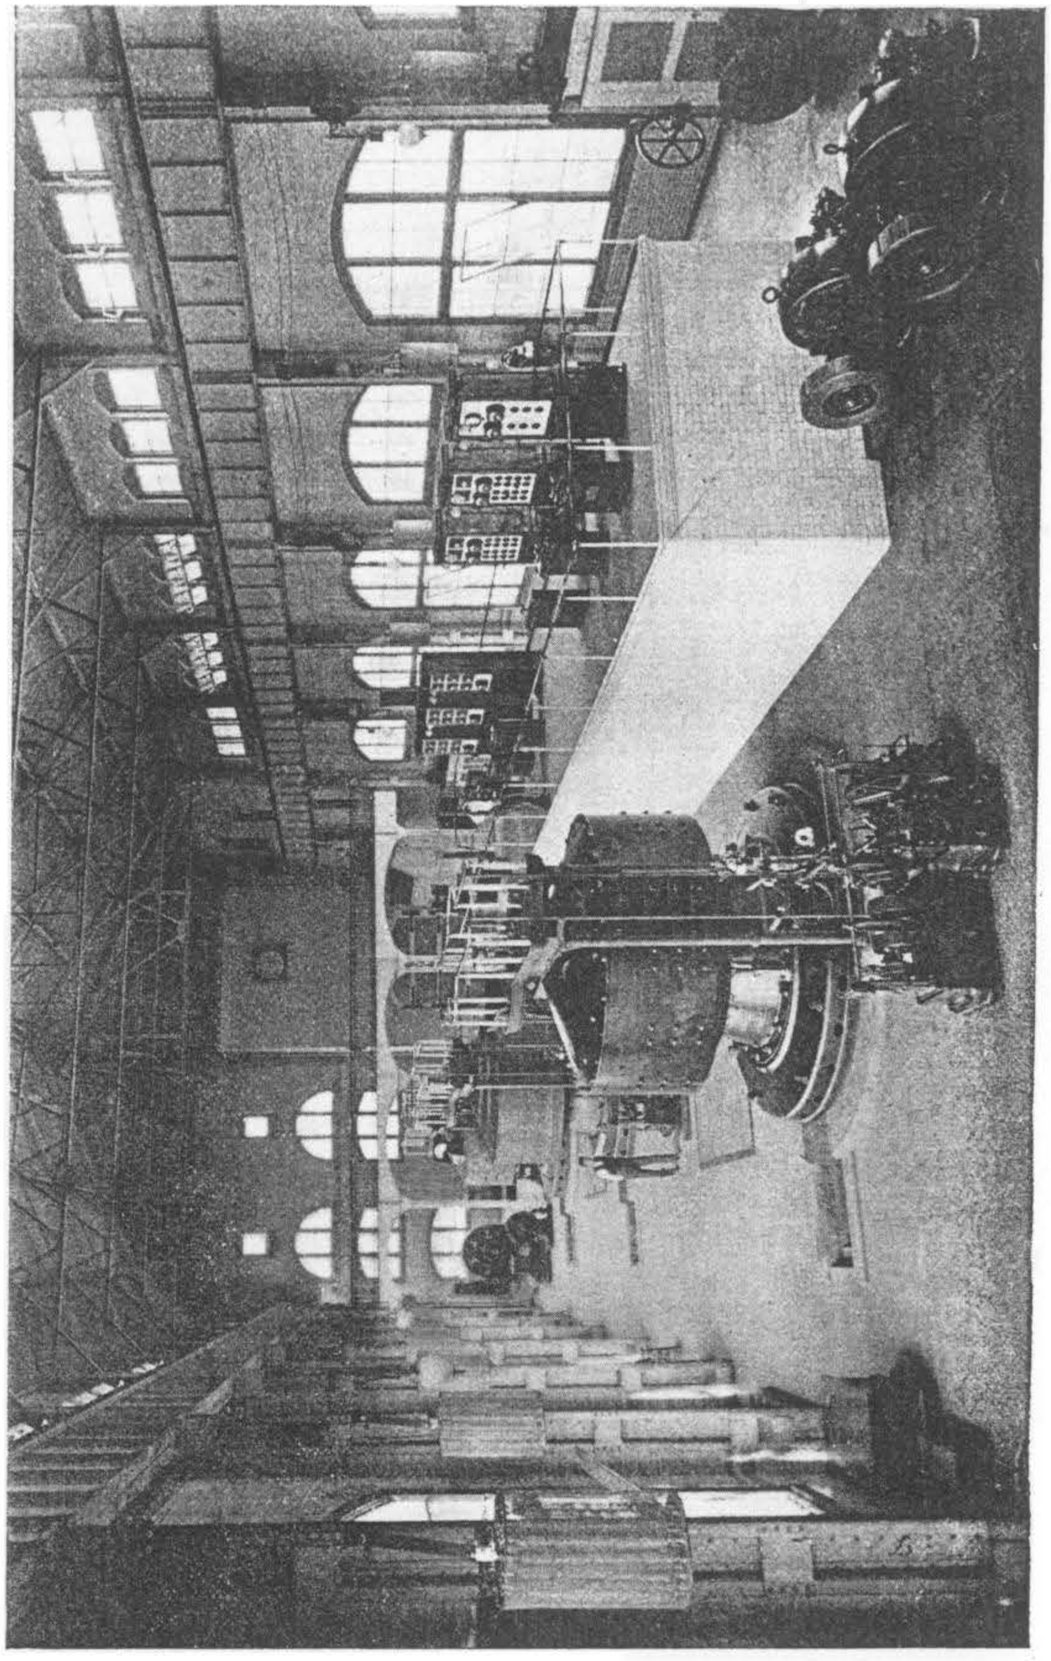

FIG. 6. INTERIOR OF THE GREAT NIAGARA POWER STATION.

In early autumn another sensational advance was scored in the starting of the enormous electric locomotives in the Baltimore & Ohio tunnel under the city of Baltimore. These colossal machines more than equalled in power the largest freight locomotives in existence, and their performance made the first great inroad into the realm of heavy railroad work,—an incursion that will be pushed into the very citadel of steam. Fig. 7 shows one of these locomotives, weighing 96 tons, and with a draw bar pull of more than 60,000 pounds.

Motor plants of every kind have multiplied, and the past year has seen greater progress than any which preceded it. Specially notable has been the transmission of power 35 miles into Fresno, Cal., at 11,000 volts,—the longest commercial transmission yet accomplished

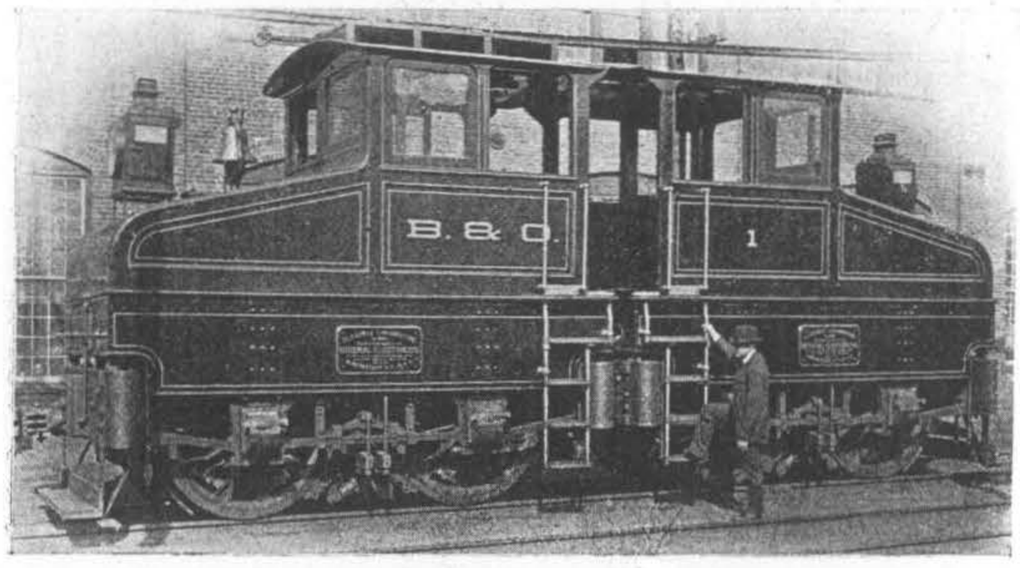

FIG. 7. BALTIMORE AND OHIO ELECTRIC LOCOMOTIVE.

anywhere; and very recently the long-delayed delivery of power from Niagara to Buffalo,—1,000 h. p. over a 27-mile line, with immense increase in immediate prospect.

And through all this growth one fact has been conspicuous; wherever electric power has come, it has found a profitable market; the steam engine has gone out, and the electric motor has come in. There has been no failure, no long struggle with unprofitable conditions; the motor has done its work, and pushed its competitors to the wall.

It is hard, indeed, to estimate the growth of electric motive power during the last decade. In place of the little group of struggling electric roads of ten years ago, we have to-day very nearly 13,000 miles of track equipped with not less than 30,000 motor cars. The railway motors in use aggregate fully a million horse power, and the generating plants close to five hundred thousand.

During the year just past, about 1,900 miles of electric-railway track have been built, and nearly 5,000 motor cars have been added to the equipment list. This increase means an aggregate investment of something like $35,000,000,—a prodigious sum to be added to a single industry in a year that has been far from prosperous.

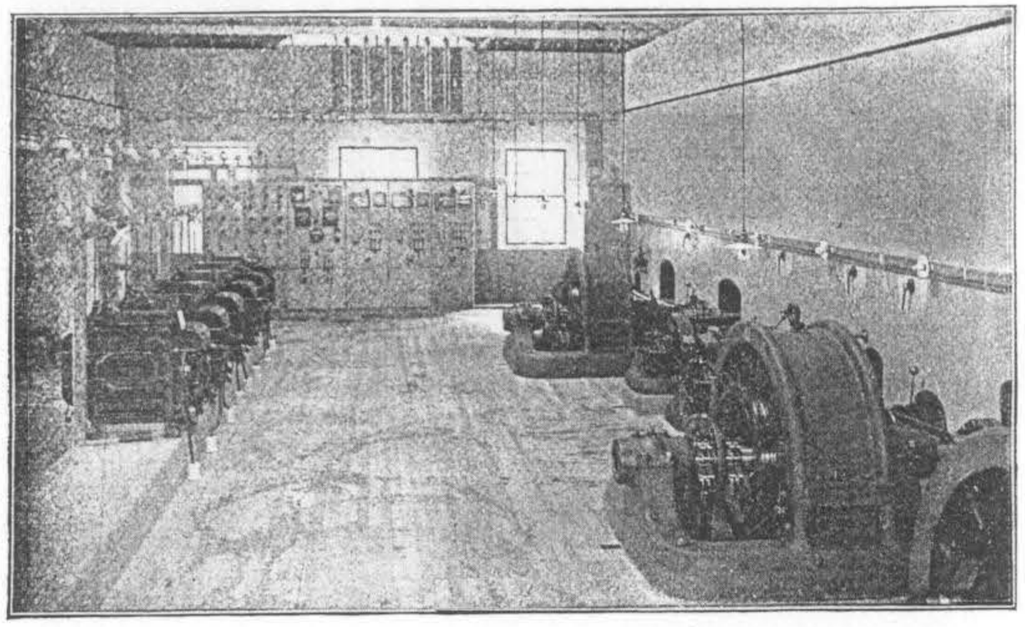
Of stationary electric motors the number defies exact calculation, in so many directions and from so many sources has the growth extended. A single plant in New York city carries nearly 10,000 h. p. in motors upon its circuits, and the aggregate of those thus operated from central stations primarily intended for lighting certainly reaches 100,000 h. p. Those operated by scattered stations and power-transmission plants, and used in miscellaneous ways, bring the probable total amount of power to 250,000 h. p. Including railway work, it is safe to say that the gross power of the electric motors used in the United States is at present not less than 1,250,000 h. p. Of power-transmission plants proper, inaugurated mainly for motor purposes, there are now probably 150,—about 100 of them using the modern polyphase systems, which, by simplifying the question of distribution, have made power transmission practicable. A score of these plants transmit power 10 miles or more, and half a dozen over 20 miles. When we compare such a list with the little group of small power plants that were running five years ago, the strength of the cause that has scored such gains in times so troublous is self-evident.

The secret of this astonishing growth lies in the simple fact that capital will be invested to effect certain retrenchment even when it cannot be obtained for any other purpose. In prosperity men will work harder to make a dollar than to save one; in adversity this tendency is reversed.

The saving secured by the use of electric power is so considerable in many cases that ordinary prudence has demanded a sufficient investment to secure this advantage. One of the mining plants to which reference has been made has been paying for itself at the rate of five per cent. a month. Under many conditions electric power must now be regarded as an industrial necessity. Its position is secure, and the burden of proof rests to-day upon those who doubt.

For the future the outlook is bright. The pioneering period has gone by, and present successes render argument needless. The growth of the next few years will be along two lines. First, we shall see an enormous extension of electric-railway work. The steam railroads are beginning to submit to the inevitable, and one by one we shall see them employing electricity, certainly for branch and suburban service, perhaps even on long lines.

When the public wants an express service at 100 miles per hour,



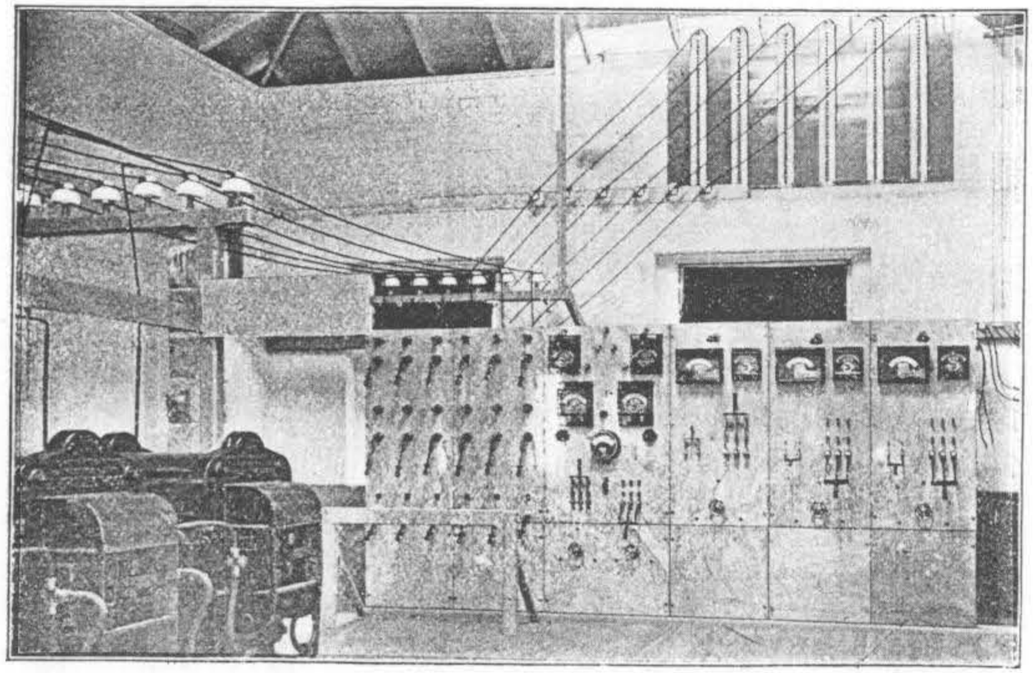


FIG. 8. THE GENERATOR ROOM OF THE FRESNO POWER-PLANT.

the means is at hand, and very little experimenting will have to be done. Not less important in its effect on the people is the growth of small electric roads in the country districts, tending to check the centralization of population and industry that is so grave a cause for anxiety in our national growth.

HIGH TENSION LINES LEADING FROM THE FRESNO STATION.

Second, there will be in the immediate future an immense development of the natural power resources of the country. One of the curious results of the power-transmission work already accomplished has been the rediscovery of numerous water powers which were quite forgotten until electrical power transmission called attention to them. Some of these have lurked in the most unsuspected places, where all the conspicuous powers had long ago been utilized. There are unemployed water powers enough within fifty miles of New York to displace every steam engine in the metropolis at a profit, if they were but rendered available.

It is now certain that the distance mentioned can be successfully overcome by apparatus already available. The recent transmission of power 35 miles into Fresno, Cal., already mentioned, has made clear the way, and no appreciable difficulties can be met in fifteen or twenty miles more. This Fresno plant, notable as the longest transmission in the world, is worthy of further description. The power house far up among the hills is shown in Fig. 8. The motive power is obtained from Pelton wheels working under an effective head of more than 1,400 feet. Each wheel is directly coupled to a three-phase generator, delivering current to the raising transformers at a pressure of 700 volts. It leaves the transformers at 11,000 volts for its long line through the foot hills and the San Joaquin valley into Fresno.

The present transmission is about 1,000 h. p., devoted to the distribution of light and power in Fresno and neighboring towns. Until this line went into operation, there was some distrust of very-long-distance work, some fears of unexpected and unpleasant developments that might be met on very long alternating-current circuits. These fears have now been finally dispelled by success, and, long before the power of Niagara was delivered in Buffalo, the success of that momentous enterprise was made certain, so far as electrical difficulties go, by the experience acquired in distant California.

With the power of overcoming long distances that has now been gained, a field is opened for the employment of electric power, the extent of which nothing short of prophesy can estimate. Not less than 5,000,000 hydraulic h. p. is ready to be utilized in this country of ours, when industry calls for it. Water power, to be sure, is not invariably a cheaper source of energy than coal, but the chances are generally in its favor.

And when water power is unavailable, there remains the splendid possibility of transmitting electrical energy instead of hauling coal,—taking the fuel at the pit's mouth and using it to spin electric motors in the thousand factories of a city fifty or one hundred miles away. The first steps have been taken in this direction already, and some

progress, at least, is certain. The time has come when cities will begin to defend themselves against the defilement of the free air. The smoke palls that hang gloomily over most large cities are blots on our boasted civilization, and they are to-day without the excuse of necessity or economy. More than this, they have passed beyond the bounds of toleration, and the general tendency of municipal legislation is now to enforce the remedy which hygiene, comfort, and domestic economy unite in demanding.

There is no good reason why every wheel that turns within the limits of a large city should not derive its motive power from a plant far beyond the city limits. Moreover, at prices now reached not infrequently by electrical-transmission plants, heating by electricity becomes economically practicable. With heat, light, and power derived from a single great plant, almost ideal conditions are realized, and such a possibility is now within our reach. When so splendid a goal is in sight, there is little chance that the advantage already gained will be lost through slothfulness and neglect, and for the great tasks pertaining to human industry electrical power will ere long have no serious competitor.

The illustrations of the Miesbach power station and the Hercules mining machine are republished by permission of *The Electrical World*.

TESLA'S NEW INTERRUPTER.

An Electrical Current Broken 80,000 000 Times a Second.

Nikola Tesla, the great electrician, has just taken outS patents for a device for producing almost incalculable electrical vibrations, and the Electrical Review gives a full description of the invention and its uses. It was by the use of this device that Mr: Tesla has been able to demonstrate the scientific possibility of producing brilliant illumination by means of vacuum tubes that were not in mechanical contact with the electric source. Under the influence of a current of electricity interrupted 60,000,000 or 80,000,000 times a second the tubes with which Mr. Tesla was experimenting burst into brilliant white light, which was demonstrated by photography to be much more powerful than the arc electric light, although the tubes were entirely disconnected and stood so far away from the exciting coils that Mr. Tesla sat in a large armchair between the tubes and the coil while he was photographed by the light of the tubes. No such effect has ever been produced by any other means, and this gives only a rough indication of the ways in which Mr. Tesla's latest patented device may be of use in the arts. For the production of Roetgen rays, the making of ozone and argon, and for electro-therapeutic treatment, the new device will find immediate use. The interruption of electrical currents for the purpose of breaking these currents into electrical waves or vibrations has heretofore been a mechanical operation. In its simplest this is done by the commutator or vibrating armature of the Rumfkoff induction coil. The vibrations of such an armature or even of the needle with which the armature has been replaced in some devices, must be confined within the narrow limit of a few hundred to the second. Rotating interrupters, connecting and breaking the electrical circuit, with a change in the position of their teeth as they revolved, added much to the number of interruptions which could be obtained, but even their best speed bore but a pitiful relationship to the 100,000,000 or more vibrations a second which Mr. Tesla calculates that he has obtained from his device.

The simplicity of the latter is one of its remarkable features.

THE TESLA PATENTS REVOKED IN GERMANY.

The Elektrotechnische Zeitschrift quoting the Köln. Ztg. states that the suit of the Allgemeine Elektricitäts-Gesellschaft of Berlin against the Aktien-Gesellschaft Helios of Cologne, for the revocation of the Tesla patents was tried before the German Patent Office and resulted in the revocation of the patents according to paragraph 11 of the German Patent Laws. The case will be appealed to the Imperial Court by the Helios Company. Just what "Tesla patents" were revoked is not stated. The term is usually applied in this country to those dealing with induction motors requiring phase currents for their operation.

The paragraph of the German Patent Law above referred to reads as follows.

§ 11. A patent can be revoked after the expiration of three years, reckoned from the date of publication of allowance.

1. If the patentee fails to carry out his invention in Germany to a suitable extent, or at least to do everything that is necessary to ensure its being carried out.

2. If the grant of license to others for using the invention appears to be demanded in the interest of public welfare, but the patentee nevertheless refuses to grant such license upon adequate compensation and against sufficient security.

Tesla Experiments. VICENTINI and PACKER. Lond. *Elec.*, Jan. 1; noticed briefly from *Nuovo Cimento*, October —They describe some experiments made with large glass plates covered with tinfoil; also an instrument called a siren, operated by Tesla discharges and producing notes from a low pitch up to one transcending the limits of hearing.

VOL. XXIII. NEW YORK, JANUARY 20, 1897. No. 455.

WHAT WILL SHE DO WITH IT?

THE marriage union of Niagara with Buffalo was celebrated last week, three months after the consummation. But in reality, the festivities were precipitate rather than tardy, for had matters been left to the ordinary course of physical events, the arrival of Niagara at Buffalo would be a convivial opportunity for our descendants 60,000 years hence. A little computation will show that at its crab-like travel of two feet a year, Niagara would not have eaten its way backward through shale and limestone to the water front of Buffalo in any shorter period. Thus do the modern inventor and the genius of electricity anticipate the flight of time. It is curious that the same year which learned the discovery of the supersubtle X-ray should have witnessed, at the other end of electricity's scale, the harnessing and distribution of Niagara's illimitable energy. The year 1896 was memorable, and when we have fairly emerged from its wrecks and disasters we shall recognize its many lasting benefits. In America we established anew our national honor; we vindicated our right to lordship in this Western world; by a treaty of arbitration we federated willing England into the American Union of mutually pacific States; and chief among the triumphs of peace, we subdued nature at Niagara that we might give larger liberty to every American workman.

How wild and fantastic it all seemed a few short years ago, this Niagara project! The tightrope dancer balancing himself painfully above the roaring, awful abyss of the Falls had not more nerve and courage than the men whose money and brain have created a new power center for the world, to whose balance industries must now poise themselves as do peoples in international politics. A region of 22 miles radius, with Buffalo as its center of attraction and Niagara as its source of power, has within six years been made the potential heart of manufactures in the United States. The organizers of the great enterprise have gone to Niagara and after a brief but decisive struggle are able to turn around and say to all who need cheap power and are willing to come to the Buffalo region for it: "We have met the great Cataract—and she is yours." The Delilah who has tamed this Samson of water powers can invite us all to witness and enjoy the spectacle, without fear of harm or future danger for anyone, and in the knowledge that Samson is the better man for having his hair cut in a civilized fashion. Of a truth, the salad, festive days of Niagara are over, and a career of strenuous effort has begun. While the older methods of utilization disfigured her, this modern plan is unobstrusive in its continuation or protection of her charms. As a matter of fact, the power of Niagara has more beauty than her beauty has power, for hitherto the human intellect and imagination have avoided her as a background for their creations. Ideas vary as to desirable qualities. Dean Stanley admired Jenny Lind immensely, but said she would have been simply delightful if she had not sung. The deep note of Niagara is now mitigated into the cheerful hum of toil; the present picturesque aspect of the Falls is preserved and conserved; Buffalo has attained the long-felt wish of seeing Niagara at play and work in her back yard—and the Power company is already selling 25,000 horse-power for somewhere around half a million dollars a year. Is not this a happy result in common for aesthete, financier, inventor and engineer? And how rarely it happens!

To Buffalo we would simply address the friendly admonition of liberality. It has cost that city absolutely nothing to have the power of Niagara brought to her doors. Freely she has received, freely let her give. Now is the time for her to encourage the Niagara Power Company to spend more money in her behalf. The whole question now that Buffalo has got the power is: What will she do with it? If she reward largeness of enterprise with corresponding largeness of welcome, there is no doubt as to her future. No greater mistake can be made than for people or city to stand suspiciously aloof when great progressive enterprises touching their welfare are afoot. "We don't own it," growled a passenger angrily when disturbed in his sleep and told that his services were needed at the pumps because the steamer was going down. Such narrowness of mind is always suicidal, and nothing that represents thrift, property and courage is ever injuriously affected without the community feeling it far more than the few individuals. The dignified and manly plea of Mr. Stetson at the banquet, for honorable treatment of his company which right through the hard times has spent its money with Niagara profusion, must find a cordial response from every public-spirited Buffalonian.

In a sense, the Niagara-Buffalo banquet was a distinct tribute to the modern electrical inventor, and as all these sentiments crystallize around personalities, the honors were paid very appropriately to Mr. Tesla, who when everybody else felt dubious, said the thing must be, taught us how to do it—and it is. That such men as Brush, Thomson, Sprague and other electricians were there to share these honors, was eminently fitting and fortunate, for while each great worker does something, no one genius can do it all. What such men need from us is encouragement, sympathy, applause. The hanging of Frank Sprague in effigy at Louisville because his trolley freed the mule, simply shows that the way of the inventor, like that of other transgressors, is generally hard. The extent of his innovation marks the degree of his impropriety, and society has usually seen to it in days gone by that the punishment should fit the crime. Even now, when the inventor is becoming more and more a person to magnify, it is all struggle for him; frequent defeat, rare victory; headlong torrents and sheer cliffs to breast and lift above; and once in a while, like Capt. Webb, the brave swimmer is carried under, a victim to his own intrepidity. We cannot follow these men in all their efforts and intuitions, but we can feel for them as fellows, sorrow when achievement lingers, rejoice when victory greets some golden morning, and, as on occasions like this Niagara banquet, drink royal toasts of amity and admiration in their honor.

Banquet Celebrating the Niagara Falls Transmission.

At the Ellicott Club in Buffalo, on Tuesday of last week, was held the banquet to celebrate the successful transmission of the power of Niagara Falls to Buffalo. About 400 guests were present. Among them were Niko a Tesla of New York, Elihu Thomson of Lynn, Mass., E. J. Houston of Philadelphia, Charles F. Brush of Cleveland, Elisha Gray of Chicago, Charles A. Coffin of Boston, George Westinghouse of Pittsburg, John E. Hudson of Boston, W. J. Johntson, D. O. Mills, Edward A. Adams, Francis Lynde Stetson, Charles Lanier and W. J. Arkel of New York, Enos Barton of Chicago, W. H. Lawrence of Cleveland, Frederic A. Nichols of Toronto, Dr. Louis Duncan of Baltimore, C. A. Cutler of New York, S. Dana Green of Schenectady, Dr. Coleman Sellers of Philadelphia, Joseph Wetzler and T. C. Martin of New York.

Letters of regret were read from President Cleveland, President elect McKinley, Governor Black and others.

When the menu had been disposed of, Francis Lynde Stetson acted as toastmaster. The toast "The Company" was responded to by Mr. Stetson himself; "Welcome to Buffalo," by Mayor Jewett; "The Empire State," by Controller Roberts; "Electricity," by Nikola Tesla; "The City of Buffalo," by Charles W. Goodyear; "Water Power," by Charles A. Pillsbury of Minneapolis.

TESLA ON ELECTRICITY.

HIS ADDRESS IN FULL ON THE OCCASION OF THE COMMEMORATION OF THE INTRODUCTION OF NIAGARA FALLS POWER IN BUFFALO AT THE ELLICOTT CLUB, JANUARY 12, 1897.

I have scarcely had courage enough to address an audience on a few unavoidable occasions, and the experience of this evening, even as disconnected from the cause of our meeting, is quite novel to me. Although in those few instances, of which I have retained agreeable memory, my words have met with a generous reception, I never deceived myself, and knew quite well that my success was not due to any excellency in the rhetorical or demonstrative art. Nevertheless, my sense of duty to respond to the request with which I was honored a few days ago was strong enough to overcome my very grave apprehensions in regard to my ability of doing justice to the topic assigned to me. It is true, at times—even now, as I speak—my mind feels full of the subject, but I know that, as soon as I shall attempt expression, the fugitive conceptions will vanish, and I shall experience certain well known sensations of abandonment, chill and silence. I can see already your disappointed countenances and can read in them the painful regret of the mistake in your choice.

These remarks, gentlemen, are not made with the selfish desire of winning your kindness and indulgence on my shortcomings, but with the honest intention of offering you an apology for your disappointment. Nor are they made—as you might be disposed to think—in that playful spirit which, to the enjoyment of the listeners, is often displayed by belated speakers. On the contrary, I am deeply earnest in my wish that I were capable of having the fire of eloquence kindled in me, that I might dwell in adequate terms on this fascinating science of electricity, on the marvelous development which electrical annals have recorded and which, as one of the speakers justly remarked, stamp this age as the Electrical Age, and particularly on the great event we are commemorating this day. Unfortunately, this my desire must remain unfulfilled, but I am hopeful that in my formless and incomplete statements, among the few ideas and facts I shall mention there may be something of interest and usefulness, something befitting this unique occasion.

Gentlemen, there are a number of features clearly discernible in, and characteristic of, human intellectual progress in more recent times—features which afford great comfort to the minds of all those who have really at heart the advancement and welfare of mankind.

First of all, the inquiry, by the aid of the microscope and electrical instruments of precision, into the nature of our organs and senses, and particularly of those through which we commune directly with the outside world and through which knowledge is conveyed to our minds, has revealed their exact construction and mode of action, which is in conformity with simple and well established physical principles and laws. Hence the observations we make and the facts we ascertain by their help are *real* facts and observations, and our knowledge is *true* knowledge. To illustrate: Our knowledge of form, for instance, is dependent upon the positive fact that light propagates in straight lines, and, owing to this, the image formed by a lens is exactly similar to the object seen. Indeed, my thoughts in such fields and directions have led me to the conclusion that most all human knowledge is based on this simple truth, since practically every idea or conception—and therefore all knowledge—presupposes visual impressions. But if light would not propagate in accordance with the law mentioned, but in conformity with any other law which we might presently conceive, whereby not only the image might not bear any likeness to the object seen, but even the images of the same object at different times or distances might not resemble each other, then our knowledge of form would be very defective, for then we might see, for example, a three-cornered figure as a six or twelve-cornered one. With the clear understanding of the mechanism and mode of action of our organs, we remove all doubts as to the *reality* and *truth* of the impressions received from the outside, and thus we bar out—forever, we may hope—that unhealthy speculation and skepticism into which formerly even strong minds were apt to fall.

Let me tell you of another comforting feature. The progress in a measured time is nowadays more rapid and greater than it ever was before. This is quite in accordance with the fundamental law of motion, which commands acceleration and increase of momentum or accumulation of energy under the action of a continuously acting force and tendency, and is the more true as every advance weakens the elements tending to produce friction and retardation. For, after all, what *is* progress, or—more correctly—development, or evolution, if not a movement, infinitely complex and often unscrutinizable, it is true, but nevertheless exactly determined in quantity as well as in quality of motion by the physical conditions and laws governing? This feature of more recent development is best shown in the rapid merging together of the various arts and sciences by the obliteration of the hard and fast lines of separation, of borders, some of which only a few years ago seemed unsurpassable, and which, like veritable Chinese walls, surrounded every department of inquiry and barred progress. A sense of connectedness of the various apparently widely different forces and phenomena we observe is taking possession of our minds, a sense of deeper understanding of nature as a whole, which, though not yet quite clear and defined, is keen enough to inspire us with the confidence of vast realizations in the near future.

But these features chiefly interest the scientific man, the thinker and reasoner. There is another feature which affords us still more satisfaction and enjoyment, and which is of still more universal interest, chiefly because of its bearing upon the welfare of mankind. Gentlemen, there is an influence which is getting strong and stronger day by day, which shows itself more and more in all departments of human activity, an influence most fruitful and beneficial—the influence of the artist. It was a happy day for the mass of humanity when the artist felt the desire of becoming a physician, an electrician, an engineer or mechanician or—whatnot—a mathematician or a financier; for it was he who wrought all these wonders and grandeur we are witnessing. It was he who abolished that small, pedantic, narrow-grooved school teaching which made of an aspiring student a galley-slave, and he who allowed freedom in the choice of subject of study according to one's pleasure and inclination, and so facilitated development.

Some, who delight in the exercise of the powers of criticism, call this an assymetrical development, a degeneration or departure from the normal, or even a degradation of the race. But they are mistaken. This is a welcome state of things, a blessing, a wise subdivision of labors, the establishment of conditions most favorable to progress. Let one concentrate all his energies in one single great effort, let him perceive a single truth, even though he be consumed by the sacred fire, then millions of less gifted men can easily follow. Therefore it is not as much quantity as quality of work which determines the magnitude of the progress.

It was the artist, too, who awakened that broad philanthropic spirit which, even in old ages, shone in the teachings of noble reformers and philosophers, that spirit which makes men in all departments and positions work not as much for any material benefit or compensation—though reason may command this also—but chiefly for the sake of success, for the pleasure there is in achieving it and for the good they might be able to do thereby to their fellow-men. Through his influence types of men are now pressing forward, impelled by a deep love for their study, men who are doing wonders in their respective branches, whose chief aim and enjoyment is the acquisition and spread of knowledge, men who look far above earthly things, whose banner is Excelsior! Gentlemen, let us honor the artist, let us thank him, let us drink his health!

Now, in all these enjoyable and elevating features which characterize modern intellectual development, electricity, the expansion of the science of electricity, has been a most potent factor. Electrical science has revealed to us the true nature of light, has provided us with innumerable appliances and instruments of precision, and has thereby vastly added to the exactness of our knowledge. Electrical science has disclosed to us the more intimate relation existing between widely different forces and phenomena and has thus led us to a more complete comprehension of Nature and its many manifestations to our senses Electrical science, too, by its fascination, by its promises of immense realizations, of wonderful possibilities chiefly in humanitarian respects, has attracted the attention and enlisted the energies of the artist; for where is there a field in which his God-given powers would be of greater benefit to his fellow-men than this unexplored, almost virgin, region, where, like in a silent forest, a thousand voices respond to every call?

With these comforting features, with these cheering prospects, we need not look with any feeling of incertitude or apprehension into the future. There are pessimistic men, who, with anxious faces, continuously whisper in your ear that the nations are secretly arming—arming to the teeth: that they are going to pounce upon each other at a given signal and destroy themselves; that they are all trying to outdo that victorious, great, wonderful German army, against which there is no resistance, for every German has the discipline in his very blood—every German is a soldier. But these men are in error. Look only at our recent experience with the British in that Venezuela difficulty. Two other nations might have crashed together, but not the Anglo-Saxons; they are too far ahead. The men who tell you this are ignoring forces which are continually at work, silently but resistlessly—forces which say Peace!

There is the genuine artist, who inspires us with higher and nobler sentiments, and makes us abhor strife and carnage. There is the engineer, who bridges gulfs and chasms, and facilitates contact and equalization of the heterogeneous masses of humanity. There is the mechanic, who comes with his beautiful time and energy-saving appliances, who perfects his flying machine, not to drop a bag of dynamite on a city or vessel, but to facilitate transport and travel. There, again, is the chemist, who opens new resources and makes existence more pleasant and secure; and there is the electrician, who sends his messages of peace to all parts of the globe. The time will not be long in coming when those men who are turning their ingenuity to inventing quick-firing guns, torpedoes and other implements of destruction—all the while assuring you that it is for the love and good of humanity—will find no takers for their odious tools, and will realize that, had they used their inventive talent in other directions, they might have reaped a far better reward than the sestertia received. And then, and none too soon, the cry will be echoed everywhere. Brethren, stop these highhanded methods of the strong, these remnants of barbarism so inimical to progress! Give that valiant warrior opportunities for displaying a more commendable courage than that he shows when, intoxicated with victory, he rushes to the destruction of his fellow-men. Let him toil day and night with a small chance of achieving and yet be unflinching; let him challenge the dangers of exploring the heights of the air and the depths of the sea; let him brave the dread of the plague, the heat of the tropic desert and the ice of the polar region. Turn your energies to warding off the common enemies and dangers, the perils that are all around you, that threaten you in the air you breathe, in the water you drink, in the food you consume. Is it not strange, is it not shame, that we, beings in the highest state of development in this our world, beings with such immense powers of thought and action, we, the masters of the globe, should be absolutely at the mercy of our unseen foes, that we should not know whether a swallow of food or drink brings joy and life or pain and destruction to us! In this most modern and sensible warfare, in which the bacteriologist leads, the services electricity will render will prove invaluable. The economical production of high-frequency currents, which is now an accomplished fact, enables us to generate easily and in large quantities ozone for the disinfection of the water and the air, while certain novel radiations recently discovered give hope of finding effective remedies against ills of microbic origin, which have heretofore withstood all efforts of the physician. But let me turn to a more pleasant theme.

I have referred to the merging together of the various sciences or departments of research, and to a certain perception of intimate connection between the manifold and apparently different forces and phenomena. Already we know, chiefly through the efforts of a bold pioneer, that light, radiant heat, electrical and magnetic actions are closely related, not to say identical. The chemist professes that the effects of combination and separation of bodies he observes are due to electrical forces, and the physician and physiologist will tell you that even life's progress is electrical. Thus electrical science has gained a universal meaning, and with right this age can claim the name "Age of Electricity."

I wish much to tell you on this occasion—I may say I actually burn for desire of telling you—what electricity really *is*, but I have very strong reasons, which my co-workers will best appreciate, to follow a precedent established by a great and venerable philosopher, and I shall not dwell on this purely scientific aspect of electricity.

There is another reason for the claim which I have before stated which is even more potent than the former, and that is the immense development in all electrical branches in more recent years and its influence upon other departments of science and industry. To illustrate this influence I only need to refer to the steam or gas engine. For more than half a century the steam engine has served the innumerable wants of man. The work it was called to perform was of such variety and the conditions in each case were so different that, of necessity, a great many types of engines have resulted. In the vast majority of cases the problem put before the engineer was not, as it should have been, the broad one of converting the greatest possible amount of heat energy into mechanical power, but it was rather the specific problem of obtaining the mechanical power in such form as to be best suitable for general use. As the reciprocating motion of the piston was not convenient for practical purposes, except in very few instances, the piston was connected to a crank, and thus rotating motion was obtained, which was more suitable and preferable, though it involved numerous disadvantages incident to the crude and wasteful means employed. But until quite recently there were at the disposal of the engineer, for the transformation and transmission of the motion of the piston, no better means than rigid mechanical connections. The past few years have brought forcibly to the attention of the builder the electric motor, with its ideal features. Here was a mode of transmitting mechanical motion simpler by far, and also much more economical Had this mode been perfected earlier, there can be no doubt that, of the many different types of engine, the majority would not exist, for just as soon as an engine was coupled with an electric generator a type was produced capable of almost universal use. From this moment on there was no necessity to endeavor to perfect engines of special designs capable of doing special kinds of work. The engineer's task became now to concentrate all his efforts upon one type, to perfect one kind of engine—the best, the universal, the engine of the immediate future; namely, the one which is best suitable for the generation of electricity. The first efforts in this direction gave a strong impetus to the development of the reciprocating high-speed engine, and also to the turbine, which latter was a type of engine of very limited practical usefulness, but became, to a certain extent, valuable in connection with the electric generator and motor. Still, even the former engine, though improved in many particulars, is not radically changed, and even now has the same objectionable features and limitations. To do away with these as much as possible, a new type of engine is being perfected in which more favorable conditions for economy are maintained, which expands the working fluid with utmost rapidity and loses little heat on the walls, an engine stripped of all usual regulating mechanism—packings, oilers and other appendages—and forming part of an electric generator; and in this type, I may say, I have implicit faith.

The gas or explosive engine has been likewise profoundly affected by the commercial introduction of electric light and power, particularly in quite recent years. The engineer is turning his energies more and more in this direction, being attracted by the prospect of obtaining a higher thermodynamic efficiency. Much larger engines are now being built, the construction is constantly improved, and a novel type of engine, best suitable for the generation of electricity, is being rapidly evolved.

There are many other lines of manufacture and industry in which the influence of electrical development has been even more powerfully felt. So, for instance, the manufacture of a great variety of articles of metal, and especially of chemical products. The welding of metals by electricity, though involving a wasteful process, has, nevertheless, been accepted as a legitimate art, while the manufacture of metal sheet, seamless tubes and the like affords promise of much improvement. We are coming gradually, but surely, to the fusion of bodies and reduction of all kinds of ores—even of iron ores—by the use of electricity, and in each of these departments great realizations are probable. Again, the economical conversion of ordinary currents of supply into high-frequency currents opens up new possibilities, such as the combination of the atmospheric nitrogen and the production of its compounds; for instance, ammonia and nitric acid, and their salts, by novel processes.

The high-frequency currents also bring us to the realization of a more economical system of lighting; namely, by means of phosphorescent bulbs or tubes, and enable us to produce with these appliances light of practically any candle-power. Following other developments in purely electrical lines, we have all rejoiced in observing the rapid strides made, which, in quite recent years, have been beyond our most sanguine expectations. To enumerate the many advances recorded is a subject for the reviewer, but I can not pass without mentioning the beautiful discoveries of Lenard and Roentgen, particularly the latter, which have found such a powerful response throughout the scientific world that they have made us forget, for a time, the great achievement of Linde in Germany, who has effected the liquefaction of air on an industrial scale by a process of continuous cooling; the discovery of argon by Lord Rayleigh and Professor Ramsay, and the splendid pioneer work of Professor Dewar in the field of low temperature research. The fact that the United States have contributed a very liberal share to this prodigious progress must afford to all of us great satisfaction. While honoring

the workers in other countries and all those who, by profession or inclination, are devoting themselves to strictly scientific pursuits, we have particular reasons to mention with gratitude the names of those who have so much contributed to this marvelous development of electrical industry in this country. Bell, who, by his admirable invention enabling us to transmit speech to great distances, has profoundly affected our commercial and social relations, and even our very mode of life; Edison, who, had he not done anything else beyond his early work in incandescent lighting, would have proved himself one of the greatest benefactors of the age; Westinghouse, the founder of the commercial alternating system; Brush, the great pioneer of arc lighting; Thomson, who gave us the first practical welding machine, and who, with keen sense, contributed very materially to the development of a number of scientific and industrial branches; Weston, who once led the world in dynamo design, and now leads in the construction of electric instruments; Sprague, who, with rare energy, mastered the problem and insured the success of practical electrical railroading; Acheson, Hall, Willson and others, who are creating new and revolutionizing industries here under our very eyes at Niagara. Nor is the work of these gifted men nearly finished at this hour. Much more is still to come, for, fortunately, most of them are still full of enthusiasm and vigor. All of these men and many more are untiringly at work investigating new regions and opening up unsuspected and promising fields. Weekly, if not daily, we learn through the journals of a new advance into some unexplored region, where at every step success beckons friendly, and leads the toiler on to hard and harder tasks.

But among all these many departments of research, these many branches of industry, new and old, which are being rapidly expanded, there is one dominating all others in importance—one which is of the greatest significance for the comfort and welfare, not to say for the existence, of mankind, and that is the electrical transmission of power. And in this most important of all fields, gentlemen, long afterwards, when time will have placed the events in their proper perspective, and assigned men to their deserved places, the great event we are commemorating to-day will stand out as designating a new and glorious epoch in the history of humanity—an epoch grander than that marked by the advent of the steam engine. We have many a monument of past ages; we have the palaces and pyramids, the temples of the Greek and the cathedrals of Christendom. In them is exemplified the power of men, the greatness of nations, the love of art and religious devotion. But that monument at Niagara has something of its own, more in accord with our present thoughts and tendencies. It is a monument worthy of our scientific age, a true monument of enlightenment and of peace. It signifies the subjugation of natural forces to the service of man, the discontinuance of barbarous methods, the relieving of millions from want and suffering. No matter what we attempt to do, no matter to what fields we turn our efforts, we are dependent on power. Our economists may propose more economical systems of administration and utilization of resources, our legislators may make wiser laws and treaties, it matters little; that kind of help can be only temporary. If we want to reduce poverty and misery, if we want to give to every deserving individual what is needed for a safe existence of an intelligent being, we want, to provide more machinery, more power. Power is our mainstay, the primary source of our many-sided energies. With sufficient power at our disposal we can satisfy most of our wants and offer a guaranty for safe and comfortable existence to all, except perhaps to those who are the greatest criminals of all—the voluntarily idle.

The development and wealth of a city, the success of a nation, the progress of the whole human race, is regulated by the power available. Think of the victorious march of the British, the like of which history has never recorded. Apart from the qualities of the race, which have been of great moment, they own the conquest of the world to—coal. For with coal they produce their iron; coal furnishes them light and heat; coal drives the wheels of their immense manufacturing establishments, and coal propels their conquering fleets. But the stores are being more and more exhausted, the labor is getting dearer and dearer, and the demand is continuously increasing. It must be clear to every one that soon some new source of power supply must be opened up, or that at least the present methods must be materially improved. A great deal is expected from a more economical utilization of the stored energy of the carbon in a battery; but while the attainment of such a result would be hailed as a great achievement, it would not be as much of an advance towards the ultimate and permanent method of obtaining power as some engineers seem to believe. By reasons both of economy and convenience we are driven to the general adoption of a system of energy supply from central stations, and for such purposes the beauties of the mechanical generation of electricity can not be exaggerated. The advantages of this universally accepted method are certainly so great that the probability of replacing the engine dynamos by batteries is, in my opinion, a remote one, the more so as the high-pressure steam engine and gas engine give promise of a considerably more economical thermodynamic conversion. Even if we had this day such an economical coal battery, its introduction in central stations would by no means be assured, as its use would entail many inconveniences and drawbacks. Very likely the carbon could not be burned in its natural form as in a boiler, but would have to be specially prepared to secure uniformity in the current generation. There would be a great many cells needed to make up the electro-motive force usually required. The process of cleaning and renewal, the handling of nasty fluids and gases and the great space necessary for so many batteries would make it difficult, if not commercially unprofitable, to operate such a plant in a city or densely populated district. Again, if the station be erected in the outskirts, the conversion by rotating transformers or otherwise would be a serious and unavoidable drawback. Furthermore, the regulating appliances and other accessories which would have to be provided would probably make the plant fully as much, if not more, complicated than the present. We might, of course, place the batteries at or near the coal mine, and from there transmit the energy to distant points in the form of high-tension alternating currents obtained from rotating transformers, but even in this most favorable case the process would be a barbarous one, certainly more so than the present, as it would still involve the consumption of material, while at the same time it would restrict the engineer and mechanic in the exercise of their beautiful art. As to the energy supply in small isolated places as dwellings, I have placed my confidence in the development of a light storage battery, involving the use of chemicals manufactured by cheap water power, such as some carbide or oxygen-hydrogen cell.

But we shall not satisfy ourselves simply with improving steam and explosive engines or inventing new batteries; we have something much better to work for, a greater task to fulfill. We have to evolve means for obtaining energy from stores which are forever inexhaustible, to perfect methods which do not imply consumption and waste of any material whatever. Upon this great possibility, which I have long ago recognized, upon this great problem, the practical solution of which means so much for humanity, I have myself concentrated my efforts since a number of years, and a few happy ideas which came to me have inspired me to attempt the most difficult, and given me strength and courage in adversity. Nearly six years ago my confidence had become strong enough to prompt me to an expression of hope in the ultimate solution of this all-dominating problem. I have made progress since, and have passed the stage of mere conviction such as is derived from a diligent study of known facts, conclusions and calculations. I now feel sure that the realization of that idea is not far off. But precisely for this reason I feel impelled to point out here an important fact, which I hope will be remembered. Having examined for a long time the possibilities of the development I refer to, namely, that of the operation of engines on any point of the earth by the energy of the medium, I find that even under the theoretically best conditions such a method of obtaining power can not equal in economy, simplicity and many other features the present method, involving a conversion of the mechanical energy of running water into electrical energy and the transmission of the latter in the form of currents of very high tension to great distances. Provided, therefore, that we can avail ourselves of currents of sufficiently high tension, a waterfall affords us the most advantageous means of getting power from the sun sufficient for all our wants, and this recognition has impressed me strongly with the future importance of the water power, not so much because of its commercial value, though it may be very great, but chiefly because of its bearing upon our safety and welfare. I am glad to say that also in this latter direction my efforts have not been unsuccessful, for I have devised means which will allow us the use in power transmission of electro-motive forces much higher than those practicable with ordinary apparatus. In fact, progress in this field has given me fresh hope that I shall see the fulfillment of one of my fondest dreams; namely, the transmission of power from station to station without the employment of any connecting wire. Still, whatever method of transmission be ultimately adopted, nearness to the source of power will remain an important advantage.

Gentlemen, some of the ideas I have expressed may appear to many of you hardly realizable; nevertheless, they are the result of long-continued thought and work. You would judge them more justly if you would have devoted your life to them, as I have done. With ideas it is like with dizzy heights you climb: At first they cause you discomfort and you are anxious to get down, distrustful of your own powers; but soon the remoteness of the turmoil of life and the inspiring influence of the altitude calm your blood; your step gets firm and sure and you begin to look—for dizzier heights. I have attempted to speak to you on "Electricity," its development and influence, but I fear that I have done it much like a boy who tries to draw a likeness with a few straight lines. But I have endeavored to bring out one feature, to speak to you in one strain which I felt sure would find response in the hearts of all of you, the only one worthy of this occasion—the humanitarian. In the great enterprise at Niagara we see not only a bold engineering and commercial feat, but far more, a giant stride in the right direction as indicated both by exact science and philanthropy. Its success is a signal for the utilization of water powers all over the world, and its influence upon industrial development is incalculable. We must all rejoice in the great achievement and congratulate the intrepid pioneers who have joined their efforts and means to bring it about. It is a pleasure to learn of the friendly attitude of the citizens of Buffalo and of the encouragement given to the enterprise by the Canadian authorities. We shall hope that other cities, like Rochester on this side and Hamilton and Toronto in Canada, will soon follow Buffalo's lead. This fortunate city herself is to be congratulated. With resources now unequaled, with commercial facilities and advantages such as few cities in the world possess, and with the enthusiasm and progressive spirit of its citizens, it is sure to become one of the greatest industrial centers of the globe.

X RAYS, APPARATUS AND METHODS.

ABSTRACT OF PAPER READ BEFORE THE ELECTRICAL SECTION OF THE FRANKLIN INSTITUTE, PHILADELPHIA, DECEMBER 1, 1896, BY ELMER G. WILLYOUNG AND H. LYMAN SAYEN.

That Professor Roentgen's discovery of the X ray has initiated many lines of thought promising to greatly extend our knowledge of physical phenomena, as well as to revise many

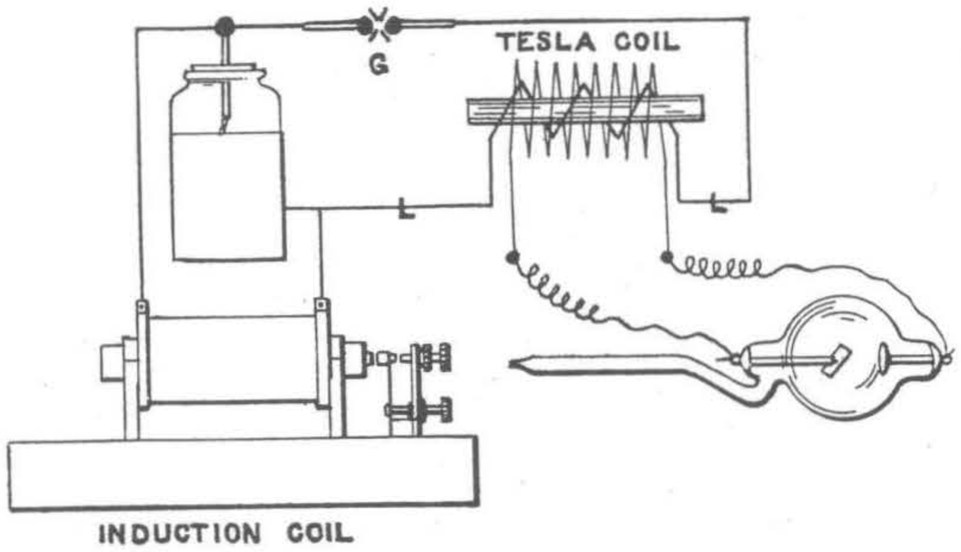

FIG. 1.—"X-RAYS, APPARATUS AND METHODS."—DIAGRAM OF TESLA HIGH-FREQUENCY COIL.

of our previously accepted views, is generally admitted. That the practical results accruing to humanity by virtue of the applications of this discovery in surgical and medical practice are of even greater promise and value is equally conceded. The writers have been engaged for a number of months past in developing apparatus and methods for practical work with especial reference to the needs of the physician and surgeon. For conciseness we split the matter under discussion into a series of subordinate heads, each of which we shall briefly treat.

THE COIL OR GENERATING SOURCE.

Thus far the only apparatus known which will produce X rays readily and profusely is the "transformer." Not the commercial transformer of every-day use, however, but its earlier and, for most purposes, less efficient form, the "induction coil." Such a transformer gives exceedingly great electro-motive forces, capable of producing discharge over long air gaps. When the discharge from such a coil is passed through properly exhausted and constructed tubes, we have a very vigorous generation of X rays.

Two arrangements of the induction coil are advocated. The one is known as the Tesla or "high-frequency" coil, and the other is the direct and old-fashioned use of the simple induction coil, in which the high secondary electro-motive force is delivered direct to the terminals of the tube.

THE HIGH-FREQUENCY COIL

consists of two induction coils, the induced secondary current of the first being used to charge a Leyden jar. The primary of the second coil is joined, in series with a spark gap, to the two coatings of the Leyden jar. When the Leyden jars are fully charged they discharge across the air gap, this discharge being, by well known laws of electrical circuit flow, an oscillating one of exceedingly high frequency—millions or more oscillations per second. We thus have the primary of the second coil excited by an alternating current of exceedingly great voltage and frequency, so that *its* secondary produces a discharge of still *greater* electro-motive force and of this same high frequency. So great is this final electro-motive force that it is generally necessary to immerse the entire second coil, primary and all, in a tank of oil, since no solid insulation has yet been found capable of standing these great electro-motive forces without breakdown.

To excite the Tesla coil we may use either an interrupted direct current or an ordinary alternating circuit joined directly to the primary of the first coil. But the final result is, in either case, an alternating, high-potential, high-frequency current. In the tube, therefore, we also have an alternating discharge.

THE INDUCTION COIL.

The primary must be excited by an interrupted direct current which may

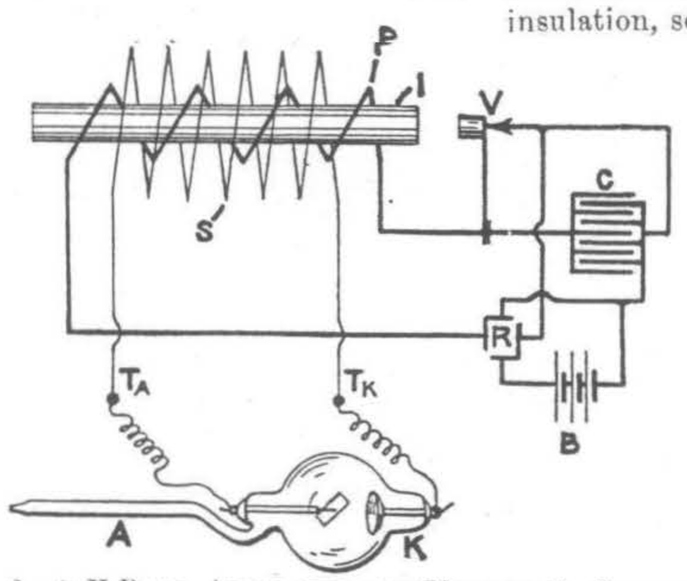

FIG. 2.—"X-RAYS, APPARATUS AND METHODS."—CONNECTIONS OF SIMPLE INDUCTION COIL.

be supplied by primary batteries, storage batteries, or a commercial circuit, as convenience and inclination may elect. The secondary is joined directly to the tube terminals. Around the primary is joined a condenser. At break this condenser charges (thus preventing the extra induced current due to the large self-induction of the primary). but, being "short circuited" by the primary, at once discharges about the iron core in a direction opposite to the regular "make" current, thus reducing (if correctly proportioned) the magnetic intensity of the iron core to zero. All this takes place so quickly that the practical effect of the action is merely to assist and intensify the dropping off of the core's magnetism —to shove it along—hasten it. Considering the secondary, now, we find that we shall have at *break* an induced discharge of greatly higher electro-motive force than the discharge at *make*, owing to the falling off of the core's magnetism *at* break being greatly sharper than its growth at make. The effect of this is to give secondary discharges in *one direction only* at all times when the parallel spark gap is not *greatly* shorter than the *maximum* obtainable spark gap for that particular condition of running the coil, the *make* induced current at such times being of too small electro-motive force to get across the gap at all. This is always the condition when X-ray tubes are used. A further function of the condenser is to suppress *burning* at the "break" terminals or points of interruption by taking up the energy of the magnetic discharge of the coil.

In the construction of the induction coil a number of points may be noted. Our secondaries are wound in sections one-eighth-inch thick (according to the plan originally proposed, we believe, by Ritchie). These sections are separated from one another by a large number of disks of paper of a brand especially selected as free from carbon particles and baked at a temperature a little below charring point for some time immediately before use—this to drive out moisture. These sections are then assembled and immediately immersed in a special insulation composition having a very high melting point and some slight viscosity at all temperatures. Paraffine we absolutely prohibit, as being apt to crack and absorb moisture. After cooking for some time in the insulation, so as to drive out the last traces of moisture, the stack of sections is subjected to a further treatment, by which it is finally cooled, with *all air removed*. This we consider a point of the highest importance, as air present anywhere in the secondary becomes electrified and bombards to and fro, gradually softening the insulation and eventually breaking down the coil. (See Tesla's writings on "High-Frequency Phenomena" for confirmation of this point.) With this plan of construction we have no static leaks of energy or small direct leaks within the coil itself, and deliver the full energy of discharge at the secondary terminals. We find ourselves able to secure in this way a full inch of spark, in all sizes of coils, with considerably less than one pound of wire, No. 34 Brown & Sharpe. We believe that, more than anything else, the large quantities of wire required to produce a given spark length with many of the coils now in use is due to the presence of air and consequent loss of energy by static bombardment in the secondary. As regards the insulating composition used by us, we may say that we find its power of resistance to spark discharge to be four or five times that of hard rubber. In the arrangement of our secondary we separate it from the primary by a heavy hard-rubber tube and, in addition, by a tube of this composition.

THE ADJUSTABLE CONDENSER.

A coil is working to best advantage when there is a certain definite relation between its primary current, secondary spark distance and condenser capacity. Frequency of break must also be considered. As coils have heretofore been built, however, the condenser value has been fixed once for all and admits of no change, albeit both spark gap and primary current, and primary current may be so changed. To remedy this we have devised a form of switch, by means of which the condenser capacity may be shifted at will and instantly by simply turning the switch. The effect upon the secondary discharge is very marked, both volume and musical note of the spark changing with the position of the switch. We have made some experiments in the use of a condenser in the parallel *with the primary*. The volume of the secondary discharge seems, in many cases, to be greatly increased. We find this idea exceedingly convenient in general experimental work with alternating currents; indeed, it being possible with it to alter condenser capacity as quickly and as readily as we may self-induction or resistance.

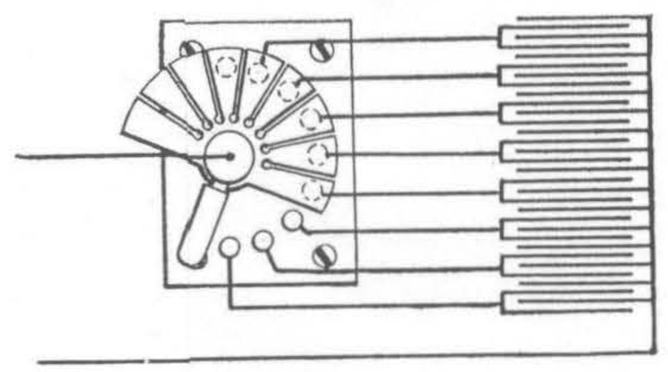

FIG. 3.—"X-RAYS, APPARATUS AND METHODS."—THE AUTHORS' FORM OF SWITCH.

In arranging coils to operate from few or many cells of battery, it is, of course, merely a matter of winding the primary of coarse or fine wire, the number of ampere turns being kept the same. It is interesting to note, as we have noted experimentally many times, that the larger the primary electro-motive force the smaller must be the condenser capacity employed, and *vice versa*. This is, of course, only to be expected, since capacity and self-induction are inverse functions of one another.

PRIMARY CURRENT.

This may be either from primary batteries, storage batteries, or from a

commercial direct-current circuit. Primary batteries have too high resistance to give sufficient current for coils of much size—say four-inch and over—unless joined in parallel, and then we need a number of such groups to secure the requisite electro-motive force. They are a nuisance to attend to, soon run down and are expensive to operate. Storage batteries are exceedingly satisfactory, are comparatively inexpensive to operate and require practically no attention. Charging them is more or less of a nuisance, however, especially where they must be sent out of the building, as they usually must, besides throwing the entire apparatus out of use while charging is going on, unless one have a reserve set of batteries.

The utilization of a direct commercial circuit, such as the Edison 110-volt E. G., where such is available, is in every way the most convenient and satisfactory. Until Professor Roentgen's discovery, no method of

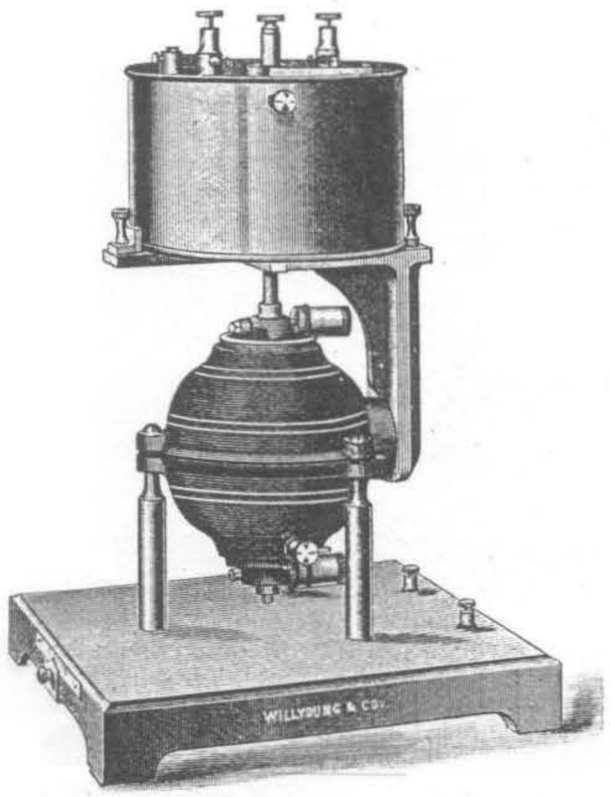

FIG. 4.— "X RAYS, APPARATUS AND METHODS."—THE AUTHORS' DEVICE FOR OPERATING COILS ON COMMERCIAL CIRCUITS.

operating large coils upon such a circuit had been developed. Recently, however, several methods have been brought out, notably that of the "air break" with air blast to blow out the spark, as used by Dr. Wm. J. Morton, Dr. M. I. Pupin and others. We have devised a form of apparatus to accomplish this purpose. A Lundell one-twelfth-horse-power motor is supported upon a base with its shaft vertical. A casting attached to the motor supports above the latter a copper can made up of two concentric cylinders joined by a ring below, so that the shaft passes up through the inner cylinder and thus avoids the necessity of a stuffing box. From the shaft is hung, well within the can, a heavy brass wheel having stretches of insulating slate let into its periphery. A hard-rubber lid fits over the top of the can. Mounted upon this lid are two brushes, one bearing against the wheel periphery and the one against the shaft; suitable springs and screws allow the brush tension to be varied. From the commercial circuit leads are brought to these two brushes, the current being first passed through the primary of the coil and a rheostat in series. Before the lid is put in place, the can is filled with distilled water; ordinary hydrant water will answer, although its usual impurity causes the water to soon dirty, besides allowing a certain amount of electrolysis during use. With distilled water the break may be run for a number of hours without change of the water, and very little heating takes place. The real function of the water is not so much to drown the spark as to prevent heating, although it does, of course, also assist in quenching the spark. But a condenser is the real spark extinguisher, and this we connect around the break just as we would around an ordinary vibrating break.

The advantages of this break over all forms of vibrating break thus far known and over other forms of rotary break are:

A. Convenience: Mere throwing of a switch being all that is required to start and stop the apparatus.

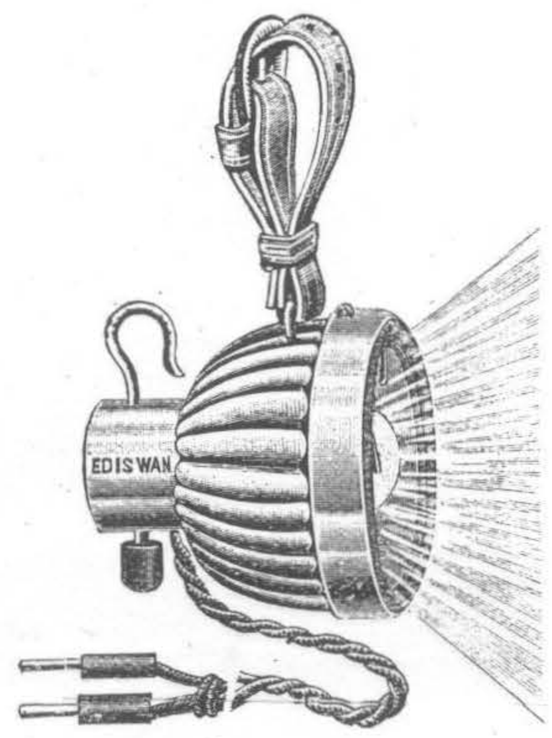
B. Noiselessness: Only the drowsy hum of the motor being heard.

C. Reliability: No chance of sticking, as with vibrating breaks.

D. Variable rate of break, secured by adjusting rheostat in base of motor.

E. Smooth, unvarying fluoroscopic images, owing to the much larger number of breaks per unit of time.

Two milled heads at top of can permit its lid (carrying brushes) to be withdrawn. A similar head at top of shaft loosens break-wheel, and two heads at bottom of can allow it to be lifted away for cleaning and renewal and replenishing of water.



We use three makes and three breaks per revolution and find best results at from 1,200 to 1,400 revolutions per minute (equal to 3,600 to 4,800 interruptions). We may secure as many as 2,000 revolutions (6,000 interruptions) per minute by cutting out the motor regulator.

In operation, the brush bearing upon break-wheel should be *positive*, so as to prevent any electrolysis of the break-wheel. We have often broken between 15 and 20 amperes through this wheel for a considerable length of time without any overheating or overwear of the wheel. Should the wheel wear in time to an undesirable degree, it may be removed and turned down. Provision is also made for replacing the brushes when desired.

GENERAL CONSIDERATIONS REGARDING BREAK FREQUENCY.

The question as to whether there is a certain best frequency of break for a given coil or tube, or both, has puzzled not a few. Very little has been experimentally determined regarding this point. It is certain, however, that, with a given coil or tube, shortness of exposure is *not* exactly inversely as the number of breaks. Indeed, it is often far from being so. Some of the best X-ray pictures that have been taken have been by use of the old "hammer" break of Ritchie, and four or five clicks of the break have sufficed. Using the same tube and coil, but a rapidly vibrating or rotary break, required 40 or 50 breaks to accomplish the same results. It would appear, hence, that the energy of X-ray radiation *per break* is a function of the number of breaks per unit of time.

We are inclined to believe that this is a matter purely of the "time constant" of the coil. The iron of the core requires a certain time to magnetize or demagnetize. With the breaks few, ample time is given for this process; but when the breaks become rapid this is no longer possible, so that the secondary electro-motive force falls. This may easily be verified by observing the maximum spark length of any coil. With single breaks few and far between, we get much longer spark maxima than if the breaks are frequent. The thickness of the sparks is also greatly increased. If, however, we increase the primary electro-motive force for the more rapid break, we may bring up the secondary spark length to the value given by the single breaks. We should thus be able to shorten the exposure as much as we please by merely increasing the rate of break

THE "CAT-EYE" ELECTRIC BICYCLE LAMP.

and the primary electro-motive force at the same time. But here we are limited by the *tube*, which can not *dissipate* more than a certain definite amount of energy in a given time, and will break down if overdriven. We see, therefore, that, whether we use slow breaks or fast breaks, the actual time of exposure remains practically the same, the few breaks requiring to be distributed over the same *time* as the much larger number of rapid breaks. All this, of course, applies to the photographic plate. For fluoroscopy we require rapid breaks, in order to escape the otherwise distressing flickering.

In the above connection particular attention is directed to one point—the rate of break *must not be too great*. If it is, the iron no longer has time to magnetize and demagnetize. The result is an *alternating* secondary discharge instead of the *direct* discharge desired, and this means blackening of the tube, rapid fluctuations of the vacuum and general deterioration of the tube. *We doubt whether with any coil of size suitable for X-ray work a rate of break greater than 5,000 per minute should ever be employed.*

[*To be concluded.*]

X RAYS, APPARATUS AND METHODS.

ABSTRACT OF PAPER READ BEFORE THE ELECTRICAL SECTION OF THE FRANKLIN INSTITUTE, PHILADELPHIA, DECEMBER 1, 1896, BY ELMER G. WILLYOUNG AND H. LYMAN SAYEN.

(*Continued from page 45.*)

TESLA COIL OR INDUCTION COIL—WHICH?

Having carefully examined the results, apparatus and methods of others all over the country, devotees some of the "high-frequency" coil, some of the induction coil, and having made many and careful experiments with both forms of apparatus ourselves, we favor the induction coil. Our reasons for this preference are briefly stated:

A. Simplicity: One coil instead of two.

B. Ease of Manipulation: There being more than double the number of factors to attend to in the Tesla coil than in the induction coil.

C. Cleanliness: The "high-frequency" coil requires an oil bath, which must be renewed from time to time to avoid gumming. It is difficult, also, to find an oil which will not, eventually, act upon the insulation of the wire by virtue of the acid or other impurities which the former may contain.

D. Sharp Definition: The "high-frequency" coil produces an alternating discharge — thus with the double-focus tube giving us two sources of X radiation and consequent blurring of the image. If a single-focus tube be used, the discharge in one direction is either lost or tears off particles of the platinum reflector, thus blackening the tube and soon destroying its effectiveness.

E. Noiselessness: This, from the surgeons' and physicians' standpoint, is perhaps the most important consideration. With tube in action the induction coil is practically noiseless, save for the low hum of motor or vibrator. Improperly designed vibrators often rattle and rasp in a very irritating manner. In the "high-frequency" coil, however, the disruptive discharge over the air gap is the vital cause of its action. It is much more violent than a discharge of corresponding length from the induction coil, being of a rattling, cracking character. That such noise can not but have a most unpleasant effect upon the patient who comes into the operating-room in a condition of more or less nervous collapse anyway is obvious.

F. Strain on Tube: It has been argued by advocates of the "high-frequency" coil that it is much less hard upon the tubes. Our own observation has been just the reverse of this and has satisfied us that the wear and tear is very much less with the induction coil.

G. Results: Although we have diligently examined, we have yet to see results obtained by any form of apparatus superior to those made right here in Philadelphia by Dr. Goodspeed, of the University of Pennsylvania; Dr. Stern, of the Polyclinic Hospital; ourselves, and many others who might be mentioned, and this either as regards detail, penetration or quickness of exposure. Indeed, we may say that we have never seen results obtained with the Tesla coil that are equal in any of the above respects to the results just referred to.

THE TUBE.

Many forms of tubes have been suggested. With practically no exception, all tubes now in use employ as cathode a concave aluminum disk, whose center of curvature is at the center of a small platinum plate (three-eighths to three-quarters square inch in area), the plane of the plate being inclined to the normal from center of the concave cathode. This platinum plate is sometimes made the anode — sometimes the anode is a separate plate or wire elsewhere in the tube. This form of tube is known as the "focus" tube, the cathode rays being focused upon the platinum plate, which then becomes the active source of X rays. In the double-focus tube we have two concave cathodes at opposite ends of the tube, the platinum wire reflector being in the form of a wedge with a side presented to each of the concave cathodes.

In the use of the tube everything depends upon the vacuum, X rays seeming to be of a heterogenous character just as are light rays, the quality of the X ray varying with the degree of vacuum. The higher the vacuum, the more penetrating power the tube has. Hence it is well to select tubes and use different tubes for different purposes. A tube of extremely high exhaustion is best for working through the body, but with forearm, hands, feet, etc., the tube has too great penetration, the bones appearing almost equally transparent with the flesh.

The chief difficulty with most tubes is the change of vacuum which takes place in use. This is thought to be due to the occlusion of the residual gas upon the inner surface of the glass—resulting in an increased vacuum. It may be partially restored by heating the tube by use of a spirit lamp or Bunden flame. This must be very carefully done, however, to avoid cracking the tube. When the platinum reflector is used simply as an anti-cathode, and the anode is aluminum, a simple reversal of the discharge will prove fairly successful. Some makers have adopted the scheme, practiced now for many years, of blowing a small side pocket upon the tube, into which is placed phosphoric anhydride or some other chemical substance or composition absorbing moisture. When heated, this substance gives off vapor to make up for the loss. It is difficult, however, to drive off just the right amount of vapor in this way, and the vacuum is liable to be made too low, in which case flesh and bone are about equally opaque. So rapid is this change of vacuum, that in most cases involving over a few minutes' exposure or running of the tube, one of the above methods becomes necessary. In any case, eventual almost complete exhaustion seems to be the rule, and the tube must then be returned to the makers and re-exhausted.

"Blackening" is another cause of decreased efficiency in the tube. It is due to deposition of platinum upon the inner surface of the tube.

The "Bowdoin" tube, shown in Fig. 5, was devised after a considerable amount of experimental work by Professors Robinson and Hutchins, of Bowdoin College. In general design it does not differ essentially from many other forms of focus tube upon the market. The two respects in which the tube does differ from other tubes are: 1st. In the arrangement of electrodes the reflector plate is not connected to the coil at all, but merely acting as an obstacle to the bombarding rays, while the anode is a disk at the end of the tube away from the cathode. This arrangement is found to perfectly and entirely prevent blackening, no matter how long the tube may be used.

The most important feature of this tube is, however, the presence upon its interior surface of a fluorescent material which has been fused right into the surface of the glass. As the tube is used, this material, either by the bombardment, or heating, or both, gives off just enough air or vapor to make up for the occlusion due to the natural working of the tube. The vacuum, therefore, tends to remain always constant. Although it seems almost absurd that one could put in just enough of this material to make up for the gas otherwise lost, yet it is a fact that these tubes remain practically unchanged in vacuum at all times, the equivalent spark length retaining its value at all times within, at the outside, a variation of 10 per cent.

In use the tube requires no "nursing" whatever. It should always have to start with a parallel spark gap which should be quite small, say an inch or an inch and one-half, and either the primary current or the vibrator tension adjusted so as to produce only very small secondary discharge. The energy of this secondary discharge may then be immediately increased until the reflector plate shows a dull red spot of about half the size of the nail of the little finger. The tube is now in its most efficient condition, and, with a well constructed and smooth-working brake, may be run for an hour or two without the slightest attention. The "getting ready," as above described, takes considerably less time than the time it has taken us to describe it. Indeed, in our own work, we do not trouble to make this preliminary adjustment at all, as we make it once for all when we first begin to work with a tube, and do not afterward disturb it, merely closing down the switch when starting work.

[*To be concluded.*]

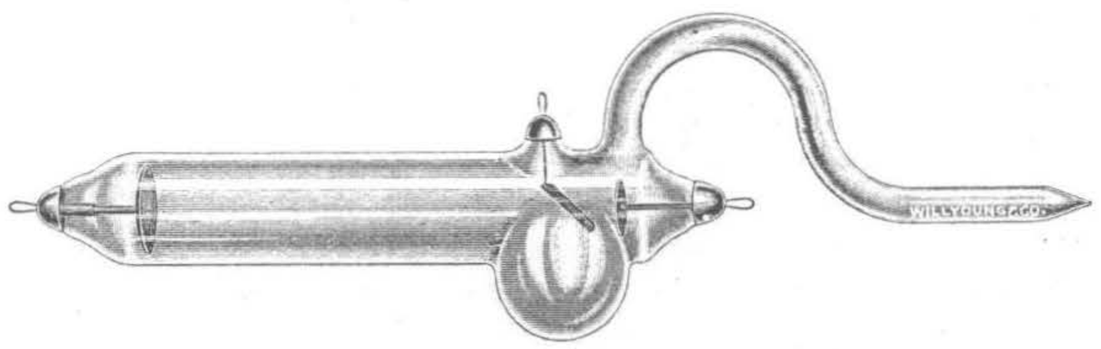


FIG. 5.—"X RAYS, APPARATUS AND METHODS."—THE BOWDOIN TUBE.

X RAYS, APPARATUS AND METHODS.

ABSTRACT OF PAPER READ BEFORE THE ELECTRICAL SECTION OF THE FRANKLIN INSTITUTE, PHILADELPHIA, DECEMBER 1, 1896, BY ELMER G. WILLYOUNG AND H. LYMAN SAYEN.

(*Concluded from page 51.*)

LIFE OF TUBES.

The life of tubes in general is limited.

A. By time required for the vacuum to become too great, hence requiring re-exhaustion.

B. By ability to stand the electrical strains.

A. Applies to all tubes so far as we know, save the Bowdoin tubes, probably six or eight hours continuous working, or the equivalent suffices to incapacitate the average tube. We think that, even with the Bowdoin tube, there is an evident tendency to eventual very high vacuum, but the time required would be very great relatively, say 10 to 15 times that operative in the case of other types of tubes.

B. All well made tubes (from the glass-blower's standpoint) are about equally liable to this limitation. It is probable that these strains are cumulative in their effects upon the tube, the latter gradually weakening until, eventually, breakdown takes place, with secondary discharges much less than would have been originally required for breakdown.

THE STAND

has been divided for applied X-ray work. With it the tube may be placed in any position within a cylinder six feet high and six feet in diameter, thus making it possible to get under or over a patient, no matter what the latter's position. Rods of vulcanized fiber clamp to the stand in any position and carry the lead wires of the tube, thus keeping them away from one another and from the metal of the stand. They carry little spring clips at their extremities, by which the wires are caught without tying or bending. The whole stand is of bicycle tubing and very rigid.

THE SUBJECT.

The patient should, of course, be placed in as easy a position as possible. For body pictures, hip and knee joints, etc., a recumbent position may be assumed. The plate should lie beneath and upon a stiff board backing to avoid risk of breakage. Work upon the shoulder, neck, head, etc., may be done with the patient straddling a straight-backed chair facing the back and leaning the body against the back for support. The plate may be bound fast to the body by bandages.

LAWS FOR EXPOSURE.

Since the X rays proceed in straight lines from (approximately) a point source, the intensity of their action varies inversely as the square of the distance from the source. Hence the time of exposure should vary directly as the thickness of the intervening substance. To apply these principles in practice, take a trial picture of the hand at five-inch distance, this being amply sufficient for good definition with such small bones. Say one minute is required for a good result. Then to take a hip joint, we estimate the thickness of the latter to be, say, 10 times that of the hand. We must, therefore, expose 10 minutes on account of thickness alone. But owing to the greater distance of bones from plate, the tube must be removed much further to get definition. At least 15 inches from the dry plate should be given—this is three times the distance used for the hand, from which the times require to be as the square of these figures, or as one is to nine. The total exposure must, therefore, be 90 minutes. This method gives something to go upon. After a little experience, perhaps the most convenient thing to do is to arrange a little table, based upon previous results, and showing times and distances required for well defined results for distinctive parts of the body.

SHORT EXPOSURES.

We have obtained, and do regularly obtain, without difficulty, well defined pictures showing complete detail of the osseous structure involved in times and with distances from dry plate to reflector, as below:

Hand and wrist, 5 to 10 seconds at 5 inches.

Forearm, 10 to 15 seconds at 5 inches.

Arm above elbow, ½ to 1 minute at 7 inches.

Shoulder, 10 to 15 minutes at 10 inches.

Thorax, 15 to 30 minutes at 10 inches.

Hip joint, 30 to 45 minutes at 12 to 15 inches.

Stones in kidneys, 30 to 45 minutes at 12 to 15 inches.

Glass, iron, lead, etc., in any part of trunk, 30 minutes on an average at 12 to 15 inches.

We have very carefully investigated every claim to quicker exposures than these, often by a personal visit, sometimes by correspondence with personal friends whose reliability was undoubted. We have been unable to learn of any results equally good having been obtained in shorter times by any one, at any place, with any form of apparatus, and we do not believe any such have been obtained.

MANIPULATION DEVELOPMENT OF THE PLATE.

Suitable and well constructed apparatus is not the only essential to good results. A great deal depends upon the operator, and comparatively trivial differences in procedure make all the difference between success and failure. We describe here the method which we follow and which allows us to count with certainty upon securing at least nine successful plates for every 10 exposures.

A. General Adjustment: First, see that the coil is working smoothly, so as to give a uniform discharge in the primary. The secondary spark points should be separated by the distance given by the makers as proper for the tube. The coil must then be adjusted, either by changing the electro-motive force at the primary or by variation of the vibrator adjusting springs so as just not to spark over this air gap. The tube should then be joined in parallel with this secondary spark gap. The coil may then be started up, using the fluoroscope to show whether direction of discharge is right. If not, the primary current should be reversed. If X rays are not now profuse, the secondary discharge points should be further separated and the vibrator springs tightened so as to produce correspondingly greater discharge. Continue this until either X rays are secured as desired or the tube becomes too hot, or possibly bluish, or pink in color. Blue denotes too low a vacuum to expect X rays, but often a gentle running of the tube for 10 or 15 minutes while in this condition will raise the vacuum to a suitable value. Pink denotes a very low vacuum and usually means, in a tube which has ever been right, a puncture or leak. Such a tube can only be made good by re-exhaustion and repair. With most tubes a vivid green fluorescence is the sign of the X-ray vacuum. With the Bowdoin tubes, as also with many others, the most efficient condition is with the platinum reflector plate at cherry-red heat over an area of half or two-thirds that of the little finger nail.

Sometimes the vacuum will be too high for the production of X rays with any length of secondary discharge. It may be reduced by gentle warming of the tube by a spirit-lamp flame. Some reverse the current in the tube, but this is apt to blacken.

Sticking of the vibrator must be guarded against; it is often fatal to the tube. This is because of the much larger current through the primary when such sticking occurs. Upon release, therefore, a secondary discharge much above normal is produced, and this the parallel spark gap is unable to carry off. The tube, therefore, receives much more energy than it should, and may break down, even though the parallel spark gap be as advised by the manufacturers.

B. The Plate and its Development: We have used at one time and another a number of different makes of plates with very fair success. For some time past we have confined ourselves to the Carbutt X-ray plates, and, though we are not prepared to say that they are the best plates to use, the results are so uniformly good as to make it seem inadvisable to us to try other plates not radically different in principle.

For developer we use the Carbutt "J. C. tabloids"—three J and three C to five ounces of water—add about two drams of restrainer (the usual 10 per cent solution). Dr. Stern, of the Philadelphia Polyclinic, advises heating this developer until quite warm to the touch just before using. This we have found so good that we have adopted it as part of our procedure.

From 15 to 20 minutes will be required for development. The image will come up very slowly and not very sharply. Not much detail will be visible by holding up to the light. Continue development until the general main outlines have appeared and faded away to a general blackness upon the glass side. Then rinse and hypo.

The fixing generally requires from a half-hour to two or three hours. This long time is probably partly due to the unusual thickness of the Carbutt X-ray films, but probably even more to some chemical condition set up by the unusually large quantities of restrainer used. Mr. Carbutt advises three J and three C tabloids to six ounces of water to 20–30 drops restrainer. Our experience is that a plate so developed always requires intensification — a tedious nuisance which can never give so good results as a normally exposed and developed plate.

TO TELEGRAPH

Around the Great World

WITHOUT WIRES.

A New System Evolved Fraught with Immense Possibilities and Which Scientists Are Studying.

LABORS OF TESLA AND EDISON.

TO girdle the earth with telegraphy without the use of telegraph wires has been the dream of many an electrical inventor. There is a fascination in the theory of harnessing those mysterious etheric streams of electricity which stratify the upper atmosphere, and harnessing them for the purpose of the world's enlightenment and civilization. But it has never been done.

Many an inventor has tried it and failed. Many an inventor has spent his life dreaming of potentialities without hitting upon the key to the secret. The whirling world generates electricity just like a dynamo. It is a sort of giant revolving battery, terrifically polarized, sparkling, streaming at one end with the aurora, which sends off its ribbons of magnetic currents in vast, flickering fingers, which girdle the earth with a power strong enough to run the world's engines, could it once be bridled and bitted and snaffled by man.

Scientists know the power is there, and they dream of it and reach for it with half blind eyes, and uncertain fingers, too weak to scratch the surface of the secret, and too dazed to do anything but grope for it.

As yet wireless telegraphy is in its infancy. It is an infancy that will grow, however, and one day in the coming century the infant may become a giant that will bowl the world down the ringing grooves of change, bound and swathed with a power that will roll the blessed old ball to the foot of God's throne—bloodless, stainless, warless and with a record as white as the wings of the sinless angels who will then inhabit it.

At least, the scientists think so, and why should I, a mere layman in scientific matters, contradict them? Telegraphing as it is at present is more or less of an annoyance compared with telephones—barring the central office; and if they can be improved so as to facilitate the transmission of general news, the sooner the problem is solved the better.

A Wonderful Invention.

The latest scientist to take a header into the sea of wireless telegraphy is a young man named Mr. Marconi, who has recently evolved a system of telegraphy without wires, which depends not on electro-magnetic but on electrostatic effects. That is to say, the new system is based on Hertzian waves, which have a vibration of not less than 250,000,000 a second.

Think of it! These Hertzian waves are to electricity what the X rays are to visual perception; but, unlike the X ray, they do not die out easily. They simply take hold of one end of an electric stream and shake it into waves so infinitesimally small and keen that it would take the ear of a fairy to hear the magnetic surf beating on the shores of cloudland.

These vibrations are projected through space in straight lines, but, like light, they are capable of reflection and refraction and of focusing, and right upon this fact the scientists have based their dreams of wireless telegraphy. With the fact that the Hertzian waves exhibit all the phenomena of light before them, the scientists have gone to work to construct instruments that will handle these waves, as heliographs handle the rays of the sun. They may succeed. It is to be hoped they will. In the meantime, Mr. Marconi, Mr. Edison and Mr. Tesla will strive for the grand result that will enable them to drum upon the electric streams as a farmer drums upon a tin pan to hive a refractory swarm of bees.

In speaking of Mr. Marconi's invention in London recently, Mr. Preece, the telegraphic expert of the London Post Office, admitted that telegraphing without wires was no new thing. Probably Mr. Preece meant that inadvertent telegraphing by means of induction was no new thing. Here in the United States, in 1878, there were but two wires running from Kansas City to Denver. Many a time I have sat in the Denver office with the first wire idle, yet the instruments were responding to the messages being sent on the second wire. And at no point in all that treeless waste of arid land between the two cities were the two wires nearer to each other than three or four feet.

It must have been this "induction" of dry and magnetic atmospheres that first gave scientific men the idea of telegraphing without wires. Mr. Preece, whom I have quoted above, says that in 1884 operators in the telephone exchange in London were able from sounds heard to read messages that were in transit from London to Bradford by the telegraph wires. The post office wires were under ground and the telephone wires above ground, and careful experiment showed that this fact accounted for the telegraphic messages to Bradford being read by the telephone company. Yet, all the same, it was a mere case of induction.

The invention of young Marconi seems to have dealt with the problem from an entirely different standpoint. It does not deal with the inducing of a current from a neighboring wire. In fact, induction has nothing to do with it. It is an electro-static wave question, and the only thing that now remains to be done is to ascertain the distance to which these telegraphic signals can be transmitted.

The great difference between the Marconi and the inductive methods of wireless telegraphy is that the former does away entirely with the wires at each end. Vibrations are set up by one apparatus and received by the other.

Tesla's Experiments.

On our side of the water wrestling with this very problem we have Nicola Tesla and Thomas Edison. Tesla is more or less of a dreamer. Give him an idea and he will expand it to the stars if he sees possibilities in it. He is an inventive electrical poet, who takes hold of an idea, and with philosophy as a fulcrum tries to unlock the universe. Nevertheless he has worked out some astonishing problems, and is even now completing an invention with which he hopes to circle the globe with telegraphic sound without the aid of wires.

Fully ten years ago Tesla declared that it would be possible to use economically the electricity in the earth's atmosphere for communication between widely divergent points. The problem in his mind was the conservation of electrical energy at the least possible cost.

Long and wearily did Tesla puzzle his brain over this problem. He discarded the induction scheme almost immediately. Induction is more or less a matter of propinquity. Then he hit upon the scheme of oscillation. He went to work upon an oscillator, which was nothing less than an instrument to throw out and produce the enormously swift Hertzian waves.

Through this instrument he thought it possible to solve the problem of aerial telegraphy. In speaking of this possibility Tesla said:—"In time the electric envelope of the earth will enable us to send messages from one part of the globe to all other parts in an instant."

This is a rather broad assertion, but there are those who believe as Tesla does, that the electrical elements of the earth and the atmosphere are infinite, and that it will be only a matter of time when these forces of nature are subjugated to the will of mankind.

Tesla also asserted that this electrical element of the earth's atmosphere might at some future time be utilized for communication with other planets of our system. Here is a dream indeed. Those who have suggested such communication in the past have expended their mental ingenuity on schemes for gigantic electric lettering on the world's deserts and plains.

This would be aerial telegraphing with a vengeance. But do not get nervous. Nothing of the kind will ever occur, unless some fool with a billion dollars to spare leases Sahara Desert for his interstellar electric plant. This is something of a digression, but let us follow it a bit further. Supposing such gigantic lettering were possible, and supposing that return signals were received, what would it prove?

Nothing more than an interchange of intelligence, surely. Nothing more would be possible. What would be the first word flashed across the abyss of space? "God," of course. And right here we would stall. No human ingenuity could go further than this, unless some strange comet should flare across the sky to hinge another word upon. Telegraphic communication along the currents of the earth's upper atmosphere may be possible, but interstellar talk is as far off as Byron's dream of darkness.

And yet Tesla believes great things of his oscillator, and, upon being asked once whether it would be possible to signal to the stars, replied:—

"Perhaps in time. Not yet. There are many things to be fixed first. I have no doubt that it would be possible to signal to the stars."

Well, it may be so. If in the future I shall stand on the pale and ghost haunted hills of the moon, looking across the soundless tracts of space to the red disk of the world, and shall hear a far cry tingling to the stars, a voice that wails through the waste lands like the cry of a lost soul, I shall know that it is Tesla, or Edison, or some terrestrial philosopher howling for the central office of the universe.

As for telegraphing around the earth without wires, ah! that is a different thing. We believe in Tesla and we believe in Edison. Give them an inch of success, and eventually they will make it a mile. Both have said that such a thing is possible, and both know what they are talking about.

As early as 1886 Edison made successful experiments in induction telegraphy from moving trains, sending and receiving telegrams on the Staten Island Rapid Transit road during almost an entire afternoon. The train from which Mr. Edison experimented consisted of five cars, with metal roofs, which were made continuous with pieces of insulated copper wire and connected in the rear car with an ordinary telegrapher's outfit. There was a leap of at least fifty feet from the train to the wires running beside the track, and the bankers and capitalists smiled when they saw the preparations. Very few of them believed that such a thing was possible.

Edison's Induction Scheme.

The train left Clifton at half-past one P. M., and before it had gone a quarter of a mile the instrument in the rear car was clicking merrily. An operator had been stationed at Clifton with a special set of instruments. To this operator the capitalists and others upon the train had delivered many sealed messages.

Before Tottenville was reached all these messages had been received on the train, leaping through the fifty feet of space to the metal roofs of the cars and so to the telegraph instrument. On the return trip despatches were sent from the train to all parts of the country. One message was in Latin, but it got through the atmosphere all right.

Mr. Henry Seligman, the banker, telegraphed to his banking house for Lake Shore quotations and got an answer before the train stopped running. On this occasion Edison stated that a leap of six hundred feet was possible.

Edison began work in 1892 on a marine telegraph based upon the principle of induction. This invention was patented, and by it Mr. Edison was enabled to telegraph a goodly distance across water without the use of wires.

But the great difficulty with all these experiments, whether with induction or Hertzian waves, is that the waves will not follow the curvature of the earth's surface. In this respect they are related to the X rays, which, in fact, seem to be a sort of illuminated electricity.

The point to overcome in telegraphing long distances without wires is to obtain a sufficient elevation to overleap the curvature of the earth's surface, and to reduce to a minimum the earth's absorption of the electric current. "At sea," said Edison, in speaking of marine telegraphy, "from an elevation of one hundred feet I can communicate a great distance without wires, and by repeating these signals from ship to ship communication can be established across seas and oceans.

"Collisions in fogs can be prevented and ships approaching a dangerous coast can be assured of safety."

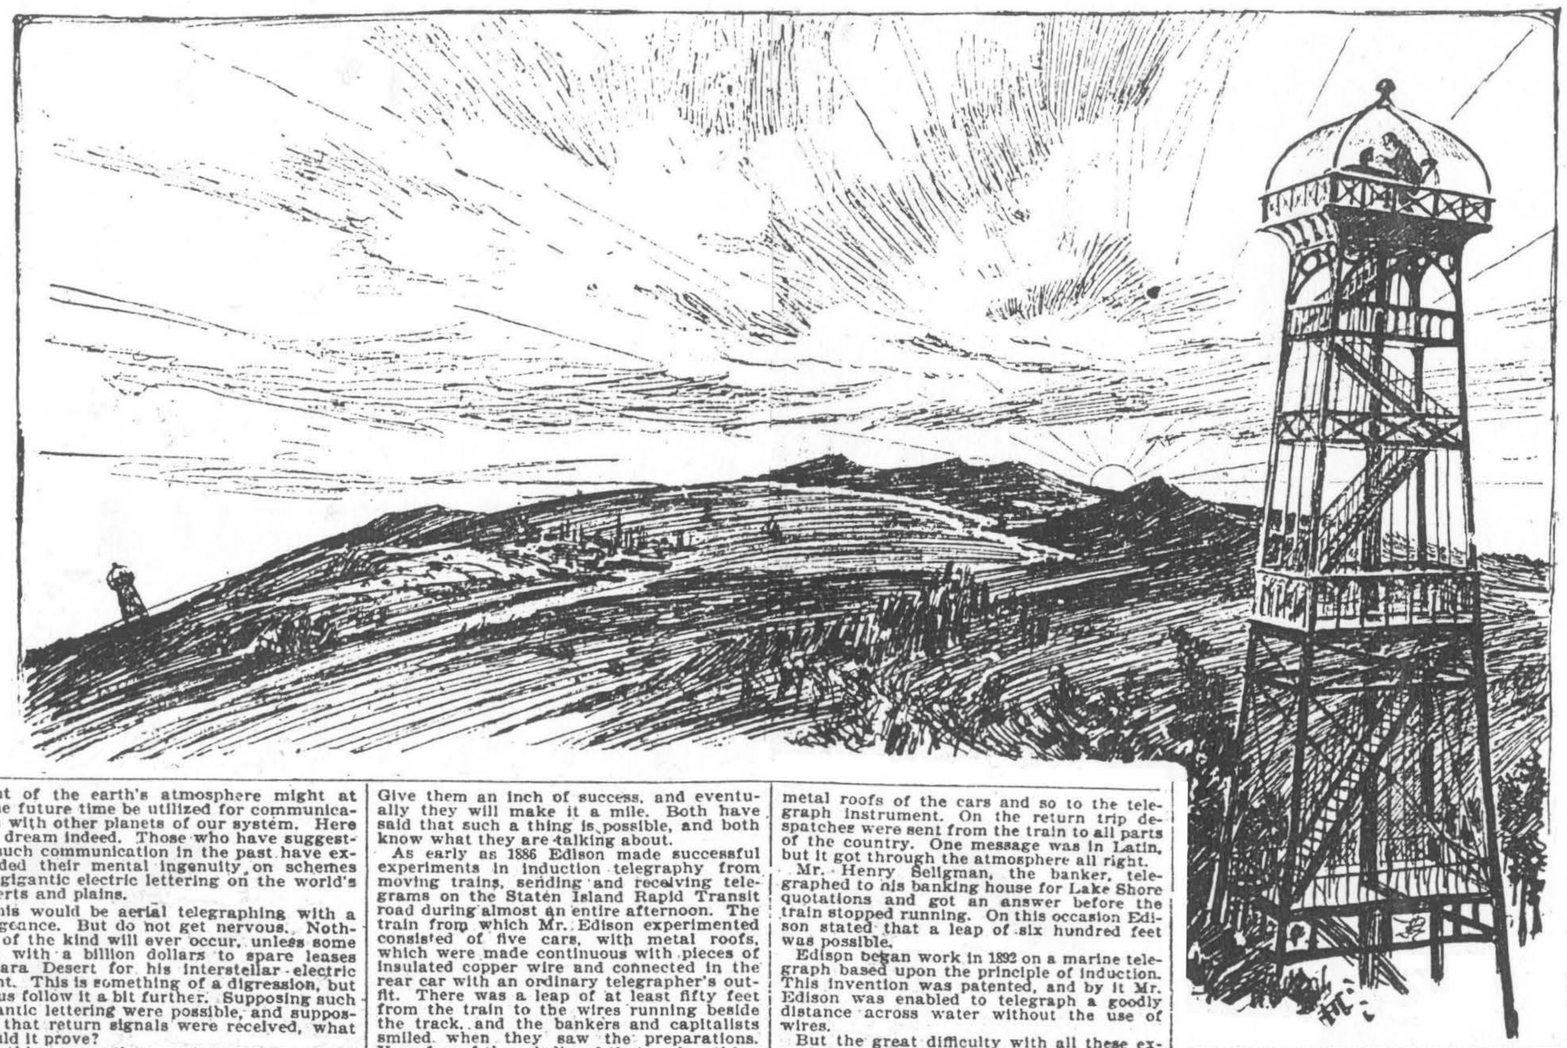
It would be rather a hard matter to obtain one hundred feet elevations at sea, but there are many mountain chains that would afford splendid opportunities for experiment, if not for practical use. In fact, Tesla has already telegraphed a goodly distance from one mountain peak to another without the use of wires.

Aerial Mountain Telegraphy.

If the terrific impulse of these Hertzian waves is not overestimated, a sort of mountain telegraph might be established from Washington Territory to Nicaragua, and, with a few towers, even to the lower part of Chili and Patagonia. From lofty Mount Everest the signals could be flashed, peak by peak, to Mount Hood, Ranier, Shasta, and so down that long continental vertebra of granite to Gray's Peak, Long's, Lincoln's, Pike's, the Holy Cross, La Veta, through the Sierra Madre to Popocatapetl, Orizaba, into Nicaragua, across the Isthmus and into the cloud soaring Cordilleras.

Here the peaks would be higher and communication probably more clear and swift. Down the lofty line of snowy summits the news would click as swift as thought, from Chimborazo to Aconcagua, and along the snowy range into strange, dismal lands, and at last the Patagonian, crouching with a wondering face over his miserable fire with the despatch in his hands, would know that Casey had struck out.

This may be an exaggeration, but the fact remains that many scientists are so thoroughly convinced that the use of atmosphere and earth currents of electricity is practicable that they are working with might and main to bring about the desired end.



In a recent interview, Marconi, the man who has recently interested London on the subject of telegraphy without wires, said:—

"I have long believed that instantaneous and simultaneous communication to all parts of the earth is possible by means of electric waves. I am becoming more convinced every day that such communication can be based upon scientific principles which can be controlled at will.

"Those huge disturbances on the sun, which are nothing more nor less than waves of electricity, are productive of similar disturbances on the earth in the form of storms. Why should not disturbances of the electric currents of the earth's atmosphere be made intelligible? It is not necessary that a conducting circuit must exist.

"An electrical disturbance at one point causing a change in the equilibrium of the earth's electricity should be felt at all points of the earth's surface, and I think it possible to record them. The possibilities of such a transmission of intelligence cannot be exaggerated. A message sent from London would be in America, Africa and Australia in an instant."

AS STATIONS FOR AERIAL TELEGRAPHY WITHOUT WIRES WOULD APPEAR.

[*Entered as second-class matter at the New York Post Office, April 9, 1888.*]

VOL. XXIII. NEW YORK, FEBRUARY 3, 1897. No. 457.

MR. TESLA'S VIEWS ON THE FUTURE OF ELECTRICITY.

THE inauguration of the Buffalo-Niagara electric transmission, brought together, as our report showed, a representative gathering of influential men and elicited a number of memorable addresses. Of the speeches devoted to the technical side, that of Mr. Tesla's deserves more than passing notice, as containing the expression of his latest views and convictions on subjects which he has made his special study for some time past. Speaking of the types of prime movers in use to-day, Mr. Tesla gives no encouragement for the future of the reciprocating high speed engine in its present form, nor for the steam turbine. His ideal engine is one which expands the working fluid with utmost rapidity and loses little heat in the walls; an engine stripped of all usual regulating mechanism, packings, oilers and other appendages and forming part of an electric generator. Mr. Tesla, though not mentioning it by name, here evidently referred to his oscillator, brought out in 1893. As to the outlook for a carbon consuming battery. Mr. Tesla does not consider it over-promising, viewed from the standpoint of a source of power. The probability of replacing the engine-dynamos by batteries is, in Mr. Tesla's opinion, a remote one, the more so as the high pressure steam engine and the gas engine give promise of a considerably more economical conversion. Mr. Tesla also sees drawbacks lurking in the fact that carbon to be consumed in batteries has to be prepared for that purpose and cannot be used as found, as it is under the boiler. The manipulation, cleaning, renewal, regulation, etc., of the batteries, and their size, together with the character of the liquids employed in them, would make it difficult, if not unprofitable, to handle such a plant in a densely populated city district. While thus expressing little faith in the carbon battery, Mr. Tesla has hopes for the ultimate supply of isolated plants or dwellings in the development of what he calls a light "storage battery," involving the use of chemicals manufactured by cheap water power, such as some carbide or oxy-hydrogen cell. We incline to the opinion that what Mr. Tesla has in mind partakes more of the nature of a primary gas battery.

But it is Mr. Tesla's conclusions on the results of his own particular work which will perhaps command the greatest attention among electrical engineers and the public at large. It will be recalled that in his very first lecture at Columbia University in 1891 he threw out the suggestion that it might be possible to operate engines at any point on the earth "by the energy of the medium." Six years of continued study have brought him beyond the stage of mere conviction, and he now feels sure that the realization of his ideas is not far off. But at the same time Mr. Tesla confesses the disappointing conclusion reached by him that under the theoretically best conditions such a method of obtaining power cannot equal in economy, simplicity and many other features the present method of converting the energy of falling water into electric current, and transmitting it over long distances at high potential. With this conviction of the greater utility of water power, Mr. Tesla has bent his energies to the means of transmitting it, and now informs us that he has devised means which permit of power transmission at potentials much higher than are now considered practical. He hints further that the progress he has made gives him fresh hope that he will be able to transmit power from station to station without the em-

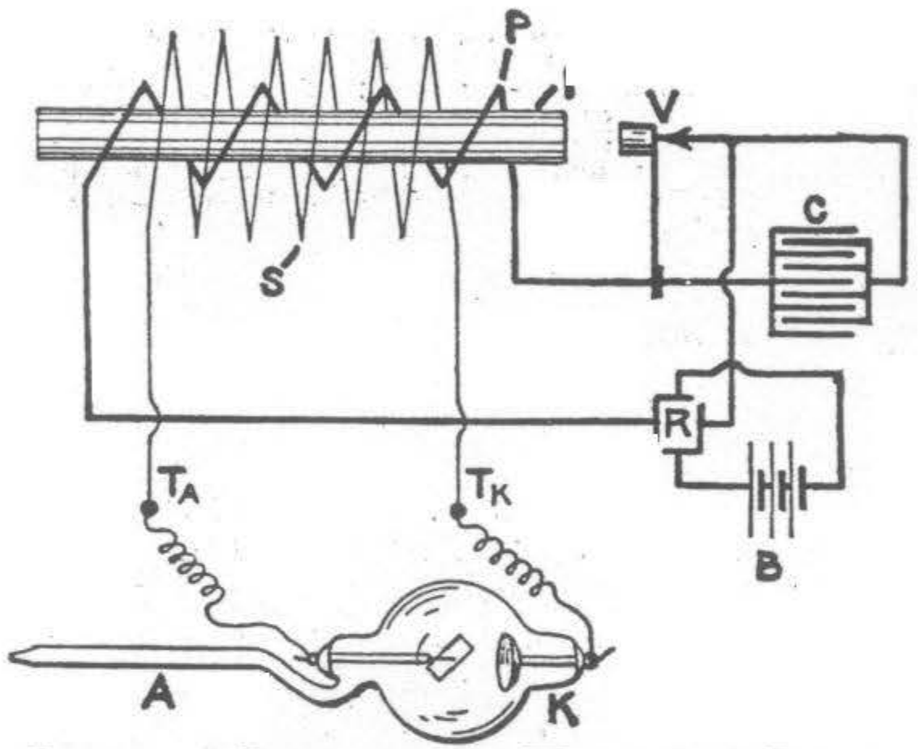
ployment of connecting wires, but he adds that, whatever method of transmission be ultimately adopted, nearness to the source of power will remain an important advantage. We cannot help expressing our gratification at this promised realization of one of Mr. Tesla's fondest dreams, but we hardly expect that the manufacturers of wire will receive the announcement in a like spirit of joy. Mr. Tesla has thrown out enough in his remarks to put the public again on the qui vive. The electrical community will await with impatience the practical demonstration of his new methods, accept the "report of progress" and "extend the time of the committee."

Electricity. Tesla. *Elec. Rev.*, Jan. 27.—A reprint in full of his recent address at Buffalo; it is very general in character. He discusses the features of human intellectual progress in recent times, which chiefly interest the scientific man, the thinker and the reasoner; he refers to the influence of the artist; electricity has been one of the most potent factors in the elevating features which characterize modern intellectual development; he refers to the merging together of the various sciences or departments of research and the connection between different forces and phenomena; only a brief reference is made to high-frequency currents; the electric transmission of power is considered to be the most important industrial application. In referring to the direct production of electricity from carbon in a battery, he states that he does not think it will be as much of an advance as some seem to believe; he favors the mechanical generation and considers the probability of replacing the present generators by batteries as a very remote one; he has confidence in the development of a light storage

battery involving the use of chemicals manufactured by cheap water power, such as some carbide or oxygen-hydrogen cell; he refers to means for obtaining energy from stores which are forever inexhaustible without combustion or waste of any material, stating that he has had the matter under consideration for a number of years, and believing the problem will ultimately be solved; he thinks the realization of the idea is not far off; he refers to the possibility of the operation of engines on any point of the earth "by the energy of the medium" (presumably a misprint); but he adds that under the theoretically best conditions such a method of obtaining power cannot equal in economy and simplicity the conversion of the energy or running water into electrical energy; he has devised means for using for transmission E. M. Fs. much higher than practical with ordinary apparatus; he believes he will succeed in transmitting power without the employment of any connecting wire.

MR. TESLA AS A BUG KILLER.

THERE can be no doubt as to the invasion of the domain of agriculture by electricity. Last week we noted the results obtained on a farm in Germany, and hardly a week goes by without its news of farmers using the telephone in their operations, experiments at agricultural stations with all kinds of current in stimulating seeds and plants, or the use of power from lighting or trolley circuits in running farm machinery. Indeed, it may be said to be doubtful whether the factory or the farm is to be the new scene of electricity's next triumphs.



It will be remembered that not long ago, Mr. Tesla suggested that part of the energy of powers like that of Niagara might be applied to furnishing nitrogenous elements to the soil, so that better crops could be secured. This may explain why a Mr. S. S. Harvey in the South wrote to him asking if electricity could not be used in a general pervasive way to kill off the bugs that are such a pest in orchards and vineyards. Mr. Tesla, with wonted courtesy, admitted the importance of the subject and said in response to the inquiry: "It is sure that we can destroy these detrimental insects in certain ways by the help of electricity, but to what extent the trees would be affected by the application of these means I do not know, and it could only be settled by a series of experiments. I have some ideas on the subject, and think that an apparatus for experimentation could be produced in a short time. I am resolved to think over the matter in the hope to arrive at some tangible result."

We have no doubt that to some people the idea of a notable electrical inventor devoting his time to devising bug traps and "sure deaths" smacks rather of the grotesque and ridiculous; but in reality Mr. Tesla could not undertake anything of more real and practical value. When one stops to consider how famine, ruin and devastation afflict the human race because of such pests as the locust, phylloxera, army worm and potato bug, it is evident there is work to do of real vital importance to a great many people.

LEGAL NOTES

THE TESLA PATENTS REVOKED IN GERMANY.

As was announced in these columns several weeks ago, two of Mr. Tesla's patents have been revoked in Germany. We now learn that these patents are numbered 47,012 and 47,885, respectively, and entitled "Combination of a Transformer and a Source of Current," and "Connection of the Coils of Current Generators with Motors."

CORRECTED DIAGRAM.—MR. WILLYOUNG'S PAPER.

A Correction in Mr. Willyoung's Paper on X Rays.

TO THE EDITOR OF ELECTRICAL REVIEW:

An error occurred in Fig. 2 of my article, "X Rays, Apparatus and Methods," in your issue of January 27. The error is one of inadvertence on the part of the draftsman, apparently. I will be glad to have it corrected through your columns. As the figure was originally printed, the battery "B" was short-circuited through the reversing switch "R."

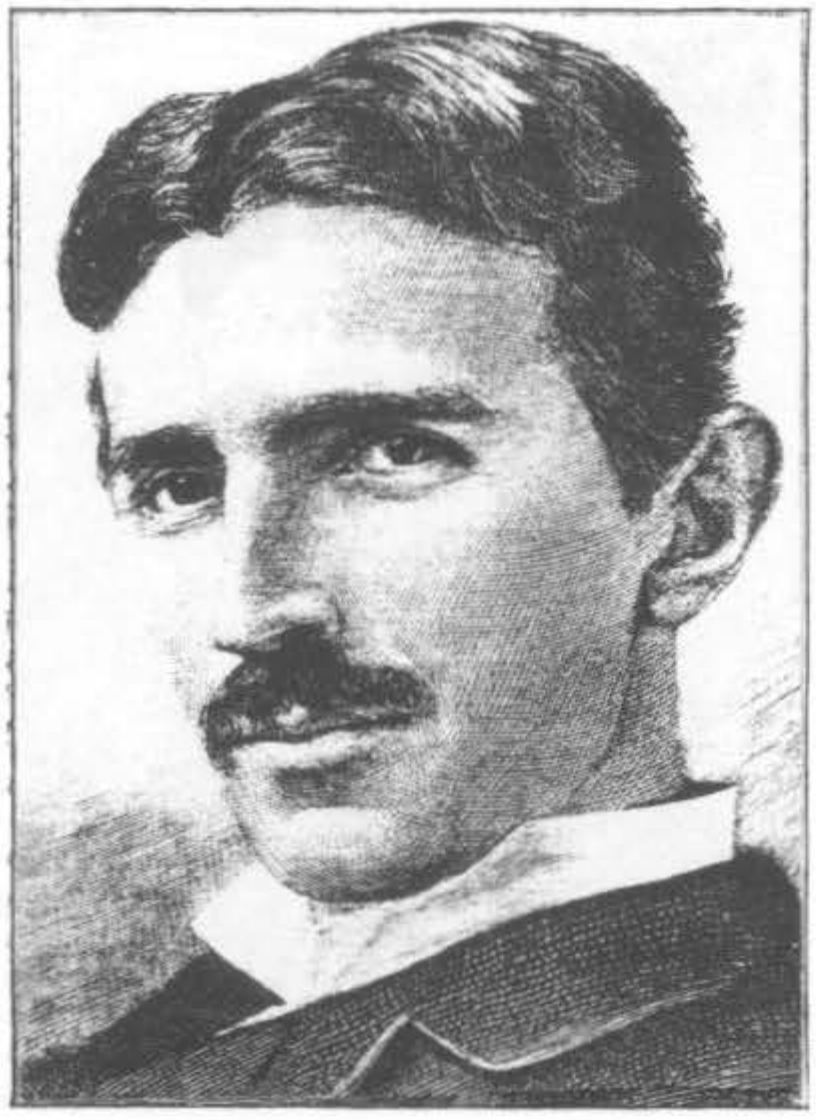
Very truly yours,

ELMER G. WILLYOUNG.

Philadelphia, February 2.

TESLA ON LONG LIFE AND SLEEP.

Being asked for his views on reasons and signs of longevity, Mr. Tesla said: "A man receives a certain term of life; so many hours to pass on this earth—I mean hours when he is alive, awake; I do not count the hours when he is sleeping; I do not believe they are, strictly speaking, included in his term of life. When a man really lives he is dying hour by hour, but when he sleeps he is accumulating vital forces which will make him go on living. In other words, in measuring out our dole of hours to each one of us, the great timekeeper stops his count while we are sleeping. Therefore, the longer a man sleeps the longer he will remain on earth. Nearly all long-lived people have been great sleepers. When De Lesseps was on the ocean he would sleep twenty hours on a stretch. Gladstone is a great sleeper, and averages twelve hours a day. I can believe that a man who would learn to sleep eighteen hours a day might live 200 years." Mr. Tesla is himself a very poor sleeper.



[90061.]—**Coil: Tesla and Skiagraphs.**—To MR. BOTTONE.—I don't think you will improve matters by using a Tesla in conjunction with your coil. The same winding as described would be suitable, in case you were inclined to try it. By "heavy" paraffin oils are meant those having a high boiling-point. But better still is good linseed oil, in which a little rosin has been dissolved. You will be able to shorten your exposures by one-half if you use Cadett's "Lightning" plates. It is quite right to use the cells coupled in parallel, because it is current in ampères, and not volts, you require. I should not advise you to use more than six cells; but I think if your cells had elements 5in. by 10in. you would get even better results. S. BOTTONE.

Cassier's Magazine March 1897

THE AGE OF ELECTRICITY.

By Nikola Tesla.

THE commemoration of the recent introduction into the city of Buffalo of electric power from Niagara Falls was made the occasion of a banquet, held at the Ellicott Club, at Buffalo, on January 12, 1897, the hosts being the Niagara Falls Power and Conduit Company, and the distinguished guests the men, principally, to whose business and engineering talents the world owes the remarkable Niagara undertaking so recently brought to successful completion. Probably none among these has been more honoured than Mr. Nikola Tesla, whose electrical researches and practical accomplish-

FROM A PHOTO BY SARONY.

Nikola Tesla

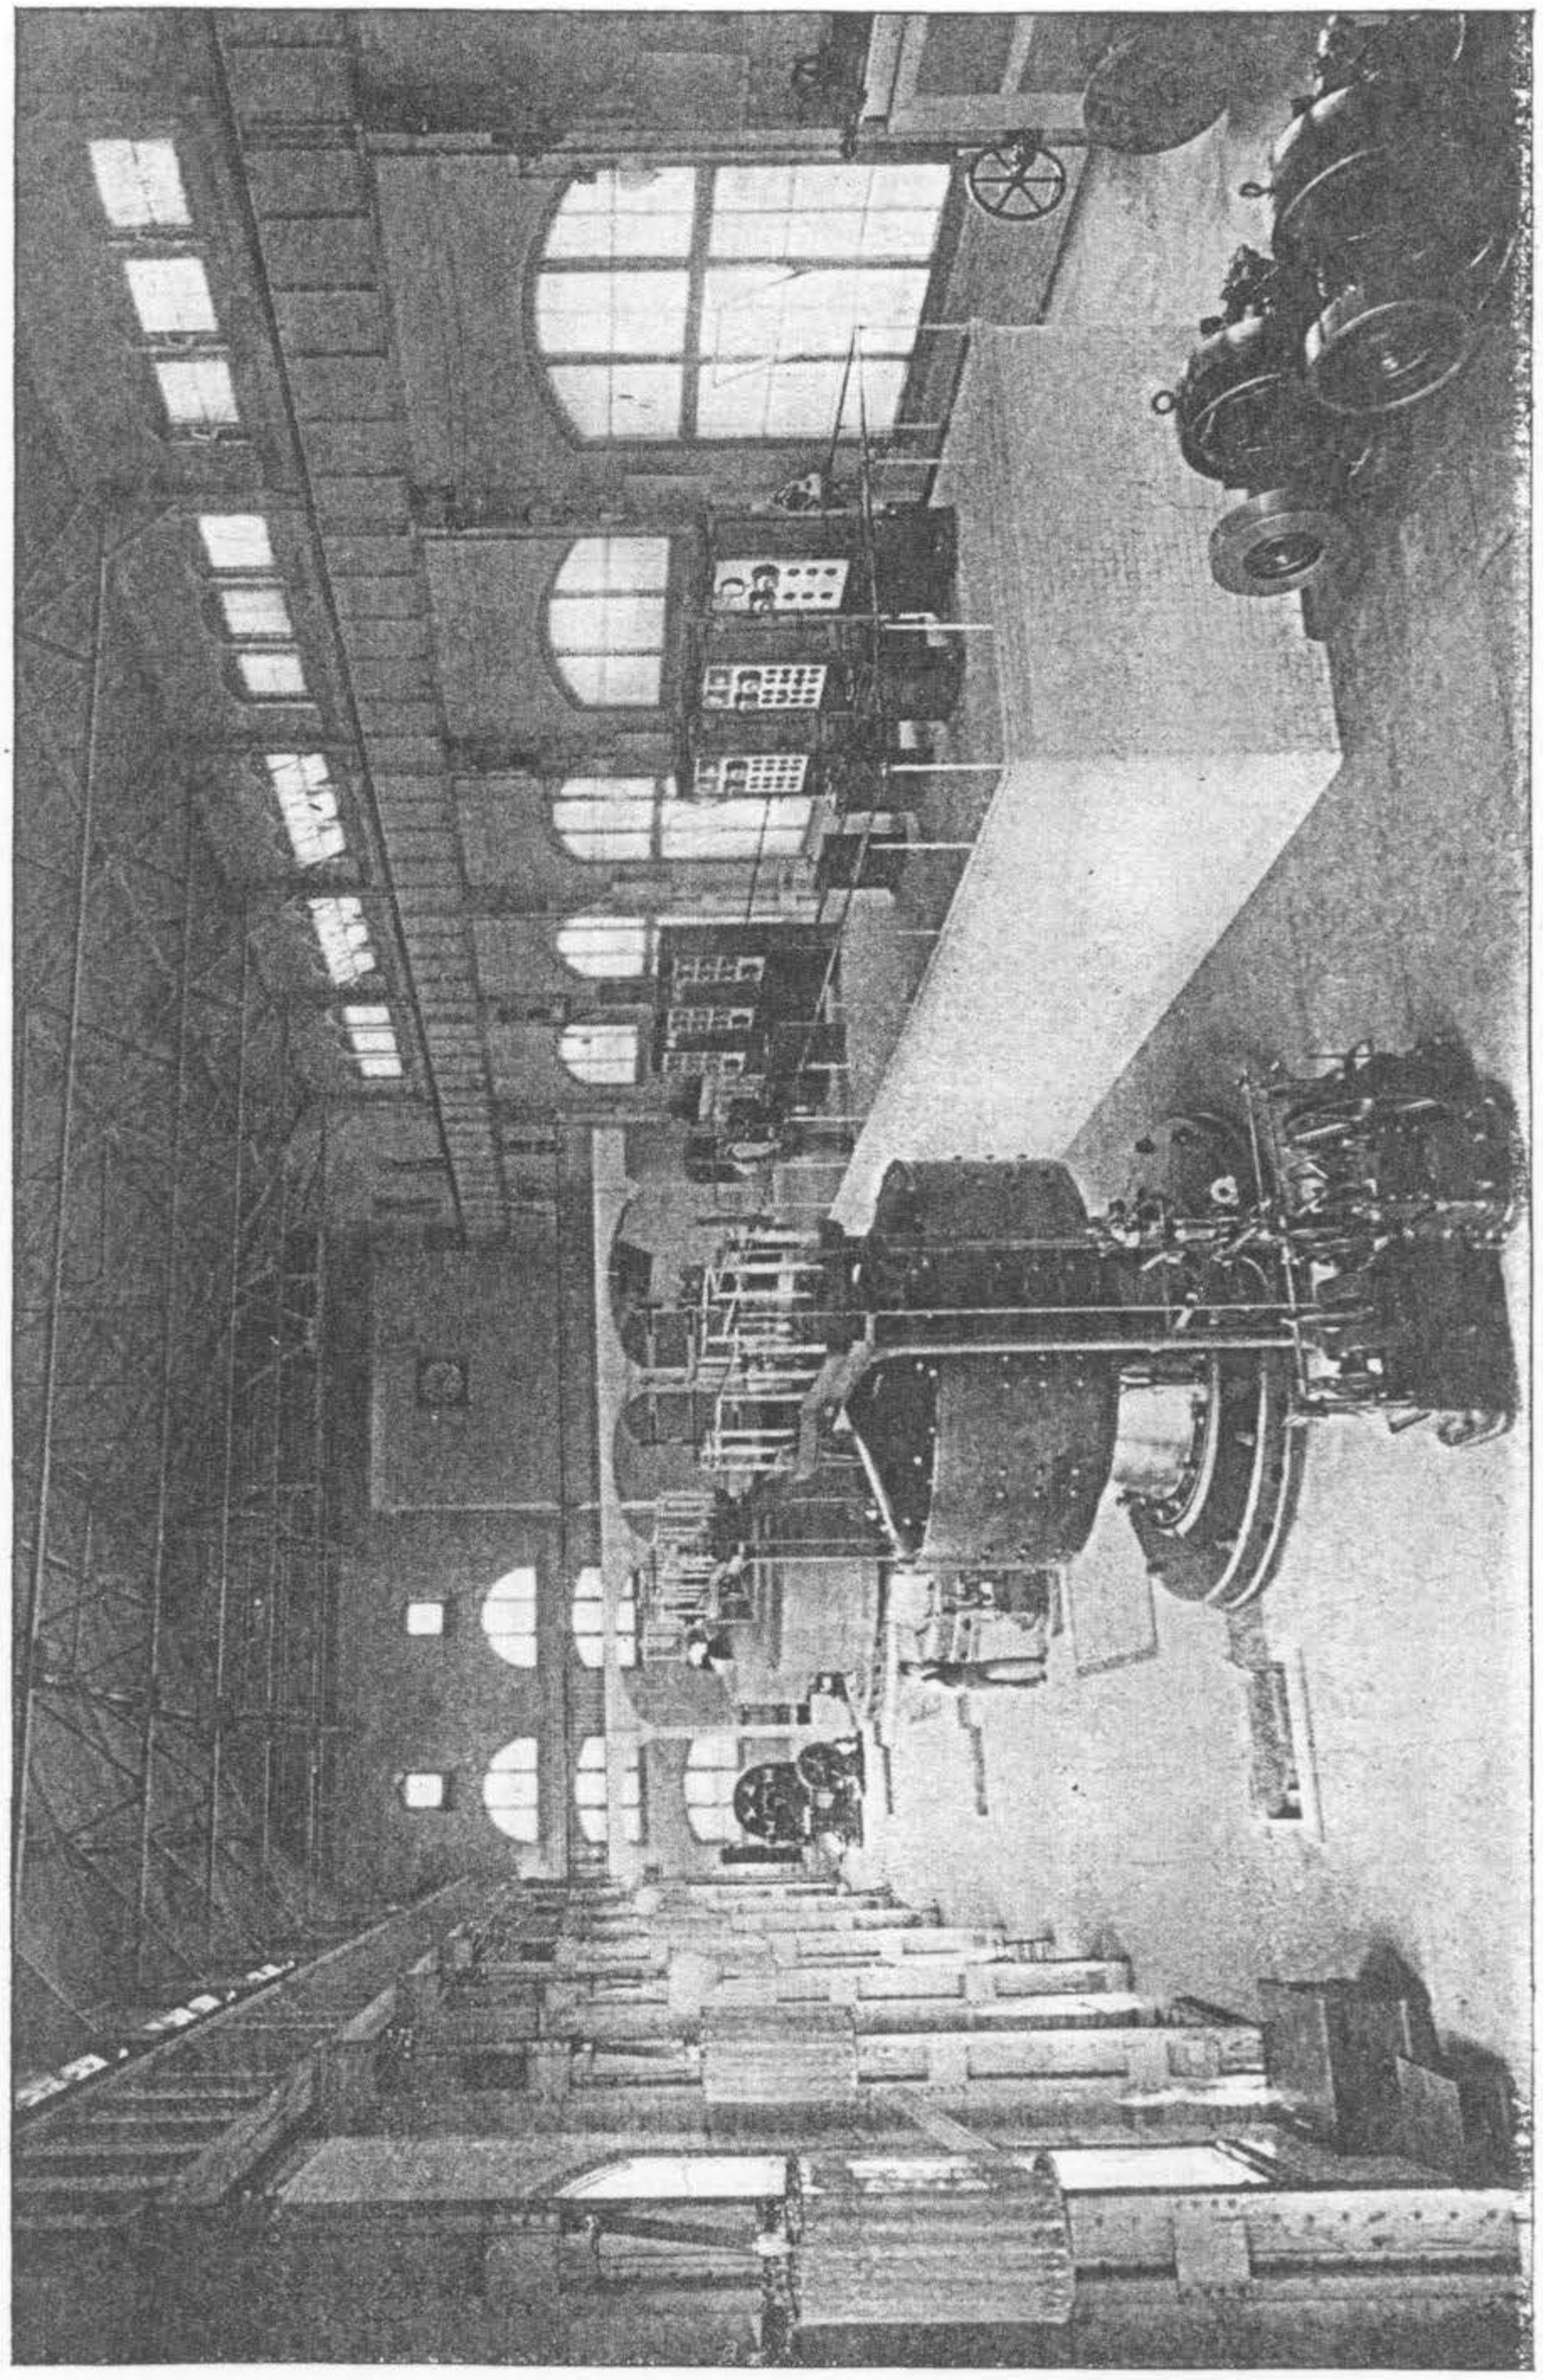
ments have been the talk of the world, and whose polyphase alternating current system was the one eventually adopted in the work at Niagara Falls. After the banquet, in responding to the toast, "Electricity," Mr. Tesla spoke at length of the various sciences, with special reference, naturally to electricity, and from his remarks the appended extracts have been made, picturing in a graphic and striking manner the dependence upon power of the development and wealth of cities, the success of nations, the progress of the whole human race, in fact, as he himself put it. —THE EDITOR.

For more than half a century the steam engine has served the innumerable wants of man. The work it was called to perform was of such variety, and the conditions in each case were so different that, of necessity, a great many types of engines resulted. In the vast majority of cases the problem put before the engineer was not, as it should have been, the broad one of converting the greatest possible amount of heat energy into mechanical power, but it was rather the specific problem of obtaining the mechanical power in such form as to be best suitable for general use. As the reciprocating motion of the piston was not convenient for practical purposes, except in very few instances, the piston was connected to a crank, and thus rotating motion was obtained, which was more suitable and preferable, though it involved numerous disadvantages incident to the crude and wasteful means employed. - But until quite recently there were at the disposal of the engineer, for the transformation and transmission of the motion of the piston, no better means than rigid mechanical connections.

The past few years have brought

forcibly to the attention of the builder the electric motor, with its ideal features. Here was a mode of transmitting mechanical motion, simpler by far, and also much more economical. Had this mode been perfected earlier, there can be no doubt that the majority of the many different types of engines would not exist, for just as soon as an engine was coupled with an electric generator a type was produced capable of almost universal use. From this moment on there was no necessity to endeavour to perfect engines of special designs capable of doing special kinds of work. The engineer's task became now to concentrate all his efforts upon one type, to perfect one kind of engine—the best, the universal, the engine of the immediate future; namely, the one which is best suitable for the generation of electricity.

The first efforts in this direction gave a strong impetus to the development of the reciprocating high-speed engine, and also to the turbine, which latter was a type of engine of very limited practical usefulness, but became, to a certain extent, valuable in connection with the electic generator and motor. Still, even the former engine, though improved in many particulars, is not radically changed, and even now has the same objectionable features and limitations. To do away with these as much as possible, a new type of engine is being perfected in which more favourable conditions for economy are maintained, which expands the working fluid with utmost rapidity and loses little heat on the walls, an engine stripped of all usual regulating mechanism—packings, oilers and other appendages—and forming part of an electric generator; and in this type, I may say, I have implicit faith.



The gas or explosive engine has been likewise profoundly affected by the commercial introduction of electric light and power, particularly in quite recent years. The engineer is turning his energies more and more in this direction, being attracted by the prospect of obtaining a higher thermodynamic efficiency. Much larger engines are now being built, the construction is constantly improved, and a novel type of engine, best suitable for the generation of electricity, is being rapidly evolved.

There are many other lines of manufacture and industry in which the influence of electrical development has been even more powerfully felt,—for instance, the manufacture of a great variety of articles of metal, and especially of chemical products. The welding of metals by electricity, though involving a wasteful process, has, nevertheless, been accepted as a legitimate art, while the manufacture of metal sheet, seamless tubes and the like affords promise of much improvement.

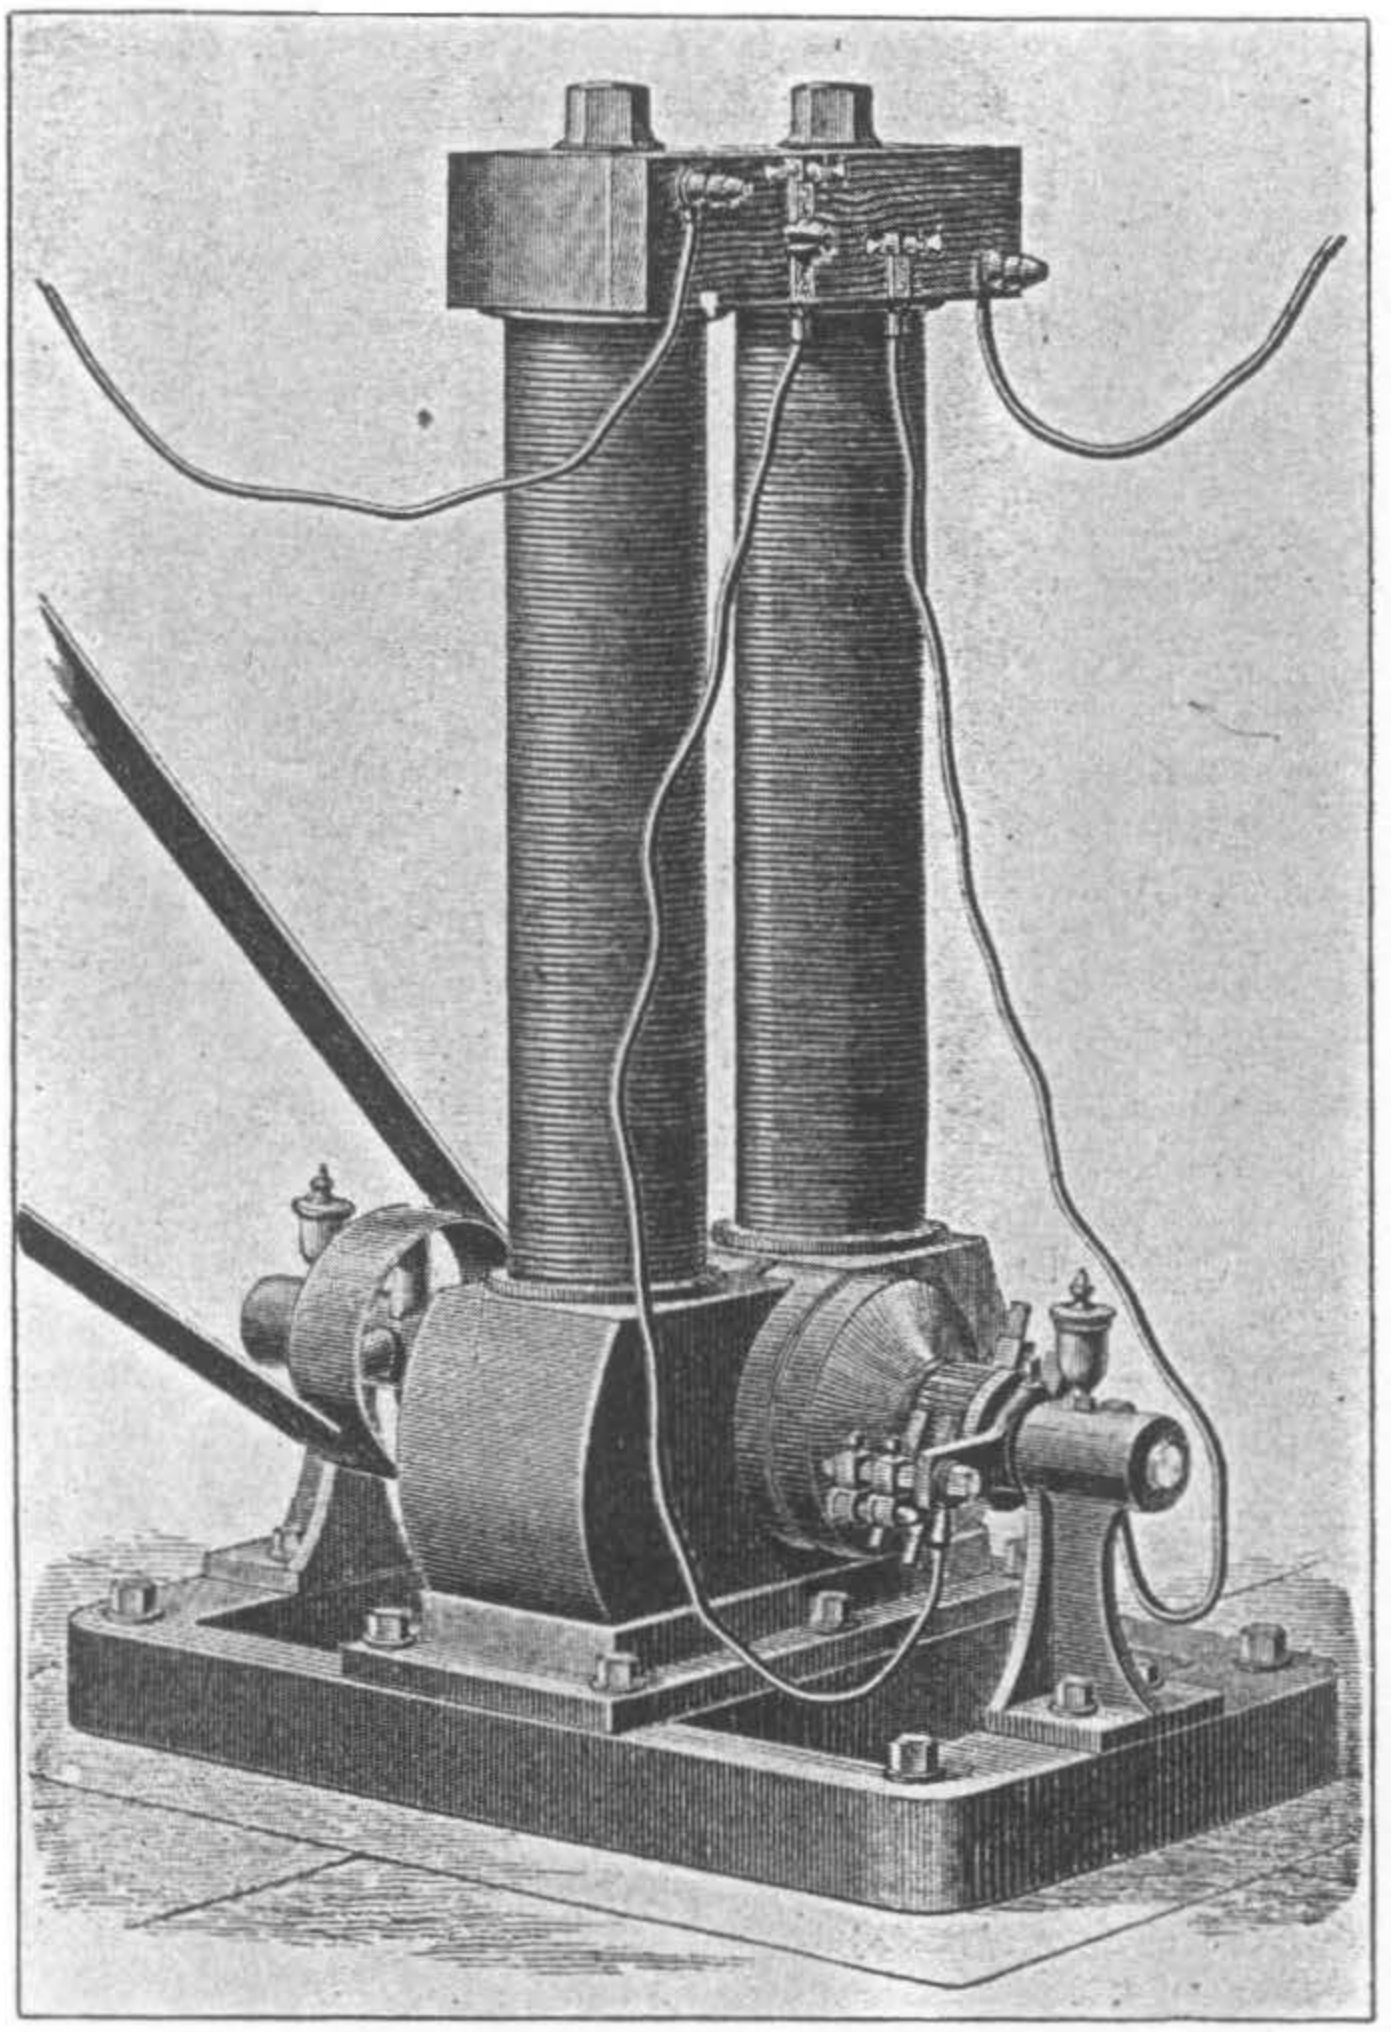
We are coming gradually, but surely, to the fusion of bodies and reduction of all kinds of ores—even of iron ores—by the use of electricity, and in each of these departments great realisations are probable. Again, the economical conversion of ordinary currents of supply into high-frequency currents opens up new possibilities, such as the combination of the atmospheric nitrogen and the production of its compounds; for instance, ammonia and nitric acid, and their salts, by novel processes.

The high-frequency currents also bring us to the realisation of a more economical system of lighting; namely, by means of phosphorescent bulbs or tubes, and enable us to produce with these appliances light of practically any candle power. Following other developments in purely electrical lines, we have all rejoiced in observing the rapid strides made, which, in quite recent years, have been beyond our most sanguine expectations.

To enumerate the many advances recorded is a subject for the reviewer, but I cannot pass without mentioning the beautiful discoveries of Lenard and Roentgen, particularly the latter, which have found such a powerful response throughout the scientific world that they have made us forget, for a time, the great achievement of Linde in Germany, who has effected the liquefaction of air on an industrial scale by a process of continuous cooling; the discovery of argon by Lord Raleigh and Professor

A RECENT VIEW OF THE INTERIOR OF THE NIAGARA FALLS POWER HOUSE.

Ramsay, and the splendid pioneer work of Professor Dewar in the field of low temperature research. The fact that the United States have contributed a very liberal share to this prodigious progress must afford to all of us great satisfaction.



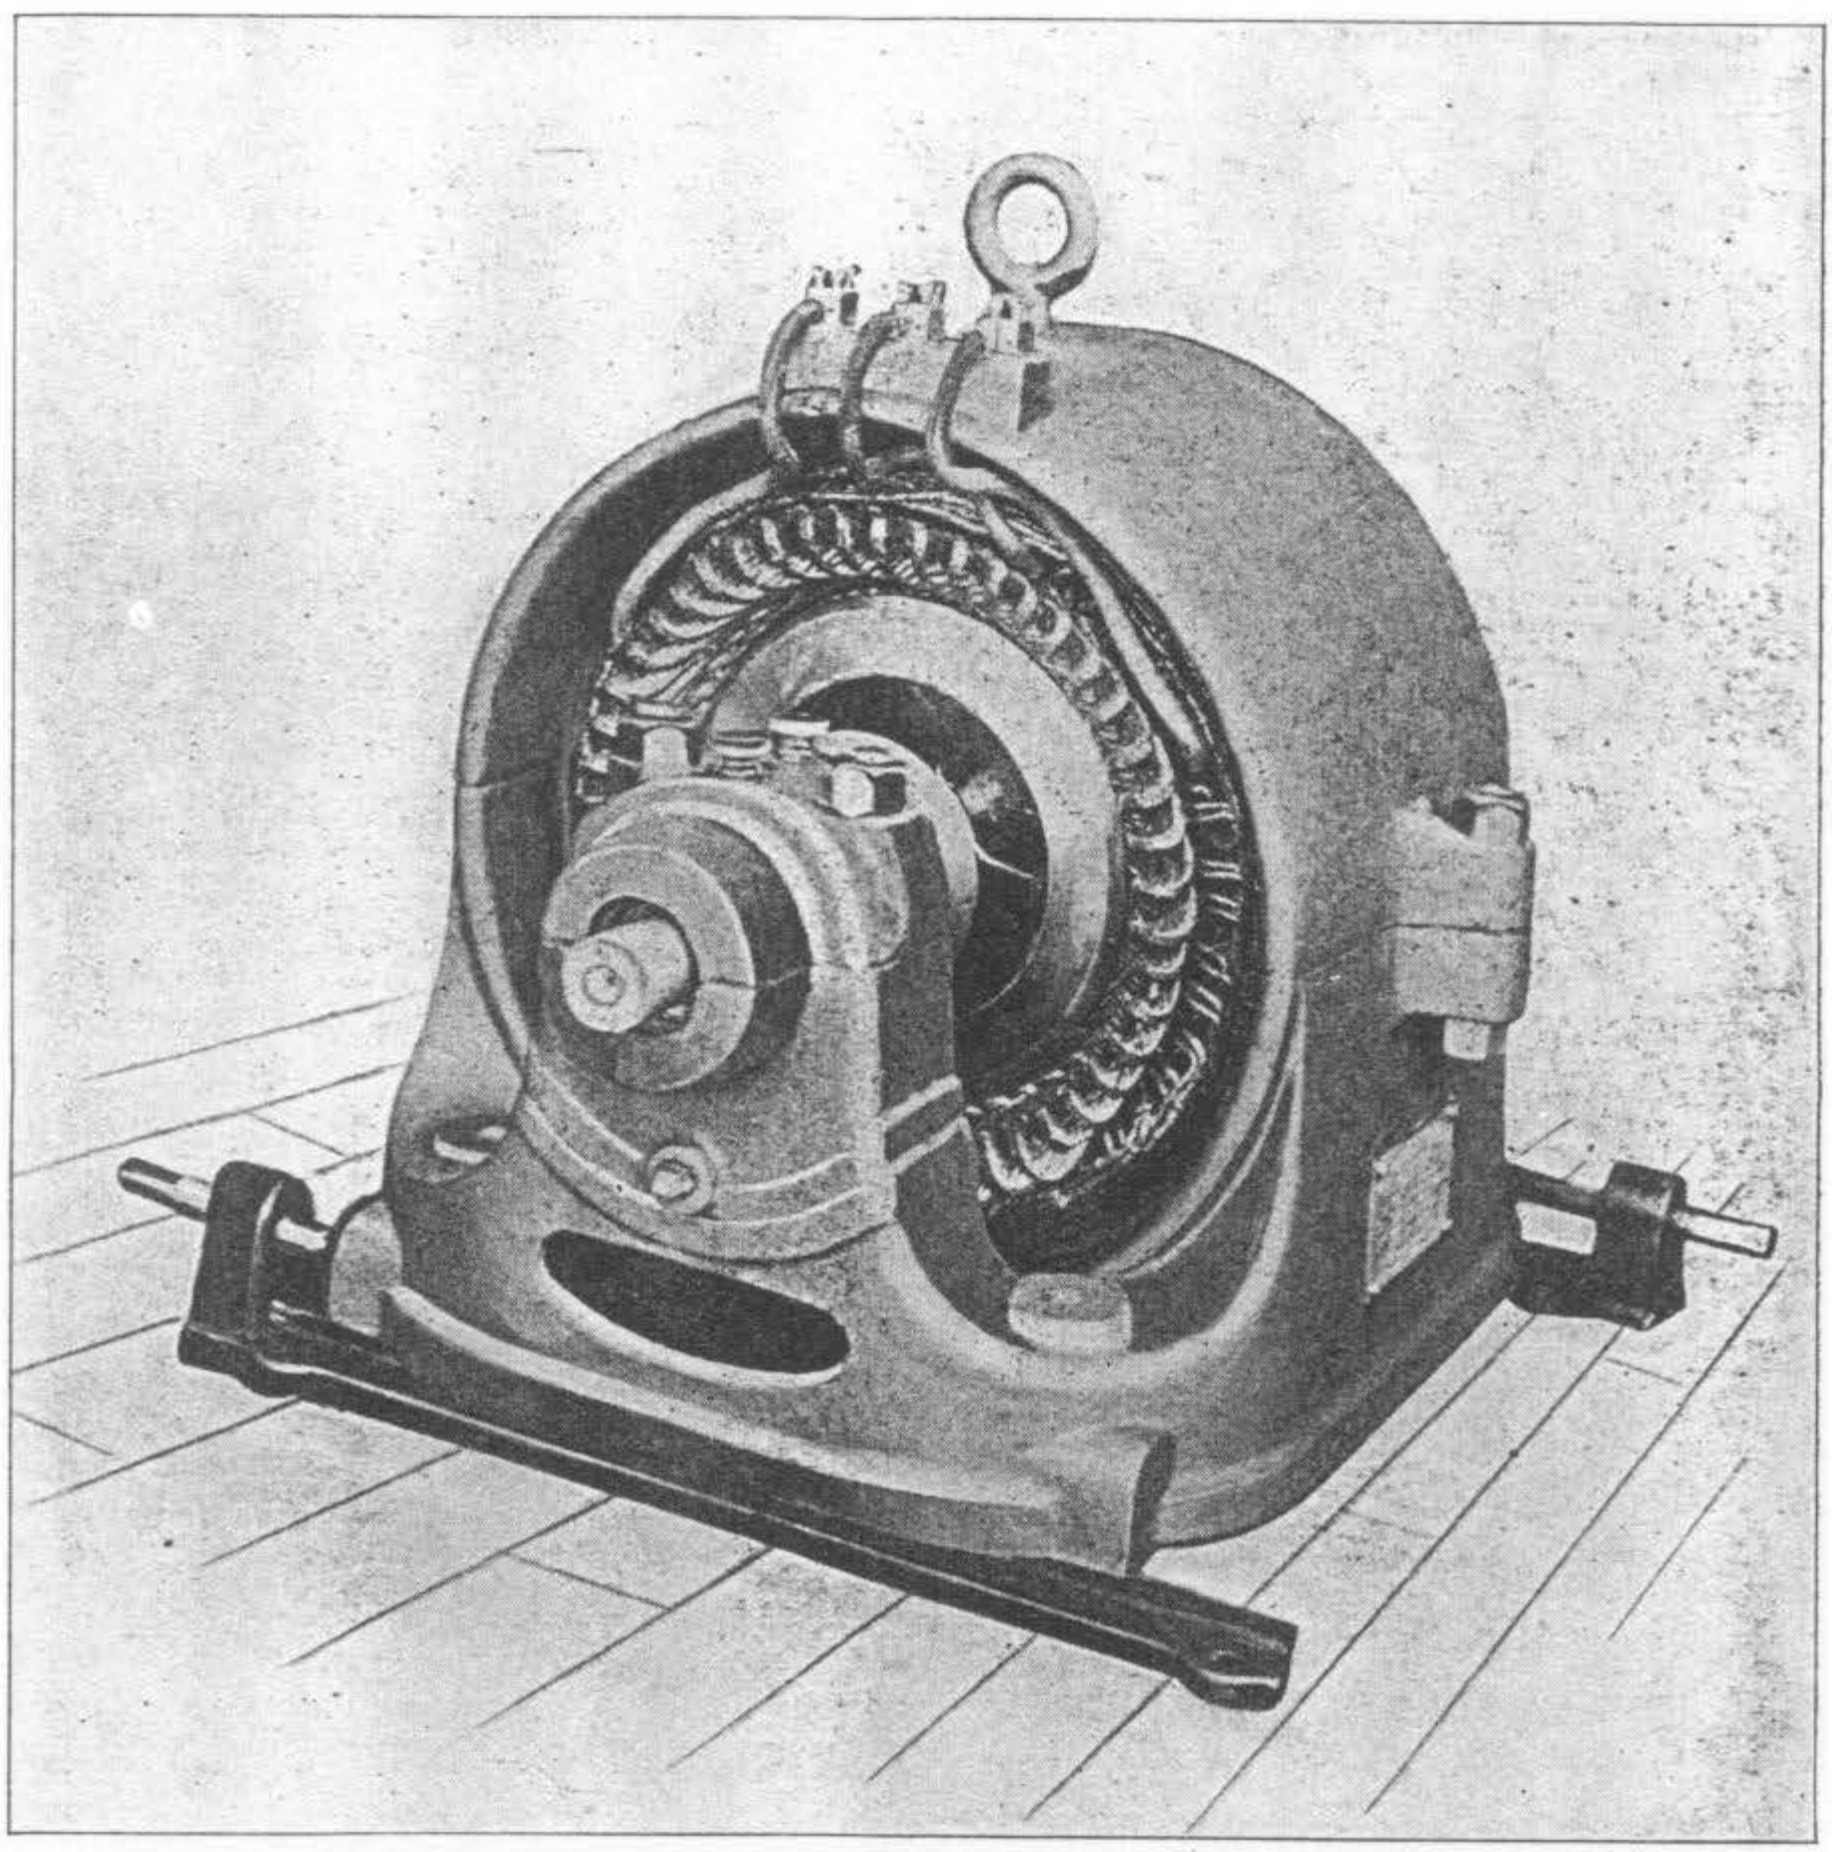
While honouring the workers in other countries and all those who, by profession or inclination, are devoting themselves to strictly scientific pursuits, Americans have particular reasons to mention with gratitude the names of those who have so much contributed to this marvelous development of electrical industry in the United States. Bell, who, by his admirable invention enabling us to transmit speech to great distances, has profoundly affected our commercial and social relations, and even our very mode of life; Edison, who, had he not done anything else beyond his early work in incandescent lighting, would have proved himself one of the greatest benefactors of the age; Westinghouse, the founder of the commercial alternating system; Brush, the great pioneer of arc lighting; Thomson, who gave us the first practical welding machine, and who, with keen sense, contributed very materially to the development of a number of scientific and industrial branches; Weston, who once led the world in dynamo design, and now leads in the construction of electric instruments; Sprague, who, with rare energy, mastered the problem and insured the success of practical electrical railroading; Acheson, Hall, Willson and others, who are creating new and revolutionising industries here under our very eyes at Niagara.

Nor is the work of these gifted men nearly finished at this hour. Much more is still to come, for, fortunately, most of them are still full of enthusiasm and vigour. All of these men and many more are untiringly at work investigating new regions and opening up unsuspected and promising fields. Weekly, if not daily, we learn through the journals of a new advance into some unexplored region, where at every step success beckons friendly, and leads the toiler on to hard and harder tasks.

But among all these many departments of research, these many branches of industry, new and old, which are being rapidly expanded, there is one dominating all others in importance—one which is of the greatest significance for the comfort and welfare, not to say for the existence, of mankind, and that is the electrical transmission of power. And in this most important of all fields long afterwards, when time will have placed the events in their proper perspective, and assigned men to their deserved places, the great event we are commemorating to-day will stand out as designating a new and glorious epoch in the history of humanity—an epoch grander than that marked by the advent of the steam enigne.

We have many a monument of past ages; we have the palaces and pyramids, the temples of the Greek and the cathedrals of Christendom. In them is exemplified the power of men, the greatness of nations, the love of art and religious devotion. But that monument at Niagara has something of its own, more in accord with our present thoughts and tendencies. It is a monument worthy of our scientific age, a true monument of enlightenment and of peace. It signifies the subjugation of natural forces to the service of man, the discontinuance of barbarous methods, the relieving of millions from want and suffering.

No matter what we attempt to do, no matter to what fields we turn our efforts, we are dependent on power. Our economists may propose more economical systems of administration and utilisation of resources, our legislators may make wiser laws and treaties, it matters little; that kind of help can be only temporary. If we want to reduce poverty and misery, if we want to give to every deserving individual what is needed for a safe existence of an intelligent being, we want to provide more machinery, more power. Power is our mainstay, the primary source of our many-sided energies. With sufficient power at our disposal we can satisfy most of our wants and offer a guaranty for safe and comfortable existence to



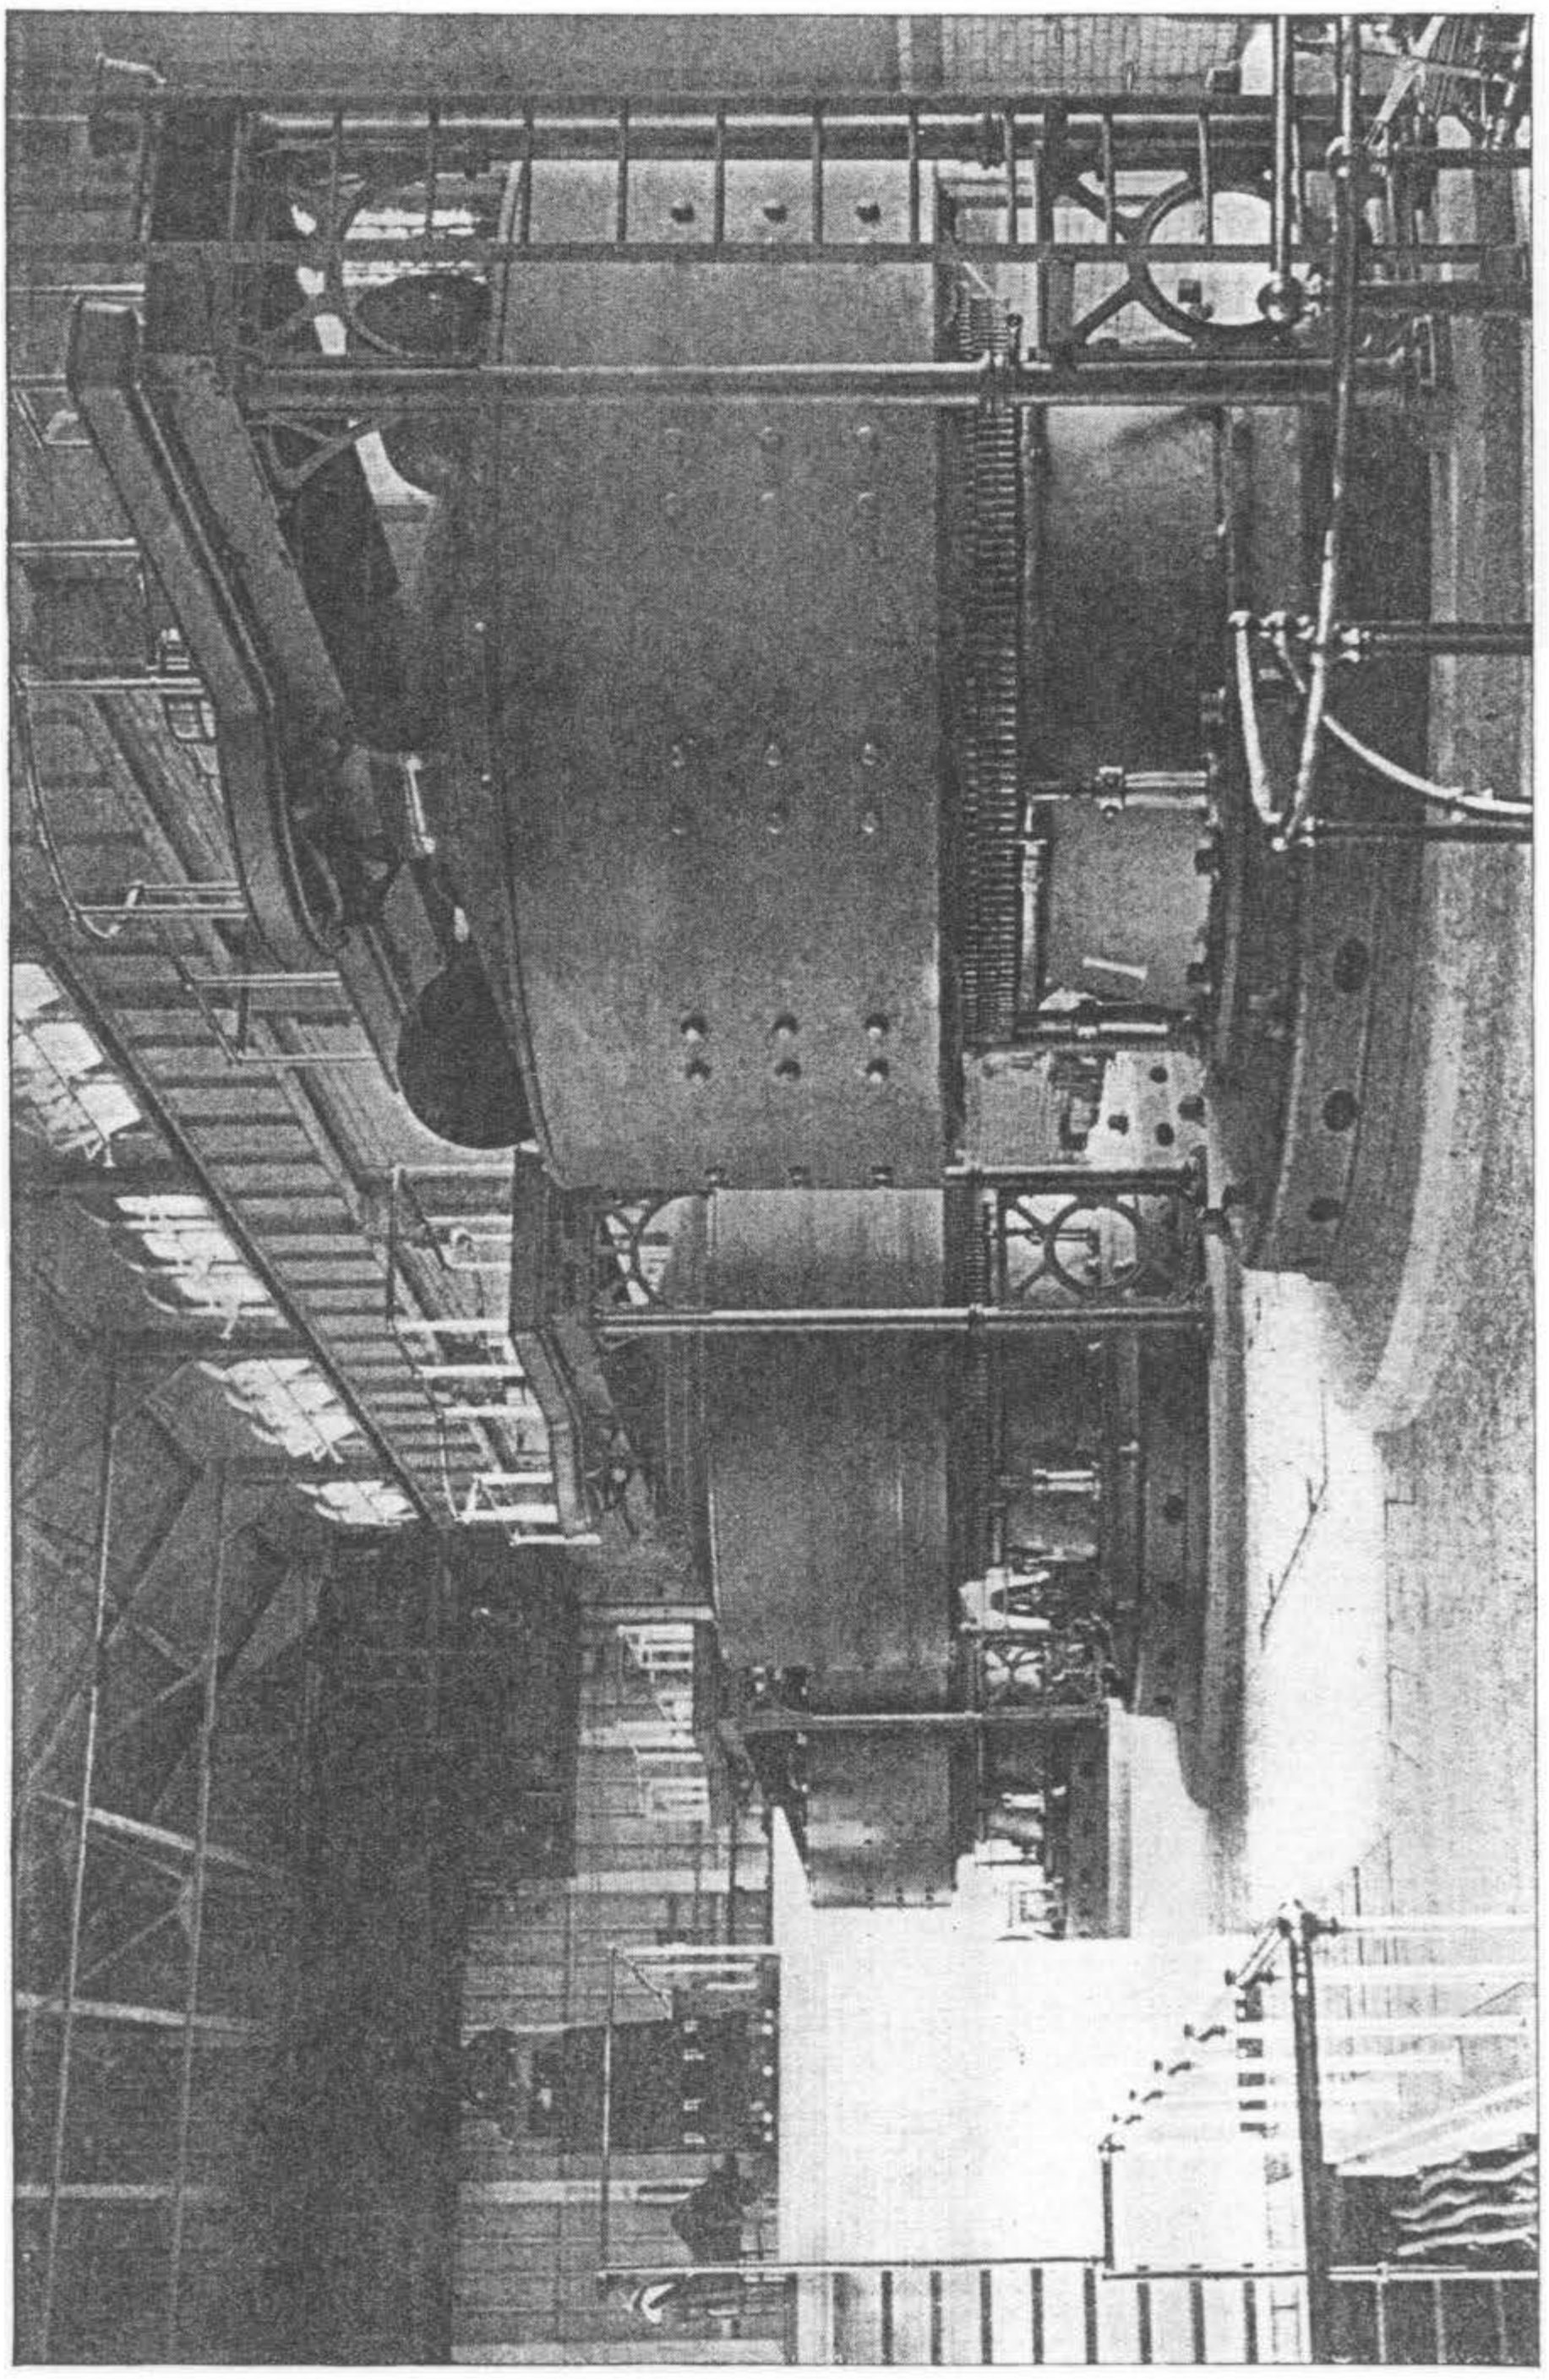
AN EARLY EDISON MOTOR, BUILT IN 1880.

all, except perhaps to those who are the greatest criminals of all—the voluntarily idle.

The development and wealth of a city, the success of a nation, the progress of the whole human race, is regulated by the power available. Think of the victorious march of the British! Apart from the qualities of the race, which have been of great moment, they owe the conquest of the world to—coal. For with coal they produce their iron; coal furnishes them light and heat; coal drives the wheels of their immense manufacturing establishments, and coal propels their conquering fleets. But the stores are being more and more exhausted, the labour is getting dearer and dearer, and the demand is continuously increasing.

It must be clear to every one that soon some new source of power supply must be opened up, or that at least the present methods must be materially improved. A great deal is expected from a more economical utilisation of the stored energy of the carbon in a battery; but while the attainment of such a result would be hailed as a great achievement, it would not be as much of an advance towards the ultimate and permanent method of obtaining power as

some engineers seem to believe. By reason both of economy and convenience we are driven to the general adoption of a system of energy supply from central stations, and for such purposes the beauties of the mechanical generation of electricity cannot be exaggerated. The advantages of this universally accepted method are certainly so great that the probability of replacing the engine dyna-



A MODERN TESLA MOTOR AS MADE BY THE WESTINGHOUSE ELECTRIC AND MFG. CO

mos by batteries is, in my opinion, a remote one, the more so as the high-pressure steam engine and gas engine give promise of a considerably more economical thermodynamic conversion.

Even if we had this day such an economical coal battery, its introduction in central stations would by no means be assured, as its use would entail many inconveniences and drawbacks. Very likely the carbon could not be burned in its natural form as in a boiler, but would have to be specially prepared to secure uniformity in the current generation. A great many cells would be needed to make up the electro-motive force usually required. The process of cleaning and renewal, the handling of nasty fluids and gases and the great space necessary for so many batteries would make it difficult, if not commercially unprofitable, to operate such a plant in a city or densely populated district.

Again, if the station be erected in the outskirts, the conversion by rotating

ANOTHER VIEW OF THE NIAGARA FALLS POWER HOUSE INTERIOR.

transformers or otherwise would be a serious and unavoidable drawback. Furthermore, the regulating appliances and other accessories which would have to be provided would probably make the plant fully as much, if not more, complicated than the present. We might, of course, place the batteries at or near the coal mine, and from there transmit the energy to distant points in the form of high-tension alternating currents obtained from rotating transformers, but even in this most favourable case the process would be a barbarous one, certainly more so than the present, as it would still involve the consumption of material, while, at the same time, it would restrict the engineer and mechanic in the exercise of their beautiful art. As to the energy supply in small isolated places, as dwellings, I have placed my confidence in the development of a light storage battery, involving the use of chemicals manufactured by cheap water power, such as some carbide of oxygen-hydrogen cell.

But we shall not satisfy ourselves simply with improving steam and explosive engines or inventing new batteries; we have something much better to work for, a greater task to fulfill. We have to evolve means for obtaining energy from stores which are forever inexhaustible, to perfect methods which do not imply consumption and waste of any material whatever. Upon this great possibility, upon this great problem, the practical solution of which means so much for humanity, I have myself concentrated my efforts for a number of years, and a few happy ideas which came to me have inspired me to attempt the most difficult, and given me strength and courage in adversity.

Nearly six years ago my confidence had become strong enough to prompt me to an expression of hope in the ultimate solution of this all-dominating problem. I have made progress since, and have passed the stage of mere conviction such as is derived from a diligent study of known facts, conclusions and calculations. I now feel sure that the realisation of that idea is not far off. But precisely for this reason I feel impelled to point out here an important fact, which I hope will be remembered.

Having examined for a long time the possibilities of the development I refer to, namely, that of the operation of engines on any point of the earth by the energy of the medium, I find that even under the theoretically best conditions such a method of obtaining power cannot equal in economy, simplicity and many other features the present method, involving a conversion of the mechanical energy of running water into electrical energy and the transmission of the latter in the form of currents of very high tension to great distances. Provided, therefore, that we can avail ourselves of currents of sufficiently high tension, a waterfall affords us the most advantageous means of getting power from the sun sufficient for all our wants, and this recognition has impressed me strongly with the future importance of the water power, not so much because of its commercial value, though it may be very great, but chiefly because of its bearing upon our safety and welfare.

I am glad to say that also in this latter direction my efforts have not been unsuccessful, for I have devised means which will allow us the use in power transmission of electro-motive forces much higher than those practicable with ordinary apparatus. In fact, progress in this field has given me fresh hope that I shall see the fulfillment of one of my fondest dreams; namely, the transmission of power from station to station without the employment of any connecting wire. Still, whatever method of transmission be ultimately adopted, nearness to the source of power will remain an important advantage.

Some of the ideas I have expressed may appear to many hardly realisable; nevertheless, they are the result of long continued thought and work. With ideas it is as with dizzy heights. At first they cause you discomfort and you are anxious to get down, distrustful of your own powers; but soon the remoteness of the turmoil of life and the inspiring influence of the altitude calm your blood; your step gets firm and sure and you begin to look—for dizzier heights.

In the great enterprise at Niagara we see not only a bold engineering and commercial feat, but far more, a giant stride in the right direction as indicated both by exact science and philanthropy. Its success is a signal for the utilisation of water powers all over the world, and its influence upon industrial development is incalculable. We must all rejoice in the great achievement and congratulate the intrepid pioneers who have joined their efforts and means to bring it about. It is a pleasure to learn of the friendly attitude of the citizens of Buffalo and of the encouragement given to the enterprise by the Canadian authorities. We shall hope that other cities, like Rochester on this side and Hamilton and Toronto in Canada, will soon follow Buffalo's lead. This fortunate city herself is to be congratulated. With resources now unequaled, with commercial facilities and advantages such as few cities in the world possess, and with the enthusiasm and progressive spirit of its citizens, it is sure to become one of the greatest industrial centres of theglobe.

ELECTRICAL SECTION.

Stated Meeting, December 22, 1897.

MR. CLAYTON W. PIKE, President, in the chair.

X-RAYS, APPARATUS AND METHODS.

BY ELMER G. WILLYOUNG AND H. LYMAN SAYEN.

That Professor Roentgen's discovery of the X-ray has initiated many lines of thought, promising to greatly extend our knowledge of physical phenomena as well as to revise many of our previously accepted views, is generally admitted. That the practical results accruing to humanity by virtue of the applications of this discovery in surgical and medical practice, are of even greater promise and value, is equally conceded. The writers have been engaged for a number of months past in developing apparatus and methods for practical work with especial reference to the needs of the physician and surgeon. For conciseness, we have arranged the matter under consideration in a series of subordinate heads, each of which we shall briefly discuss. Your programme committee has thought that some of the results secured might be interesting, in view of the fact that very little literature regarding the technique of X-ray work has thus far been published.

The Coil or Generating Source.—Thus far the only apparatus known which will produce X-rays readily and profusely is the "transformer." By this, however, we do not mean the commercial transformer of every-day use, but its earlier, and for most purposes less efficient form, the "induction coil." Such a transformer gives exceedingly great electromotive forces capable of producing discharge over long air gaps. When the discharge from such a coil is passed through properly exhausted and constructed tubes, we have a very vigorous generation of X-rays.

Two arrangements of the induction coil are advocated. The one is known as the Tesla or "high-frequency" coil, and the other is the direct and old-fashioned use of the simple induction coil, in which the high secondary E.M.F. is delivered direct to the terminals of the tube.

The High-Frequency Coil.—Fig. 1 shows the diagram of the Tesla combination or "high-frequency" coil. It consists, as will be seen, of two induction coils, the induced secondary current of the first being used to charge a Leyden jar. The primary of the second coil is joined, in series with a spark gap, to the two coatings of the Leyden jar. When the Leyden jars are fully charged, they discharge across

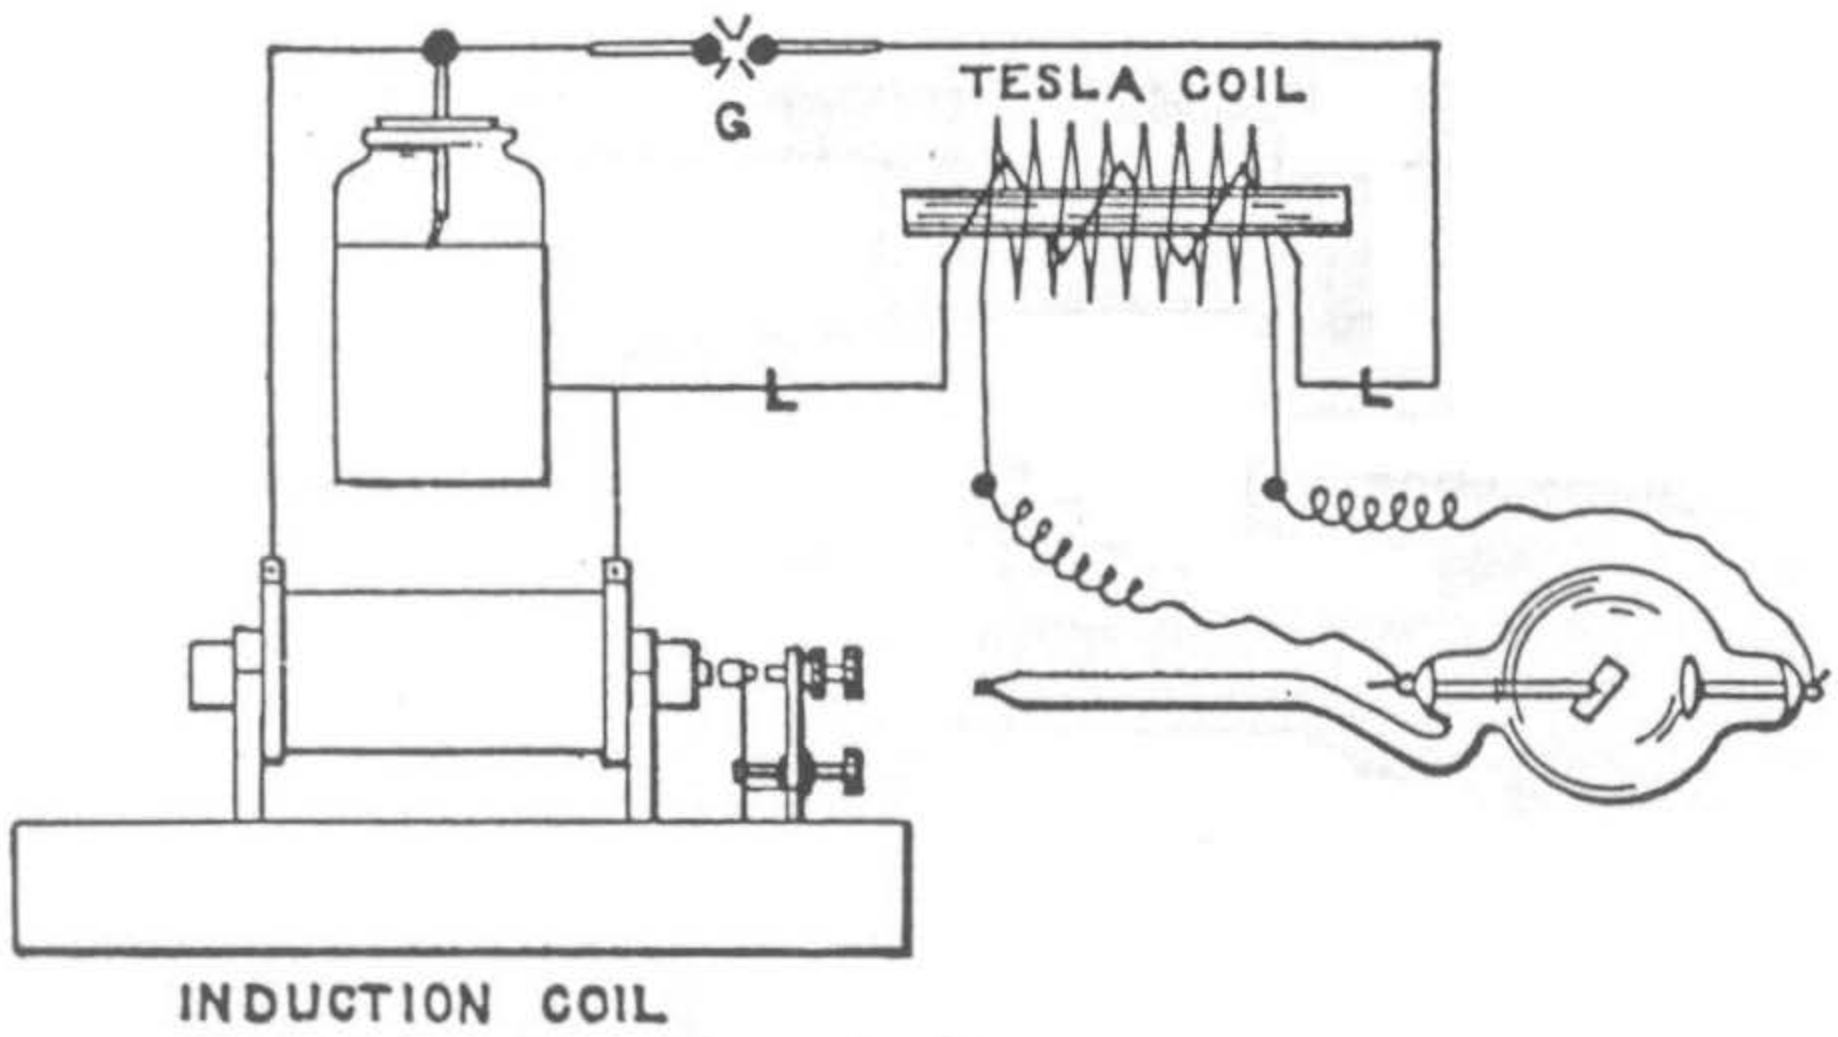


FIG. 1.

the air-gap, this discharge being, by well-known laws of electrical circuit flow, an oscillating one of exceedingly high frequency—millions or more oscillations per second. We thus have the primary of the second coil excited by an alternating current of exceedingly great voltage and frequency, so that *its* secondary produces a discharge of still *greater* E.M.F. and of this same high frequency. So great is this final E.M.F., that it is generally necessary to immerse the entire second coil, primary and all, in a tank of oil, since no solid insulation has yet been found capable of standing these great E.M.F.'s without breakdown.

To excite the Tesla coil, we may use either an interrupted direct current or an ordinary alternating circuit joined directly to the primary of the first coil. But the final result is, in either case, an alternating, high-potential, high-frequency current. In the tube, therefore, we also have an alternating discharge.

The Induction Coil.—We illustrate, in *Fig. 2*, the scheme of connections, etc., of the simple induction coil. The primary must be excited by an interrupted direct current, which may be secured from primary batteries, storage batteries, or a commercial circuit as may be determined by convenience or inclination. The secondary is joined directly to the tube

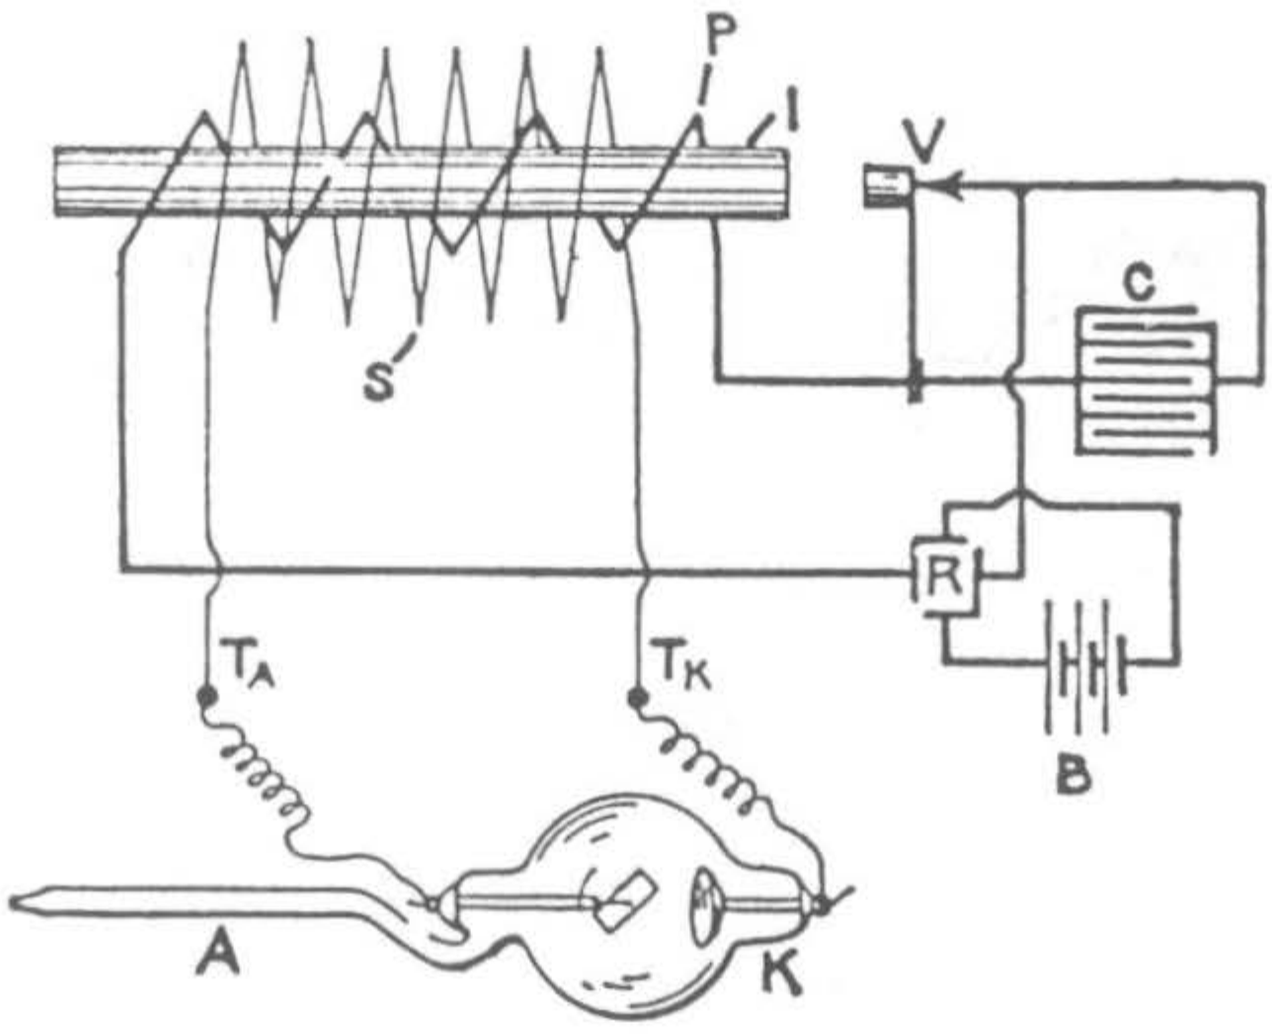

FIG. 2.

terminals. The usual means employed for securing the interruptions is some form of vibrating spring device, automatically operated by the core of the coil itself, the magnetic pull of the core attracting a mass of iron which, by its motion, separates two contact points, thus allowing a properly placed spring to draw it back, closing the circuit again, when the cycle is repeated. Such a device is employed in most forms of virbating electric bells and is indicated in the diagram. Around the break is placed a condenser. At break, this condenser charges (thus preventing the extra induced current due to the large self-induction of

the primary), but, being "short-circuited" by the primary, at once discharges about the iron core in a direction *opposite* to the regular "make" current, thus reducing (if correctly proportioned) the magnetic intensity of the iron core to zero. All this takes place so quickly that the practical effect of the action is merely to assist and intensify the dropping off of the core's magnetism—to shove it along—hasten it. Considering the secondary, now, we find that we shall have at *break* an induced discharge of greatly higher E.M.F. than that at *make*, owing to the falling off of the core's magnetism *at* break being greatly sharper than its growth at make. The effect of this is to give secondary discharges in *one direction only* at all times when the spark gap is not *greatly* shorter than the *maximum* obtainable spark gap for that particular condition of running the coil, the *make* induced current at such times being of too small E.M.F. to get across the gap at all. This is always the condition when X-ray tubes are used. A further function of the condenser is to suppress *burning* at the "break" terminals or points of interruption by taking up the energy of the magnetic discharge of the coil.

In the construction of the induction coil, a number of points may be noted. Our secondaries are wound in sections $\frac{1}{8}$-inch thick (according to the plan originally proposed, we believe, by Ritchie). These sections are separated from one another by a large number of discs of paper of a brand especially selected as free from carbon particles, and baked at a temperature a little below charring point for some time immediately before use—this to drive out moisture. These sections are then assembled and immediately immersed in a special insulation composition having a very high melting point, with high specific heat, and some slight viscosity at all temperatures.

Paraffine we absolutely prohibit as being apt to crack and absorb moisture. The melting point of paraffine, also, is so low (not over about 140° F. for the highest), that in warm weather there is serious risk of displacement of some of the sections by their own weight; for the same reason but little energy can be dissipated from the secondary.

Another grave danger in the use of paraffine is that due to the acid which it usually contains. This attacks the wire, forming copper sulphate, which dissolves gradually into and throughout the mass of the paraffine, thus effectually destroying its insulating properties.

After cooking for some time in the insulation, to drive out the last traces of moisture, the stack of sections is subjected to a further treatment, by which it is finally cooled *with all air removed.* This we consider a point of the highest importance, as air present anywhere in the secondary becomes electrified and bombards to and fro, gradually softening the insulation and eventually breaking down the coil. (For confirmation of this point, see Tesla, on "High-Frequency Phenomena.") With this plan of construction we have no static leaks of energy, or small direct leaks within the coil itself, and deliver the full energy of discharge at the secondary terminals. We find ourselves able to secure in this way a full inch of spark in all sizes of coils with considerably less than 1 pound of wire, No. 34 B. & S.* We believe that, more than anything else, the large quantities of wire required to produce a given spark length with many of the coils now in use is due to the presence of air, and consequent loss of energy by static bombardment, in the secondary. As regards the insulating composition used by us, we may say that we find its power of resistance to spark discharge to be four or five times that of hard rubber. In the arrangement of our secondary, we separate it from the primary by a heavy hard-rubber tube, and, in addition, by a tube of this composition.

The Adjustable Condenser.—A coil is working to best advantage when there is a certain definite relation between its primary current, secondary spark distance, and condenser capacity. Frequency of break must also be considered. As coils have heretofore been built, however, the condenser value has been fixed once for all and admits of no change, albeit both spark gap and primary current may be so

---

* In our latest coils not over three-quarters of a pound to the inch of spark is used.

changed. To remedy this, we have devised a form of switch shown in the diagram, *Fig. 3*, by means of which the condenser capacity may be shifted, at will and instantly, by simply turning the switch. The effect upon the secondary discharge is very marked, both volume and musical note of the spark changing with the position of the switch. We find this idea exceedingly convenient in general experimental work with alternating currents, it being possible with it to alter condenser capacity as quickly and as readily as we may self-induction or resistance. (We have made some experiments in the use of a condenser in parallel *with the primary*. The volume of the secondary discharge seems, in many cases, to be greatly increased.)

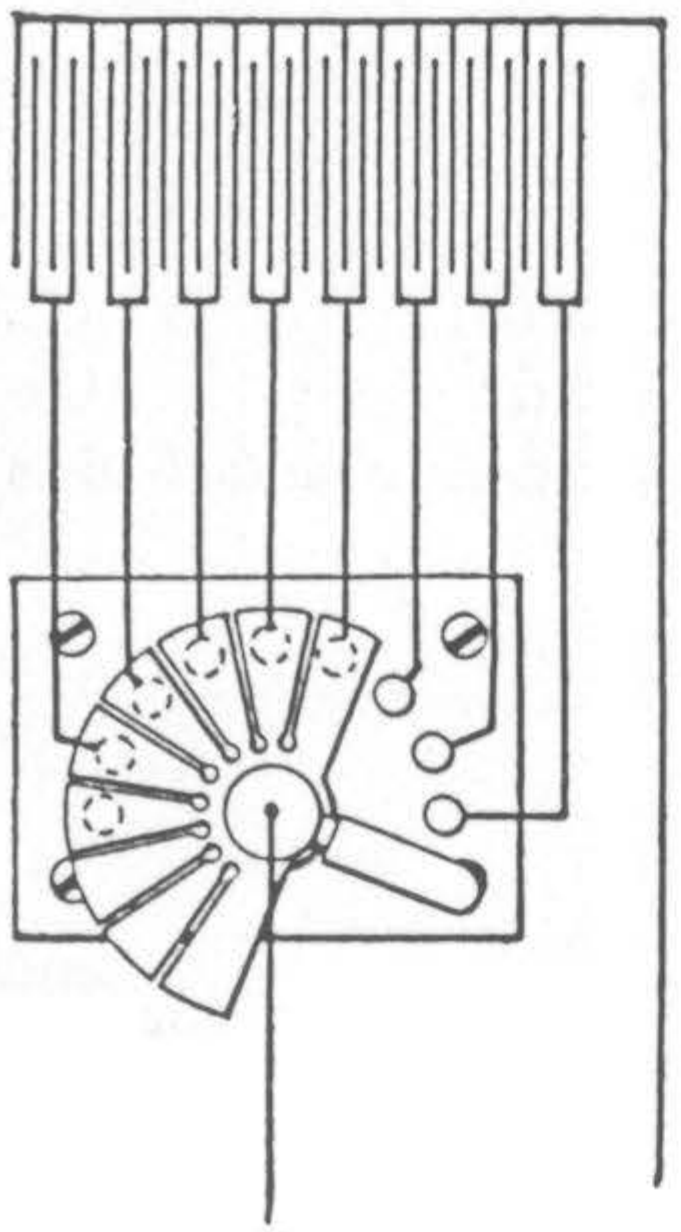

FIG. 3.

In arranging coils to operate from few or many cells of battery it is, of course, merely a matter of winding the primary with coarse or fine wire, the number of ampère turns being kept the same. It is interesting to note, as we have noted experimentally many times, that the larger the primary E.M.F. the smaller must be the condenser capacity employed, and *vice versa*. This is, of course, only to be expected, since capacity and self-induction are inverse functions of each other.

Primary Current.—This may be either from primary batteries, storage batteries, or from a commercial direct-current circuit. Primary batteries have too high resistance to give sufficient current for coils of much size—say 4 inches and over—unless joined in parallel, and then we need a number of such groups to secure the requisite E.M.F. They require constant attention, soon run down, and are expensive to operate. Storage batteries are exceedingly satisfactory, are comparatively inexpensive to operate, and require practically no attention. Charging them is more or less of an annoyance, however, especially where they must be sent

out of the building, as they usually must, besides throwing the entire apparatus out of use while the charging is going on, unless one have a reserve set of batteries.

The utilization of a direct commercial circuit, such as the Edison 110-volt (*c. g.*, where such is available), is, in every way, the most convenient and satisfactory. Until Professor Roentgen's discovery, no method of operating large coils upon such a circuit had been developed. Recently, however, several methods have been brought out, notably that of the

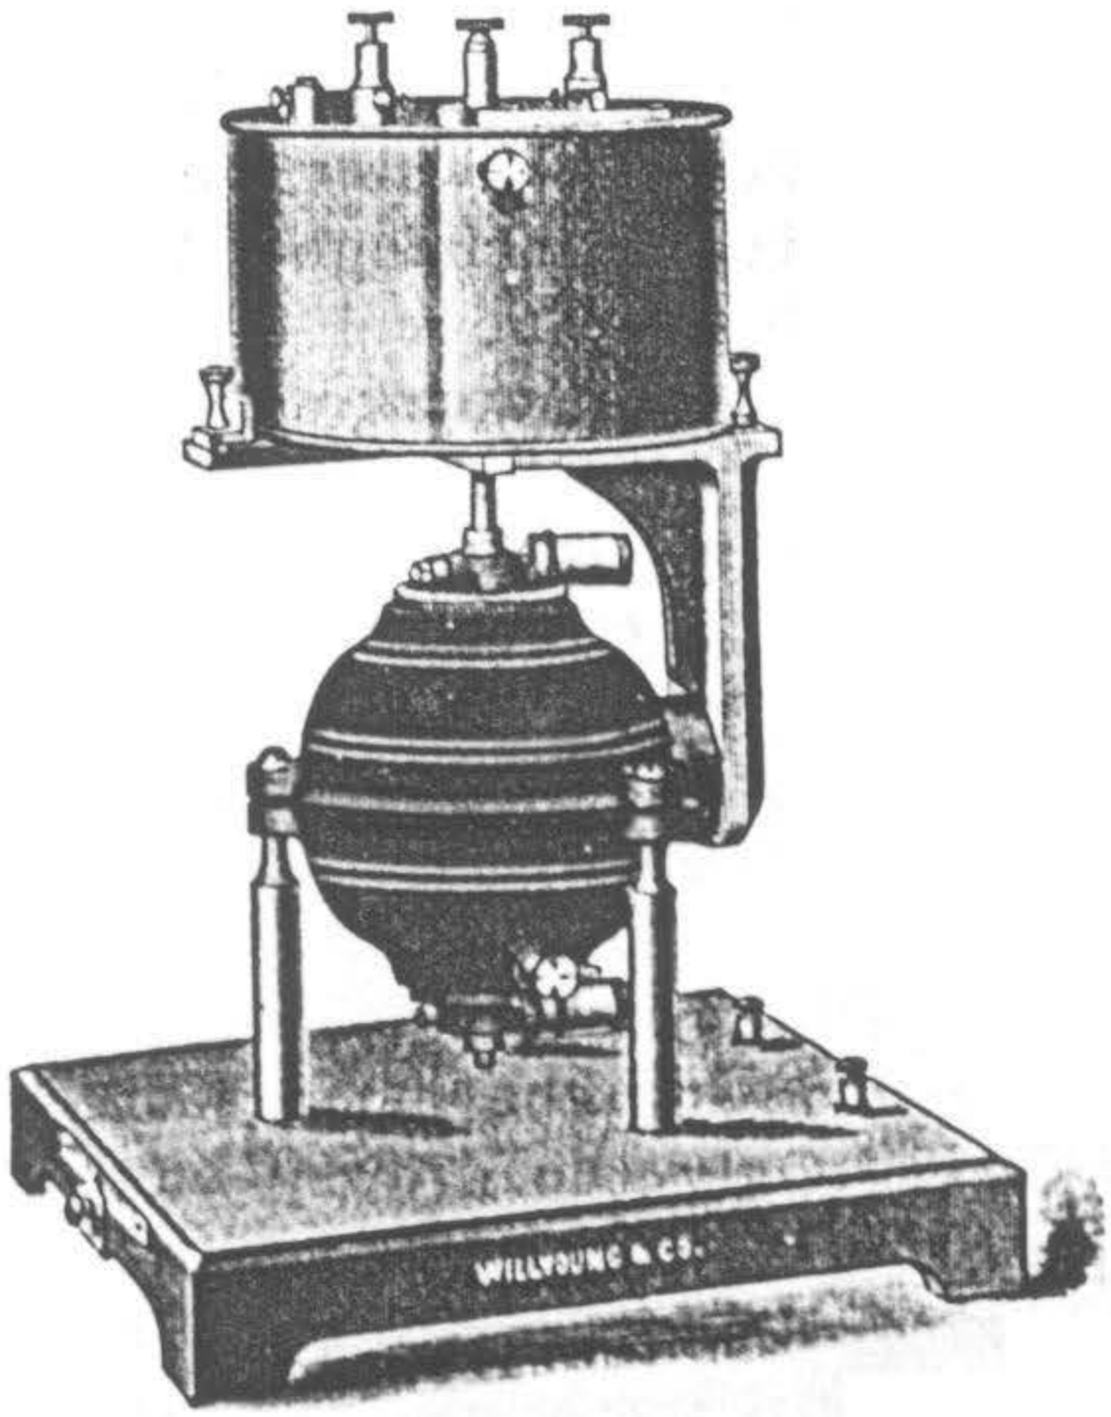

FIG. 4.

"air break," with air blast to blow out the spark, as used by Dr. Wm. J. Morton, Dr. M. I. Pupin, and others. In *Fig. 4* we show a form of apparatus devised by us to accomplish this purpose. A Lundell $\frac{1}{12}$ horse-power motor is supported upon a base with its shaft vertical. A casting, attached to the motor, supports above the latter a copper can made up of two concentric cylinders joined by a ring below, so that the shaft passes up through the inner cylinder and thus avoids the necessity of a stuffing-box. From the shaft is

hung, well within the can, a heavy brass wheel, having stretches of insulating slate let into its periphery. A hard-rubber lid fits over the top of the can. Mounted upon this lid are two brushes, one bearing against the wheel periphery and one against the shaft; suitable springs and screws allow the brush tension to be varied. From the commercial circuit leads are brought to these two brushes, the current being first passed through the primary of the coil and a rheostat in series. Before the lid is put in place the can is filled with distilled water; ordinary hydrant water will answer, although its usual impurity soon causes the water to become dirty, besides allowing a certain amount of electrolysis during use. With distilled water the break may be run for a number of hours without change of the water and very little heating takes place. The real function of the water is not so much to drown the spark as to prevent heating, although it does, of course, also assist in quenching the spark. But a condenser is the real spark extinguisher, and this we connect around the break just as we would around an ordinary vibrating break.

The advantages of this break over all forms of vibrating break thus far known, and over other forms of rotary break, are:

(*a*) *Convenience.*—Mere throwing of a switch being all that is required to start and stop the apparatus.

(*b*) *Noiselessness.*—Only the drowsy hum of the motor being heard.

(*c*) *Reliability.*—No chance of sticking, as with vibrating breaks.

(*d*) *Variable Rate of Break.*—Secured by adjusting rheostat in base of motor.*

(*e*) *Smooth, Unvarying Fluoroscopic Images* by reason of the large number of breaks per unit of time.

Another great advantage of the rotary break is the almost perfect control which it gives over the spark length.

---

* We have found that the vacuum of a tube often gets into such a condition as to make the tube absolutely unworkable at a given frequency of break, whereas, a slight *change* of frequency immediately restores the X-radiation.

This is on account of the independence of the coil and the break, thus permitting the breaking of any desired value of current without the slightest change in either frequency or character of break. With the usual vibrating break, operated by the core of the coil, the character and frequency of break is necessarily a function of the value of current, being broken and changed with it. It is impossible, with a large coil, *e. g.*, to get uniform and continuous secondary discharges of a length very small compared with the maximum capacity of the coil, since to such short sparks would correspond a magnetization of the core insufficient to operate the vibrator at all. But with the rotary break we may make the current as small as we please, without in the slightest degree interfering with the frequency and precision of the break.

Two milled heads at top of can permit its lid (carrying brushes) to be withdrawn. A similar head at top of shaft loosens break-wheel, and two heads at bottom of can allow it to be lifted away for cleaning and renewal and replenishing of water.

We use three makes and three breaks per revolution and find best results at from 1,200 to 1,400 revolutions per minute (equal to 3,600 to 4,800 interruptions). We may secure as many as 2,000 revolutions (6,000 interruptions) per minute, by cutting out the motor regulator.

In operation, the brush bearing upon break-wheel should be *positive*, so as to prevent any electrolysis of the break-wheel. We have often broken between 15 and 20 ampères through this wheel for a considerable length of time without any overheating or excessive wear of the wheel. Should the wheel wear in time to an undesirable degree it may be removed and turned down. Provision is also made for replacing the brushes when desired.

General Considerations Regarding Break Frequency.—The question as to whether there is a certain best frequency of break for a given coil or tube or both, has puzzled not a few. Very little has been experimentally determined regarding this point. It is certain, however, that, with a given coil or tube, shortness of exposure is *not* exactly inversely as the

number of breaks. Indeed, it is often far from being so. Some of the best X-ray pictures that have been taken have been by the use of the old "hammer" break of Ritchie, and 4 or 5 clicks of the break have sufficed. Using the same tube and coil, but a rapidly vibrating or rotary break, required 40 or 50 breaks to accomplish the same results. It would appear, hence, that the energy of X-ray radiation *per break* is a function of the number of breaks per unit of time.

We are inclined to believe that this is a matter purely of the "time constant" of the coil. The iron of the core requires a certain time to magnetize and demagnetize. With the breaks few, ample time is given for this process, but when the breaks become rapid this is no longer possible, so that the secondary E.M.F. falls—this may easily be verified by observing the maximum spark length of any coil--with single breaks, few and far between, we get much longer spark maxima than if the breaks are frequent. The thickness of the sparks is also greatly increased. If, however, we increase the *primary* E.M.F. for the more rapid break we may bring up the secondary spark length to the value given by the single breaks. We should thus be able to shorten the exposure as much as we please, by merely increasing the rate of break and the primary E.M.F. at the same time; but here we are limited by the *tube* which cannot *dissipate* more than a certain definite amount of energy in a given time and will break down if overdriven. We see, therefore, that whether we use slow breaks or fast breaks, the actual time of exposure remains practically the same, the few breaks requiring to be distributed over the same *time* as the much larger number of rapid breaks. All this, of course, applies to the photographic plate. For fluoroscopy we require rapid breaks in order to escape the otherwise distressing flickering.

In the above connection, particular attention is directed to one point—the rate of break *must not be too great*. If it is, the iron no longer has time to magnetize and demagnetize. The result is an *alternating* secondary discharge instead of the *direct* discharge desired, and this means blackening of

the tube, *rapid fluctuations of the vacuum, and general deterioration of the tube. We doubt whether, with any coil of size suitable for X-ray work, a rate of break greater than 5,000 per minute should ever be employed.*

Tesla Coil or Induction Coil—Which?—Having carefully examined the results, apparatus and methods of others all over the country, devotees some of the "high-frequency" coil, some of the induction coil, and having made many and careful experiments with both forms of apparatus ourselves, we favor the induction coil. Our reasons for this preference are briefly stated:

(*a*) *Simplicity.*—One coil instead of two.

(*b*) *Ease of Manipulation.*—There being more than double the number of factors to attend to in the Tesla coil than in the induction coil.

(*c*) *Cleanliness.*—The "high-frequency" coil requires an oil bath, which must be renewed from time to time to avoid gumming. It is difficult, also, to find an oil which will not, eventually, act upon the insulation of the wire by virtue of the acid or other impurities which the former may contain.

(*d*) *Sharp Definition.*—The "high-frequency" coil produces an alternating discharge - thus with the double focus tube giving us *two* sources of X-radiation and consequent blurring of the image. If a single focus tube be used, the discharge in one direction is either lost or tears off particles of the platinum reflector, thus blackening the tube and soon destroying its effectiveness.

(*e*) *Noiselessness.*—This, from the surgeon's and physician's standpoint, is, perhaps, the most important consideration. With tube in action, the induction coil is practically noiseless, save for the low hum of motor or vibrator. Improperly designed vibrators often rattle and rasp in a very irritating manner. In the "high-frequency" coil, however, the disruptive discharge over the air gap is the vital cause of its action. It is much more violent than a discharge of corresponding length from the induction coil, being of a rattling, cracking character. That such noise cannot but have a most unpleasant effect upon the patient who comes

into the operating room in a condition of more or less nervous collapse to begin with is obvious.

(*f*) *Strain on Tube.*—It has been argued by advocates of the "high-frequency" coil that it is much less hard upon the tubes. Our own observation has been just the reverse of this, and has satisfied us that the wear and tear is very much less with the induction coil.

(*g*) *Results.*—Although we have diligently examined, we have yet to see results obtained by any form of apparatus superior to those made in Philadelphia by Dr. Goodspeed, of the University of Pennsylvania; Dr. Stern, of the Polyclinic Hospital; ourselves, and many others who might be mentioned, and this either as regards detail, penetration or quickness of exposure. Indeed, we may say that we have never seen results obtained with the Tesla coil that are equal in any of the above respects to the results just referred to.

The Tube.—Many forms of tubes have been suggested. With practically no exception, all tubes now in use employ as cathode a concave aluminum disc, whose center of curvature is at the center of a small platinum plate ($\frac{3}{8}$ to $\frac{3}{4}$ square inch in area) the plane of the plate being inclined to the normal from center of the concave cathode. This platinum plate is sometimes made the anode—sometimes the anode is a separate plate or wire elsewhere in the tube. This form of tube is known as the "focus" tube, the cathode rays being focussed upon the platinum plate, which then becomes the active source of X-rays. In the double-focus tube we have two concave cathodes at opposite ends of the tube, the platinum wire reflector being in the form of a wedge with a side presented to each of the concave cathodes.

In the use of the tube everything depends upon the vacuum, X-rays seeming to be of a heterogeneous character, just as are light rays, their quality varying with the degree of vacuum. The higher the vacuum the more penetrating power the tube has, hence it is well to select tubes and use different tubes for different purposes. A tube of extremely high exhaustion is best for working through the body, but with forearm, hands, feet, etc., such a tube has

too great penetration, the bones appearing almost equally transparent with the flesh.

The chief difficulty with most tubes is the change of vacuum which takes place in use. This is thought to be due to the occlusion of the residual gas upon the inner surface of the glass—resulting in an *increased* vacuum; advocates of the bombardment theory believe it to mean an actual driving of the gas out through the body of the tube. It may be partially restored by heating the tube by use of a spirit lamp or Bunsen flame. This must be very carefully done, however, to avoid cracking the tube. When the platinum reflector is

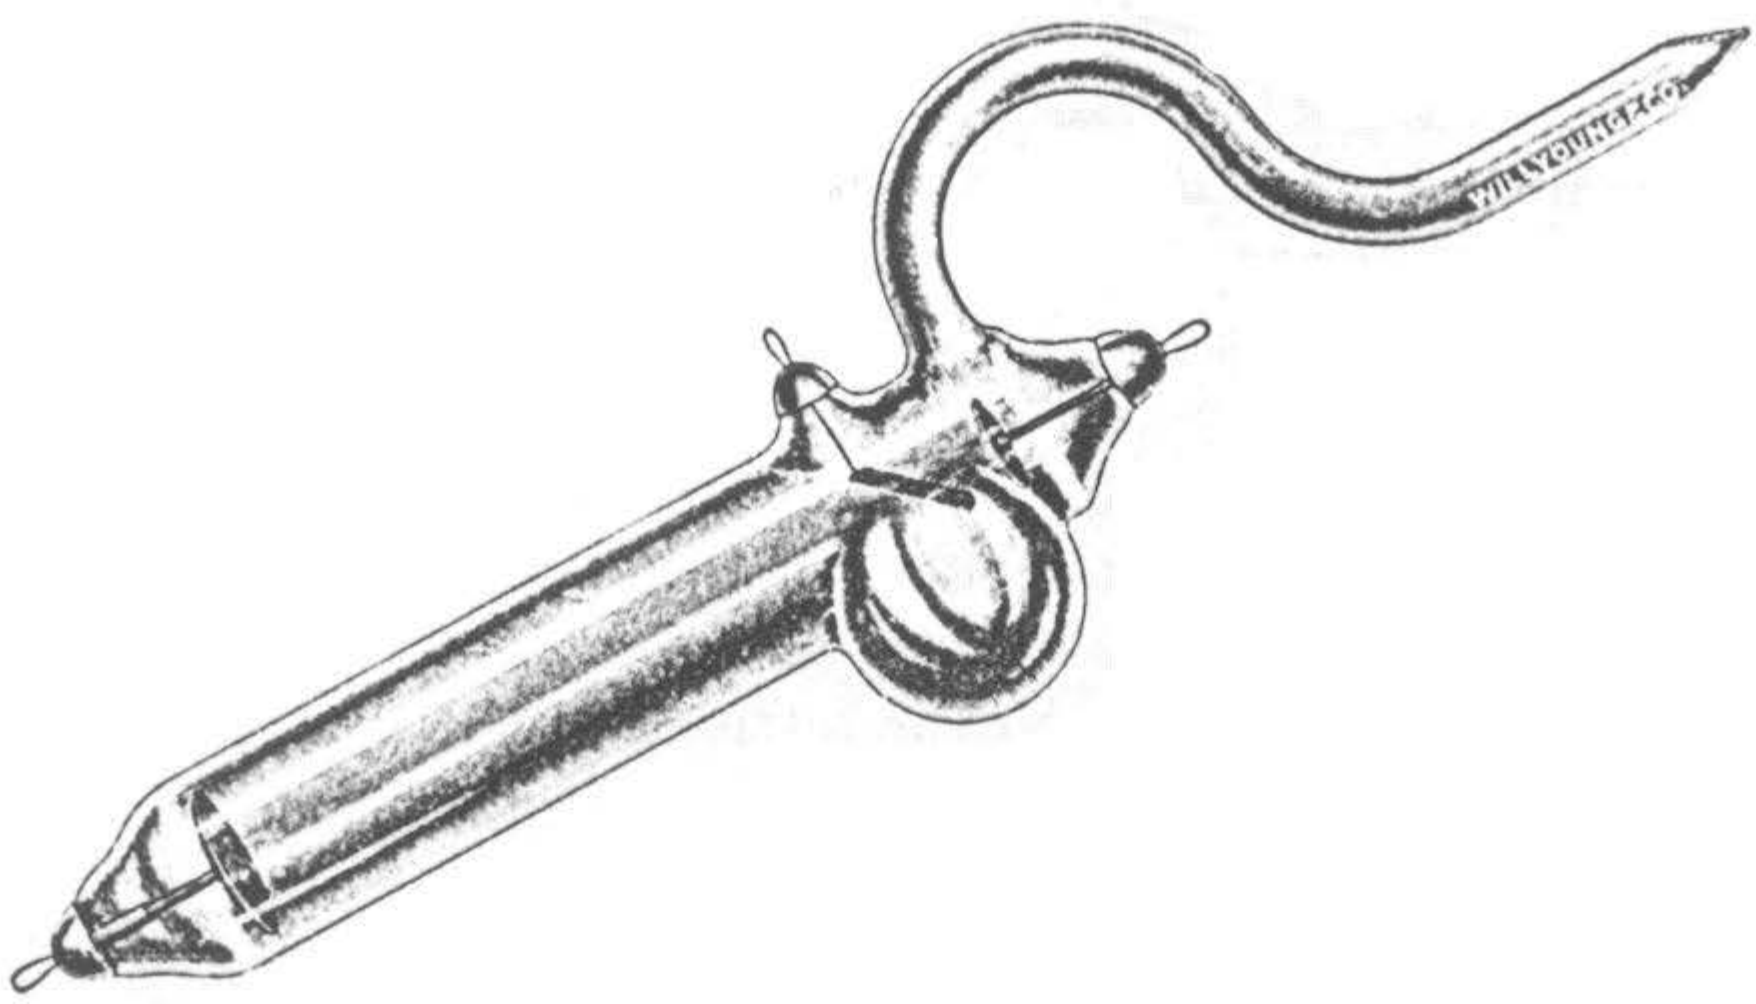

FIG. 5.

used simply as an anti-cathode, and the anode is aluminum, a simple reversal of the discharge will prove fairly successful. Some makers have adopted the scheme, practised now for many years, of blowing a small side pocket upon the tube, into which is placed phosphoric anhydride or some other chemical substance or composition absorbing moisture. When heated, this substance gives off vapor to make up for the loss; it is difficult, however, to drive off just the right amount of vapor in this way, and the vacuum is liable to be made too low, in which case flesh and bone are about equally opaque. So rapid is this change of vacuum with the majority of tubes, that in most cases involv-

ing over a few minutes' exposure or running of the tube one of the above methods becomes necessary. In any case, eventual, almost complete, exhaustion seems to be the rule, and the tube must then be returned to the makers and re-exhausted.

"Blackening" is another cause of decreased efficiency in the tube. It is due to deposition of platinum upon the inner surface of the tube.

The "Bowdoin" tube, shown in *Fig. 5*, was devised after a considerable amount of experimental work, by Profs. Robinson and Hutchins, of Bowdoin College. In general design it does not differ essentially from many other forms of focus tube upon the market. The two respects in which the tube does differ from other tubes are, first, in the arrangement of electrodes, the reflector plate not being connected to the coil at all, but merely acting as an obstacle to the bombarding rays, while the anode is a disc at the end of the tube away from the cathode. This arrangement is found to perfectly and entirely prevent blackening, no matter how long the tube may be used.

The most important feature of this tube is, however, the presence upon its interior surface of a fluorescent material which has been fused into the surface of the glass.* As the tube is used, this material, either by the bombardment or heating, or both, gives off just enough air or vapor to make up for the occlusion due to the natural working of the tube. The vacuum, therefore, tends to remain always constant. Although it seems almost absurd that one could put in just enough of this material to make up for the gas otherwise lost, yet it is a fact that these tubes remain practically unchanged in vacuum for a very long period.

In use the tube requires no "nursing" whatever. It should always have, to start with, a parallel spark gap, which should be quite small, say 1 inch or 1½ inch, and either the primary current or the vibrator tension adjusted so as to

---

*The fluorescent quality is not supposed to have any effect upon the result; it merely *happens* that the particular substance found most effective is fluorescent.

produce only a very small secondary discharge. The energy of this secondary discharge may then be immediately increased until the reflector plate shows a dull red spot of about half the size of the nail of the little finger. The tube is now in its most efficient condition, and, with a well constructed and smooth working break, may be run for an hour or two without the slightest attention. The "getting ready," as above described, takes considerably less time than the time it has taken us to describe it. Indeed, in our own work, we do not trouble to make this preliminary adjustment at all, as we make it once for all when we first begin to work with a tube and do not afterward disturb it, merely closing down the switch when starting work.

Life of Tubes.—The life of tubes in general is limited—

(*a*) By time required for the vacuum to become too great, hence requiring re-exhaustion.

(*b*) By ability to stand the electrical strains.

(*a*) Applies to all tubes, so far as we know, save the Bowdoin tubes—probably six or eight hours' continuous working, or the equivalent suffices to incapacitate the average tube. We think that even with the Bowdoin tube there is an evident tendency to eventual very high vacuum, but the time required is quite large, relatively, say ten to fifteen times that operative in the case of other types of tubes.

(*b*) All well-made tubes (from the glass-blower's standpoint) are about equally liable to this limitation. It is probable that these strains are cumulative in their effects upon the tube, the latter gradually weakening until eventually breakdown takes place with secondary discharges much less than would have been originally required for breakdown.

The Stand.—The stand, shown in *Fig. 6*, has been devised by us for applied X-ray work. With it the tube may be placed in any position within a cylinder 6 feet high and 6 feet in diameter, thus making it possible to get under or over a patient, no matter what the latter's position. Four rods (two are not shown in the figure) of vulcanized fibre clamp to the stand in any position and carry the lead wires of the tube, thus keeping them away from one another and

from the metal of the stand. They carry little spring clips at their extremities, by which the wires are caught without tying or bending.* The whole stand is of bicycle tubing and very rigid.

The Subject.—The patient should, of course, be placed in as easy a position as possible. For body pictures, hip and knee joints, etc., a recumbent position may be assumed. The plate should lie beneath and upon a stiff board backing to avoid risk of breakage. Work upon the shoulder, neck, head, etc., may be done with the patient straddling a straight-backed chair, facing the back, and leaning the body against the back for support.† The plate may be bound fast to the body by bandages.

FIG. 6.

Laws for Exposure.—Since the X-rays proceed in straight lines from (approximately) a point source, the intensity of their action varies inversely as the square of the distance from the source. Hence, the *time of exposure* should vary directly as the *thickness* of the intervening substance and the square of the distance from the plate. To

---

* This is also a great convenience in changing the position of the stand after everything is connected up—as must often be done. The wires simply slip out of the clips, thus relieving the tube of all strain.

† For this suggestion we are indebted to the practice of Dr. Max Stern, of the Philadelphia Polyclinic.

apply these principles in practice, take a trial picture of the hand at 5 inches distance, this being amply sufficient for good definition with such small bones. Say one minute is required for a good result. Then to take a hip joint, we estimate the thickness of the latter to be, say, ten times that of the hand. We must, therefore, expose ten minutes on account of thickness alone. But, owing to the greater distance of bones from plate, the tube must be removed much further to get definition. At least 15 inches from the dry plate should be given—this is three times the distance used for the hand from which the *times* require to be as the squares of these figures, or as one is to nine. The *total* exposure must, therefore, be ninety minutes. This method gives something to go upon. After a little experience, perhaps the most convenient thing to do is to arrange a little table, based upon previous results, and showing times and distances required for well-defined results for distinctive parts of the body.

Short Exposures.—We have obtained and do regularly obtain without difficulty well-defined pictures, showing complete detail of the osseous structure involved in times and with distances from dry-plate to reflector, as below:

Hand and wrist	5 to 10 seconds,	at 5	inches.
Forearm	10 " 15 "	" 5	"
Arm above elbow	½ " 1 minute,	" 7	"
Shoulder	10 " 15 minutes,	" 10	"
Thorax	15 " 30 "	" 10	"
Hip joint	30 " 45 "	" 12 to 15	inches.
Stones in kidneys	30 " 45 "	" 12 " 15	"
Glass, iron, lead, etc., in any part of trunk	30 minutes on an average,	at 12 to 15	inches.

We have very carefully investigated every claim to quicker exposures than these, often by a personal visit, sometimes by correspondence with personal friends whose reliability was undoubted. We have been unable to learn of any results equally good having been obtained in shorter times by any one at any place with any form of apparatus, and we do not believe any such have been obtained.

Manipulation—Development of the Plate.—Suitable and well-constructed apparatus is not the only essential to good results. A great deal depends upon the operator, and com-

paratively trivial differences in procedure make all the difference between success and failure. We describe here the method which we follow and which allows us to count with certainty upon securing at least nine successful plates for every ten exposures.

General Adjustment.—First see that the coil is working smoothly and so as to give a uniform discharge in the primary. The secondary spark points should be separated by the distance given by the makers as proper for the tube. The coil must then be adjusted either by changing the E.M.F. at the primary or by variation of the vibrator adjusting springs, so as just *not* to spark over this air gap. The tube should then be joined in parallel with this secondary spark gap. The coil may then be started up, using the fluoroscope to show whether direction of discharge is right. If not, the primary current should be reversed. If X-rays are not now profuse, the secondary discharge points should be further separated and the vibrator springs tightened so as to produce correspondingly greater discharge. Continue this until either X-rays are secured as desired, or the tube becomes too hot, or possibly bluish or pink in color. Blue denotes too low a vacuum to expect X-rays, but often a gentle running of the tube for ten or fifteen minutes, while in this condition, will raise the vacuum to a suitable value. Pink denotes a *very* low vacuum and usually means, in a tube which has ever *been* right, a puncture or leak; *such a tube* can only be made good by re-exhaustion and repair. With many tubes a vivid green fluorescence is the sign of the X-ray vacuum. With the Bowdoin tubes, as also with many others, the most efficient condition is with the platinum reflector plate at cherry-red heat over an area of one-half or two-thirds that of the little finger nail.

Sometimes the vacuum will be too high for the production of X-rays with *any* length of secondary discharge. It may be reduced by gentle warming of the tube by a spirit-lamp flame. Sometimes reversal of the current in the tube will answer, but this is apt to blacken.

Sticking of the Vibrator must be guarded against—*it is often fatal to the tube.* This is because of the much larger

current through the primary when such sticking occurs. Upon release, therefore, a secondary discharge much above normal is produced, and this the parallel spark gap is unable to carry off. The tube, therefore, receives much more energy than it should, and may break down even though the parallel spark gap be as advised by the manufacturers.

(*b*) *The Plate and Its Development.*—We have used at one time and another a number of different makes of plates with very fair success. For some time past we have confined ourselves to the Carbutt X-ray plates, and though we are not prepared to say that they are the best plates to use, the results are so uniformly good as to make it seem advisable to us to try other plates not radically different in principle.

For developer, we use the Carbutt "J. C. tabloids"—3 J and 3 C, to 5 ounces of water—*add about 2 drachms of restrainer* (the usual 10 per cent. solution). Heating this developer to about 65° or 70° F. just before using, we also find to have beneficial results.

From 15 to 20 minutes will be required for development. The image will come up very slowly and not very sharply. Not much detail will be visible by holding up to the light. Continue development until the general main outlines have appeared and faded away to a general blackness upon the glass side. Then rinse and hypo.

The fixing generally requires from a half hour to two or three hours. This long time is probably *partly* due to the unusual thickness of the Carbutt X-ray films, but probably even more to some chemical condition set up by the unusually large quantities of restrainer used. Mr. Carbutt advises *3* J and *3* C tabloids to *6* ounces of water to *20-30 drops restrainer*. Our experience is that a plate so developed *always requires intensification*; a tedious nuisance, which can never give as good results as a normally exposed and developed plate.

Fluoroscopy.—As a really efficient aid to investigation or to surgical practice, the fluoroscope has thus far proved rather disappointing. In case of very definite fractures of arm or of leg below the knee, as also in certain cases of gunshot wound in these same parts, the fluoroscope will afford definite knowl-

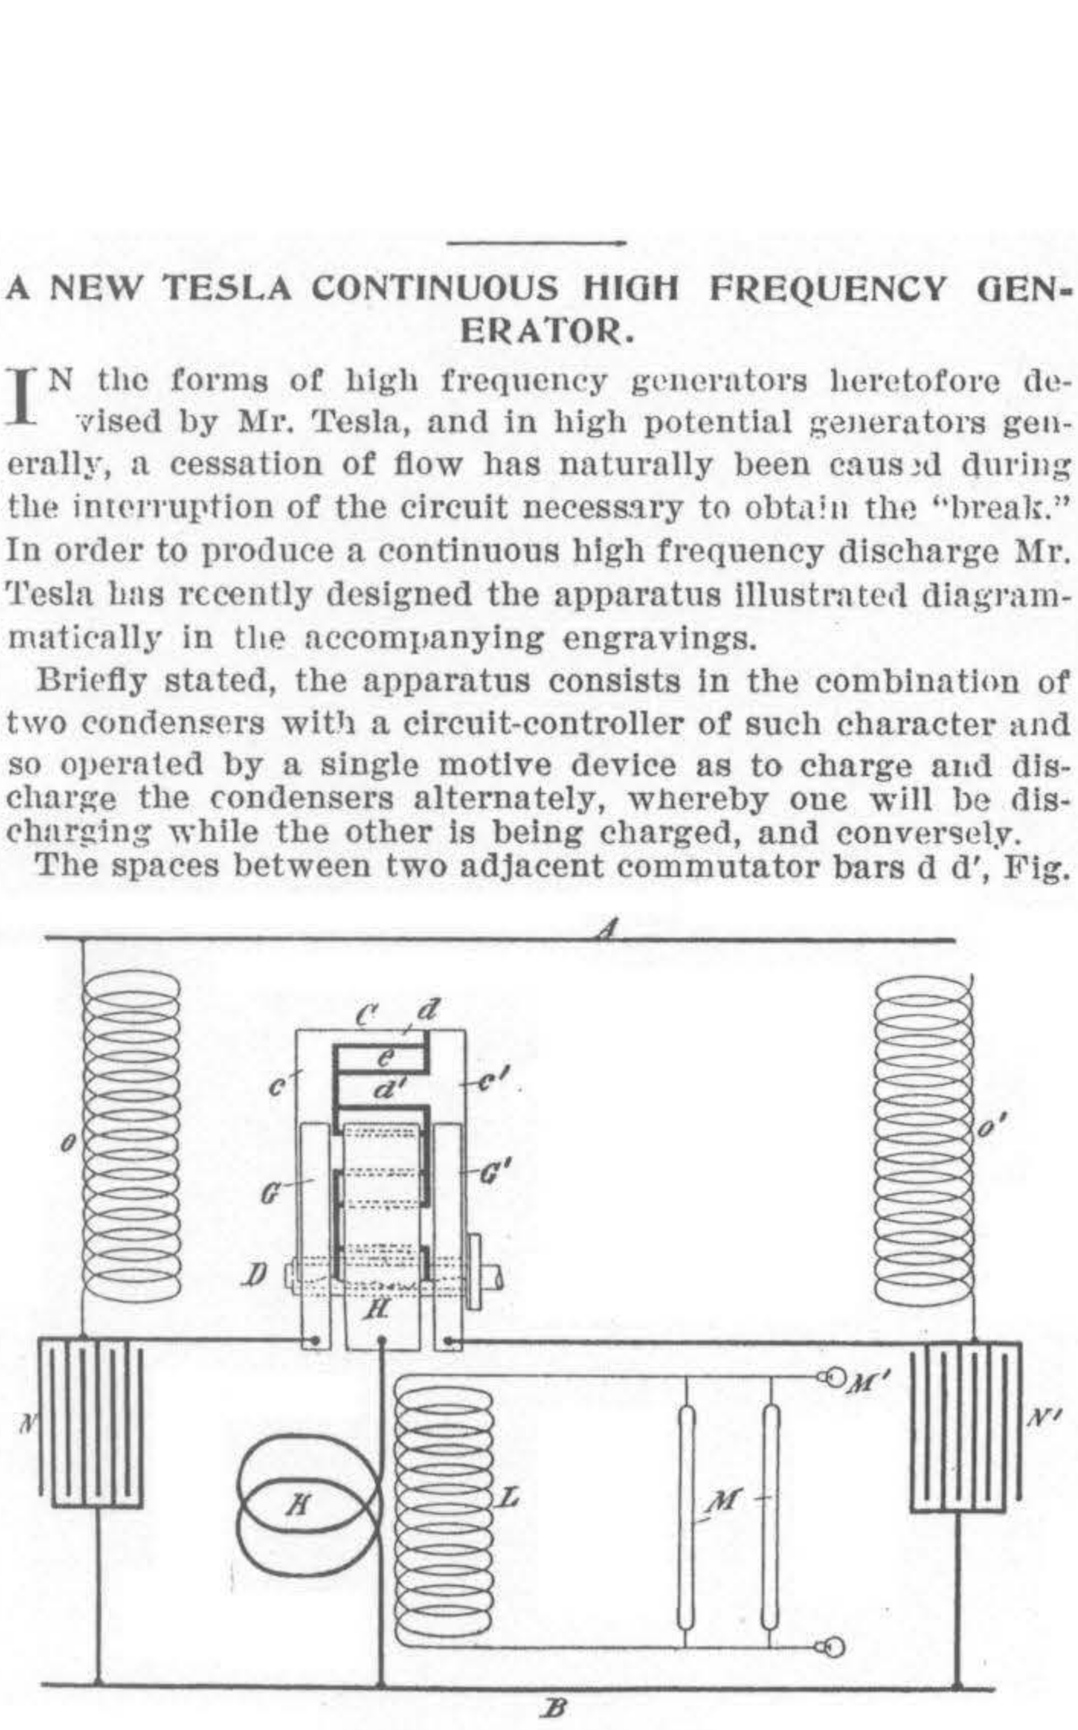
edge. But in all troubles affecting the trunk, upper leg, etc., the indications are too blurred and vague to be relied upon. A good part of this indefiniteness is doubtless due to the *phosphorescent* quality of the screen, which causes images to be retained for an appreciable time after they are formed, so that unsteady holding produces superposed images, while we also have a molecular disturbance extending in every direction in the plane of the screen, producing visibility where no direct X-ray disturbance has been produced. Part of the difficulty is also probably due to the natural inefficiency of the screen, which, as employed in this country, is merely of tungstate of calcium. The platinum salts, especially the platinum barium cyanide, is much superior to the tungstate of calcium, but considerably more expensive; it is generally used abroad. The results obtained with it are much more brilliant than those gotten with the tungstate. It is probable that there are other salts or combinations of salts still more powerful than the platinum.

In using the fluoroscope the room should be made as dark as possible, as the eye thus becomes many times as sensitive. Good tubes are often condemned on account of lack of appreciation of this fact and because they do not reveal much detail when used in a lighted room. We have often seen tubes which would not reveal even the bones of the hand in a lighted room, which, after keeping the eyes in the dark for five or ten minutes, would give very clear fluoroscopic images of the ribs, spinal vertebræ, heart, etc.

It does not follow at all that tubes giving poor fluoroscopic results will also give poor photographic results, or *vice versa*, although usually there is a certain correspondence between the two ideas.

General Considerations.—Speaking mainly from the surgeon's point of view, only experience can insure good results with X-ray apparatus. No matter how simple the apparatus may be, how many safeguards be embodied in it, how explicit and full the directions, there are still a vast number of little points which no book can teach, no tongue tell, and which must be learned. To do the best work, one must be something of a physicist, a photographer, surgeon and doc-

tor, all in one. If he *is* not he must *learn* to be by occasionally injuring his apparatus, and certainly by breaking many tubes.



Particularly must the practitioner be cautioned against expecting too much. Many come to their fluoroscope or X-ray photograph for the first time, expecting to see the whole structure of the body exposed before them as if upon a painted wall chart. This is never the case. Except in the case of the hand, foot or forearm, but little could ever be made out in the fluoroscope were one unaware of what *should* be seen. The photographic plate results are usually better and more definite, but even here interpretation is often difficult.

A NEW TESLA CONTINUOUS HIGH FREQUENCY GENERATOR.

IN the forms of high frequency generators heretofore devised by Mr. Tesla, and in high potential generators generally, a cessation of flow has naturally been caused during the interruption of the circuit necessary to obtain the "break." In order to produce a continuous high frequency discharge Mr. Tesla has recently designed the apparatus illustrated diagrammatically in the accompanying engravings.

Briefly stated, the apparatus consists in the combination of two condensers with a circuit-controller of such character and so operated by a single motive device as to charge and discharge the condensers alternately, whereby one will be discharging while the other is being charged, and conversely.

The spaces between two adjacent commutator bars d d', Fig.

FIGS. 1 AND 2.

2, are equal in arc to the width of one of the bars and are filled in with blocks of metal insulated from the other conducting portions of the device. The two heads c c' are insulated from each other. Upon the periphery of this commutator bear three brushes G G' H, the two former resting upon the continuous metallic portions of the two heads, respectively, the latter being in position to bear upon the projections d d' and blocks e alternately.

The brush H is connected to the main B through a primary coil K of low self-induction in inductive relation to a secondary L, which constitutes the ultimate source of the current of high frequency which the apparatus is designed to develop. The brushes G G' are connected with the main B through condensers N N', respectively, and to the main A through self-induction or choking coils O O', these latter being used in order that the inductive discharge of the accumulated energy therein may be taken advantage of in charging the condensers.

The operation of the apparatus is as follows: By the rotation of the commutator C the brush H is caused to pass over the projections d, closing the circuits through the primary K and the two cylinders alternately. These two circuits are so adjusted as to have the same capacity, self-induction, and resistance. When this brush is in electrical connection with any projection d' from the part c', the circuit is closed between mains A and B through coil O', brush G', brush H, and coil K. Energy is therefore accumulated in the coil O'. At the same time the condenser N' is short-circuited through the brush G', brush H, and coil K, and discharges through this circuit the energy stored in it, the discharge being in the form of a series of impulses which induce in the secondary L corresponding impulses of high potential. When brush H breaks the circuit through coil O', the high-potential discharge or "kick" from the latter rushes into and recharges the condenser N', but as soon as the brush H has passed over the intervening block e and reached the next segment d it closes the circuit through coil O and short-circuits the condenser N, so that high-frequency currents from either one or the other of the two condensers are flowing through the primary K practically without interruption. Thus without increasing the size or power of the motive device or complicating in any material degree the commutator these devices are made to perform double duty and the output of the apparatus as a whole greatly increased.

It is also evident that all phase differences in the charging and discharging of the condensers may in like manner be se- and reached the next segment d it closes the circuit through the same motor and circuit-controller might be made to charge more than two condensers in succession and to discharge them in the same order.

Tesla's Improved Condensers and Induction Coils.

Ever since Mr. Tesla discovered the hurtful action of the air and gaseous matter in induction coils and condensers, he has applied himself to perfecting his apparatus and methods with the view of overcoming the fatal defects produced by these causes. As an evidence of his progress in this direction, the ELECTRICAL REVIEW publishes herewith an abstract of a patent granted to Mr. Tesla on February 23, 1897, which was filed in the United States Patent Office on November 5, 1896. In his specification Mr. Tesla says:

My invention is an improvement in

TESLA'S METHOD OF MANUFACTURING INDUCTION COILS, CONDENSERS AND SIMILAR DEVICES.

the manufacture of electrical condensers, coils and other devices of a similar character, in which conductors designed to form paths for currents of high potential are brought into close proximity with each other. Among such devices are included many forms of condensers, transformers, self-induction coils, rheostats and the like.

It has heretofore been shown by me that the efficiency and practicability of such devices are very greatly enhanced by the exclusion of air or gas from the dielectric separating the conductors or remote portions of the same conductor, and the object of my present improvement is to secure such exclusion of air in as perfect a manner as possible in a convenient and practicable way. To this end I place the condenser, or other device to be treated, in a receptacle, from which the air may be more or less perfectly exhausted, and while in vacuum I introduce an insulating substance, which liquefies when subjected to heat, such as paraffine, which surrounds the said device and finds its way into its interstices.

When the device has become thoroughly saturated with the insulating material, it is allowed to cool off usually until the material begins to solidify. Air is then admitted under pressure to the receptacle containing the device, and the pressure maintained until the whole mass of insulating material has solidified. By this treatment, the presence of air or vacuous spaces in the dielectric, which are otherwise liable to form by the contraction of the insulating material when cooling, is prevented.

Any plan may be followed or apparatus used for securing the two conditions necessary to the attainment of the desired result; that is to say, applying the fluid insulating material in vacuum and subsequently subjecting it to or solidifying it under pressure. The degree of exhaustion or of pressure may vary, very good results being secured by a vacuum of about 29 inches and a pressure of about 100 pounds. It may be stated, however, that when hydraulic pressure is applied, very much higher pressures are readily secured and are of advantage.

In order to facilitate the carrying out of the process, I have devised a simple and useful apparatus, which is illustrated partly in section in the accompanying drawing. As the parts of said apparatus are all of well known construction, the apparatus as a whole will be fully understood without a full description of its details.

A is a tank or receptacle that may be closed air-tight. Within this tank is a steam coil C, surrounding a vessel B, preferably with slightly sloping sides and provided with a tube or pipe D, opening into it near its base.

The condenser or other device to be treated is placed in the vessel B, and around the receptacle is packed a suitable insulating material in quantity sufficient, when liquefied by heat, to flow through the pipe D into the vessel B, and fill the space in the latter up to the top of the condenser or other device placed therein.

It is desirable to run into the pipe D enough melted material to fill it before using the apparatus, and to make the pipe of a poor heat-conducting material, so that a little time will elapse after the heat is applied to melt the material in the tank A before the flow through the pipe begins.

When the apparatus has been thus prepared, the air from the interior of the tank A is withdrawn as completely as practicable by an air-pump E, and steam is passed through the coil C. In order to prevent access of any of

the volatile constituents of the insulating material to the pump, a condenser F, with a cooling coil G, is interposed in the piping between the tank and pump. After a partial vacuum has been secured in the tank A, and the liquefied insulating material has been run into the vessel B, the pump may be stopped and the tank connected with a receiver H, from which the air has been exhausted, and the apparatus allowed to stand until all the interstices of the condenser have been permeated with the insulating material. The steam is then shut off and cold water passed through the coil C. The connections with the pump are then reversed and air is forced into the tank and receiver H, and the further cooling and solidification of the insulating material carried on under a pressure considerably greater than that of the atmosphere. After the insulating material has cooled and solidified, the condenser or other device, with the adhering mass of insulating material, is removed from the receptacle, and the superfluous insulating material taken off.

I have found that condensers, transformers and similar apparatus treated by this process are of very superior quality, and especially suited for circuits which convey currents of high frequency and potential. * * * *

The claim of the patent reads as follows :

The improvement in the manufacture of electrical devices, such as condensers, which consists in inclosing the device in an air-tight receptacle, exhausting the air from the receptacle, introducing into a vessel containing the device an insulating material rendered fluid by heat, and then, when said material has permeated the interstices of the said device, subjecting the whole to pressure, and maintaining such pressure until the material has cooled and solidified.

LENARD RAYS, DISCHARGING POWER, GREAT VARIETY AND MAGNETIC DEFLECTION IN HYDROGEN.

BY EDWARD P. THOMPSON.

The contents of a communication from Dr. Philip Lenard, of Heidelberg, may be of interest as shedding some light on the relations between X-rays and external cathode rays. The occasion of the open letter is my treatment of the external radiations from a discharge tube (Crookes tube), and especially my discussion of his own researches, which were originally published in several foreign proceedings of societies, and in foreign languages, some of them being published by *Berlin Akad.*, January 15, 1893; *Wied. Ann.*, January, 1894, LVI, p. 225; *Wied. Ann.*, vol. LI, p. 259, and papers and articles of 1895 and 1896.

Translations of these and other papers, discussions of Lenard's results by other investigators and Lenard's latest theories were considered in my own language, under about 20 headings, in the book, "Roentgen Rays and Phenomena of the Anode and Cathode," setting forth in a classified manner the various facts, principles and theories relating to external cathode (or Lenard) rays.

Dr. Lenard, in stating that "we agree in all you have said on my experiments in the text of your book", discloses succinctly his present valued opinions on three points in this English letter. One of his remarks seems to indicate that he does not agree in all points with Professor Roentgen.

In Section 77, I stated:

"A remarkable occurrence was the accomplishment of the discharge at a much greater distance than that at which phosphorescence was exhibited. See also experiments of Roentgen, who suggested that Lenard had to do with X-rays in his experiment, but thought they were cathode rays. The maximum distance for the discharge was 30 centimetres, measured normally to the aluminum window. He (Lenard) admitted that the experiment was not carried far enough to know whether the effect was due to the action of the cathode rays upon the surrounding air or upon the plate."

The above related experiments were performed, it should be remembered, before Roentgen's discoveries.

Dr. Lenard now says, as stated in the letter referred to:

"I do not think the electric (discharging) actions at a great distance from the window of my apparatus due to Roentgen rays, because I have convinced myself in the meantime that these latter rays are only present in minute traces, and that there is another explanation of the effect observed. The air is made conducting by the deflectible cathode rays near the window, and afterwards extends to parts further apart, whilst retaining its conducting property."

As to the next point, I went so far in the matter of the variety of rays as to head one paragraph "*Cathode Rays of Various Kinds are Variably Diffused.*" As intimated in his early papers, Lenard still reasons in the present open letter that there are "rays of an unbroken series of an infinitely great number of different rays, varying gradually in properties".

Lenard has generally been misunderstood regarding the magnetic deflection of cathode rays outside of the discharge tube. Dr. Lenard makes this point very clear. The book states, on page 66:

"The author could not find in Lenard's papers any positive or negative proofs that he had actually deflected the external cathode rays by a magnet while passing through air or gas *at ordinary pressures.* * * * *" Dr. Lodge, who briefly reviewed Lenard's experiments, expressed the same opinion. (See *The Electrician*, London, January 31, 1896, p. 439.) Dr. Lenard modifies this by saying, "I have effected the deflection in hydrogen. The deflection is not visible in air of ordinary pressure, only because such air is too turbid to show any distinct rays at all which could be distinctly observed at sufficient length to show deflectibility."

Regarding the book in general, he very graciously condescends to compliment and encourage an American author by saying, "I find it very useful for getting information as to the very extended recent literature on the subject;" and he exhibits the usual great man's modesty by referring to his world-wide known and wonderful discoveries, thus: "You have given much space to my own little share in the work."

Time of X-Ray Exposures.

To the Editor of Electrical Review:

In your issue of February 17 I note two letters, entitled "Time of Exposure in X-Ray Work" and "X-Ray Apparatus," which refer to statements made in the recent Franklin Institute paper by Mr. Sayen* and myself, just abstracted in your columns, and which require reply.

Regarding time of exposure, your correspondent, Dr. Monell, states that "five minutes, a good tube and a good operator will suffice for the trunk"; also, that he obtained "a negative of metallic objects through the trunk, etc., * * * * in five minutes". In our paper I stated that as a regular thing 15 to 30 minutes is required for a trunk picture "*showing complete detail of osseous structure involved*". To obtain metallic objects *through* the body is generally considerably easier than to get the same object *in* the body, largely because, in the former case, the object is *on* the plate, so that the shadow is compact and sharp. I should consider five minutes rather a *long* exposure for a bullet *through* the body (bullet being on plate side) with a good tube, apparatus and operator. But *detail* of bony structure, etc., is a very different matter, and to the best of my knowledge can not be regularly secured in times less than I stated. That there may be *occasional* cases of exposures greatly less than I have given, producing fine results, I do not doubt. One case has recently been recalled to my attention, though it had slipped my mind at the time my paper was written. It is that of a trunk picture taken by Dr. A. W. Goodspeed, of the University of Pennsylvania, only a few weeks after the original Roentgen announcement was made. The tube was the orthodox pear-shaped "aluminum cross" tube of the Crookes series—distance from plate something like 20 inches, and time of exposure *one minute*. The result was almost perfect, the bony structure being very completely and shapely detailed. But Dr. Goodspeed has never been able to do anything like this again, either with the same or other tubes, and has no explanation to offer for the wonderfully good result on this occasion. Probably "there are others."

Regarding Mr. Renny's letter, I think probably we both have the same views as to low and high-exhaustion tubes. The use of such terms in such a connection is purely relative. If we get the exhaustion *too* high, we *do* wipe out almost everything; if *too low*, everything casts equal shadows. Speaking generally, we must use low tubes for hand, arm and leg, from knee down; high tubes for body, hip joint, etc.

I should be glad to know how Mr. Renny's Tesla coil, "having none of the disadvantages which he says such coils must necessarily have", is made. The disadvantages of the Tesla coil, as compared with the induction coil, and as given by me, were:

1. Tesla coil has at least twice the number of parts—more complex.

2. Tesla coil uses oil—not so cleanly.

3. Tesla coil requires an operating spark gap—noisy.

4. Tesla coil produces alternating currents—we get either *two* foci and consequent blurring, *or* reversal of the tubes and consequent blackening.

1 and 3 *must* be true, since they embody the very definition of the Tesla coil; 2 is not necessarily true, but happens to be actually true, according to the practice of the majority of manufacturers of Tesla apparatus; 4 is true in all the tubes I know of, or, at least, recall at present. I would not say that a tube might not be constructed, of which this objection would not be true, but I know of no such tube now made.

Whether or not the Tesla coil or induction coil puts the larger strain upon the tube is a matter of opinion, and I so implied in my paper.

Elmer G. Willyoung.

Leslie's Weekly March 18, 1897

Tesla's New World.

THIS revolving globe generates every moment enough electricity, if it could be stored in batteries, to run all the machinery of the world for the balance of time. At the North Pole this electricity streams off in beautiful red ribbons called the auroras, and we see this phenomenon on account of the highly attenuated condition of the atmosphere. But everywhere, as high as the air reaches, around this earth is this immense wealth of nature, yet man, in his blindness and puniness, continues to manufacture with his little dynamos what nature has placed before him in such abundance. He does not need to manufacture another spark; he needs only to use an infinitesimal fraction of what is already made and the world of intelligence will become a whispering-gallery, and the world of his machinery will move in its appointed motion out of the forces of the invisible air.

For more than ten years scientists have known that man was wasting his time and energy burning coal and wood, denuding his forests, impoverishing his soil, and blackening the air of his cities, and then, with all his boasted speed, to move comparatively as a cripple. A few of them knew this, and one of them, Nikola Tesla, was bold enough to say that he could change all this. Well, it hasn't yet been changed, but while I was in his laboratory the other day he looked up from one of his machines with the confidence of Archimedes lighting his face. "I have found the way of my dream and will soon show it to the world." Mr. Tesla, as is well known, has harnessed Niagara and now he is read to harness the globe.

A few hundred feet in the air, just above what is known as the magnetic disturbance of the earth's surface, the electric waves run in long, straight lines. They are called the Hertzian waves, after young Hertz, their discoverer. These waves are, in fact, found everywhere in the air, but up there they can be used without the danger of local disturbance, and Mr. Tesla has, by a long series of experiments, learned to take hold of them and flash a light precisely as a sunbeam is flashed from a mirror. He has also learned to throw the electric energy of these waves into a battery and turn a distant machine connected with this battery by a wire. Mr. Tesla has a machine in his laboratory, that he calls an oscillator, that generates these waves and projects them into the atmosphere just as nature does. With this oscillator he has succeeded in making every calculation necessary to flash a message without a wire to any part of the earth, or to take the electric waves generated by the great power of Niagara and grind wheat in Argentina, or run the trolley-cars in Sydney. This is no longer speculation, but science, and with time and capital such a gigantic scale will be realized.

What is necessary is to build here and there, on the high points of the earth, tall towers and put into the tops of these towers machines to gather and focus these waves, just as the mirror gathers and focuses the sunbeams. Mr. Tesla said to me that, with a tower tall enough and with machines big enough, he could send a message from New York to London without a wire, but for transmitting electric energy for running machinery at this distance it would require a series of towers. But there never will be any necessity for running machinery at that long distance from the source of energy. It is over long distances that we want to telegraph. With such a station at New York not only could we talk to Europe without wires, but every ship on the Atlantic could communicate with us, and assistance could be rendered to any one of them in distress. The seas would be robbed of over half their terrors. But this means of communication would render it impossible for a few persons to conceal important information long enough to take advantage of the public. Every financial panic has had its origin in the way the telegraph or cable news has been concealed, but a tall tower flashing its messages on the city would protect the public and would immensely help nations to readily understand each other in an international crisis threatening war.

It is now known that light is sound carried to a point of vibration beyond hearing. There are scientists, and among them Mr. Tesla, who believe that the two terms may be convertible—that is to say, that we might take a sunbeam and so graduate it down as to hear something of the terrific storms that are constantly sweeping over that luminary. So it may not be impossible to attach the telephone and phonograph to these waves that may be made to blink around the globe as the winking diamonds in the girdle of a woman's waist. If we ever talk and sing across the wide seas this is possibly the only way, for it should be understood that wires can be distributed from these high stations into every house.

Mr. Tesla has gone so far as to say that it is possible to communicate with other planets of our system by throwing gigantic letters with these tall-tower lights on the face of the earth. This is downright dreaming, and here we part company with this great artist of science.

D. F. ST. CLAIR.

Mr. Remy's Tesla Coil.

TO THE EDITOR OF ELECTRICAL REVIEW:

Your issue of March 3 contains an article regarding some of my work, which I wish to answer. I agree with Mr. Willyoung that taking metallic objects placed next to plate, after the rays have passed through the body, and taking objects embedded in the body are two different things. When experimenting, to learn the time of exposure, I place objects *on* the body opposite the plate and next the tube. I will now attempt to describe, as Mr. Willyoung suggests, my Tesla coil, which does not have the disadvantage he enumerates. The disadvantages named in the article are:

1. "Tesla coil has at least twice the number of parts—more complex."

This is, of course, true; but in the instrument I use, the high-potential transformer, condenser and Tesla coil are permanently fixed in a permanently closed wooden box, which has not been open since the instrument was made. The terminals and spark-gap are, of course, on the outside of this box.

A machine may be constructed in this way, which is more convenient to operate, as only one adjustment—the length of operating spark-gap—is necessary, and this may be accomplished by simply turning one screw. A machine of this kind, properly designed, is much less liable to damage by use, or jars, or improper handling.

2. "Tesla coil uses oil—not so cleanly."

My coil does not use oil; there are streamers in the box, I suppose, but the machine takes less current than two 16-candle-power lamps, anyway, and the streamers are not hurting the insulation, as the only insulation depended on is space, or air.

3. "Tesla coil requires an operating spark-gap—noisy."

I use about 5,000 or 6,000 volts for Tesla coil primary, and it makes no more noise than a vibrator for induction coil.

4. "Tesla coil produces alternating currents—we get either two foci, and consequent blurring, or reversal of the tubes, and consequent blackening."

Good detail may be obtained with double focus tubes where the foci are close together; but for the very finest work single focus tubes may be made for Tesla coil current; in fact, such tubes can now be bought on the market, but, of course, they take twice the time, other things being equal.

B. P. REMY.

Anderson, Ind., March 23.

ELECTRIC POWER TRANSMISSION.

"CASSIER'S" for March prints a portion of the remarks made by Nikola Tesla, the inventor, in responding to the toast, "Electricity," at a banquet held in Buffalo in January last to commemorate the introduction into that city of electric power from Niagara Falls.

Naturally Mr. Tesla dwelt on the immense significance of the electrical transmission of power and its attendant problems. "We have to evolve means," he said, "for obtaining energy from stores which are forever inexhaustible, to perfect methods which do not imply consumption and waste of any material whatever."

"Nearly six years ago my confidence had become strong enough to prompt me to an expression of hope in the ultimate solution of this all dominating problem. I have made progress since, and have passed the stage of mere conviction such as is derived from a diligent study of known facts, conclusions and calculations. I now feel sure that the realization of that idea is not far off. But precisely for this reason I feel impelled to point out here an important fact, which I hope will be remembered.

ADVANTAGES OF WATERFALLS.

"Having examined for a long time the possibilities of the development I refer to—namely, that of the operation of engines on any point of the earth by the energy of the medium—I find that even under the theoretically best conditions such a method of obtaining power cannot equal in economy, simplicity and many other features the present method, involving a conversion of the mechanical energy of running water into electrical energy and the transmission of the latter in the form of currents of very high tension to great distances. Provided, therefore, that we can avail ourselves of currents of sufficiently high tension, a waterfall affords us the most advantageous means of getting power from the sun sufficient for all our wants, and this recognition has impressed me strongly with the future importance of the water power, not so much because of its commercial value, though it may be very great, but chiefly because of its bearing upon our safety and welfare.

"I am glad to say that also in this latter direction my efforts have not been unsuccessful, for I have devised means which will allow us the use in power transmission of electro-motive forces much higher than those practicable with ordinary apparatus. In fact, progress in this field has given me fresh hope that I shall see the fulfillment of one of my fondest dreams—namely, the transmission of power from station to station without the employment of any connecting wire. Still, whatever method of transmission be ultimately adopted, nearness to the source of power will remain an important advantage."

NOTES.

A New Tesla Apparatus.—In the forms of high-frequency apparatus heretofore devised by Mr. Tesla, and in high-potential generators generally, a cessation of flow has, says the New York *Electrical Engineer*, naturally been caused during the interruption of the circuit necessary to obtain the "break." In order to produce a continuous high-frequency discharge Mr. Tesla has recently designed an apparatus, which, briefly stated, "consists of the combination of two condensers with a circuit controller so operated by a motive device as to charge and discharge the condensers alternately, whereby one will be discharging while the other is being charged, and conversely." The effect of such an arrangement would appear to be simply to double the number of discharges per second, and to complicate a necessarily somewhat delicate arrangement of apparatus.

The New York Herald April 7, 1897

TESLA TELLS OF HIS DISCOVERY.

The Distinguished Investigator Finds a New Source of the Roentgen Rays.

IT IS BY AN ELECTRIC ARC.

Members of New York Academy of Sciences Listen to an Address on His Recent Experiment.

SATISFIED OF ITS VALUE.

The fourth annual reception and exhibition of the New York Academy of Sciences, in the American Museum of Natural History, were brought to an interesting close last evening. In addition to addresses by Professor J. J. Stevenson, president of the Academy, and by Morris K. Jesup, president of the Museum, Nicola Tesla also spoke about some of his recent experiments.

The most important part of Dr. Tesla's address, which was "On the Streams of Lenard and Roentgen, with Novel Apparatus for Their Production," was an announcement that he had discovered a new source of the Roentgen ray.

"This new source of the Roentgen ray," said he, "I discovered recently. An electric arc is the source. That is the simple way of putting it. In my experiments I found that the arc gave a wonderful light, which surprised and delighted me. My experiment is to be developed, but I have found enough to satisfy me of the value of the new source."

EXPECTS GOOD RESULTS.

Dr. Tesla then described that when the arc went to the cathode there was a strong light, but it was when it went to the anode that the wonderful results were obtained. The speaker said that he worked with a platinum cathode and an aluminum cathode.

"I cannot say anything more about this experiment at the present time," continued he, "but I think that in the future the results will be satisfactory in every way."

The speaker had before him on the table some of his novel electrical apparatus, by which he showed several of his experiments, particularly in producing electrical vibrations.

Dr. Tesla finally announced that he would not trespass further upon the time of the audience, in spite of the gesticulations of the Academy members to go on.

HE WAS HUNGRY.

"To be frank with you," said he, "I have had no dinner."

THEIR WISHES GRATIFIED.

The audience applauded, and there were earnest appeals for him to continue. Then they left their seats and made a rush for the platform to induce Dr. Tesla to explain more about his experiments. He gratified their wishes by giving them a half hour's additional description of his work with the apparatus.

In his address President Stevenson, of the New York Academy of Sciences, referred to the encouraging results of the investigators of the organization, and thanked the authorities of the American Museum of Natural History for the use of the building. President Jesup, of the Museum, in response said that the Academy members were always welcome to the Museum. He referred to the happy and cordial relations that exist in the Scientific Alliance.

The New York Times April 7, 1897

A CROWD TO HEAR TESLA.

The Academy of Science Exhibition This Year Draws Well.

It is estimated that at least 4,000 persons went to the American Museum of Natural History yesterday afternoon and last evening, to see the exhibit made by the Academy of Science.

In an address in the lecture room, R. E. Dodge, Secretary of the academy, said that not only was it the most successful exhibition of the society in point of scientific display and attendance, but people who went were not actuated by mere curiosity. They asked questions about all that they saw, and asked them with an intelligent understanding.

An address much to the same effect was made by Prof. J. J. Stevenson, President of the academy.

Nicola Tesla, the electrician, delivered a short address to all the people that the large lecture room would hold. He had with him on the platform an array of his high-pressure, rapid-vibration instruments, which he used to demonstrate his remarks.

The New York Post April 8, 1897

LENNARD-RAY PHOTOGRAPHS.

Nikola Tesla's Successful Experiments.

"I have been greatly disappointed," said Nikola Tesla, speaking to-day of his address before the Academy of Science on Tuesday evening, "that I entirely forgot to mention one of the most interesting and important facts in connection with the photographs I exhibited. How I could have forgotten anything so salient I do not know, but I did, and it has ever since much vexed me. I had been describing my discovery of the identity of the Lennard-ray and the Roentgen-ray, and when I showed the photographs I failed to say that most of them had been taken by means of the Lennard bulb. As you can see, the photographs are wonderfully clear, showing even the muscles of the subject, and of course are vital confirmation of my discovery of the identity of the Lennard with the Roentgen-ray. What I did was first to take Lennard's bulb and use it in connection with the ordinary transformer, the result being the same as in the experience of Lennard, namely, a failure to produce a light. But when I used it with my new transformer it proved perfectly effective, and enabled me to take these fine photographs."

Mr. Tesla exhibited to the members of the Academy the wonderful new apparatus which he called electrical oscillators, a novel kind of transformers based upon a discovery made by him six years ago which enabled him to produce from ordinary currents, direct or alternating, electrical vibrations of 1,500,000 per second. These vibrations were desirable for the attainment of many practical results, the most important being the improvement of electric lighting. This system is inefficient and expensive, and to produce the same or better results upon lines of economy requires enormous electrical vibrations, which Mr. Tesla has been able to secure by his new apparatus. These vibrations can be used in many other ways for the economical production of things necessary to mankind. Mr. Tesla said that they could, for instance, be used profitably in the manufacture of ozone and other chemical products and fertilizers. He said it furnished an ideal instrument for the production of the Roentgen rays. Its advent means the abolition of many devices of older design, particularly, Mr. Tesla said, of the use of the induction coil. A remarkable feature of the machine Mr. Tesla exhibited was that, although it can furnish any pressure desired, it contains no fine wire.

Coming to the subject of the Roentgen rays, Mr. Tesla announced that he had made two important discoveries. The first is a powerful source in an electric arc under certain conditions. The second is the demonstration in a peculiar way, which he described, of the deflection of the rays by a magnet. The discovery is particularly important in that this fact was needed to establish the identity of the Roentgen-ray and the ray discovered by Lennard in 1891. Through this discovery Lennard appears as the original discoverer of these rays, although in his address on Tuesday night Mr. Tesla said that he did not want to take from Prof. Roentgen the least bit of credit for his remarkable achievement in this line.

Mr. Tesla showed diagrams and designs tending to prove his theory that Roentgen-rays were formed by streams of minute electrified particles of matter projected from the bulb at an extreme velocity. This view is not in accordance with that adopted by the great majority of scientists, which is that the rays are formed by transverse vibration. Prof. Roentgen's theory is that they are formed by longitudinal vibration. Mr. Tesla promised that the tremendous vibration established by him would ultimately result in telegraphing without wires.

TESLA'S NEW DISCOVERIES.

GREAT ACHIEVEMENTS ANNOUNCED TO THE ACADEMY OF SCIENCE.

One Will Revolutionize the Methods of Electric Lighting, and One, He Promised, Will Result Ultimately in Telegraphing Without Wires—Roentgen Rays Are Lennard Rays.

After many months of silence, Nikola Tesla spoke night before last at the Academy of Science, and, as always happens on such occasions, the scientific knowledge of the world was the richer thereby. Mr. Tesla, without going deeply into the details of his methods, announced three discoveries that he has made, and gave practical illustrations of them. One will revolutionize the present methods of electric lighting, will exert a tremendous influence upon a hundred different things, and will open to the investigator an infinite number of highways of research, and will end, Mr. Tesla says, in bringing about that sought-for end of all electricians, the transmission of information through space without the agency of wires now needed. The second discovery announced was that of a new and more powerful source of the Roentgen rays. The third, and Mr. Tesla says this will be the most important and interesting to scientists, is the identification of the Roentgen with the Lennard rays.

Mr. Tesla exhibited on Tuesday night a new and perfected apparatus which he called electrical oscillators, a novel kind of transformers based upon a discovery made by him six years ago which enabled him to produce from ordinary currents, direct or alternating, electrical vibrations of many millions per second. These vibrations were desirable for the attainment of many practical results, the most important being the present system of lighting. This system is inefficient and expensive, and to produce the same or better results upon lines of economy requires enormous electrical vibrations, which Mr. Tesla has been able to secure by his new apparatus. By the use of these vibrations a vacuum tube may be made to emit a powerful light and furnish a lamp that is practically indestructible.

This bare statement of fact is all that Mr. Tesla is willing to give to the public at the present time, for he has not yet explained his methods to the scientific world, but his demonstration of his discovery at the Academy of Science was most complete. Its importance, as can be easily seen, hardly can be exaggerated.

These vibrations can be used in many other ways for the economical production of things necessary to mankind. Besides the lighting problem there are others that require extraordinarily frequent vibrations for their economical solution. Mr. Tesla announces that the manufacture of ozone and other chemical products now attained by costly processes may be done economically and cheaply by these vibrations. Mr. Tesla announced not long ago that by the use of these currents it was possible to manufacture fertilizers by using no other agent than merely mechanical power such as a waterfall or steam.

The use of these currents in the transmission of power is also very probable. Mr. Tesla has worked on this principle a large part of the time since he made his announcement before the Scientific Societies in 1891, and, as he said on Tuesday night, the machine he exhibited before the Academy of Sciences was the consummation of his labors in this direction. He said it furnished an ideal instrument for the production of the Roentgen rays, and what renders it particularly valuable is that it can be attached to any circuit and will furnish high economies. Its advent means the abolition of many devices of older design, particularly, Mr. Tesla said, of the use of the induction coil. A remarkable feature of the machine Mr. Tesla exhibited was that, although it can furnish any pressure desired, it contains no fine wire, and he illustrated by a simple experiment the advantage of the new principle over the old. The coils of the older principle require several miles of fine wire to develop a pressure equivalent to that developed by Mr. Tesla's machine that has none.

Coming to the subject of the Roentgen rays, Mr. Tesla announced that he had made two important discoveries. The first is a powerful source in an electric arc under certain conditions. This opens up a new field for research, and is most promising, as the rays obtained are very powerful and produce clearer images than those produced by present methods. The second and the one Mr. Tesla places in importance above the other is the demonstration in a peculiar way, which he described, of the deflection of the rays by a magnet. The discovery is particularly important in that this fact was needed to establish the identity of the Roentgen ray and the ray discovered by Lennard in 1891. Through this discovery Lennard appears as the original discoverer of these rays, although in his address on Tuesday night Mr. Tesla said that he did not want to take from Prof. Roentgen the least bit of credit for his remarkable achievement in this line. Mr. Tesla said that in 1894 he himself was investigating the actinic action of phosphorescent bodies and observed the Roentgen rays, but did not recognize them. He said that ever since Roentgen's announcement of his discovery scientists have been endeavoring to establish the identity between the Roentgen and Lennard rays by deflecting them by a magnet. The deflection, however, was so slight that the finest instruments could not record it. Mr Tesla tried for a long time and failed. At last he invented an instrument that accumulated the rays until he got such a power that a boy could perform the experiment.

Besides the things already referred to, Mr. Tesla showed diagrams and designs tending to prove his theory that Roentgen rays were formed by streams of minute electrified particles of matter projected from the bulb at an extreme velocity. This view is not in accordance with that adopted by the great majority of scientists, which is that the rays are formed by transverse vibration. Prof. Roentgen's theory is that they are formed by longitudinal vibration.

Mr. Tesla promised that the tremendous vibration established by him would ultimately result in telegraphing without wires.

The New York Times April 9, 1897

TESLA KEEPS HIS SECRETS.

Refrains from Gratifying the Curiosity of Electricians About His Experiments.

It is only once in two or three years that Nicola Tesla, the electrician, can be persuaded to give a lecture. He contributes occasionally to electrical publications, but he carefully refrains in these communications from letting his fellow-electricians know what he is driving at in his experiments.

When it was announced that he was to deliver a demonstrative lecture recently before the Academy of Science, in this city, the large lecture hall in the American Museum of Natural History was crowded until there was not standing room. Tesla is not an agreeable lecturer. Despite his long residence in this country, he speaks decidedly broken English, and as he persists in using technical words, many of them coined by himself, it is very difficult to follow him.

Two hundred or more electricians who went to hear him speak before the academy in hope that he would reveal something of the nature of his investigations were disappointed. They failed to discover what he is "driving at." Tesla made apparently free use of his wonderful high power instruments for producing rapid vibration, but beyond suggesting their value in scientific experiments, and remarking that their practical value would be made apparent to everybody before long, he kept his own counsel. His closing sentence was an epigram: "What Nature does not choose to reveal to us, it is no use trying to force from her by bolts and screws."

VOL. XXIII. NEW YORK, APRIL 14, 1897. No. 467.

Notice of Removal.

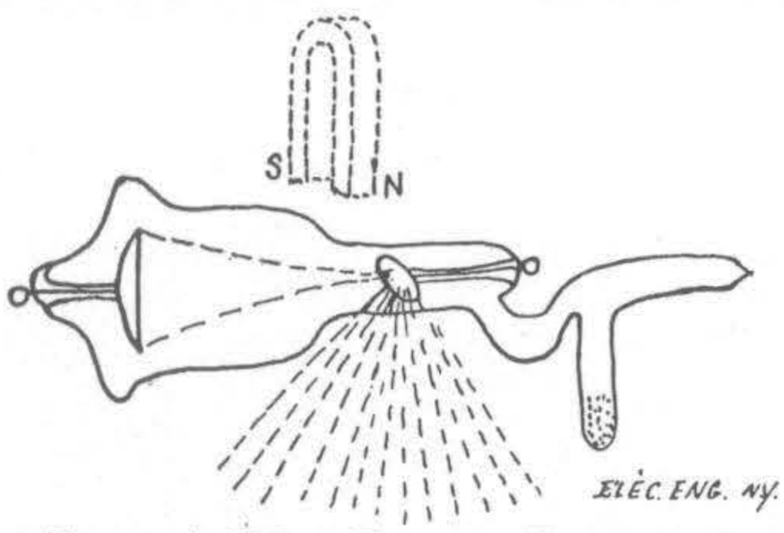
THE ELECTRICAL ENGINEER

on and after April 14 will occupy its handsome and commodious new suite of offices, entire south wing, eleventh floor, of the Beard Building, 120 Liberty street, New York City. It will not only thus be most advantageously situated at the heart of the machinery and electrical district, but will enjoy an increase of several hundred feet floor space. The offices are convenient to all railroads and ferries, and an invitation to visit them is cordially extended to all friends and patrons of the journal.

MR. TESLA ON ROENTGEN RAYS.

LAST week Mr. Tesla gave some of the results of his experiments in the domain of Röntgen rays, before the New York Academy of Sciences, and showed some of his latest types of high frequency generators. Mr. Tesla still adheres to his original view that the Röntgen effects are due to the action of molecules projected from the tube at high velocities, but we must confess our inability to reconcile this view with the results of his experiments in deflecting the Röntgen rays by means of a magnet, unless we assume the molecules charged and at the same time endowed with a vortical motion, a point which Mr. Tesla did not elaborate on. It is so rarely that Mr. Tesla appears on the lecture platform that it is to be regretted that the conditions surrounding his last appearance were not more favorable. It was hardly fair to Mr. Tesla, or to the large audience which had assembled solely to greet him, to delay his appearance until two other estimable speakers had taken up the time of the audience for nearly three-quarters of an hour. The result was that it was close on to 10 o'clock before Mr. Tesla began, and he was forced to conclude his address in its initial stages. It is to be hoped, for the benefit of the science at large that Mr. Tesla will find time to write out his address in full for the Transactions of the Academy. Brief as his utterances were, they were extremely interesting and they evidenced a mellowing and a mastery indicative of higher perfection than ever of his powers as an investigator and elucidator of obscure natural phenomena.

ROENTGEN RAYS



ROENTGEN RAY BURNS.

BY PROF. ELIHU THOMSON.

THE cause of the injury to the skin which follows an exposure to a source of Röntgen rays is still a subject for discussion. It is known that a comparatively short exposure at sufficiently small distances from the source will produce the effect. It has been claimed by some that Röntgen rays do not produce the mischief, but that the effect is essentially electro-static. Others have expressed the opinion that ozone and other substances present in the neighborhood of the excited tube are the real causes of the injury.

It has seemed desirable to set at rest, by experiment, these doubtful theories. The very peculiar nature of the injury itself, its course of development, the accidental circumstances under which it has occurred, have all tended to negative any theory except that which regards rays from the tube as the true cause. These rays might be either Röntgen rays, or rays so closely analogous as to be with difficulty distinguished therefrom.

The first effect after exposure is a slight reddening of the skin which is made more easily discernible by a little friction over the spot affected. This lasts two, three or more days and tends to fade. In the writer's experience, at the end of a week there has been an almost complete absence of any noticeable effect on the skin. On the ninth day, however, the affected part was found to redden, and this increased for a few days until blistering and sloughing took place with slow and tedious healing. These effects were noted in the case of the exposure of the little finger of the left hand and are at present writing in progress upon a portion of the third finger of the same hand, in consequence of an exposure for only twelve minutes to the rays from a special tube. This tube was made for the purpose of obtaining strong effects by lessening the working distance from the bombarded spot on the platinum, which is the source of the rays.

PROF. THOMSON'S X-RAY TUBE FOR POWERFUL EFFECTS.

The accompanying sketch shows the general form of the tube. It is narrowed around the platinum anode and the glass is also made thin around the same. It is thus possible to get the finger, the fluorescent screen, or the photographic film, very close to the bombarded spot on the platinum anode. The distance need be not over one-half an inch as a minimum. By the use of a magnet the spot on the platinum could be shifted so as to be very close to the glass and upon the edge of the platinum sheet. The intensity of the radiation per unit of surface was increased thereby, according to the law of inverse squares, which seems to hold in this case. This use of the magnet is indicated in dotted lines and is very convenient for directing the cathode rays upon any part of the platinum anode; which anode might in fact be faced with a variety of different substances, or have its surface differently formed, or curved at places while the cathode beam could be directed first to one part and then to another and the effects noted. If a platinum anode has been perforated by the beam at one point the tube is still useful, for a slight effect of the magnet puts the beam upon a new surface. Many a good tube may thus be made to do service even after several holes have been melted through the platinum sheet.

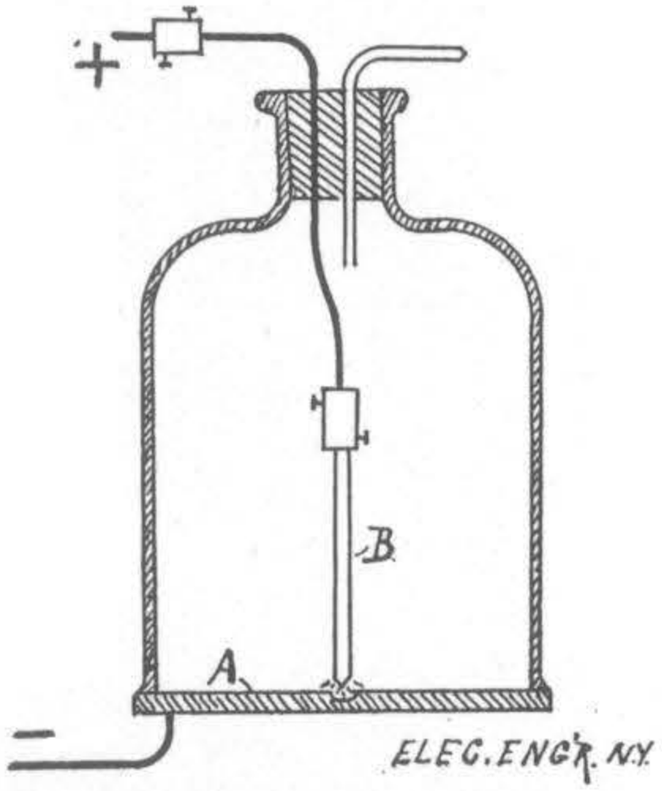
With such a source of rays as the tube shown it was easy to try an experiment the result of which seems to the writer to leave no doubt of the fact that Röntgen rays, or rays of the same general characteristics, do actually cause the burns and injury which may follow prolonged exposures to the Röntgen radiation. The left hand was covered with a lead sheet of over 1-16 inch in thickness and an oblong hole of about three-fourths of an inch long and about five-sixteenths inch wide, cut through it at the part just over the third finger between the first and second joint. This limited the passage of rays to the part of the finger under the opening.

But around the finger and under the middle of the opening was placed a strip of heavy tinfoil about 3-16 inch wide. This divided the exposed area into two parts. One of these parts in turn was covered with two layers of thin aluminum leaf gummed to the finger. Thus there were, in fact, three spots on the finger within the opening, one covered with aluminum foil or leaf, another with heavy tinfoil, and the third left entirely bare. The opening in the lead sheet was brought close to the platinum anode, so that the finger was about ⅝ inch distant from the bombarded spot.

The exposure was for a period of twelve minutes, which it was thought would be sufficient. The result at first was two faintly reddened spots, one having the outline of the part under the opening in the lead shield covered by the aluminum foil, and corresponding thereto, and the other corresponding to the bare spot. Under the tinfoil strip there was no action. These reddened spots, though scarcely visible, could be developed by slight friction, but gradually faded until, at the end of a week, from the time of exposure, they were with great difficulty distinguishable from the rest of the skin, even after the spot was rubbed. On the ninth day, however, they returned and the spots became painful and a little swollen. This has continued to increase and will probably end in blistering, sloughing and final healing. The part covered by the tinfoil is sharply marked from the others in being entirely unaffected. The effect produced through the aluminum leaf is about the same as on the bare spot, showing that thin aluminum does not stop the rays which produce harm.

It is needless to say that the effect is proved by the experiment to be neither electro-static, nor ozonic, but merely a result of certain rays reaching the skin surface, and such rays are probably those of the Röntgen rays not readily absorbed. According to the law of inverse squares an exposure of 12 minutes at ⅝ inch distance would require, at 10 inches distance, for equal effects, about 50 hours, or over two days. There is, then, no occasion for any alarm at the effects of Röntgen rays, as exposures of sufficient duration to produce harm are rarely if ever necessary.

In regard to the claim which has been made that injury only follows exposures made by induction coils, while static machines do not produce the effect, it may be said that in the writer's former experiment, of which the little finger was made the subject, a large capacity static machine was used, and the result was severe enough. The present experiment was made with an induction coil as the source of electric discharges, and as yet there is no difference in the results. The effect is now, of course, limited to two small spots a little distance apart.



MR. TESLA BEFORE THE NEW YORK ACADEMY OF SCIENCES.

ON April 6, Mr. Nikola Tesla delivered before the New York Academy of Sciences an address "On the Streams of Lenard and Röntgen, with Novel Apparatus for Their Production." The lecturer began by stating that in 1894, in experimenting to determine the actinic action of phosphorescent light emanating from vacuum tubes, he had found that the actinic power of Crookes tubes varied greatly, and in the most anomalous manner. Thus some tubes emitting a strong light had very little action on photographic plates, while some showing a feeble light acted very strongly on such plates. A large number of these plates, made by Tonnele for the Century Magazine, were stored in Mr. Tesla's laboratory when it was destroyed by fire, and thus he was unable now to examine them for the Röntgen effects. He believed that he had just missed the discovery which made Röntgen famous and though he was thoroughly familiar with Lenard's work, he did not see far enough.

Mr. Tesla then reviewed his work in the direction of obtain-

ing a reliable apparatus for generating high frequency currents, which he recognized as the keynote to the production of vacuum tube lighting. He told how he had met with difficulties at every point; how a small bubble of air would destroy the value of the coil, or how one-quarter of an inch of wire too much or too little would throw a coil out of balance; how one day a coil would run cold and on another day hot, etc. By finally calling to his aid the condenser, Mr. Tesla stated, he had succeeded in obtaining the desired action and now nothing stood in the way of securing millions of vibrations from ordinary circuits. The lecturer then briefly explained the principle of the condenser discharge as applied to high frequency currents, and pointed to various types of apparatus on the lecture table designed to utilize the principle.

In order to demonstrate the action of the high frequency currents Mr. Tesla attached a circular loop of heavy copper wire to the terminals of a high frequency generator and

TESLA'S ARC X-RAY GENERATOR.

brought to brilliant incandescence a small lamp connected diametrically across the heavy loop; the illumination of the lamp could be varied by connecting it to various points on the diameter of the loop. Mr. Tesla also lit the lamp by the current induced in a second loop brought in proximity to the first. He explained that the coil accomplishing this work had a resistance of 600 ohms and an inductance of 6 henrys; the coil was connected to the circuit one-half the time and took from the primary circuit only 5 watts.

Mr. Tesla next showed a vacuum tube lit from the terminals of another high frequency machine. He also showed a coil consisting of a single turn of heavy wire which formed the core, as it were, of a small coil of a few turns wound on a paper cylinder surrounding the heavy wire. When connected to a high frequency generator, this apparatus gave a 4-inch spark with an expenditure of energy equal to that taken by one lamp. Mr. Tesla stated that his high frequency generators were so constructed that they could be connected to any existing circuits, direct or alternating.

Returning to the Röntgen rays, the lecturer stated that he had succeeded in discovering a new source of these rays, far more powerful than any heretofore available, though the difficulty of maintaining it was very great. This new source is the electric arc; not the ordinary arc, however. The arc required for the purpose is that maintained between a platinum terminal and an aluminum plate, as illustrated in the accompanying diagram, where A represents the aluminum plate and B the platinum, enclosed in a glass jar.

Mr. Tesla stated that he had also succeeded in deflecting the Röntgen rays by a magnet. He had proved this by deflecting the rays into a condenser placed a long distance from the source of the rays, and which in 5 seconds was charged sufficiently to throw a galvanometer needle off the scale.

THE NEW YORK ACADEMY OF SCIENCE.

AN INTERESTING ELECTRICAL EXHIBITION — ADDRESS BY NIKOLA TESLA, ANNOUNCING RECENT ACHIEVEMENTS.

The New York Academy of Sciences gave its fourth annual reception and exhibit of recent progress in science in the American Museum of Natural History, New York, April 5 and 6.

In the division devoted to chemistry, in charge of Charles A. Doremus, were exhibited a number of electric furnaces, and in the electrical division, in charge of G. F. Sever, were to be seen a number of historical collections of incandescent and arc lamps, instruments of precision, Crookes tubes, induction coils, etc. Mr. W. H. Meadowcroft exhibited a Thomson 14 inch spark inductorium, and tubes and fluoroscopes, and Dr. M. I. Pupin had on view an induction coil and circuit breaker for the generation of Roentgen rays. Dr. Max Osterberg exhibited some specimens of German tubes, and Dr. Doremus showed one of the original Henry induction coils.

Tuesday evening a large audience assembled to listen to an address by Nikola Tesla on "The Streams of Lenard and Roentgen and Novel Apparatus for their Production". The lecturer had on exhibition a number of his perfected electrical oscillators, designed particularly to be used in place of the induction coils of old type. He exhibited numerous diagrams illustrating results obtained by him in his experiments, to ascertain the nature of the Roentgen rays. There were over 100 different working drawings of bulbs, showing the extent of the ground covered by the lecturer in this field. There were, besides, a number of remarkable photographs exhibited, which were taken by means of one of the small oscillators exhibited. These instruments and photographs were examined with the keenest interest after the lecture by a large number who remained and insisted on a supplementary lecture, which Mr. Tesla kindly consented to give, notwithstanding that, as he playfully remarked, he had not yet had his dinner.

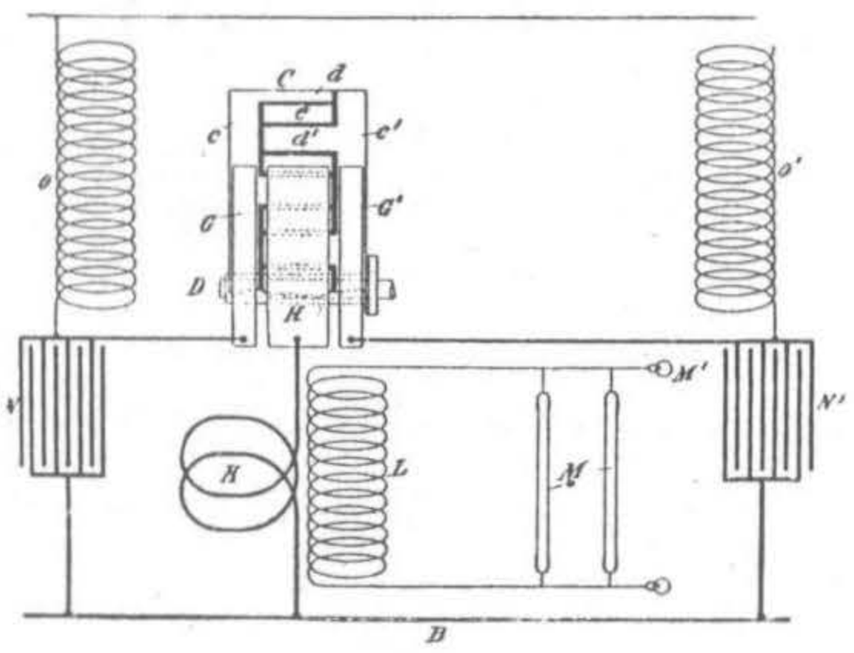
Mr. Tesla introduced the subject of his lecture by stating that at the close of 1894 he investigated the actinic power of phosphorescent bodies, and during these experiments, which were carried on by the assistance of Tonnelé & Company, photographers of this city, working for the *Century Magazine*, a great number of plates showed curious marks and defects, which were noted both by the speaker and the photographers, but not recognized as being due to the Roentgen rays. Just as he was beginning to look into the nature of the phenomena his laboratory was burned, and before his work was thoroughly resumed in his new laboratory Roentgen's discovery was announced.

Mr. Tesla first described the instruments exhibited, dwelling on the principles underlying them, and he illustrated, in a few striking experiments, the practical and economical features of the machines. The greatest interest seemed to be evinced by the audience when he lighted brilliantly a vacuum tube with one of his machines, giving, as he said, 800,000 vibrations a second. What rendered them particularly valuable, he stated, was that they worked equally well on alternating or direct-current circuits, and transform these currents with high economy into high-frequency electrical vibrations.

Mr. Tesla announced two important discoveries relating to the Roentgen rays. First, he said he had discovered a new and powerful source of the rays in an electric arc, formed under peculiar conditions. The second discovery was the deflection of the Roentgen rays by means of a magnet. This discovery is particularly important in establishing the identity of the Roentgen rays, and those discovered by Lenard in 1891, and is, therefore, one of the most valuable contributions to our knowledge of these rays.

Tesla dwelt also on some phenomena of rotation of bodies in bulbs, and, among other things, described his method of determining exactly the speed of a dynamo when taking readings.

To a few interested scientific men Mr. Tesla showed a great number of diagrams illustrating experiments he had performed which tended to prove the correctness of the views he holds in regard to the Roentgen phenomena being caused by material particles projected with great velocity.



The ELECTRICAL REVIEW hopes to be able to present in full, in an early issue, Mr. Tesla's lecture.

A NEW TESLA CONTINUOUS HIGH FREQUENCY GENERATOR.*

In the forms of high frequency generators heretofore devised by Mr. Tesla, and in high potential generators generally, a cessation of flow has naturally been caused during the interruption of the circuit necessary to obtain the "break." In order to produce a continuous high frequency discharge Mr. Tesla has recently designed the apparatus illustrated diagrammatically in the accompanying engravings.

Briefly stated, the apparatus consists in the combination of two condensers with a circuit controller of such character and so operated by a single motive device as to charge and discharge the condensers alternately, whereby one will be discharging while the other is being charged, and conversely.

The spaces between two adjacent commutator bars, *d d'*, fig. 2, are equal in arc to the width of one of the bars, and are filled in with blocks of metal insulated from the other conducting portions of the device. The two heads, *c c'*, are

Figs. 1 and 2.

insulated from each other. Upon the periphery of this commutator bear three brushes, G G' H, the two former resting upon the continuous metallic portions of the two heads, respectively, the latter being in position to bear upon the projections, *d d'*, and blocks, *e*, alternately.

The brush, H, is connected to the main, B, through a primary coil, K, of low self-induction in inductive relation to a secondary, L, which constitutes the ultimate source of the current of high frequency which the apparatus is designed to develop. The brushes, G G', are connected with the main, B, through condensers, N N', respectively, and to the main, A, through self-induction or choking coils, O O', these latter being used in order that the inductive discharge of the accumulated energy therein may be taken advantage of in charging the condensers.

The operation of the apparatus is as follows:—By the rotation of the commutator, C, the brush, H, is caused to pass over the projections, *d*, closing the circuits through the primary, K, and the two cylinders alternately. These two circuits are so adjusted as to have the same capacity, self-induction, and resistance. When this brush is in electrical connection with any projection, *d'*, from the part, *c'*, the circuit is closed between mains, A and B, through coil O', brush, G', brush, H, and coil, K. Energy is therefore accumulated in the coil, O'. At the same time the condenser, N', is short-circuited through the brush, G', brush, H, and coil, K, and discharges through this circuit the energy stored in it, the discharge being in the form of a series of impulses which induce in the secondary, L, corresponding impulses of high potential. When brush, H, breaks the circuit through coil, O', the high-potential discharge or "kick" from the latter rushes into and recharges the condenser, N', but as soon as the brush, H, has passed over the intervening block, *e*, and reached the next segment, *d*, it closes the circuit through coil, O, and short-circuits the condenser, N, so that high-frequency currents from either one or the other of the two condensers are flowing through the primary, K, practically without interruption. Thus without increasing the size or power of the motive device or complicating in any material degree the commutator, these devices are made to perform double duty and the output of the apparatus as a whole greatly increased.

It is also evident that all phase differences in the charging and discharging of the condensers may in like manner be obtained, and the same motor and circuit-controller might be made to charge more than two condensers in succession and to discharge them in the same order.

X RAYS ARE ATOMS.

Atomic Disturbance Causes the Most Recently Observed X Ray Phenomena, Say Scientists.

NICOLA TESLA'S DECISION.

Disagrees with Roentgen That They Are Merely a Disturbance of Ether.

HIS RECENT EXPERIMENTS.

The Rays Are Due to a Longitudinal Disturbance of a Material Nature, Says Dr. Tesla.

Profound interest has been aroused among electricians and physiologists in this city concerning the information that at a recent meeting of the Academy of Sciences in Paris the phenomena of the influence of the X or Roentgen rays upon the human physique had been discussed at length. Professor Sorel, of Havre, said he had found the use of the rays dangerous, inasmuch as they had caused in some of the persons on whom he had experimented violent inflammation of the lungs.

Professor Crookes, the inventor of the tubes, added that he believed the effect of the rays was immensely varied, and that he had discovered some instances in which patients rather enjoyed the burning sensations caused by the rays.

TESLA AHEAD OF THE FRENCH.

These declarations call attention again to the statements made many months ago by Nicola Tesla, who in the discovery of these phenomena was the pioneer. He told of the effect of the rays upon human flesh, as well as upon the nerves and muscles, and the declarations before the Academy of Sciences in Paris have been really supplemental to his statements.

Within a very few days Dr. Tesla held his hand before a very powerful bulb, whence were thrown the Roentgen rays and after a comparatively short interval found that it had been affected by them to a degree that surprised him. The appearance of the hand and the sensation were as though the member had been held before an open fire until the cuticle had dried.

When the pain had passed away Dr. Tesla made another experiment with the hand and discovered that it was extremely sensitive to the influence of the rays, the hand's sensation of burning being increased as it was placed as a whole or in part within the rays. This convinced him anew that the rays were composed of atomic matter, and that the effect upon the flesh was caused by the dynamic force of the discharge of these millions of atoms of matter.

MANIFOLD ACTIONS ON TISSUES.

During the course of a conversation yesterday with Dr. Tesla it was learned that more and more evidences are being obtained that the Crookes bulbs emitting Roentgen or Lenard rays exercise manifold actions on the human tissues. Outside of the superficial effects produced on the skin, they seem to be capable of affecting even internal tissues.

Dr. Tesla said it had been reported in a number of instances that, when a conducting object was placed behind the person, either accidentally or with a view of increasing the effect upon the photographic plate, a burn similar to that produced on the portion of the body directly exposed to the bulb was also found on the back of the body, and such a result could only be due to secondary actions of the bulb and not directly to any kind of radiation.

PLATINUM'S HURTFUL EFFECTS.

Dr. Tesla's own observations have shown so far that the hurtful actions are chiefly produced by bulbs in which platinum is used, either as electrode or as impact plate. As Dr. Tesla suggested some time ago, a screen of aluminum wire interposed between the person and the bulb and connected to the ground by a wire is a very effective remedy against injury.

In presence of many observations of like nature it is difficult to look upon the rays as being due to transverse vibrations of the ether, a view held by the majority of scientific men. There are abundant facts now that they are rather a longitudinal disturbance of a material nature and not merely such a disturbance of the ether as Roentgen originally announced.

THE TESLA PATENTS IN ENGLAND.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Our attention has just been called to a paragraph in your issue of the 9th inst., on the subject of "The Polyphase Patents in Germany," in which the following passage occurs:—"In view of the manner in which the Westinghouse Company keeps the English Tesla patents 'hung up,' it would be interesting to know just what they and the English manufacturers think of the present situation."

The statement that the English Tesla patents, of which we are the owners, are being "hung up" by us, is entirely without foundation, and therefore misleading. The facts are, we became possessed of these patents about ten months since, when we immediately took the very earliest opportunity of acquainting the trade generally that such was the case, and we have responded to all applications which we have received for licences, and have already granted a number. As no doubt you did not intentionally wish to state that which is not entirely in accordance with the facts, we should be much obliged if you would be good enough to insert this letter in your next issue.—Yours, &c.,

WESTINGHOUSE ELECTRIC COMPANY (LIMITED).
Arthur E. Scanes, Secretary,
4, Victoria-mansions, London, S.W., April 15, 1897.

TESLA ON THE HURTFUL ACTIONS OF LENARD AND ROENTGEN TUBES.

To the Editor of Electrical Review:

The rapidly extending use of the Lenard and Roentgen tubes or Crookes bulbs as implements of the physician, or as instruments of research in laboratories, makes it desirable, particularly in view of the possibility of certain hurtful actions on the human tissues, to investigate the nature of these influences, to ascertain the conditions under which they are liable to occur and—what is most important for the practitioner—to render all injury impossible by the observance of certain rules and the employment of unfailing remedies.

As I have stated in a previous communication to your esteemed journal (see Electrical Review of December 2, 1896), no experimenter need be deterred from using freely the Roentgen rays for fear of a poisonous or deleterious action, and it is entirely wrong to give room to expressions of a kind such as may tend to impede the progress and create a prejudice against an already highly beneficial and still more promising discovery; but it can not be denied that it is equally uncommendable to ignore dangers now when we know that, under certain circumstances, they actually exist. I consider it the more necessary to be aware of these dangers, as I foresee the coming into general use of novel apparatus, capable of developing rays of incomparably greater power. In scientific laboratories the instruments are usually in the hands of persons skilled in their manipulation and capable of approximately estimating the magnitude of the effects, and the omission of necessary precautions is, in the present state of our knowledge, not so much to be apprehended; but the physicians, who are keenly appreciating the immense benefits derived from the proper application of the new principle, and the numerous amateurs who are fascinated by the beauty of the novel manifestations, who are all passionately bent upon experimentation in the newly opened up fields, but many of whom are naturally not armed with the special knowledge of the electrician—all of these are much in need of reliable information from experts, and for these chiefly the following lines are written. However, in view of the still incomplete knowledge of these rays, I wish the statements which follow to be considered as devoid of authoritativeness, other than that which is based on the conscientiousness of my study and the faith in the precision of my senses and observations.

Ever since Professor Roentgen's discovery was made known I have carried on investigations in the direction indicated by him, and with perfected apparatus, producing rays of much greater intensity than it was possible to obtain with the usual appliances. Commonly, my bulbs were capable of showing the shadow of a hand on a phosphorescent screen at distances of 40 or 50 feet, or even more, and to the action of these bulbs myself and several of my assistants were exposed for hours at a time, and although the exposures took place every day, not the faintest hurtful action was noted—as long as certain precautions were taken. On the contrary, be it a coincidence, or an effect of the rays, or the result of some secondary cause present in the operation of the bulbs—as, for example, the generation of ozone—my own health, and that of two persons who were daily under the influence of the rays, more or less, has materially improved, and, whatever be the reason, it is a fact that a troublesome cough with which I was constantly afflicted has entirely disappeared, a similar improvement being observed on another person.

In getting the photographic impressions or studying the rays with a phosphorescent screen, I employed a plate of thin aluminum sheet or a gauze of aluminum wires, which was interposed between the bulb and the person, and connected to the ground directly or through a condenser. I adopted this precaution because it was known to me, a long time before, that a certain irritation of the skin is caused by very strong streamers, which, mostly at small distance, are formed on the body of a person through the electrostatic influence of a terminal of alternating high potential. I found that the occurrence of these streamers and their hurtful consequence was completely prevented by the employment of a conducting object, as a sheet of wire gauze placed and connected as described. It was observed, however, that the injurious effects mentioned did not seem to diminish gradually with the distance from the terminal, but ceased abruptly, and I could give no other explanation for the irritation of the skin which would be as plausible as that which I have expressed; namely, that the effect was due to ozone, which was abundantly produced. The latter peculiarity mentioned was also in agreement with this view, since the generation of ozone ceases abruptly at a definite distance from the terminal, making it evident that a certain intensity of action is absolutely required, as in a process of electrolytic decomposition.

In carrying further my investigations, I gradually modified the apparatus in several ways, and immediately I had opportunities to observe hurtful influences following the exposures. Inquiring now what changes I had introduced, I found that I had made three departures from the plan originally followed: First, the aluminum screen was not used; second, a bulb was employed which, instead of aluminum, contained platinum, either as electrode or impact plate; and third, the distances at which the exposures took place were smaller than usual.

It did not require a long time to ascertain that the interposed aluminum sheet was a very effective remedy against injury, for a hand could be exposed for a long time behind it without the skin being reddened, which otherwise invariably and very quickly occurred. This fact impressed me with the conviction that, whatever the nature of the hurtful influences, it was in a large measure dependent either on an electrostatic action, or electrification, or secondary effects resulting therefrom, such as are attendant to the formation of streamers. This view afforded an explanation why an observer could watch a bulb for any length of time, as long as he was holding the hand in front of the body, as in examining with a fluorescent screen, with perfect immunity to all parts of his body, with the exception of the hand. It likewise explained why burns were produced in some instances on the opposite side of the body, adjacent to the photographic plate, whereas portions on the directly exposed part of the body, which were much nearer to the bulb, and consequently subjected to by far stronger rays, remained unaffected. It also made it easy to understand why the patient experienced a prickling sensation on the exposed part of the body whenever an injurious action took place. Finally, this view agreed with the numerous observations that the hurtful actions occurred when air was present, clothing, however thick, affording no protection, while they practically ceased when a layer of a fluid, quite easily penetrated by the rays, but excluding all contact of the air with the skin, was used as a preventive.

Following, now, the second line of investigation, I compared bulbs containing aluminum only with those in which platinum was used besides, ordinarily as impact body, and soon there were enough evidences on hand to dispel all doubt as to the latter metal being by far the more injurious. In support of this statement, one of the experiences may be cited which, at the same time, may illustrate the necessity of taking proper precautions when operating bulbs of very high power. In order to carry out comparative tests, two tubes were constructed of an improved Lenard pattern, in size and most other respects alike. Both contained a concave cathode or reflector of nearly two inches in diameter, and both were provided with an aluminum cap or window. In one of the tubes the cathodic focus was made to coincide with the center of the cap, in the other the cathodic stream was concentrated upon a platinum wire supported on a glass stem axially with the tube a little in front of the window, and in each case the metal of the latter was thinned down in the central portion to such an extent as to be barely able to withstand the inward air pressure. In studying the action of the tubes, I exposed one hand to that containing aluminum only, and the other to the tube with the platinum wire. On turning on the former tube, I was surprised to observe that the aluminum window emitted a clear note, corresponding to the rythmical impact of the cathodic stream. Placing the hand quite near the window, I felt distinctly that something warm was striking it. The sensation was unmistakable, and, quite apart from the warmth felt, differed very much from that prickling feeling produced by streamers or minute sparks. Next I examined the tube with the platinum wire. No sound was emitted by the aluminum window, all the energy of the impact being seemingly spent on the platinum wire, which became incandescent, or else the matter composing the cathodic stream was so far disintegrated that the thin metal sheet offered no material obstruction to its passage. If big lumps are hurled against a wire netting with large meshes, there is considerable pressure exerted against the netting; if, on the contrary—for illustration—the lumps are very small as compared with the meshes, the pressure might not be manifest. But, although the window did not vibrate, I felt, nevertheless, again, and distinctly, that something was impinging against the hand, and the sensation of warmth was stronger than in the previous case. In the action on the screen there was apparently no difference between the two tubes, both rendering it very bright, and the definition of the shadows was the same, as far as it was possible to judge. I had looked through the screen at the second tube a few times only when something detracted my attention, and it was not until about 20 minutes later, when I observed that the hand exposed to it was much reddened and swollen. Thinking that it was due to some accidental injury, I turned again to the examination of the platinum tube, thrusting the same hand close to the window, and now I felt instantly a sensation of pain, which became more pronounced when the hand was placed repeatedly near the aluminum window. A peculiar feature was that the pain appeared to be seated, not at the surface, but deep in the tissues of the hand, or rather in the bones. Although the aggregate exposure was certainly not more than half a minute, I had to suffer severe pain for a few days afterward, and some time later I observed that all the hair was destroyed and that the nails on the injured hand had grown anew.

The bulb containing no platinum was now experimented with, more care being taken, but soon its comparative harmlessness was manifest, for, while it reddened the skin, the injury was not nearly as severe as with the other tube. The valuable experiences thus gained were: The evidence of something hot striking the exposed member; the pain *instantly* felt; the injury produced *immediately* after the exposure, and the increased violence due, in all probability, to the presence of the platinum.

Some time afterward I observed other remarkable actions at very small distances from powerful Lenard tubes. For instance, the hand being held near the window only for a few seconds, the skin seems to become tight, or else the muscles are stiffened, for some resistance is experienced in closing the fist, but upon opening and closing it repeatedly the sensation disappears, apparently no ill effect

(Continued on page 211.)

TESLA ON THE HURTFUL ACTIONS OF LENARD AND ROENTGEN TUBES.

(*Continued from page 207.*)

remaining. I have, furthermore, observed a decided influence on the nasal discharge organs similar to the effects of a cold just contracted. But the most interesting observation in this respect is the following: When such a powerful bulb is watched for some time, the head of the observer being brought very close, he soon after that experiences a sensation so peculiar that no one will fail to notice it when once his attention is called to it, it being almost as positive as touch. If one imagines himself looking at something like a cartridge, for instance, in close and dangerous proximity, and just about to explode, he will get a good idea of the sensation produced, only, in the case of the cartridge, one can not render himself an account where the feeling exactly resides, for it seems to extend all over the body, this indicating that it comes from a general awareness of danger resulting from previous and manifold experiences, and not from the anticipation of an unpleasant impression directly upon one of the organs, as the eye or the ear; but, in the case of the Lenard bulb, one can at once, and with precision, locate the sensation: it is in the head. Now, this observation might not be of any value except, perhaps, in view of the peculiarity and acuteness of the feeling, were it not that exactly the same sensation is produced when working for some time with a noisy spark gap, or, in general, when exposing the ear to sharp noises or explosions. Since it seems impossible to imagine how the latter could cause such a sensation in any other way except by directly impressing the organs of hearing, I conclude that a Roentgen or Lenard tube, working in perfect silence as it may, nevertheless produces violent explosions or reports and concussions, which, though they are inaudible, take some material effect upon the bony structure of the head. Their inaudibility may be sufficiently explained by the well founded assumption that not the air, but some finer medium, is concerned in their propagation.

But it was in following up the third line of inquiry into the nature of these hurtful actions, namely, in studying the influence of distance, that the most important fact was unearthed. To illustrate it popularly, I will say that the Roentgen tube acts exactly like a source of intense heat. If one places the hand near to a red-hot stove, he may be instantly injured. If he keeps the hand at a certain small distance, he may be able to withstand the rays for a few minutes or more, and may still be injured by prolonged exposure; but if he recedes only a little farther, where the heat is slightly less, he may withstand the heat in comfort and any length of time without receiving any injury, the radiations at that distance being too weak to seriously interfere with the life process of the skin. This is absolutely the way such a bulb acts. Beyond a certain distance no hurtful effect whatever is produced on the skin, no matter *how long* the exposure. The character of the burns is also such as might be expected from a source of high heat. I have maintained, in all deference to the opinions of others, that those who have likened the effects on the skin and tissues to sunburns have misinterpreted them. There is no similarity in this respect, except in so far as the reddening and peeling of the skin is concerned, which may result from innumerable causes. The burns, when slight, rather resemble those people often receive when working close to a strong fire. But when the injury is severe, it is in all appearances like that received from contact with fire or from a red-hot iron. There may be no period of incubation at all, as is evident from the foregoing remarks, the rays taking effect immediately, not to say instantly. In a severe case the skin gets deeply colored and blackened in places, and ugly, ill-foreboding blisters form; thick layers come off, exposing the raw flesh, which, for a time, discharges freely. Burning pain, feverishness and such symptoms are of course but natural accompaniments. One single injury of this kind, in the abdominal region, to a dear and zealous assistant—the only accident that ever happened to any one but myself in all my laboratory experience—I had the misfortune to witness. It occurred before all these and other experiences were gained, following directly an exposure of five minutes at the fairly safe distance of 11 inches to a very highly-charged platinum tube, the protecting aluminum screen having been unfortunately omitted, and it was such as to fill me with the gravest apprehensions. Fortunately, frequent warm baths, free application of vaseline, cleaning and general bodily care soon repaired the ravages of the destructive agent, and I breathed again freely. Had I known more than I did of these injurious actions, such unfortunate exposure would not have been made; had I known less than I did, it might have been made at a smaller distance, and a serious, perhaps irremediable, injury might have resulted.

I am using the first opportunity to comply with the bitter duty of recording the accident. I hope that others will do likewise, so that the most complete knowledge of these dangerous actions may soon be acquired. My apprehensions led me to consider, with keener interest than I would have felt otherwise, what the probabilities were in such a case of the internal tissues being seriously injured. I came to the very comforting conclusion that, no matter what the rays are ultimately recognized to be, practically all their destructive energy must spend itself on the surface of the body, the internal tissues being, in all probability, safe, unless the bulb would be placed in very close proximity to the skin, or else, that rays of far greater intensity than now producible were generated. There are many reasons why this should be so, some of which will appear clear from my foregoing statements referring to the nature of the hurtful agencies, but I may be able to cite new facts in support of this view. A significant feature of the case reported may be mentioned. It was observed that on three places, which were covered by thick bone buttons, the skin was entirely unaffected, while it was entirely destroyed under each of the small holes in the buttons. Now, it was impossible for the rays, as investigation showed, to reach these points of the skin in straight lines drawn from the bulb, and this would seem to indicate that not all the injury was due to the rays or radiations under consideration, which unmistakably propagate in straight lines, but that, at least in part, concomitant causes were responsible A further experimental demonstration of this fact may be obtained in the following manner: The experimenter may excite a bulb to a suitable and rather small degree, so as to illuminate the fluorescent screen to a certain intensity at a distance of, say, seven inches. He may expose his hand at that distance, and the skin will be reddened after a certain duration of exposure. He may now force the bulb up to a much higher power, until, at a distance of 14 inches, the screen is illuminated even stronger than it was before at half that distance. The rays are now evidently stronger at the greater distance, and yet he may expose the hand a very long time, and it is safe to assert that he will not be injured. Of course, it is possible to bring forth arguments which might deprive the above demonstration of force. So, it might be stated, that the actions on the screen or photographic plate do not give us an idea as to the density and other quantitative features of the rays, these actions being entirely of a qualitative character. Suppose the rays are formed by streams of material particles, as I believe, it is thinkable that it might be of no particular consequence, in so far as the visible impression on the screen or film is concerned, whether a trillion of particles per square millimetre strike the sensitive layer or only a million, for example; but with the actions on the skin it is different; these must surely and very materially depend on the quantity of the streams.

As soon as the before-mentioned fact was recognized, namely, that beyond a certain distance even the most powerful tubes are incapable of producing injurious action, no matter how long the exposure may last, it became important to ascertain the safe distance. Going over all my previous experiences, I found that, very frequently, I have had tubes which at a distance of 12 feet, for illustration, gave a strong impression of the chest of a person with an exposure of a few minutes, and many times persons have been subjected to the rays from these tubes at a distance of from 18 to 24 inches, the time of exposure varying from 10 to 45 minutes, and never the faintest trace of an injurious action was observed. With such tubes I have even made long exposures at distances of 14 inches, always, of course, through a thin sheet or wire gauze of aluminum connected to the ground, and, in each case, observing the precaution that the metal would not give any spark when the person was touching it with the hand, as it might sometimes be when the electrical vibration is of extremely high frequency, in which case a ground connection, through a condenser of proper capacity, should be resorted to. In all these instances bulbs containing only aluminum were used, and I therefore still lack sufficient data to form an exact idea of what distance would have been safe with a platinum tube. From the case previously cited, we see that a grave injury resulted at a distance of 11 inches, but I believe that, had the protecting screen been used, the injury, if any, would have been very slight. Taking all my experiences together, I am convinced that no serious injury can result if the distance is greater than 16 inches and the impression is taken in the manner I have described.

Having been successful in a number of lines of inquiry pertaining to this new department of science, I am able at present to form a broader view of the actions of the bulbs, which, I hope, will soon assume a quite definite shape. For the present, the following brief statement may be sufficient. According to the evidences I am obtaining, the bulb, when in action, is emitting a stream of small material particles. There are some experiments which seem to indicate that these particles start from the outer wall of the bulb; there are others which seem to prove that there is an actual penetration of the wall, and, in the case of a thin aluminum window, I have now not the least doubt that some of the finely disintegrated cathodic matter is actually forced through. These streams may simply be projected to a great distance, the velocity gradually diminishing without the formation of any waves, or they may give rise to concussions and longitudinal waves. This, for the present consideration, is entirely immaterial, but, assuming the existence of such streams of particles, and disregarding such actions as might be due to the properties, chemical or physical, of the projected matter, we have to consider the following specific actions:

First. There is the thermal effect. The temperature of the electrode or impact body does not in any way give us an idea of the degree of heat of the particles, but, if we consider the probable velocities only, they correspond to temperatures which may be as high as 100,000 degrees centigrade. It may be sufficient that the particles are simply at a high temperature to produce an injurious action, and, in fact, many evidences point in this direction. But against this is the experimental fact that we can not demonstrate such a transference of heat, and no satisfactory explanation is found yet, although, in carrying my investigations in this direction, I have arrived at some results.

In our present issue we publish a communication from Nikola Tesla, giving, in an exhaustive and instructive manner, the results of his experiments with the Roentgen rays, relating chiefly to their deleterious actions on human tissues. The many novel facts which Mr. Tesla brings out, and his careful deduction from them, will afford valuable and most welcome information to the vast army of experimenters who are engaged in exploring this attractive field. Mr. Tesla, while recognizing the existence of certain grave perils, suggests safeguards and repeats his warning against statements prejudicial to the development of this new and wonderful art.

ROENTGEN RAYS MADE HARMLESS.

Nicola Tesla Tells in a Carefully Prepared Paper How They May Become Safe for All Uses.

DISCOVERY OF THEIR CAUSE.

It Is the Discharge of Small Material Particles, and He Advises the Use of Aluminum.

TREATMENT FOR THE BURNS.

It has been known for some time that Nicola Tesla has been making exhaustive investigations concerning the Roentgen rays, not alone for their use in scientific demonstration, but also for their effects upon the human system. He has made a number of valuable announcements before scientific bodies, notably before a recent meeting of the Academy of Sciences, and has made important communications through the HERALD.

Mr. Tesla has now given voice to his deductions, so far as he has determined them, in a long statement of his experience with the rays in to-day's Electrical Review, and in the course of it makes some announcements certain to create wide discussion and comment in the scientific world. Summing up his experimental experiences, Mr. Tesla says:—

FOUR CHANGES SUGGESTED.

It would seem advisable, first, to abandon the use of bulbs containing platinum; second, to substitute for them a properly constructed Lenard tube, containing pure aluminum only, a tube of this kind having, besides, the advantage that it can be constructed with great mechanical precision, and therefore is capable of producing much sharper impressions; third, to use a protective screen of aluminum sheet, or instead of this a wet cloth or a layer of fluid; fourth, to make the exposures at a distance of at least fourteen inches, and preferably to expose longer at a greater distance.

Mr. Tesla cites several instances of the injurious effects of the rays which have come under his personal observation in his laboratory, which go far to bear out the announcements, already made in the HERALD, of the manner in which the rays affect the system, but beyond this Mr. Tesla has discovered why the rays have this injurious influence, and the theory is as novel as it is valuable. He says:—

According to the evidences I am obtaining, the bulb, when in action, is emitting a stream of small material particles. There are some experiments which seem to indicate that these particles start from the outer wall of the bulb; there are others which seem to prove that there is an actual penetration of the wall, and in the case of a thin aluminum window I have now not the least doubt that some of the finely disintegrated cathodic matter is actually forced through.

These streams may be simply projected to a great distance, the velocity gradually diminishing without the formation of any waves, or they may give rise to concussions and longitudinal waves. This for the present consideration is entirely immaterial.

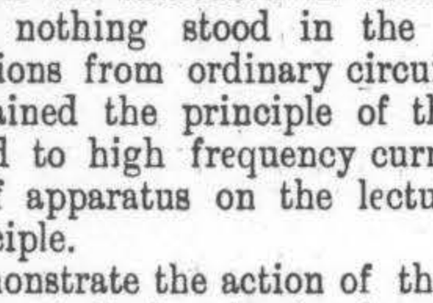
ENERGY SPENT ON THE SURFACE.

After his own painful experience with the rays, as well as their effect upon other persons whom he had observed, Mr. Tesla comes to this conclusion as to their effect beyond the surface.

"I come," he says, "to the very comforting conclusion that no matter what the rays are ultimately recognized to be, practically all their destructive energy must spend itself on the surface of the body, the internal tissues being in all probability safe, unless the bulb should be placed in very close proximity to the skin, or else that rays of far greater intensity than now produceable are generated."

Mr. Tesla cites a case where the rays had a serious effect on one of his assistants, and incidentally gives the treatment for the burns produced. Concerning this he says:—

In a severe case the skin gets deeply colored and blackened in places, and ugly, ill foreboding blisters form; thick layers come off, exposing the raw flesh, which for a time, discharges freely. Burning pain, feverishness and such symptoms are, of course, but natural accompaniments.



An injury of this kind happened to one of Tesla's assistants following directly an exposure of five minutes at the fairly safe distance of eleven inches. Warm baths, free application of vaseline and general bodily care soon repaired the ravages.

MR. TESLA ON X RAYS.

On April 6th, Mr. Nikola Tesla delivered before the New York Academy of Sciences an address "On the Streams of Lenard and Röntgen, with Novel Apparatus for Their Production." The lecturer began by stating that in 1894, in experimenting to determine the actinic action of phosphorescent light emanating from vacuum tubes, he had found that the actinic power of Crookes tubes varied greatly, and in the most anomalous manner. Thus some tubes emitting a strong light had very little action on photographic plates, while some showing a feeble light acted very strongly on such plates. A large number of these plates, made by Tonnele for the *Century Magazine*, were stored in Mr. Tesla's laboratory when it was destroyed by fire, and thus he was unable now to examine them for the Röntgen effects. He believed, says the New York *Electrical Engineer*, that he had just missed the discovery which made Röntgen famous, and though he was thoroughly familiar with Lenard's work, he did not see far enough.

Mr. Tesla then reviewed his work in the direction of obtaining a reliable apparatus for generating high frequency currents, which he recognised as the keynote to the production of vacuum tube lighting. He told how he had met with difficulties at every point; how a small bubble of air would destroy the value of the coil, or how one-quarter of an inch of wire too much or too little would throw a coil out of balance; how one day a coil would run cold and on another day hot, &c. By finally calling to his aid the condenser, Mr. Tesla stated, he had succeeded in obtaining the desired action, and now nothing stood in the way of securing millions of vibrations from ordinary circuits. The lecturer then briefly explained the principle of the condenser discharge, as applied to high frequency currents, and pointed to various types of apparatus on the lecture table designed to utilise the principle.

In order to demonstrate the action of the high frequency currents Mr. Tesla attached a circular loop of heavy copper wire to the terminals of a high frequency generator and brought to brilliant incandescence a small lamp connected diametrically across the heavy loop; the illumination of the lamp could be varied by connecting it to various points on the diameter of the loop. Mr. Tesla also lit the lamp by the current induced in a second loop brought in proximity to the first. He explained that the coil accomplishing this work had a resistance of 600 ohms and an inductance of 6 henrys; the coil was connected to the circuit one-half the time, and took from the primary circuit only 5 watts.

Mr. Tesla next showed a vacuum tube lit from the terminals of another high frequency machine. He also showed a coil consisting of a single turn of heavy wire which formed the core, as it were, of a small coil of a few turns wound on a paper cylinder surrounding the heavy wire. When connected to a high frequency generator, this apparatus gave a 4-inch spark with an expenditure of energy equal to that taken by one lamp. Mr. Tesla stated that his high frequency generators were so constructed that they could be connected to any existing circuits, direct or alternating.

Returning to the Röntgen rays, the lecturer stated that he had succeeded in discovering a new source of these rays, far more powerful than any heretofore available, though the difficulty of maintaining it was very great. This new source is the electric arc; not the ordinary arc, however. The arc required for the purpose is that maintained between a platinum terminal and an aluminium plate, as illustrated in the accompanying diagram, where A represents the aluminium plate and B the platinum, enclosed in a glass jar.

Mr. Tesla stated that he had also succeeded in deflecting the Röntgen rays by a magnet. He had proved this by deflecting the rays into a condenser placed a long distance from the source of the rays, and which in 5 seconds was charged sufficiently to throw a galvanometer needle off the scale.

VOL. XXIII. NEW YORK, MAY 12, 1897. No. 471.

MR. TESLA ON X-RAY BURNS.

IT may be considered a rule of nature that every beneficent manifestation of force may be accompanied by deleterious effects unless guarded against by suitable precautions, and the Röntgen ray is no exception to the rule. The very earliest experimenters in this field noted a harmful action of the rays on the skin, but of late instances have been reported of serious injury due to so-called X-ray burns. It is probable that the cases mentioned are due more to neglect or improper treatment of the injury than to the original effect of the "burn;" nevertheless, it is eminently desirable that all possible means be adopted for the prevention of the injury to begin with, on the old principle that an ounce of prevention is better than a pound of cure. Mr. Nikola Tesla has doubtless done as much X-ray work as any one, and with apparatus whose sheer power has probably not been exceeded by that of any worker in this field and invariably without harmful results, when certain precautions were taken. The means employed with such good results, and their raison d'être, are described in an interesting communication appearing in our contemporary, The Electrical Review.

For the prevention of X-ray burns Mr. Tesla finds that a chief precaution is to interpose between the bulb and the person a thin sheet of aluminum or aluminum wire gauze, connected to the ground directly or through a condenser. This screen, according to Mr. Tesla, prevents the formation of electro-static streamers, which would otherwise issue from the body, and which have an irritating effect. In the course of his experiments, Mr. Tesla observed, however, that the injurious effects did not seem to diminish gradually with the distance from the terminal, but ceased abruptly. He accounts for this as due to the effect of the ozone generated, and supports this view by the fact that the generation of ozone ceases at a definite distance from the terminal.

But perhaps the most striking fact developed by Mr. Tesla in these investigations is, that bulbs containing platinum electrodes are more injurious that those provided with alu-

minum electrodes, in support of which assertion he cites a number of experiments.

To sum up, Mr. Tesla advises: 1. The abandonments of bulbs containing platinum. 2. The substitution for them of a properly constructed Lenard tube, containing pure aluminum only. 3. The use of a protecting aluminum screen, as indicated above, or, instead of this, a wet cloth or a layer of fluid. 4. Exposure at no less distance than 14 inches, and preferably to expose longer at a greater distance. As regards other physiological influences of the X-ray, Mr. Tesla records the fact that since he has begun to work with the X-rays his health has been improved and he has been entirely relieved of a troublesome cough; this same effect was observed on another person. He has also observed that when the head is brought close to a powerful tube the effect is similar to that produced when working for some time with a noisy air gap. As the X-ray tube gives forth no sound, Mr. Tesla concludes that the tube produces violent explosions and concussions, which, though they are inaudible, have some effect on the bony structure of the head. Their inaudibility, he explains on the assumption that not air, but some finer medium, is concerned in their propagation. In conclusion, it may be stated that Mr. Tesla still adheres to his oft-expressed opinion, that the X-ray tube when in action emits a stream of small material particles. Some of his experiments would seem to indicate that these particles start from the outer wall of the tube; others again seem to prove that there is an actual penetration of the wall, and, in the case of a thin aluminum window, Mr. Tesla has not the least doubt that some of the finely disintegrated cathodic matter is actually forced through. Mr. Tesla stands practically alone in his advocacy of the corpuscular theory of the Röntgen rays, but his faith in its correctness seems to be growing stronger as time passes and his experiments multiply.

The Electrical Engineer.

Vol. XXIII. MAY 19, 1897. No. 472.

THE HARMFUL EFFECTS OF THE X-RAY.

BY DR. F. S. KOLLE.

THE editorial in the last issue of The Electrical Engineer on Mr. Tesla's investigations of the harmful effects of the X-ray is a very timely contribution to the literature of the subject.

It seems to be a peculiar fact that these harmful results or effects are kept from the eyes of experimenters, whereas in my estimation they should be recorded for the benefit of all. Even Tesla reluctantly cites a case of dermatitis, as having occurred in his laboratory. If we cannot receive the valuable inferences of such experimenters as Edison, Tesla, Thomson, etc., then we cannot expect to advance in perfecting this scientific discovery. It should therefore be the duty of every one to record such effects from time to time, as he deems valuable, without further consideration or question whether or not such report might harm or decrease the revenue, derived from the new art. It is self-evident that we must all profit thereby in the end.

Tesla divides the effects of the rays into four divisions, namely, thermal, electrical, electro-chemical and mechanical.

The thermal effect he believes to be shown by the injurious results produced, resembling exposure to heat; although no idea of the degree of heat of the particles is given, yet he says: "If we consider the probable velocities only, they correspond to temperatures which may be as high as 100,000 degrees Centigrade." That this thermal property exists, is certainly shown by the heat effects, such as reddening, pain and even blistering, when a part of the body is injudiciously brought too near an active tube. If this is true, then we are at a loss to demonstrate the transference of the temperature by any present known method.

2. That the rays exhibit certain electrical properties is readily shown by their power of discharging electrified bodies, in an exceedingly short space of time. I consider this in favor of the theory of Tesla that the rays owe their property to minute material particles. This electrical property might have some influence on the skin or part of body exposed. If these local currents are so strong or destructive they certainly resemble the high frequency current effect of Tesla, as no actual shock is experienced by such currents, yet these direct currents of extremely high potential show no hurtful action on the body.

3. If we are to believe that the rays exterior to the tube are made up of material particles of whatever nature, then it is possible that these particles may carry with them or are composed of an electro-chemical substance, and here Tesla holds that with the rays coming from a tube, whose reflectors or impact plate were made of aluminum, no hurtful effects were noted, claiming just the contrary for tubes containing platinum electrodes. This is certainly a most interesting study, and need not necessarily surprise us. I have rarely used focus tubes whose impact electrode consisted of aluminum. The tubes as used in my laboratory contain the usual concave mirror of aluminum and the platinum plate. The fact that the one is dangerous or more so than the other, can only be ascertained, in my belief, by such men as Tesla, Edison, Thomson, etc. For such study, and to develop sufficient evidence, large and complicated apparatuses are required which few are fortunate enough to possess. The usual outfit, that is, one that will answer all purposes medico-surgically, need be put of from 12 to 14 inches spark capacity, and with such apparatus it would be quite impossible to obtain such results as Tesla gives us.

4. The theory of material particles holds good in the mechanical effects produced. It is quite likely that particles of whatever nature violently thrown against each other or the tissues of the body, must necessarily produce heat which may be sufficient to create tissue change. From the above conclusions of Tesla, we must always consider his theory of the nature of the rays, one or the other of his classifications would hardly hold, if other theories be advanced. Yet all these are plausible, and further results are eagerly awaited, as light in darkness, by thousands of experimenters. That the harmful action of the rays have been exaggerated, may be said to be true, when we consider the number of amateurs working in this enchanting art; most, with the exception of very few cases, would hardly have come to the ears of the eager public, who, believing all and considering none, only too readily condemn the entire work. And no wonder! It is but a short time ago I received a communication from Germany, where iodoform had been mistaken for pieces of glass in a man's arm and two operations were undertaken to remove same, where none actually existed. The radiogram showed a foreign body, but this happened to be the dressing applied to the wound in the arm. Such mistakes would not occur if responsible men undertook the work.

As the first experimenter in Brooklyn, and since February 4, 1896, I have had but one case of irritation of the skin and one of alopecia or baldness, resulting from exposure to the rays, during which time I have used tubes daily for hours at a time. The case of dermatitis, otherwise known as inflammation of the skin, was of mild type and under proper treatment abated in 12 days. The case of resulting baldness which is believed to be the first recorded in the world, was fully described in a previous number of The Electrical Engineer, and even here a complete recovery followed.

Yet, I have been called upon to treat numerous cases for other experimenters and in each case I was satisfied that the result was, to a great extent, due to too short a distance between the tube and part exposed. In fact, I have recently seen a case where a large gangrenous piece of the integument had to be removed. Such discharging and blistered wounds make up a great number of these painful affections. That they do not respond to treatment as quickly as diseases of similar nature, produced by other causes, is not true. No one would expect skin to grow under a layer of fine and gangrenous material. Instead, the acrid discharge retards and aggravates the conditions. Proper treatment is required to obtain a happy result.

But all this is not preventive. What shall be done as a prophylactic measure to protect the patient from such effects? Simply study your apparatus, know what it is capable of doing, know from experience the distance your tube should be placed from the body, know its value in emanations, and you will experience little trouble. A further preventive to protect the parts, as I have said in former papers, is the use of an unguentum, in the form of lanoline or vaseline, applied to the skin of the part to be exposed. This protects it from the powerful action of the ozone produced, which is known to be a powerful destructive agent of organic material. I have never felt any ill effects from the ozone generated by an induction apparatus; in truth, I feel better now than ever, and a slight post pharyngeal catarrh has disappeared during the last few moments of experimenting.

Moist dressings protect the parts as well as an ointment; this accounts for few bad effects in tissue by hospital radiographers, where injured members are usually dressed with moist dressings. Tesla uses a thin sheet or netting of aluminum connected to a condenser or the earth, as a collector of the electrical effects of the rays, being placed between the tube and the part exposed. That the interposition of such a metal products, can be readily felt by the amau-radiscope which I have used in the experiments with the blind (N. Y. Med. Journ., Jan. 16, '97). By using such screen the peculiar strain felt in the region of the frontal lobes of the brain is not felt as much as with the usual fluoroscope. I believe the marked anæsthetic effects noted by early experimenters, were due to the continued and monotonous vibrations of the rheotome and need not necessarily be accredited to the rays, although the highly vibrated etheric waves may have some appreciable effect on the auditory nerve.

Distance and time of exposure need careful study, and I would advise all beginners rather to increase the time than to shorten the distance and less harmful results will be attained. Until we receive further convincing proof of preventives the above precautions can be relied upon with comparative safety.

216 Seventeenth street, Brooklyn, N. Y.

[90743.]—**Tesla Apparatus.**—As I have used this apparatus many times for X-ray work, I can give "H. B." (query 90743) the information he asks for. Working off the main with a transformer and Tesla coil, I have obtained perfect radiographs, and without damaging the Crookes tube. The great point to be observed is to have the current on only for short intervals, say on for five seconds, then off for the same period, and so on; by this means the tube is kept cool, and may be used many times. Do not use the double cathode tubes, as the "focus" is indifferent: the resulting picture obtained with such tubes frequently shows the bones double. With an ordinary focus tube, a carefully-adjusted condenser, a small spark gap, and an intermittent current, the Tesla is quite satisfactory for X-ray work. Moreover, old tubes that refuse to work on an induction coil may be readily excited by the higher tension currents of the Tesla; but if you have a continuous current, use it with an induction coil. I have premised that you intend working off the alternating main, for which the outlay (a transformer and small Tesla) is only £6. F. J. R.

[90743.]—**Tesla Apparatus.**—With ordinary "focus" tubes of, say, 3in. to 4in. spark capacity, little or no advantage is gained by using a Tesla, as these tubes can be served equally well by an ordinary 3in. or 4in. induction coil. But with some of the larger bianodic tubes, such as I am now putting on the market, taking 6in. and 8in. sparks to work them, Tesla transformers, worked direct from alternating-current mains, present great advantages. They give at once the high E.M.F., the fairly large ampèrage, and the high frequency of discharge which is essential to rapid photogra phic and clearly visible "screen" effects. S. BOTTONE.

[90743.]—**Tesla Apparatus.**—I should like to exchange experiences with regard to above. My spark coil gives a full 3in. spark using an accumulator, a good steady current, and I get a fully exposed "radiograph" of the hand in from four to six minutes. I made a Tesla according to a specification which, to be brief, "was to make the above 3in. coil do the work of a 6in. or 8in." It did nothing of the sort. I, therefore, made another with modifications, an immense improvement on the first; but I do not get an *increased length of spark*, and with X-ray tubes I do not notice any advantage in the use of the Tesla adaptation—rather the reverse, because the tube appears to tire very rapidly. On the other hand, the luminous effects obtained are remarkable. I get, with ease, the effects (to the extent, of course, of my somewhat limited electrical resources) described by Tesla himself, such being, I need hardly say, most interesting. From a strictly X-ray point of view, so far as my experience goes, I find no advantage whatever from the Tesla over the ordinary coil. I do not find that you get "any more out of it than you put in"—e.g., if you are using a weak and spasmodic source of electrical current, you cannot expect powerful results. I say this because from certain writings (not in the "E.M.") one would infer that, with a 1in. or 2in. spark coil and two or three chromic-acid cells, you can do the work of a £30 outfit. I am not so rash as to deny this altogether; but in the absence of further detail and information, I rather doubt it. P.S.—If likely to interest any of our readers, I will send sketch of my own home-made Tesla.

TESLA GRIPS THE WORLD.

HIS WIRELESS TELEGRAPH PERFECTED AT LAST.

Already He Has Sent and Received Signals at a Distance of 20 Miles—Instantaneous Communication with the Uttermost Parts of the Earth Without Wires the Possible Outcome.

At last Nikola Tesla has reached a point in his investigation of the possibility of telegraphing without wires to make a positive announcement of his achievements. It has been one of his dreams for years. He has worked at the problem long and anxiously. But his talk has always been guarded and indefinite. He spoke of the possibility that the thing might be done, and once, a few months ago, he went so far as to call it a probability. He was more positive and sanguine then than ever before, but still he was not ready to talk of achievements. But at last the work has reached a stage where the modest attitude of uncertainty and hope gives way to positiveness and assurance, and the definite announcement of success is made. Mr. Tesla declares that he has produced electrical devices with which he can actually send and receive messages by a system which can be so applied as to make it possible for an operator in New York to communicate with ease and certainty with the people of any part of the earth, and perhaps, even with those of the stars, if any of these are inhabited.

"The machines which I have completed," Mr. Tesla said yesterday, "will carry messages through the earth for a distance of twenty miles or so. I have sent and received signals with them, and I feel confident that I am not mistaken in saying that the problem upon which I have spent many days and nights is solved. Of course it is possible that I am mistaken. I have made mistakes before, but not many. I shall at once make machines which I expect will enable me to telegraph to any part of the earth as readily as I can within a limited distance by means of the ones I have.

"If I have a machine which will throw a stone from here to there," continued Mr. Tesla, pointing from the floor at his feet to the door of his laboratory, "then I do not need to doubt that I can make one which will throw the stone fifty miles if I can control the necessary power."

Mr. Tesla was not ready to explain in detail the devices which he uses for telegraphing without wires, but he talked freely about the principles which were involved and made it clear that the results were obtained by the use of some form of his electrical oscillator, recently patented. As long ago, he said, as when he was putting up telephone wires in Budapest he observed that electrical impulses were carried long distances without the intervention of wires. There was a telegraph cable one and a half or two miles away over which messages were being sent by the Morse code, and at times he could read these messages through the telephone. This set him to investigating the electrical condition of the air. He became satisfied that the messages were conveyed to the telephone wires by induction.

In 1890 he announced his belief that by means of electrical impulses of an extremely high rate, never yet attained at that time, bright light might be obtained from Crookes tubes, and in 1891 he made this announcement in London.

"I believed at that time that telegraphing might be conducted through the earth without wires," he said yesterday, "but I was afraid to say so for fear I should be laughed at and discredited by the older and abler men who were the leaders in electrical science."

It was not until 1893, when he appeared before the National Electrical Lighting Association at St. Louis, that he first declared his belief in the possibility of telegraphing over the whole earth without wires. Then he explained the general method which he believed would make this possible, if he could get a machine which should be able to disturb the static electricity of the earth. In that year he had an electrical exhibit at the World's Fair in Chicago and among his visitors was Prof. Helmholz.

"I spoke of my project to Prof. Helmholz," Mr. Tesla said yesterday, "and told him how I thought it might be accomplished. 'Yes, it is possible,' he said, 'but it would take much power.' I was very much pleased with this admission by this great master, and gratified that he did not condemn the idea, as many of my coworkers had done. I did not tell him then that I had already solved that part of the problem."

The solution to which Mr. Tesla referred was brought about through the work which he had done in developing his electrical oscillator, which he was working upon particularly in connection with the production of light from the Crookes tubes. The energy of the electric current, like that of flowing water, is displayed only when the current is interrupted. A familiar example of this may be seen in the common medical battery where the current flowing from one pole to the other may be passed through the most sensitive parts of the body, and yet not be felt. Pass the same current through a Ruhmkorff coil, interrupting the secondary current by the vibrations of the commutator, and it will twist up the muscles of the strongest man and make him powerless.

Before Tesla's time interruptions of this sort had been produced only by mechanical means and could number only a few hundred a second. His electrical oscillator acts upon the principle of a bell, where a single stroke of the hammer sets the metal vibrating with a rapidity commensurate with its bulk, and these vibrations can be continued indefinitely by repeated strokes of the hammer at slow intervals. Mr. Tesla now makes oscillators which will interrupt the current millions of times in a second. In explaining the theory upon which his new devices for telegraphing over the whole earth works, Mr. Tesla used a simple simile.

"Suppose the whole earth," he said, "to be like a hollow rubber ball filled with water, and at one place I have a tube attached to this, with a plunger in the tube. If I press upon the plunger the water in the tube will be driven into the rubber ball, and as the water is practically incompressible, every part of the surface of the ball will be expanded. If I withdraw the plunger, the water follows it and every part of the ball will contract. Now, if I pierce the surface of the ball several times and set tubes and plungers at each place the plungers in these will vibrate up and down in answer to every movement which I may produce in the plunger of the first tube. If I were to produce an explosion in the centre of the body of water in the ball, this would set up a series of vibrations in the whole body. If I could then set the plunger in one of the tubes to vibrating in consonance with the vibrations of the water, in a little while and with the use of a very little energy I could burst the whole thing asunder."

This, Mr. Tesla said, would explain in a rude way how he proposed to set the whole of the static electricity of the earth in motion, for telegraphic purposes, by taking advantage of the incompressibility and elasticity of the electric fluid. Then he told of some of the interesting results which he had accomplished in studying the theory and effect of vibrations. In one case he set a steel ring, four inches thick, vibrating, and by repeated but gentle continuations of the vibrations burst the ring. In another case he took a steel bar an inch in diameter, set it vibrating, and kept it going until its internal disturbance was so great that first a section of the rod broke loose from one end and flew off and then another section flew off from the other end.

In applying these principles to the telegraphic purpose Mr. Tesla had first to work out the theory and then to make instruments which would set up the proper vibrations and others again which would catch and record them.

"I have perfected my machines and got excellent results," Mr. Tesla said yesterday. "I have thought of this system of telegraphing not as a mere commercial matter, but as a means of bringing the nations of the earth closer together. I conceive that the use of this system will not do away with the use of telegraph wires, but will on the other hand make more work for them. It is true that millions of my machines might be used without those of one lot interfering with those of another lot, but the manner in which I conceive that the system should be used is this: Have a machine at each commercial or political centre and send out from each place, under an international agreement, all the political, financial, or other news, to be read at every other part of the world at the same moment. The news could be distributed then over the wire lines or otherwise. Financial panics and even wars might be done away with if this were done."

Mr. Tesla says the transmission of signals is not the only result which may be achieved by his new scheme.

"This was what I at first thought," he said, "but from the results of my experiments I am now hopeful that I shall be able to substantiate another thing—the transmission of power from place to place."

If it were proved possible to transmit power without wires, and to considerable distances, it would solve the greatest problem which now constricts the use of electricity for many purposes.

"If ever we are able to communicate with the stars it would be by this method," Mr. Tesla declared.

When asked what the effect of electrical storms would be on his system, Mr. Tesla said they would undoubtedly interfere more or less with the working of the instruments locally.

Before the interview with him ended he made a statement regarding his Crookes tubes lighting system which will interest many persons.

"The system is now a commercial possibility," he declared. "I don't like the word 'commercial,'" he added, "but what I mean is that I have succeeded in bringing down the cost of the light so that it will compare favorably with other means of lighting."

Mr. Tesla took up one of the many lighting tubes which were lying about and, starting the current through one of his oscillators, held the tube near the poles. The tube was shaped like a gridiron and was about eight inches square. As it drew near the electric arc of the oscillator it began to glow, and when it was close by it was all ablaze with a pure light.

"If it were night," Mr. Tesla said, "this light would diffuse itself over this whole room, so that you could read anywhere, although the candle power of the light is low."

His lights would be supplied by wires running across each room, but they could be produced without any connection with the wires if desired. Another form of tube, he said, gave a light many times more brilliant than the arc electric light, and this was suitable for such things as searchlights.

The New York Herald June 7, 1897

TESLA'S LATEST INVENTION.

Hopes To Be Able to Communicate by Electricity Throughout the Earth Without Wires.

Nikola Tesla feels certain that he has at last perfected a system of telegraphy without wires which will enable him to communicate with any point on the surface of the earth, and perhaps even with the stars, if any beings exist there intelligent enough to receive and return a message.

So far Mr. Tesla has experimented only within limited distances, but the success which he has met with induces him to believe that he has realized his hopes. He has long believed that messages might be sent through the earth without wires, and he has for several years been working upon his plans.

The necessary energy for performing the work of transmission is secured through the electrical oscillators which he invented, and which are capable of interrupting a current millions of times in a single second. His idea is based upon the elasticity of the static electricity of the earth, and his theory is that if this is disturbed by vibrations at a given point the same vibrations may be felt and recorded at any other given point. He is at work upon machines which are to transmit and receive these vibrations. He says that he has secured excellent results and that he has been able to send messages through twenty miles of earth.

Mr. Tesla thinks that his invention may be of the utmost importance in transmitting news affecting international interests throughout the entire world at the same moment, thus preventing wars and panics. He hopes also that he may be able by the same method ultimately to transmit power. If communication with the stars is ever established, he is confident that it will be through his method.

In addition to this discovery, Mr. Tesla has been experimenting with light derived from Crookes tubes, and he thinks that he has devised a system which will make them.

The New York Herald June 7, 1897

CAUSE AND EFFECT.

To illustrate certain powerful electrical experiments he is making, Professor Tesla compares the earth to a hollow ball filled with water. He says:—"At one place I have a tube attached to this, with a plunger in the tube. If I press upon the plunger the water in the tube will be driven into the ball." The Professor is liable to be accused of producing the recent earthquakes and the eruption of Aetna.

The New York World June 7, 1897

TESLA'S TRIUMPH.

When Morse found out the possibility of sending messages from one place to another by the electric telegraph his invention was only the clumsy beginning of a system. He used two wires to complete the circuit.

Presently somebody discovered that only one wire was necessary, because by "grounding" it at each end the earth could be made to do the rest of the work.

From that hour to this—from the time when it was discovered that the earth could be made to do half the work—it has been the problem of electricians to make the earth do all of it. It has been certain that sooner or later we should do our telegraphing without wires.

Mr. Tesla now announces that he has accomplished this. He can send signals for twenty miles without the use of wires. Any system that sends signals can be made to send messages. And when signalling for twenty miles is possible, signalling for any conceivable distance is a thing not far off.

This earth of ours is a great magnet, a gigantic dynamo. We have only to learn how to apply its practically illimitable magnetic powers to our uses in order to "make the whole world kin" in a degree never dreamed of by the poet who invented that phrase.

ALL THE WORLD IN INSTANT TOUCH.

Tesla's Greatest Idea Is Ready for a Practical Test.

MESSAGES BUT NO WIRES.

Twenty Miles the Limit Now, but His New Machine May Reach the Antipodes.

THE STARS NOT OUT OF REACH.

Electrical Energy Will Be Much Cheaper with No Costly Wiring Needed.

A LIGHT THAT RIVALS THE SUN.

Garrett P. Serviss Discusses the Famous Electrician's Marvelous Inventions.

Mr. Nicola Tesla has anticipated the twentieth century by telegraphing without wires. He has transmitted electric signals through the earth a distance of twenty miles, and received similar signals in return.

He believes that the system he has just perfected will render it possible to communicate intelligence from any point on the globe to any other point without the intervention of wires or connecting lines of any kind.

At present only a beginning has been made, but the principle is established, and when the details have all been worked out it may be that greater distances than those which separate the different quarters of the earth will prove to be traversable by electric vibrations under the control of human intelligence.

If a message can be sent around the earth without wires or cables, it may possibly be sent from the earth to the moon or to Venus or to Mars.

All this, however, is for the future. At present it is enough to know that such messages have actually been transmitted a distance as great as from New York to Menlo Park.

The details of his method have not yet been made public by Mr. Tesla, but his experiments with high frequency electric currents and the wonderful results he has attained in the production of light without wires have prepared the public as well as the world of science for some such announcement as that which now comes concerning the new system of telegraphy.

How eagerly and expectantly men of science have been peering in the direction of this great discovery is well shown by some remarks made by an English authority, Prof. W. E. Ayrton, in a recent lecture in London.

He was speaking particularly of marine telegraphy and of the difficulties at present encountered in connecting the continents by wire.

"But there is no doubt," he said, "that the day will come, may be when you and I are forgotten, when copper wires, gutta-percha coverings and iron sheathings will be relegated to the museum of antiquities.

"Then when a person wants to telegraph to a friend, he knows not where, he will call in an electro-magnetic voice which will be heard loud by him who has the electro-magnetic ear, but will be silent to every one else.

"He will call 'Where are you?' and the reply will come loud to the man with the electro-magnetic ear, 'I am at the bottom of the coal mine, or crossing the Andes, or in the middle of the Pacific.'

"Or perhaps no voice will come at all, and he may then expect the friend is dead. Think what that will mean. Think of the calling which goes on from room to room, then think of that calling when it extends from pole to pole—a calling quite audible to him who wants to hear, absolutely silent to him who does not."

The ink that printed the report of Prof. Ayrton's lecture was not yet dry when Mr. Tesla had begun the accomplishment of the scientific miracle which the lecturer described.

Indeed, probably before the lecture was composed on one side of the Atlantic the feat had been done on the other side.

For Prof. Ayrton's "electro-magnetic voice" put one of Mr. Tesla's electric oscillators, and for his "electro-magnetic ear" one of Mr. Tesla's electric receivers, and practically you have what was in London a mere dream of the scientific imagination transmitted in New York into a dazzling scientific fact.

Astounding as this discovery seems, many things have heretofore shown clearly that it was coming, but few probably expected that it would come so soon.

How rapidly it will be developed will depend upon the possibility of increasing the energy of the impulses sent out through the ether and of improving and perfecting the devices for their reception.

But if a message of this kind can be transmitted twenty miles to-day there is reason to hope that it may be transmitted across the sea or the continent before the end of the century.

GARRETT P. SERVISS.

TESLA TELLS THE STORY.

Will Make the Earth Vibrate to a Signal Code and Furnish Light Without Filaments.

Nikola Tesla announces that he has so nearly perfected three of his wonderful discoveries that he will soon be ready to put them to a practical test.

One, of which he had given some hint before, is a machine which will set the whole earth in vibration.

These vibrations, set to the measures of an international code, may be read at any part of the earth, this making possible communication, without wires, between any place and its antipode.

Then he has so improved his electrical oscillator that he is able to produce from a glass tube, without the usual filament of the incandescent lamp, a white light, in which only 10 per cent. of the electrical energy will be expended in heat, instead of 97 per cent., as in the incandescent light.

And last, though by no means least, he fully believes he will be able to transmit electrical power from place to place without the use of wires.

"I have so improved my machine," he says, "that I am able to transmit signals through the earth for a distance of twenty miles. I am now at work on another which will not be hampered or affected by any distance, even though it be half around the globe.

"But, more, the transmission of signals in this manner is not the only result I have arrived at, although it was the only end I had in view.

"I have been able to substantiate the principle that it is a possibility to send electrical energy from one point to another without wires."

Think, for a moment, of the immense advantage of knowing instantly what is going on in all the commercial centres of the world; of being informed at once of any international embroglio which may affect the business interests of the whole globe.

Every city in the world would be a station on an immense ticker circuit, and important news would go from one part of the world to the other with the rapidity of a lightning flash.

Imagine, if you will, an immense rubber bag filled with water. At one point a tube is inserted and in this tube is a piston. Press on the piston rod and the incompressible water expands the rubber bag.

Withdraw the piston and the bag shrinks just as much as there is water drawn into the tube. Now place in the rubber another tube with a piston. At every pressure on the first piston rod the effect will be felt and measured in the second tube.

Let a certain action of one piston indicate a word or a sentence; watch the other piston and you may read it.

This illustrates the principle upon which Tesla bases his idea of telegraphing through the earth. The qualities of electricity are inertia, incompressibility and elasticity.

He decided, after investigation, that if the electro-static condition of the earth could be disturbed in one place, the disturbance would be felt all over the earth.

Then, if this disturbance was created by a machine, any similar machine, at any other point, should be susceptible to the disturbance.

What then, he argues, is necessary other than to have each degree of disturbance accord with a code signal, regulate the disturbance so as to send any message you wish, and, at all other places where there are similar machines the message will be recorded.

The idea first occurred to Tesla when he was putting up a telephone system in Budapest. Two miles away was a Morse telegraph cable, and on the telephone wire every message that went over the cable could be heard.

Although the telephone wire and the cable were grounded the communication was by induction.

Tesla devoted himself to the idea, occasionally speaking about it. He received little encouragement until he was at the Chicago Exposition, and Prof. Helmholz, the greatest electrician of the century, called on him. To him Tesla outlined his plan. The professor thought for a minute and then said:

"Yes, I think you can do it. The great obstruction, however, is that you will require such enormous power."

Even then Tesla had in mind a machine which, he felt assured, would remove that obstruction. It is this machine he has perfected.

Just what it is like he declines to say, but inasmuch as at the time of his talk with Prof. Helmholz he was developing his electric oscillators that he might substantiate his claim that light might be produced from tubes it is believed the oscillator is the machine.

It is a producer of wonderful vibrations, Tesla claiming he can get 50,000,000 vibrations a second. He exhibited the very way which, he said, developed 800,000 vibrations a second.

More than probable it is that by means of the application of one of these oscillators to the static electricity in the earth he hopes to produce the disturbances without employing a remarkable amount of power.

With one of these oscillators Tesla has caused a bar of steel one inch thick to vibrate with such rapidity that literally it has broken itself to pieces, a fragment falling from one end, a second from the other and so on. In the same way he has shattered a ring of steel four inches wide.

"What experiments have you made in the transmission of signals by this apparatus?" he was asked.

"I have one that I know will operate over a distance of twenty miles. What more do I need? I know my best machine will do all I require of it.

"If I have a machine that will throw a stone five feet it is not necessary for me to construct another before I can know the stone may be thrown ten feet. All that is necessary is that I thoroughly understand the motive power, and from that I can tell."

"In what way will your discovery be applied?"

"There might be one in every large city in the world operated by an international agreement, so that all public news might be known instantly in every country.

"It would put every important point in the world in instant touch with every other. Millions of these stations might be established.

"No. I do not think it will do away with the telegraph lines or the cables, for it would be almost impossible to use these machines to filter all the news to the public.

"To my mind it will increase the business of the telegraph and cable companies.

"I feel it will be a great boon to humanity. To my mind it will avoid wars, will prevent panics and will enlist the sympathies of all the rest of the world for any section that may be in distress.

"This may be only a dream, but I feel that if we are ever to communicate with the stars it will be by this method and this only."

"There are wonderful commercial opportunities in this discovery made by Tesla as to the transmission of electrical power from point to point without wires.

It makes possible the erection of one central station, from which power can be sent wherever needed at a cost greatly below what is charged at present, for the copper feeding wires which are now used to transmit power from the central station are the heaviest item of expense.

When the question of motive power for the underground road was under consideration by the Rapid Transit Commission and electricity was advocated it was stated that the cost of the feeding wires alone for the underground line would be $7,000,000.

Could the electrical power produced at Niagara Falls be distributed without wires the cost would be so lessened that many more persons could avail themselves of the power, and the same condition might have its effect in the report of the commission which has just examined the Falls of the Nile, with a view to their adaptability to the production of electrical energy.

Factories and large workshops where electricity is employed, distributed among the various rooms by wire, would be operated at a greatly reduced expense; railroads would do away with their costly trolleys, and in every branch of trade where the electric fluid plays its part the outlay would be decreased.

No idea as to how he will accomplish this wireless transmission could be gained from Inventor Tesla, but it may be guessed that his oscillators will be brought into play in the development of his plan.

They are the important factor in the production of the new white light he has invented.

"I can safely say now," he declared, "that from tubes a white light can be produced at a cost which is at least comparable to that of other light, and easily within the reach of all."

He picked up a Crookes tube and placed it near the points of an oscillator, which developed 800,000 vibrations a second.

Instead of the phosphorescent glow usually produced from the tubes, a white light, wonderfully diffusive, was given out, even though the sunlight was streaming in through the windows.

The muscles of Tesla's arm contracted as the contact was first made.

"That was a voltage of 50,000," he said, as he put away the tube, "and it entered my body, as you saw."

The difficulty of producing such light heretofore was that its cost, because of the electrical energy required, was nearly ten times as great as that of the incandescent lamps.

With the oscillators it is different, however. They give the required energy and at a reduced cost.

"This light," said Tesla, "is not so brilliant as to be of a high candle power, yet it is very diffusive and will fill a room with a beautiful illumination. By the way, we have always accustomed our eyes to a light that is too brilliant.

"While in the incandescent lamp more than 96 per cent. of the power is expended in heat, I have got as much as 60 per cent. of light out of one of these tubes. But of course such an amount is not practical.

"I have also another tube, which, taking its energy from the oscillator, is brighter than any arc light by ten times, and makes a wonderful searchlight not to be compared to any that are in use. It is really like the sun."

Regarding the application of these tubes to houses Tesla said it would be done ordinarily with wires through each room, though where this was impossible the light could be produced without wires.

EDISON POOH-POOHS IT.

Nikola Tesla's Announcement Is Incomprehensible to the Wizard of Menlo Park.

Thomas A. Edison smiled when a World reporter asked for his views of Tesla's claims. "I don't find anything in them for discussion," said he. "It is all incomprehensible to me. He does not tell of anything accomplished. There is nothing that I can grasp, no facts that form even a basis of discussion.

"I have done something in the general field of work suggested by Mr. Tesla's claims, but I left it when I found that it was not profitable or practicable.

"For instance, a few years ago we succeeded in telegraphing from a moving train of cars to a terminal station or to another train. We could throw a current over the train, and by a simple apparatus. The entire plant would cost only $150. The process was fully described in the newspapers at the time.

"It was never of any practical value, aside from locating work trains along the road. We also showed that a current could be transmitted from one kite to another in the air.

"It might be possible," Mr. Edison said, with a smile, "to send a wave to England by the use of 5,000,000 or 6,000,000 horse-power, a wave that would transmit a letter, and it might be possible to transmit twenty waves or a word a day. The power required would be enormous. No, I can see nothing in this scheme described in such a vague, uncertain way."

TRANSMITTING SOUND THROUGH PIKE'S PEAK.

TESLA'S WIRELESS TELEGRAMS.

Nearly every telegraphic inventor has for years dreamed in his waking hours of the possibility of communicating without wires. From time to time there has appeared in the technical journals a reference to experiments showing the almost universal belief among electricians that, some day, wires would be done away with. Experiments have been made attempting to prove the possibilities, but it has remained for Mr. Nikola Tesla to advance a theory, and experimentally prove it, that wireless communication is a possibility, and a by no means distant possibility. Indeed, after six years of careful and conscientious work, Mr. Tesla has arrived at a stage where some insight into the future is possible.

A representative of the ELECTRICAL REVIEW receives the assurance personally from Mr. Tesla who, by the way, is nothing if not conservative, that electrical communication without wires is an accomplished fact, and that the method employed and principles involved have nothing in them to prevent signals and messages being transmitted and intelligibly received between distant points. Already he has constructed both a transmitting apparatus and an electrical receiver, which at distant points is sensitive to the signals of the transmitter, regardless of earth currents or points of the compass. And this has been done with a surprisingly small expenditure of energy.

Naturally, Mr. Tesla is averse to explaining all details of his invention, but allows it to be understood that he avails himself of what, for the present, may be termed the electrostatic equilibrium; that if this be disturbed at any point on the earth, the disturbance can with proper apparatus be distinguished at a distant point, and thus the means of signaling and reading signals becomes practicable once the required concrete instruments are available. Some years ago Mr. Tesla announced his belief in the possibilities, but he did so only after having satisfied himself by actual tests of apparatus designed by him. Much work had yet to be done, and he has since then given close attention and study to the problem.

Details are not yet available, for obvious reasons, and we now merely chronicle Mr. Tesla's statement that he has really accomplished wireless communication over reasonably long distances with small expenditure of energy, and has only to perfect apparatus to go to any extent. Morse's 40-mile experiment in the old days was on a far less certain basis than the wireless possibilities of to-day.

Tesla's work with high frequency and high-potential currents has been notable. As long ago as 1891 he foretold the present results, both as to vacuum tube lighting and intercommunication without wires. The former had in his hands assumed a condition capable of a public demonstration of the phenomena of the electrostatic molecular forces. Numberless experiments were carried out, and from what then was a startling frequency of 10,000 per second, Mr. Tesla has advanced to what now is moderate work at 2,000,000 *oscillations per second*. Such almost inconceivable results are plainly out of all possible reach by any mechanical rotation of a commutator. And so long as efficiency of lighting is, as Mr. Tesla observes, dependent upon extremely high frequency, it would seem his efforts are in the one and only direction likely, in vacuum tube lighting, to lead to success. Success, according to Mr. Tesla, is already assured, but he will not come before the public until every detail of a practicable and commercial system is complete, and the day for such a consummation, he now states, is near at hand.

[90848.]—**Tesla Coil.**—The subjoined figures will, I hope, do away with the necessity for a very verbose description:—Procure a glass tube, 2in. diameter and 6in. in length. This can be bought for 5d. or 6d.—the short glass chimneys used for Argand burners exactly answer the purpose. Fit a bung to each end, insert about the half of a 3in.

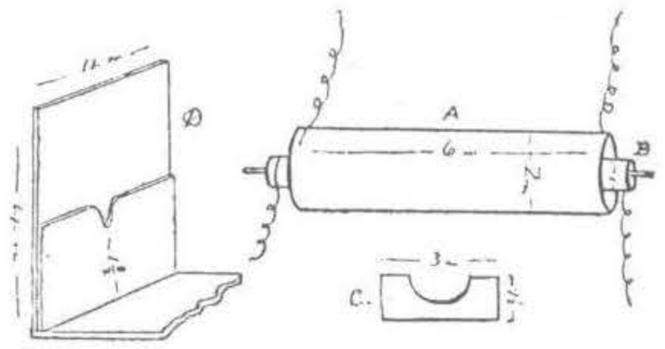

FIG. 1.—A, glass tube, 2in. diameter, wound with about 450 turns of No. 36 s.c. wire; the tube is kept off the bottom of box by two narrow strips of guttapercha, ⅛in. thick, shaped as at C. B, wood cylinder for primary, wound with about 50 turns of g.p.c. wire, No. 22; cylinder is 1in. longer than glass tube through which it passes, held or fixed in position by the thin wood projections in ends, which fit in grooves cut in, or specially glued on, ends of box. D, one end of box shown.

wire nail, and mount between a couple of small brackets. It will then be comparatively easy to wind upon it the length of No. 36 wire required. The wire I use is double silk-covered. The reel of wire is tested for continuity, then soaked in melted paraffin wax, and mounted on a temporary spindle ready for winding from. Coil about 12in. of the wire into a spiral, and fasten it securely with a bit of waxed thread ¼in. from one end of tube and start winding, fairly tight, close and even turns, until within ¼in. of other end of tube; tie here same side as started from and leave 12in. free wire. Now wind primary much in the same way. The rod is a length of hardwood ruler, 1in. diameter and 1in. longer than the glass tube. The extra lengths shown (as at B) are merely to support the primary exactly in centre of tube to keep it fixed there. With these extensions, therefore, the primary rod will be the exact length of box. Put on primary 50 turns of No. 22 wire, evenly separated; tie the ends tightly, then go over the whole surface of wire turns three or four times with shellac varnish. It is hardly necessary to say that the G.P. supports for tube (as C, Fig. 1) are made to adhere to the glass simply by warming the edges. The containing-box is of ¼in. walnut (fretwork wood), and measures

made 4 by 4 by 8, put together with glue and screws, thoroughly well varnished inside and out, and the joins inside covered with pitch. Boiled oil is provided sufficient to reach within ½in. of top. All the free ends of wires must be passed through rubber tubes: the two from secondary taken out on one side of box, and the primary on the other. Below (Fig. 2) is ground plan of connections. I mount these on one end of a board, 10 by 12, or so; thus leaving room for Tesla tank to stand at the other end. The terminals *a* and *c* are mounted on raised blocks of wood; the stand itself has been practically soaked in shellac varnish, and is mounted on four glass supports. The condenser is a quart Leyden jar. The utmost care must be taken with the "secondary" ends to secure the best insulation. In default of "hard rubber tubing of great thickness," I take these rubber-covered ends as soon as they come out of the oil and are "on the straight," so to speak,

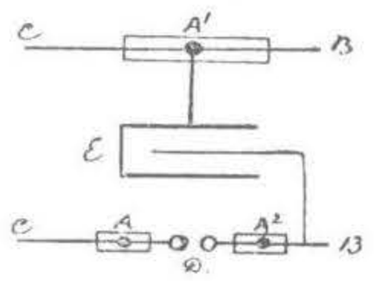

FIG. 2.—A^1 A^2 A, ordinary binding-screws; B B, wires to Ruhmkorff secondary terminals; C C, wires from Tesla primary; D, spark gap; E, condenser (outside connected to A^1, inside to A^2).

through glass tubes of various thicknesses fitting one within the other, building them up in two upright cases, one at each end of the tank, using plenty of pitch and rubber wherever possible, then terminal binding screws at top of each. A lid should be fitted to tank, and after pouring in the oil some hours should elapse before attempting to use the coil. I think above will be clear enough; if not, I shall be glad to assist anyone, in spite of a feeling that I am quite a tiro myself. I repeat, I get with above coil no longer spark than with the ordinary coil used by itself, but increased vibrations as I understand it, different effects altogether—e.g., attach to the terminals two L-shaped pieces of brass wire, so as to get two parallel lengths of wire 3in. to 4in. apart. From this little instrument, which from its cost, so cheap is it, that it might almost be reckoned a toy, to quote Dr. Tesla's article, "the discharge appears in the form of powerful brushes and luminous streams issuing from all points of the two straight wires," &c. J. P. N.

Telegraphing Without Wires

NICOLA TESLA, in an Interview in the New York *Sun*

The machines which I have completed will carry messages through the earth for a distance of twenty miles or so. I have sent and received signals with them, and I feel confident that I am not mistaken in saying that the problem upon which I have spent many days and nights is solved. Of course it is possible that I am mistaken. I have made mistakes before, but not many. I shall at once make machines which I expect will enable me to telegraph to any part of the earth as readily as I can within a limited distance by means of the ones I have. I spoke of my project to Prof. Helmholz in 1893 and told him how I thought it might be accomplished. "Yes, it is possible," he said, "but it would take much power." I was very much pleased with this admission by this great master, and gratified that he did not condemn the idea, as many of my co-workers had done. I did not tell him then that I had already solved that part of the problem. I have perfected my machines and got excellent results. I have thought of this system of telegraphing, not as a mere commercial matter, but as a means of bringing the nations of the earth closer together. I conceive that the use of this system will not do away with the use of telegraph wires, but will on the other hand make more work for them. It is true that millions of my machines might be used without those of one lot interfering with those of another lot, but the manner in which I conceive that the system should be used is this: Have a machine at each commercial or political center and send out from each place, under an international agreement, all the political, financial, or other news, to be read at every other part of the world at the same moment. The news could be distributed then over the wire lines or otherwise. Financial panics and even wars might be done away with if this were done. From the results of my experiments I am now hopeful that I shall be able to substantiate another thing—the transmission of power from place to place.

In explaining the theory upon which his new devices for telegraphing over the earth work, Mr. Tesla said:

Suppose the whole earth to be like a hollow rubber ball filled with water, and at one place I have a tube attached to this, with a plunger in the tube. If I press upon the plunger the water in the tube will be driven into the rubber ball, and as the water is practically incompressible, every part of the surface of the ball will be expanded. If I withdraw the plunger, the water follows it and every part of the ball will contract. Now, if I pierce the surface of the ball several times and set tubes and plungers at each place the plungers in these will vibrate up and down in answer to every movement which I may produce in the plunger of the first tube. If I were to produce an explosion in the center of the body of water in the ball, this would set up a series of vibrations in the whole body. If I could then set the plunger in one of the tubes to vibrating in consonance with the vibrations of the water, in a little while and with the use of a very little energy I could burst the whole thing asunder.

New York *Sun*

Mr. Tesla was not ready to explain in detail the devices which he uses for telegraphing without wires, but he talked freely about the principles which were involved and made it clear that the results were obtained by the use of some form of his electrical oscillator, recently patented. As long ago, he said, as when he was putting up telephone wires in Budapest he observed that electrical impulses were carried long distances without the intervention of wires. There was a telegraph cable one and a half or two miles away over which messages were being sent by the Morse code, and at times he could read these messages through the telephone. This set him to investigating the electrical condition of the air. He became satisfied that the messages were conveyed to the telephone wires by induction. Then he told of some of the interesting results which he had accomplished in studying the theory and effect of vibrations. In one case he set a steel ring, four inches thick, vibrating, and by repeated but gentle continuations of the vibrations burst the ring. In another case he took a steel bar an inch in diameter, set it vibrating, and kept it going until its internal disturbance was so great that first a section of the rod broke loose from one end and flew off and then another section flew off from the other end.

Electrical Review, New York

A representative of the *Electrical Review* receives the assurance personally from Mr. Tesla who, by the way, is nothing if not conservative, that electrical communication without wires is an accomplished fact, and that the method employed and principles involved have nothing in them to prevent signals and messages being transmitted and intelligibly received between distant points. Already he has constructed both a transmitting apparatus and an electrical receiver, which at distant points is sensitive to the signals of the transmitter, regardless of earth currents or points of the compass. And this has been done with a surprisingly small expenditure of energy. Naturally, Mr. Tesla is averse to explaining all details of his invention, but allows it to be understood that he avails himself of what, for the present, may be termed the electrostatic equilibrium; that if this be disturbed at any point on the earth, the disturbance can with proper apparatus be distinguished at a distant point, and thus the means of signaling and reading signals becomes practicable once the required concrete instruments are available. Morse's 40-mile experiment in the old days was on a far less certain basis than the wireless possibilities of to-day.

WIRELESS TELEGRAPHY.

The discoveries and inventions of Nikola Tesla have excited much interest in the scientific world, and, notwithstanding the fact that he has been very reticent regarding his achievements and prospective improvements, hints of his purposes have been dropped occasionally; so that so much of the public as is interested in him or his discoveries has been able to form a fair idea of the nature of his work. His inventions in the line of alternating current generators and motors are now well known, but his experiments in currents of high frequency and high potential are not so familiar.

Very recently Mr. Tesla has announced that he has completed his wireless telegraph to such an extent as to permit of telegraphy through the earth for a distance of 20 miles or more, and his experiments satisfy him of the feasibility of wireless telegraphy on a much more extended scale. In fact, he aims at nothing less than the establishment of a system of telegraphy that shall include the whole earth, and by which items of news may be distributed from one political or commercial center to every other such center throughout the world. This, Mr. Tesla claims, is possible without the interference of one set of signals with another.

He has constructed and tested both transmitting and receiving apparatus, and has found that a surprisingly small expenditure of energy is required. It is impossible at this writing to secure details of the apparatus, but it is known that he utilizes the static equilibrium of the earth. This he disturbs at one point, making signals which can be distinguished at one or more distant points.

In his earlier experiments in high frequency currents Mr. Tesla attained a frequency of 10,000 per second; now 2,000,000 oscillations per second is not deemed extraordinary. It is said that the success of the system is assured, but he will not come before the public until every detail is completed. It is understood that the transmission of power from place to place by means of a similar system is contemplated.

While Mr. Tesla has been wrestling with this great problem in this country, Mr. Marconi, a young Anglo-Italian, has been working on the same line in England under the direction of Mr. Preece. It is reported that Mr. Preece has succeeded in telegraphing with certainty and sufficient rapidity from Penarth to Weston-super-Mare, a distance across the water of seven or eight miles, without wires, and it is believed that this distance can be greatly extended.

It is said by The Engineer that the apparatus devised by Marconi is extremely ingenious, and has for its object the getting out of the Hertzian vibrations sufficient work for telegraphic purposes. The apparatus comprises a transmitter and receiver. The former consists mainly of a small Ruhmkorff induction coil excited by a couple of battery cells. The secondary or high tension wires terminate each in a metallic ball. Between the two balls is placed a cubical box containing oil. In the opposite sides of the box are fixed two brass balls, oiltight, so that one-half of each ball is in the oil in the box and the other half outside of the box. The balls do not touch. The whole arrangement has been designed by an Italian professor, Righi. On sending a current through the induction coil, Hertzian vibrations are set up in the balls and communicated to the ether. The oil has a peculiar effect, acting as a species of brake, the rapidity of the wave vibrations being only about one-half of that stated by Dr. Lodge. These vibrations are then given off into space all around in every direction. So far as known, nothing save metals appears to be opaque to them, and here, therefore, we have an analogy with the Roentgen ray.

Marconi's receiver consists of a tube about ¼ of an inch in diameter and 3 inches long, in which are two silver plugs terminating in wires, the ends of which are soldered to the silver plugs. The wires are fused into the glass. The tube is exhausted to a near approach to absolute vacuum. The faces of the two silver plugs are very close to each other, and the space between is filled up with an impalpable metallic dust. On the nature of this dust much depends. It must suffice to say that there are in it three constituents, one of which is nickel. Under ordinary conditions this powder will not conduct electricity, save feebly. Its resistance is very high. If a Hertzian ray falls on the little tube, the dust is polarized like the filings in a Hughes test tube, and the powder becomes a conductor. It will be seen at once that we have here a make and break which can be acted on from a distance, and an ordinary Morse sounder does the rest. But matters, after all, are not quite so simple. It is easy to dispatch into space Hertzian waves at intervals corresponding to dots and dashes, but the powder in the receiver, once polarized, remains polarized. To get over this obstacle, a tiny hammer is so arranged that, the moment a current passes through the tube, the hammer taps the side of the tube and depolarizes the powder ready for the next signal.

There is nothing in common between ethereal or wireless telegraphy and telegraphy by induction; the phenomena are wholly distinct. The Hertzian radiance is akin to light, and the polarization of the powder in the receiver finds its analogue in the molecular change which is wrought by light in a sensitized plate.

HERTZ WAVE TELEGRAPHY BY THE MARCONI SYSTEM.

(From our London Correspondent.)

AT last the truth about the "Marconi mysteries" has been revealed. In a lecture at the Royal Institution on June 4, Mr. W. H. Preece told us what the Marconi invention really is—and a great many other things as well which we knew before. The sensational articles in the lay magazines and in the daily papers ascribed to Marconi the discovery (or invention, as it was perhaps more appropriately termed) of a new kind of electrical radiations which had quite different properties to Hertz rays, which would penetrate anything from a brick wall or a few hundred yards of solid hill to iron plates a foot or so in thickness and blow up the powder magazine of an enemy's ironclad, and do several other truly remarkable and characteristic feats. Marconi has actually devised a very sensitive and seemingly reliable form of coherer, which can detect Hertz waves generated by a Righi radiator several miles distant.

Marconi no doubt deserves great commendation for having worked out an ingenious and efficient apparatus, and having brought us a step nearer to the practical utilization of Hertz waves; but the fact of his abstaining from stating in the interviews and articles that have been published that his work has been nothing more than modifications in the details of apparatus devised by his more illustrious predecessors, has entirely prevented him from receiving that genuine tribute of praise, which almost amounts to veneration, usually accorded so freely to successful workers in the realms of science.

The Marconi coherer consists of a small glass tube four centimetres long, into which two silver pole-pieces are inserted, separated from each other by about half a millimetre. This thin space is filled with a mixture of nickel and silver filings—96 per cent. of nickel, 4 per cent. of silver and a trace of mercury. The tube is exhausted to a vacuum of 4 mm. and sealed. It forms part of a circuit containing a battery cell and a sensitive telegraph relay. Normally the resistance across the powder gap of the receiver is several thousands of ohms, but when the Hertz wave falls on it, it is reduced to about 5 ohms.

Mr. Preece did not say whether the increased sensitiveness of the relay was chiefly due to the composition or the finely divided state of the metal filings, or to the use of a vacuum. In other respects the coherer does not differ very much from that devised by Lodge some four years ago; the principle was first shown by M. E. Branly in 1890. The main defect in the Lodge coherer was that after receiving a wave it did not "decohere" without being shaken or tapped. Marconi gets over this difficulty by putting in the "local" circuit of the relay a small electrically worked hammer, so that on the reception of each signal the glass tube is lightly tapped. The sound made by this little hammer upon the glass is sufficient to read Morse signals from, but, of course, a Morse ink writer or any other instrument can be put in the local circuit.

The transmitter is, as already stated, Prof. Righi's form of Hertz radiator. Two spheres of solid brass, 4 inches in diameter, are fixed in an oil-tight case of insulating material, filled with vaseline oil, so that a hemisphere of each is exposed, and the other hemisphere is immersed in the oil bath. The oil seems to maintain the surfaces of the spheres clean, thus obviating the frequent polishing required in the original apparatus of Hertz. Mr. Preece also stated that it impresses on the waves excited by the sparks between the spheres a uniform and constant form. Two smaller spheres are fixed close to the opposite sides of the two larger spheres, and these smaller ones are connected to the secondary of the induction coil. Morse signals are made by a key in the primary circuit of the coil. The waves produced by this apparatus are very short, generally about 120 cm. long. With a 6-inch spark coil, signals were transmitted to a distance of four miles; for greater distances sparks up to 20 inches were used. Mr. Preece has succeeded in transmitting signals over a distance of eight miles across the Bristol Channel with the Marconi apparatus.

For shorter distances the poles of the coherer are connected to two "wings" of copper, each in series with a small retardation coil. When signalling over longer distances the wings are removed, one pole of the coherer is connected to earth, and the other extended to the top of a mast or by a kite connected with aluminum wire to the coherer. It seems that during the experiments signals were actually received through hills. Mr. Preece explained this by a diagram in which the electric ray was depicted curving round the top of the hill in a very accommodating way. It would seem more probable, however, that, as the beam is naturally somewhat diffused, some rays may be reflected round the sides of the hill by other conducting obstacles, or perhaps the hill was actually not a good enough conductor to absorb the rays, and was to a certain extent transparent to them. Another "apparent anomaly" was that Marconi's relay acts even when enclosed in a metal box. During the lecture Mr. Preece put the instrument in a galvanized iron dust bin, and yet it received the signals transmitted from another room. He also assured his audience that he had performed the same experiment in a hermetically sealed box. This would only prove, however, that the coherer is extremely sensitive and that the intensity of the waves transmitted is so great, that they are not entirely absorbed by the fraction of an inch of metal.

Besides intending to employ this system of telegraphy to signal to lightships and lighthouses from the shore, Mr. Preece intends to use it for a regular public telegraph service to the island of Sark, in the English Channel, as this island is at present not connected to any submarine cable.

When Marconi's patents have been published an interesting question will be whether they have any commercial value. We believe that the use of a vacuum in a coherer has been proposed and even used before. The combination of a coherer with a relay is no new idea, and Lodge proposed in 1894 the employment of an electric vibrator to act as what Mr. Preece calls a decoherer. Moreover, without wishing to lessen the credit due to Marconi, we cannot but think that had the British Telegraph Administration given one of the great English physicists like experimental facilities, the same, or even better, results would have been obtained.

TESLA'S TELEGRAPH TO MARS.

Discussing methods of telegraphing to Mars, Mr. Nikola Tesla says: "The inhabitants of the planets, Mars, for example, must have intelligence. Their life must be made up of events. They must have a conception of time. And therefore they must have means of measuring time, of recording events. Without that they could have no history.

"Thus upon a mathematical basis I believe a system could be founded which in the course of time could be developed into an intelligible code, capable even of conveying the most intricate communications. There is no limit to the possibilities of its development.

"It is upon the result of that calculation that I base the declaration of my belief that a serious attempt at transfer of intelligence to Mars will be made within a short time. Of course, I mean 'short' in the scientific sense. But I would not undertake to say how short or how long that time will probably be."

Tesla's Transmission without Wires.—Mr. Tesla announces in an American journal that by his well known system of transmitting intelligence by means of electrical "resonance" between points widely apart, without any connecting wires, he has lately been able to signal 20 miles. Mr. Tesla confesses, says the N.Y. *Electrical Engineer*, that the system is still liable to break down in bad weather, but such results will doubtless encourage him to persevere until the distance is many times greater, and the method is quite independent of disturbing atmospheric or terrestrial effects.

A DREAM TO BANISH NIGHT.

Nicola Tesla has had a dream. He has thought to banish night by pouring out the sunlight upon the earth even after the orb of day has passed below the horizon. Patiently for years he has experimented in his laboratory, and now he dares to proclaim a dimly glowing reality to his dream.

The wand of his magic is the vacuum tube. It realizes the desideratum of light without heat eagerly sought by Edison, Moore and other magicians of the dawning century. Brought near a current of electricity, but with no direct connection, the tube brightens into a soft, clear white light. The intensity of the light varies with the pressure of the current and the quantity of air left in the tube.

The wizard has done more than this. By passing a current through a broken circuit he has produced luminous clouds without a vacuum. This triumph opens the way for the fulfilment of his dream.

He would use the rarefied air of the earth itself as a medium. Erecting one lofty pole at New York and another a hundred miles away at Philadelphia, he would send a powerful current from one to the other through the upper regions of the rarefied air. Under the pressure of a few thousand horse-power he believes that the sky along its pathway would give forth a light bright as that of the clear full moon. Increase the current to higher potency, and even the light of day might descend upon the earth.

A height of ten miles above the earth would be necessary to reach in order to obtain air of a rarety best adapted to the path of the light. Yet with a more powerful current at the lower altitude, light might be produced which would serve every practical purpose.

Could standards be raised ten miles into the air? Let Tesla demonstrate that light cheap and powerful can be so produced, and more than one bold engineer will be ready to attempt the feat.

WESTINGHOUSE COMPANY'S ANNUAL REPORT.

FULL TEXT OF PRESIDENT WESTINGHOUSE'S REPORT TO THE STOCKHOLDERS—ANNOUNCEMENT OF A LARGE CONTRACT—A DIVIDEND DECLARED — BOARD OF DIRECTORS RE-ELECTED.

Your board of directors present herewith the balance sheet showing the financial condition of your company as of March 31, 1897.

Owing to the removal operations from the old into the new shops, your board of directors was unable to present a balance sheet for March 31, 1896, based upon actual values of inventories.

The class of electrical business conducted by your company has been in a depressed condition during the past two years, owing to the almost complete interruption in the building of new railways and new power stations. Notwithstanding these unfavorable conditions and the heavy charges to current expense account, due to the removal to the new works and the making of new tools, patterns, etc., the company's earnings have exceeded the amount required for the dividends on the preferred stock, which have been promptly paid.

By comparing the present balance sheet with that for March 31, 1895, it will be seen that there has been made a reduction in the surplus account of $1,577,735.93, due to amounts written off in connection with the disbandment of the old factories, the sale of obsolete tools, machinery and stock, depreciation of inventory, bad debts, the adjustment and settlement of old accounts, and the book loss from the sale of stocks and bonds owned by the company, and also the book loss resulting from the sale, at the price mentioned below, of $3,000,000, par value, of "assenting stock."

On June 4, 1896, your company authorized the increase of its capital stock from $10,000,000 to $15,000,000, and your board of directors effected a sale of $3,000,000, par value, of the new assenting stock thus authorized to the Security Investment Company, of Pittsburgh, which realized to the company $2,489,000, of which amount $1,260,000 was received in cash, $329,000 was represented by patents and property, and the remaining $900,000 in interest-bearing notes secured by collateral; $300,000 of such notes were payable July 5, 1897, and have been paid; $300,000 are payable July 5, 1898, and the remaining $300,000, July 5, 1899.

Pursuant to the terms of the contract with the General Electric Company, for the exchange of licenses under the patents of the two companies, of which you were notified by a circular letter dated April 2, 1896, your company has purchased outright for $216,600 the Tesla patents for multiphase-current motor, in order that both companies might manufacture apparatus covered by those patents without the payment of royalties, other than those provided for in the agreement between the two companies. For like reasons your company purchased, for $72,231.17, the entire capital stock of the R. D. Nuttal company, which has a complete workshop for its purposes, and manufactures trolleys for the General Electric Company and your company, and gears and other railway supplies for the general market. The stock purchased is considered fully worth its par value of $118,000. Your company also purchased for $58,500 and the transfer of certain patents acquired through its agreement with the Security Investment Company, 12,433 shares of the Electro-Magnetic Traction Company, out of a total issue of 20,000 shares.

The agreement between the General Electric company and your company has been in force a little over a year, and the wisdom and value of the union of patents has been fully established. The patents of the two companies, thus brought together, have a commercial value which can not be adequately appreciated by those not familiar with the electrical business. These patents are numbered by the thousand, and, within the field covered by the company's business, relate to every conceivable electric system and kind of apparatus to the minutest detail. Their present book value is less than the sum expended in acquiring and developing them. The terms of the contract between the General Electric Company and your company fix the respective values of the patents at 62½ per cent for the General Electric Company and 37½ per cent for your company. The patents owned by your company are carried at $4,689,080.89, or less than 37½ per cent of the aggregate book value of the patents of both companies. Many of these patents have already been sustained by the courts, while in numerous instances infringers, after being made acquainted with the situation, have agreed to cease infringing.

During the past year many valuable patents have been acquired in the interest of the two companies at moderate cost, while the expense of carrying on suits has been greatly less than the sum formerly expended by the two companies.

A liberal course is being pursued in the enforcement of these valuable rights, and there is reason to expect that the time is near at hand when the patent property now being managed as a common interest will be generally recognized as exceeding in value and importance that of any other manufacturing interest.

These items appear on the books at cost. It was the expectation of your board of directors that a large part of the bonds and stocks of lighting companies on hand could be disposed of from time to time, but there has been no market for the sale of such securities during the past two years. These stocks and bonds have, as a rule, increased in intrinsic value, and it is proposed to pursue the policy of selling them whenever advantageous terms can be secured.

It has not yet been possible to dispose of the old factories of your company and of the United States and Consolidated companies. It is expected that with the improvement of business a market will be found for these properties.

It is the hope of your board of directors that the proceeds of the sale of stocks and bonds and old factories will, in the near future, be sufficient to care for the indebtedness of the company, leaving the quick assets for the regular current business.

The utilization of water power, and its transmission by electricity, have given great prominence to the Tesla patents, which, together with numerous other patents controlled by your company and the General Electric Company, should insure to the two companies the sale of all the power-transmission apparatus used in this country.

About two years ago your company installed at Niagara Falls, for the Cataract Construction Company, three 5,000-horse-power generators, and in January of this year were awarded by that company the contract for five additional generators of the same capacity, which are now under construction.

Your company has also just been awarded a contract for 15 5,000-horse-power generators by the St. Lawrence Power Company, which is the largest single order yet given for power-transmission apparatus.

Your company should derive great benefit from the execution of this contract, since no other company has yet attempted work of this size and importance. The securing of these contracts was, without doubt, due to the success of your apparatus at Niagara Falls, and to the most complete facilities which your company now has at its new works, at East Pittsburgh, for the manufacture of large electrical units.

Your company has made marked progress in the development of apparatus for the operation of suburban and interurban trains on main railways, and it has installed at East Pittsburgh, on the tracks of the Pennsylvania Railroad, experimental apparatus, where important experiments are constantly being carried on. We believe your company is now more fully equipped and has better facilities for work of this kind than any other concern.

Your workshops at East Pittsburgh are in complete order, and have the advantages for manufacturing which it was contemplated they should possess. Its facilities, arrangements, machinery and tools enable it to undertake work of the largest character which may be proposed. All that has been said heretofore with reference to the property of your company at this place, and the opportunity it affords for economical operations, has been more than borne out by the facts. These works stand on your books at $2,769,886.26, of which $1,290,732.85 is for real estate and buildings, and $1,479,153.41 for machinery and tools, making an exceptionally low cost for works of such great capacity.

The engineers of your company have acquired a world-wide reputation in mechanical and electrical engineering, a fact well illustrated by the close copying by other manufacturers of plans, systems and designs which had their origin in your offices or works. The character of the apparatus turned out at your new works has given your company substantial trade advantages.

By order of the board,

GEORGE WESTINGHOUSE,
President.

Pittsburgh, Pa., June 23.

BALANCE SHEET, MARCH 31, 1897.

ASSETS:		
Cash in banks		$330,193 89
Bills receivable		43,207 09
Accounts receivable		1,604,547 19

The old board of directors was re-elected as follows: Charles Francis Adams, Lemuel Bannister, August Belmont, N. W. Bumstead, A. M. Byers, Marcellus Hartley, George W. Hebard, Henry B. Hyde, Brayton Ives and George Westinghouse.

On June 22 Treasurer Kobbé sent out this announcement:

At a meeting of the board of directors of the Westinghouse Electric and Manufacturing Company held this day, a regular quarterly dividend of one and three quarters per cent (1¾%) upon the preferred stock of the company was declared, payable July 1, 1897, to stockholders of record, the transfer books to close on June 25, 1897, at 3 P. M., and to open on July 3, 1897, at 10 A. M.

NIKOLA TESLA, THE ELECTRICIAN.

BY CHARLES BARNARD.

THE republic has the property of a magnet; it attracts iron characters. New York is the intellectual and commercial center of the country and the magnetic "field of force" is most intense in our greatest city. It has been said by many that, while the city attracts strong characters, it is not the best place for the higher intellectual life. The student and thinker should seek the calm of sleepy, academic towns "far from the madding crowd." These forget that modern life makes it possible to have the deepest seclusion and space for high thinking in the very focus of the city. Eternal calm is not the only desirable thing. Friction, attrition, even heavy grinding are as essential to the intellectual life as to cut glass.

It is, therefore, not surprising to find to-day one of the few great students of our times, a man of remarkable intellectual gifts, drawn from the far East of Europe to our chief city. In the turmoil of the dry-goods district he has set up his workshop, and by his presence added new fame to Broadway. Just as Ericsson lived and worked in New York, far from his native fiords, so to-day Nikola Tesla works in his Houston Street laboratory, far from the mountain home of his ancient Serbian race.

In Smiljan Lika, Austria-Hungary, there has long lived an old and respected family. One branch of this family had born to them in 1857 a son. The father was a clergyman in the Greek Church, the mother apparently a Connecticut Yankee astray in another race. She was not only a good housemother, but she had the precious gift of handiness, and was a designer and maker of those ancient tools the loom and churn. It is small wonder that the son of such parents should have at once the mechanic and the prophetic mind.

NIKOLA TESLA.

The boy Nikola attended the public school at Gospich. At the end of three years he graduated to the *Real Schule.* At the end of three more years he advanced to the higher *Real Schule* at Carstatt, Croatia, graduating in 1873. It is curious to note that it was here the youthful Nikola first saw a locomotive. Naturally the father hoped the son's education would lead him to the church, but the boy's bent of mind was too pronounced to long admit of such expectations. He seemed plainly destined for a professor of physics, and joined the Polytechnic School at Gratz. This too proved a blind guess at the young man's future. In the lecture-room there was soon mental rebellion. In vain the professor demonstrated the impossible. The student denied the impossible. Curiously, the subject under discussion was a Gramme dynamo, requiring, as was clearly demonstrated, commutators or brushes. The student imagined a dynamo without brushes. Imagination is the mother of invention. The youth clearly had an inventive mind. He could see the impossibilities of other minds quite possible in his own. Teaching was not for such a student. After one year at the Polytechnic he began the study of engineering. On graduation he, with a broad grasp of the great world-sciences, saw that he must be a linguist, and mastered several languages that he might be unhampered by locality. His feet turned westward. Prague and Budapest were but way-stations in his progress. He served as assistant engineer in the government telegraph engineering department and began at once to suggest improvements on the practical side of the science. The field was too small. He must go farther, was soon in Paris, where he secured employment in an electric light company.

Here he seemed to catch the wider air of another land. He met Americans who

told him of the greater chances of a newer civilization. He was already a dreamer of dreams scientific. Where could dreams be so quickly realized as in America? Without hesitation he sailed at once for New York and went on the day he landed to the laboratory of Edison. Mind sought mind. Smiljan, Prague, Paris, Orange, New Jersey, marked the progress to the West. Here was room and space enough to work—to realize dreams, to prove the impossible to be real and practical. Naturally, with an original mind there must be special methods, peculiar environment, and in time the young Tesla sought, in the heart of roaring Broadway, the seclusion and calm of his own laboratory, where he might work out in his own way his own ideas. The experience in the Edison laboratory was invaluable, but it was an experience and not an end.

Almost immediately in his new workshop Tesla brought with infinite diligence some of his ideas to practical commercial results. He had come to the right place. Business and capital are the handmaids of invention. It is wise to dream in their neighborhood. Now began the real life of an original mind exploring the higher ranges of the most difficult and least known science in the world. Under his eye the dim horizon of the unknowable began to retreat, in his workshop a light that was never seen on sea or land flared up in purple fires—the flames of the cosmos, the very pulse-beats of the planet made visible in almost unearthly fire.

It is one of the perplexities of science that the schoolmasters have fenced the field into town lots of knowledge, while there is clearly to-day one great science of the universe. For the common mind it is enough to master a corner lot of knowledge. For greater minds mathematics, chemistry, mechanics, physics are only branches of knowledge, and the student must possess all. To be a great electrician you must be mechanic, engineer, chemist, steamfitter, gas-man, lineman—everything, and be good in every trade. To be an inventor and discoverer means to add to all knowledge patience, diligence, and imagination—and the greatest of these is imagination. This universal knowledge, this imagination, appear to be the chief characteristics of the student workman Nikola Tesla. It is their rare combination and the remarkable results that have come from his labors that have attracted the attention of the scientific world and made the Houston Street workshop famous.

There was printed three years ago a book* of five hundred pages cataloguing Mr. Tesla's inventions and discoveries up to 1874. A single invention would have been regarded as sufficient for the fame of a lifetime, and yet since the publication of that immense list of work accomplished Mr. Tesla has gone on perfecting and completing work already done and invading new fields of science. To the average reader this catalogue of Mr. Tesla's work is simply unintelligible, because the science of electricity has been compelled to coin new terms to express new knowledge. "Polyphase currents," "rotating magnetic fields," "currents of high frequency and high potential" are terms employed to express in part some of Mr. Tesla's work, and yet it is almost impossible to make them clear without a new language.

Broadly stated, Mr. Tesla's inventions are improvements in the making of dynamos, the reduction of the cost of producing and conveying electricity. His most remarkable researches have been in that new field of electrical study made possible by his own inventions. He creates electrical conditions unknown before, and under these new conditions exhibits nature in wholly new and unexpected aspects. Producing by new appliances new forms of electrical manifestations, he proves that under new conditions new phenomena appear. Some of these phenomena are so strange that they appear unreal, unearthly. Light that is cold, white, harmless, flames that do not burn, innocent lightnings suggest the magical art, yet they are simply workshop experiments that may some day be household conveniences.

---

* Inventions, Researches and Writings of Nikola Tesla. Martin. New York: The Electrical Engineer.

The most striking application of his ideas to practical work upon a large scale is shown at Niagara. Here was designed to be the greatest utilization of natural power ever attempted. It was proposed to harness the power of the falls and to convey the power to a distance by means of electricity. Familiar plans and appliances were suggested. Mr. Tesla proposed new plans, new methods, and declared that new results could be obtained. His advice was taken and the actual utilization of the power of Niagara in the streets of Buffalo is to-day a monument to his prophetic insight. The most interesting single invention brought out by Mr. Tesla is, perhaps, his mechanical and electrical oscillator. This prime mover or motor is in line with modern science, because it seeks to reduce the steam-engine to the last simplicity, to reduce the number of its parts, to reduce its cost of construction and maintenance, and to increase its value as a prime mover used to produce electricity. It is a steam-engine joined to a dynamo, but free from all belts, gearing, or other mechanical transformer of power. It is direct acting, its own piston-rod bearing the armature of the dynamo. Its invention and application show its inventor to have combined the mind of a Watt and a Franklin with the highest skill of the steam-engine builder.

This most important invention is still the subject of study. Its perfected form may or may not be reached. It is potential of great things, because it has already opened a new field in electrical research, already suggested whole districts of work and study in which other able men are already busy.

Civilization is to-day based on power. The continued progress of the race demands cheap and abundant power. The very front and aspect of all our cities are being changed because cheap power has come into our streets. If people can be conveyed quickly and cheaply their houses will be farther apart, gardens and parks will grow, tenements will be deserted for cottages, flats for homes. Manufactures, commerce, governments, armies, and navies are everywhere seeking power. Human strength and labor and the labor of animals are daily freed from heavy toil because power can be conveyed by a wire. Power cheapens living and makes life easier. It is better than charity because it reduces the struggle for existence. The true helper of the race is the man of science who shows us how to produce and convey power cheaply. True science seeks to utilize power as found in nature for the benefit of humanity. All science is for the uplifting of men and women.

These simple statements are doubly interesting because they express Nikola Tesla's own thoughts upon science. He said much of this in other words in a notable speech at a banquet in Buffalo given to celebrate the conveyance of power from Niagara to Buffalo. Tesla is not alone a plodding workman. He is a dreamer of wise dreams, a poet, and a humanitarian, working with new tools for the benefit of all. He is a man who wonders at the folly of men who invent guns when they might invent tools. His spirit is naturally hopeful. He looks forward to new things, to improved science that shall work to uplift the common lot of man. He looks not so much at the world as at the universe. He finds power in the waterfall, and at the same time looks forward to a time when we may, perhaps, tap the unseen forces of the planets and use the cosmic energy that swings the stars in their courses. He looks to a time when power shall be so cheap, so universal, that all labor shall be done by tireless machines and every man's life be thus so much more worth living.

Born in Eastern Europe, it is interesting to observe that Tesla's speeches and writings are examples of clear and vigorous English. He can explain in the purest technical language his inventions to the understanding of men of science, and yet speak to plain folks in English that is simple, direct, and touched with a Shakespearian flavor, as if he had gone to the right source for his models. His first important paper was read before the American Institute of Electrical Engineers in New York in May, 1888. Since then he has spoken before learned bodies in England and in France

and several times in this country. Everywhere he has been received with the highest honors, everywhere listened to with profound attention. To show the spirit of the man we may quote two paragraphs from a lecture delivered before the Institution of Electrical Engineers, London, England, in February, 1892. They also happily illustrate the man's use of a language not his mother tongue. Speaking of Crookes and his experiments and writings, he says:

> When I was at college, a good while ago, I read in a translation (for then I was not familiar with your magnificent language), the description of his experiments on radiant matter. I read it only once in my life—that time—yet every detail about that charming work I can remember to this day. Few are the books, let me say, which can make such an impression upon the mind of a student.

In the same lecture he says:

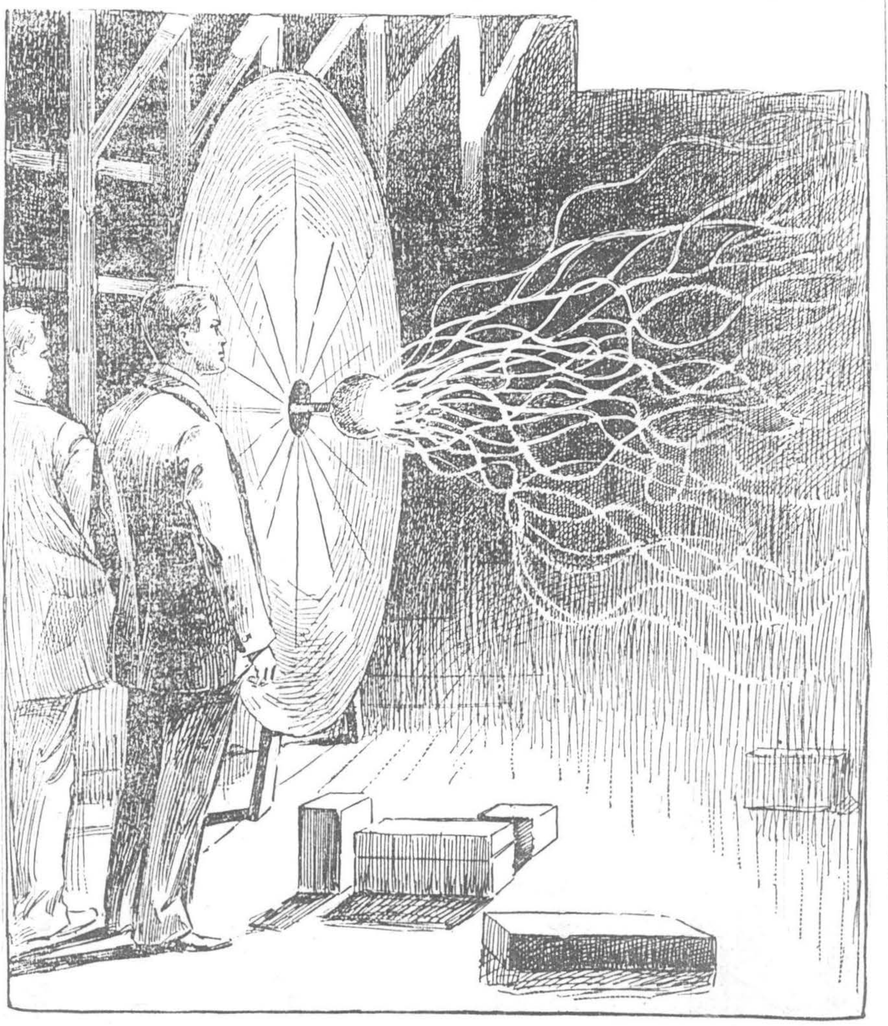
> We observe how the energy of an alternating current traversing the wire manifests itself—not so much on the wire as in the surrounding space—in the most surprising manner, taking the forms of heat, light, mechanical energy, and, most surprising of all, even chemical affinity. All these observations fascinate us, and fill us with an intense desire to know more of these phenomena. Each day we go to our work in the hope of discovering—in the hope that some one, no matter who, may find a solution of one of the great pending problems; and each succeeding day we return to our task with renewed ardor. And even if we are unsuccessful our work has not been in vain: in these efforts we have found hours of untold pleasure, and we have directed our energies to the benefit of mankind.

It is one of the essentials of modern scientific research and invention that there be uninterrupted seclusion. Mr. Tesla is at work. His workshop is therefore sacred to work, and few people have visited or can visit it. He is at work. It is enough for us to wait until the master workman comes forth in his own time and in his own way tells us what he is doing. It is enough that he is at work not alone for himself and for those who may buy and sell his inventions, but for "the benefit of mankind." He has been thought to be a dreamer, because no stream of practical, every-day, selling "notions" flows from his shop. Yet what he has done has modified much that is done in this special field of work. His position is that of a leader, an inspirer, the guide blazing a new path through the forest, leading toward undiscovered countries of knowledge. It is fortunate for us he is here in our own time and country, if for nothing more than the inspiration of his presence, the example for all our young people. He is at home now. He is an American in the best sense, working here because this is the grandest place in the world to do grand work. The roar of Broadway that jars the windows of his shop cannot disturb its calm, and yet this very nearness to the active life of a great city is of itself a help and inspiration to work. He is still a young man, of tireless energy and exhaustless patience. Wonders have already come from his hand and mind, greater things may yet be near. At present we can simply wait, knowing that such minds never labor long in vain.

Electrical Progress.

Tesla's Wireless Telegrams.

Experiments have been made attempting to prove the possibilities, but it has remained for Nikola Tesla to advance a theory, and experimentally prove it, that wireless communication is a possibility, and a by no means distant possibility. Indeed, after six years of careful and conscientious work, Mr. Tesla has arrived at a stage where some insight into the future is possible. He is averse to explaining all details of his invention, but allows it to be understood that he avails himself of what, for the present, may be termed the electrostatic equilibrium; that if this be disturbed at any point on the earth, the disturbance can with proper apparatus be distinguished at a distant point, and thus the means of signaling and reading signals becomes practicable once the required concrete instruments are available. Some years ago Mr. Tesla announced his belief in the possibilities, but he did so only after having satisfied himself by actual tests of apparatus designed by him. Much work had yet to be done, and he has since then given close attention and study to the problem.



Details are not yet available, and we now can merely chronicle Mr. Tesla's statement that he has really accomplished wireless communication over reasonably long distances with small expenditure of energy, and has only to perfect apparatus to go to any extent. Morse's forty-mile experiment in the old days was on a far less certain basis than the wireless possibilities of today.

Tesla's work with high frequency and high-potential currents has been notable. As long ago as 1891 he foretold the present results, both as to vacuum tube lighting and intercommunication without wires. The former had in his hands assumed a condition capable of a public demonstration of the phenomena of the electrostatic molecular forces. Numberless experiments were carried out, and from what then was a startling frequency of 10,000 per second, Mr. Tesla has advanced to what now is moderate work at 2,000,000 *oscillations per second.* Such almost inconceivable results are plainly out of all possible reach by any mechanical rotation of a commutator. And so long as efficiency of lighting is, as Mr. Tesla observes, dependent upon extremely high frequency, it would seem his efforts are in the one and only direction likely, in vacuum tube lighting, to lead to success. Success, according to Mr. Tesla, is already assured, but he will not come before the public until every detail of a practicable and commercial system is complete, and the day for such a consummation, he now states, is near at hand.—Electrical Review.

A Demonstration Made at Tesla's Laboratory Yesterday.

In his laboratory, in Houston street, Nicola Tesla gave a demonstration yesterday of his great discovery. A huge disc was hung on a frame. From the centre of the disc an electrode protruded. The demonstration was certainly weird. A crackling sound filled the room. Serpent-like flames shot from the electrode—not from pole to pole, but darting out until they vanished. Tesla said the electrical disturbance created was felt throughout the globe.

TESLA ELECTRIFIES THE WHOLE EARTH.

The Inventor Announces the Success of His Life-Long Dream.

MADE A DEMONSTRATION

Produces an Electrical Disturbance Which, He Says, Is Felt Everywhere.

A TREMENDOUS VOLTAGE.

Fiery Flames, Like Serpents, with Power to Kill, Spring from an Electrode.

WILL PUBLISH THE DISCOVERY.

Says His Facts Will Be Given to Science as Soon as His Data, Now Being Arranged, Is Completed.

Nicola Tesla announced yesterday the completion of his latest discovery—the simultaneous transmission of messages by means of the earth's electrical currents to as many scattered points on the surface of the globe as may be desired. This he regards as by far his greatest achievement. He will follow his usual custom and lay his information before the world of science in his own words and accompanied by his own computations and conclusions. To a few intimates he gave a thrilling demonstration of the operation of his device for arresting and subjecting to control under natural laws the electrical substances in and about the earth. His latest invention, device or discovery is to produce such a disturbance of the electricity of the earth which can be felt and noted simultaneously at all parts of the globe.

The Private Demonstration.

Tesla had his rooms in the laboratory on Houston street darkened. From a room adjoining the one in which he and his visitors stood a current was turned on invisibly. A huge black disk hung on a frame about eight feet in diameter, from the centre of which protruded a brass electrode seven inches in diameter. As the group gazed at this the apartment was filled with a crackling sound, which increased till it sounded like the rattle of musketry. Bright flames shot from the electrode, not from pole to pole, as in ordinary demonstrations. Like fiery serpents the wavy coils of flame darted in graceful lines around the disk. The longest sparks were fully eight feet from the point when they burst into dazzling brilliancy to the vanishing point. These electrical sparks were undoubtedly the longest flashes of light ever produced by similar means.

A Meteorological Display.

It seemed like a terrific lightning display, with the snapping, crackling sound, displacing the reverberation of heaven's artillery, and all remarked the weird and awing effect of the exhibition.

"What are you doing?" was asked Tesla.

"I am producing," said he, "an electrical disturbance of intense magnitude, which is continuing throughout the entire earth. In other words, I am producing a disturbance of the earth's charge of electricity which can be felt to the uttermost parts of the earth."

"And the result will be?"

"Ah," said Tesla, his face lighting up and his spare figure vibrant with pride and enthusiasm, "that is almost incomprehensible. This electrical disturbance by means of certain simple instruments can be felt and appreciated at any point of the globe. In this way messages can be sent the entire earth around and be taken up at any part of the earth without the aid or intervention of wires in any way at all."

Voltage Beyond Computation.

"What is the voltage?" Tesla was asked.

He motioned expressively with his long finger and said quickly, "As far as voltage is concerned, that is almost beyond computation. Yet, let me tell you, I stood in front of that flame and had that charge shot through me and experienced no unpleasant sensation. Dangerous? Yes, it is dangerous and I shall not repeat the experiment, for it exposes the blood to a terrific tension. If those tongues of living flame touched an artery and it burst, in an instant one would be bloodless and lifeless."

"Practically then if, say, Queen Victoria were to die, and these instruments for picking up and appreciating the vibrating ether were in place, a message could be sent simultaneously to every quarter of the British Empire, and all her subjects apprised of her demise?" inquired a spectator.

"Precisely. The shock transmitted from the sending point would be appreciable anywhere on earth. This is my greatest and latest discovery, which I intend to give to the scientific world as soon as my data, which is now virtually complete, is arranged."

The Brooklyn Eagle August 4, 1897

TESLA'S NEW DISCOVERY.

Claims to Be Able to Utilize Free Electrical Currents.

The New York Journal this morning prints the following:

Nicola Tesla announced yesterday the completion of his latest discovery—the simultaneous transmission of messages by means of the earth's electrical currents to as many scattered points on the surface of the globe as may be desired. This he regards as by far his greatest achievement. He will follow his usual custom and lay his information before the world of science in his own words and accompanied by his own computations and conclusions. To a few intimates he gave a thrilling demonstration of the operation of his device for arresting and subjecting to control under natural laws the electrical substances in and about the earth. His latest invention, device or discovery is to produce such a disturbance of the electricity of the earth which can be felt and noted simultaneously at all parts of the globe.

Tesla had his rooms in the laboratory on Houston street darkened. From a room adjoining the one in which he and his visitors stood a current was turned on invisibly. A huge black disk hung on a frame about eight feet in diameter, from the center of which protruded a brass electrode seven inches in diameter. As the group gazed at this the apartment was filled with a crackling sound, which increased till it sounded like the rattle of musketry. Bright flames shot from the electrode, not from pole to pole, as in ordinary demonstrations. Like fiery serpents the wavy coils of flame darted in graceful lines around the disk. The longest sparks were fully eight feet from the point when they burst into dazzling brilliancy to the vanishing point. These electrical sparks were undoubtedly the longest flashes of light ever produced by similar means.

It seemed like a terrific lightning display, with the snapping, crackling sound displacing the reverberation of heaven's artillery, and all remarked the weird and awing effect of the exhibition.

"What are you doing?" was asked Tesla.

"I am producing," said he, "an electrical disturbance of intense magnitude, which is continuing throughout the entire earth. In other words, I am producing a disturbance of the earth's charge of electricity which can be felt to the uttermost parts of the earth."

"And the result will be?"

"Ah," said Tesla, his face lighting up and his spare figure vibrant with pride and enthusiasm, "that is almost incomprehensible. This electrical disturbance by means of certain simple instruments can be felt and appreciated at any point of the globe. In this way messages can be sent the entire earth around and be taken up at any part of the earth without the aid or intervention of wires in any way at all."

"What is the voltage?" Tesla was asked.

He motioned expressively with his long finger and said quickly, "As far as voltage is concerned, that is almost beyond computation. Yet, let me tell you, I stood in front of that flame and had that charge shot through me and experienced no unpleasant sensation. Dangerous? Yes, it is dangerous and I shall not repeat the experiment, for it exposes the blood to a terrific tension. If those tongues of living flame touched an artery and it burst in an instant one would be bloodless and lifeless."

Practically, then, say, if Queen Victoria were to die, and these instruments for picking up and appreciating the vibration ether were in place, a message could be sent simultaneously to every quarter of the British Empire and all her subjects apprised of her demise?" inquired a spectator.

"Precisely. The shock transmitted from the sending point would be appreciable anywhere on earth. This is my greatest and latest discovery, which I intend to give to the scientific world as soon as possible."

TESLA DID NOT INDORSE IT.

Electrical Expert Says He Subscribed for No Stock in Mansione's Flying Machine.

Gaetano Mansione, "formerly of Naples, Italy," is calling the attention of his New York friends to "his recent invention of a flying machine, patent applied for." Mr. Mansione, it is announced, is ready to let a company put the new invention on the market, provided persons desiring to join the company will buy shares at $50 each, the par value of the shares being $500.

"Experts who have examined the plans," Mr. Mansione's circular explains, "pronounce the machine practicable and express their belief that Mr. Mansione has solved the problem of aerial navigation." To this bit of information is added the further statement that "the money subscribed for stock is to be used in building the machine for experimental purposes," and that "no payment is due until the corporation is effected."

It is set forth in the circular that Nicola Tesla, the electrical expert, "has subscribed for the first share of stock and indorses the machine." Mr. Tesla was much surprised when I showed him the circular containing this statement, and said:—

"Gaetano Mansione called on me some time ago and stated that he had invented a flying machine which, he thought, was to revolutionize everything before done in this direction. I believed him deserving enough to offer him small help, which he accepted, but I advised him to perfect his machine and to show it in working order to some people of means. That is all I know about it.

"If I ever would indorse any flying machine it would be one constructed by men like Langley or Maxim. It is unnecesary to say that most of the people who are working in this field have not the remotest idea of the difficulties to be overcome. I myself have spent many spare hours in the solution of the problem, and so far my chief result can be summed up in the statement that I have learned to appreciate the difficulties of it. I wish you would emphatically disconnect my name with any such scheme as the one you have just shown to me."

I was unable to find Mr. Mansione, to ask about the success of his efforts to form a flying machine company. His machine, I learned, consists of a balloon to keep the outfit above the earth and an apparatus to guide its flight through the air.

NIKOLA TESLA'S EXPERIMENTS.

Denies That He Announced Completion of His Wireless Telegraphy Tests.

Nikola Tesla this morning denied the report that he had announced the completion of his discovery of a method of telegraphy without wires. Occasional reports of the progress of the work had been published from time to time, he said. His experiments had been repeatedly shown in strict confidence to some of his personal friends, but the publication of them in any detail must have been a violation of confidence. As a matter of fact, no experiments were made at the laboratory yesterday. The inventor, however, was willing to give some account of his work up to the present time.

"In a lecture delivered about four years ago," he said, "before the National Electric Light Association in St. Louis—that was in March, 1893—I explained a certain scheme for producing electrical disturbances with the object of transmitting intelligible messages, and even power, from place to place without the use of any wires.

"The principle is this: An electrical oscillator is connected by one of its terminals to earth and another is led to an insulated object of considerable bulk. This object should preferably be at a great height where the air is less dense and transmits more easily the disturbance.

"Such an apparatus is then exactly what in mechanics would be a suction pump. Periodically it draws electricity out and forces it again into the earth, thereby altering rhythmically the electrostatic potential in the earth as well as in the air.

"This scheme I had, as a matter of fact, conceived many years before. But I had previously lacked the courage to present it to the scientific world. At the time of the St. Louis lecture I had already seen such results that I gathered courage enough to announce the project seriously.

"Shortly afterward, on my return to this city, I actually demonstrated by means of an improved apparatus that I was indeed able to create a disturbance in the manner described in the lecture.

"In my pleasure and excitement at this success I could not refrain from showing the first experiments to a few intimate friends. When later my laboratory burned down and the first instrument with which I had succeeded in my demonstration, and which I valued above any other, was destroyed, it was no small consolation to me that a few men whom I hold in high esteem had seen the first evidence of my success. They were my friends. Of course, all the experiments that I have made to this day have been shown only in confidence and with the express understanding that no popular publication should be made of them until I had acquainted the scientific world with my results.

"It appeared several years ago that the result I aimed at would be very difficult, if not impossible, to attain. The method, nevertheless, as I have outlined it, is simple, involving merely the use of a properly constructed oscillator connected with the ground and with an elevated object; also a sensitive and properly adjusted receiver at a distance, similarly connected with the ground and with an object at a considerable height. For the purposes of this receiver I consider a balloon most suitable.

"These disturbances with which I am experimenting are produced by methods and devices which I have been perfecting more recently, and from present results I do not consider it at all impracticable to obtain, if such were desired, electric sparks a mile in length. They could be readily secured by apparatus designed on these novel lines. I now obtain sparks as long as eight feet, and can produce local disturbances. What I affirm is that the disturbances in this city may be made perceptible in London or throughout the world.

"The voltage is very high, beyond computation. For a wild guess I should place the voltage at 50,000,000. I have stood in the course of the sparks, but I consider them dangerous.

"Scientific results are what I have been chiefly interested in. But there are many possibilities of turning the methods to practical use. For instance, if I wished to make a fortune I should have only to take out patents on methods for exploding torpedoes or powder magazines at a distance by means of electrical disturbances produced in this manner. But to dispel popular and erroneous opinions on this point it is appropriate to say that whereas it is perfectly possible to ignite an explosive by a suitably arranged apparatus at a distance, yet this fact will not revolutionize warfare. The enemy could avail himself of similar methods with like results."

TESLA ELECTRIFIES THE EARTH.

According to the New York "Journal," of August 4, Mr. Tesla announces the completion of his work for the transmission of messages from one point to another on the earth, without the aid of wires. To give an idea of the high potential currents used in this work, he showed a large disc, from the center of which protruded a spherical electrode shooting forth long streams of ethereal flame. Mr. Tesla stated that the electrical disturbance thus created was felt throughout the globe. The article is graphically illustrated with a large picture of the contrivance for emitting the discharge.

The New York Herald August 5, 1897

TESLA BUILDS A MARVEL OF FORCE

His Oscillator, He Declares, Will Transmit Without Wires Power Thousands of Miles.

MANY MILLIONS OF VOLTS.

He Says the Electrical Disturbance Caused by the Machine Will Be Felt All Over the Globe.

A ROARING, SILVER FLAME,

Nikola Tesla announced four years ago that he had discovered a plan for transmitting intelligible signals and power to great distances without wires, but his assertion was received with scepticism, notwithstanding he described the principles of his discovery in lectures before the Franklin Institute, in Philadelphia, and before the National Electric Light Association, in St. Louis.

Mr. Tesla, not discouraged, pursued his investigations, and now declares his discovery is capable of producing an electrical disturbance strong enough to be felt all over the earth. He says his discovery will not only make it possible to send messages, but also to transmit power without wires by means of an immense electrical tension, measuring many million volts.

GIVES FORTH A ROARING, WHITE FLAME.

Mr. Tesla recently has given several demonstrations of his discovery. I saw the apparatus in his laboratory yesterday. It resembles a spider web of wires fastened to a black disk ten feet in diameter. The wires coine together in the centre, where there is a brass ball six inches in diameter. The machine, which its inventor calls an oscillator, is fastened to a wooden screen. Mr. Tesla allowed me to see the oscillator from a distance, but refused to give any technical description of it.

The wires are all arranged with perfect exactness, not varying a hair's breadth from the right position. When the machine is in action a roaring flame, resembling a stream of molten silver, breaks from the brass ball and shoots into the air for eight or ten feet. The noise made by the crackling flame is deafening. Power to operate the apparatus is obtained from an ordinary electric current.

According to Mr. Tesla's theory, the earth and air being charged with electricity, his apparatus operates on the earth as would pumping air into a rubber bag. The disturbance from the machine is felt instantly all over the globe.

NO LIMIT TO ITS POWER.

This electrical disturbance travels on the alternating currents with which the earth and air are charged at the rate of several million miles a second. The inventor's idea is to take up the vibrations from his apparatus with a delicate instrument that makes them perceptible and intelligible in several ways.

Mr. Tesla told me that these vibrations could not be directed to any given place, but must radiate to every quarter of the globe. To send messages of a private nature, a code must be used. He said a machine built on a large scale would transmit great power through the upper strata of the air.

Mr. Tesla said this power could be transmitted, theoretically, to any distance. His invention, described in his own language, might be compared to a pump which forces electricity in and out of the earth, producing a violent disturbance.

TESLA HAS FIRED THE SPARK FLASHED ROUND THE WORLD

The Wizard of Science Says He Has Enslaved Earth's Mightiest Force for the Use of Man.

Most Marvellous Method of Transmitting Power Universally by Means of Electric Vibration.

By Julius Chambers.

THIS is the Electric age.

Nicola Tesla has completed the device or machine by which he expects to project electrical vibratory impulses to the most distant part of the world. He will do this by battery, and harnessing a force that no human ingenuity could create. He will cause the earth to vibrate in certain keys for definite utilities.

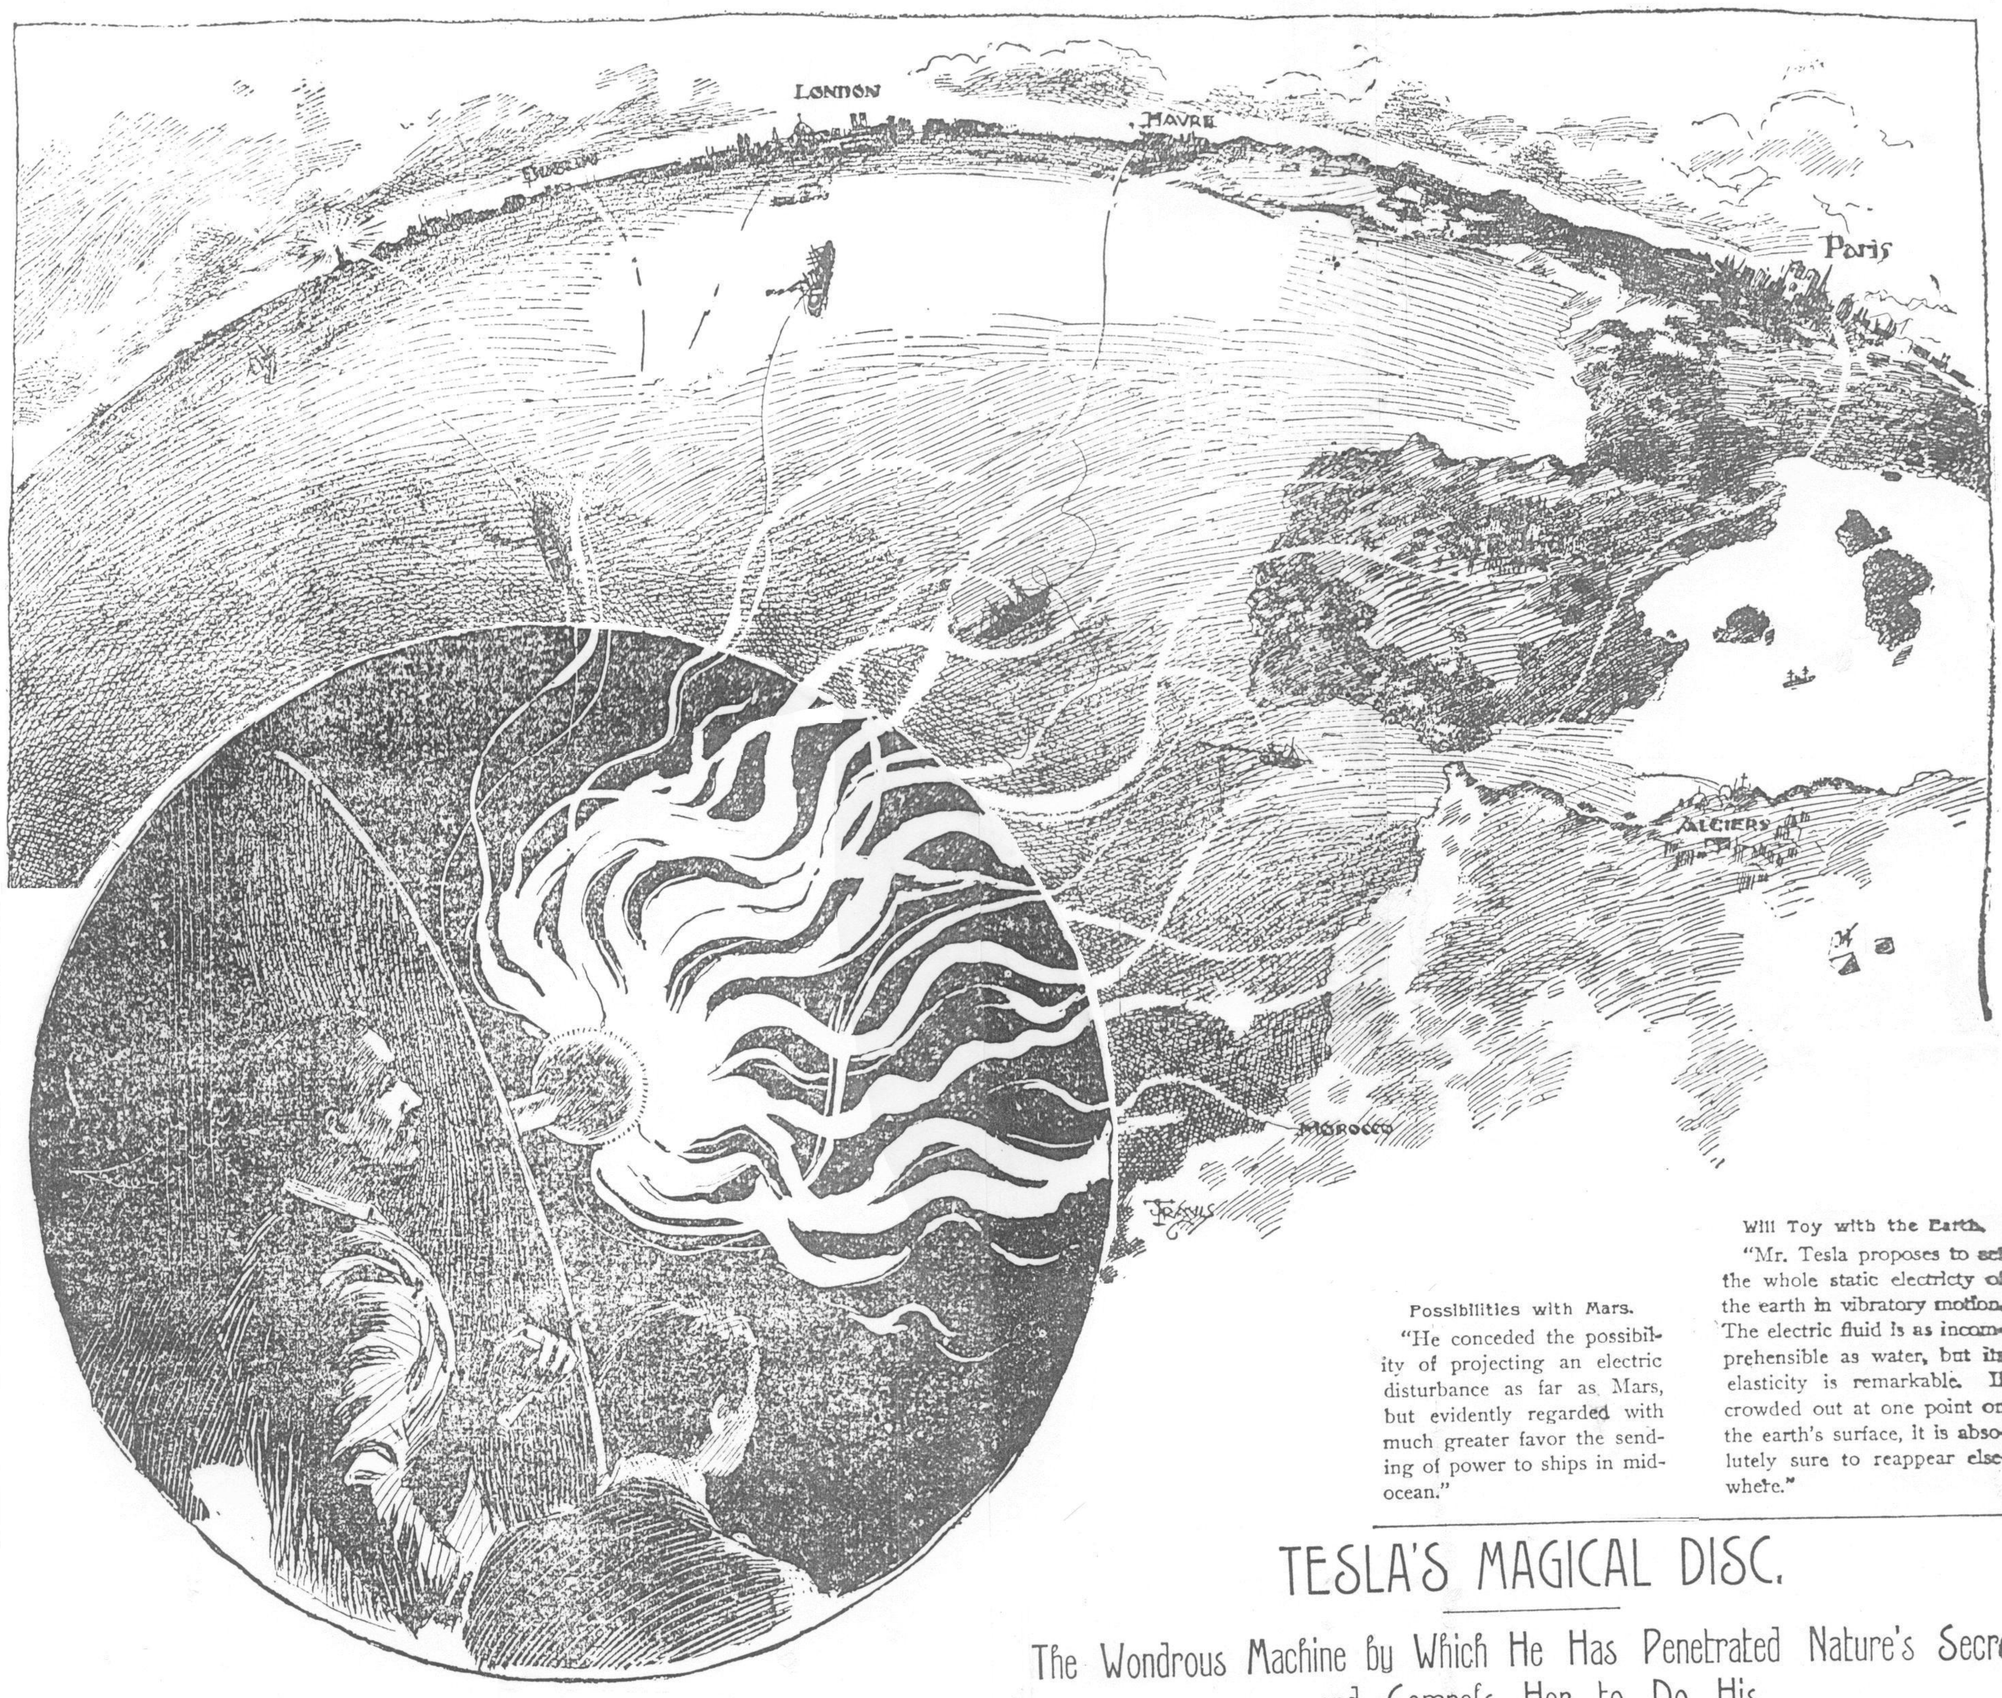
Tesla declares that he is misunderstood by those who think that he is seeking merely to transmit intelligence from one part of the globe to another without wires. Telegraphy is a small factor in his marvellous problem. He aims at the transmission of power—power that will produce mechanical effects, such as the propulsion of ships and the operating of mills. This is a utilitarian era, and nobody recognizes that fact more clearly than this remarkable young wizard of science.

"The Journal's description of my completed invention was quite accurate," said Mr. Tesla, as we stood together in his wondershop on Houston street. "I have gone far enough to assure myself and to convince others that my theory regarding the transmission of electric vibration, for whatever purpose it may be utilized, is practicable."

"How do you expect to recognize the vibrations at a point distant from the place of original projection?" I asked.

"That is a mere detail," exclaimed the inventor, his whole body vibrant with enthusiasm. "Instruments pitched in the proper key will promptly indicate the presence of the electric wave. Vibrationsof of different intensities will be taken up by these delicate appliances at different places. If the instruments at Paris, for example, are caused to operate, it will be because the vibratory current is pitched in the key to which they are set. If the wave passes over London and Paris and be recognized at Berlin or Moscow, it will be because the vibratory wave was originally projected with a view to recognition only by the mechanism located at one or other of those places. You see how simple that is?"

"And you feel confident of complete ultimate success?" was asked.



"I believe that with the machine now completed I can disturb the electrical conditions of the earth," was the prompt rejoinder. "That I shall be able to transmit thought or information I am convinced; and I hope with equal assurance to supply power to distant localities on this earth, without the medium of wires."

"Give me an example."

"At Niagara it may be possible to generate electrical energy that can be used to drive mills in New England, railroad trains across the prairies and steamships across the sea."

The tall, spare figure of the young scientist seemed to grow in stature. His wonderful eyes gave much character to his pale face as he talked of forging nature's own thunderbolts into human thought and harnessing earth's own forces to do new and incredible service for mankind.

It is impossible not to be filled with admiration for genius. This idea of overpowering

TESLA'S EXTRAORDINARY PREDICTION.

"I believe that with the machine now completed I can disturb the electrical conditions of the earth," was the prompt rejoinder. "That I shall be able to transmit thought or information I am convinced; and I hope with equal assurance to supply power to distant localities on this earth, without the medium of wires.

"At Niagara it may be possible to generate electrical energy that can be used to drive mills in New England, railroad trains across the prairies and steamships across the sea!"

ble!" Bulwer in "The Coming Race" had Tesla in mental contemplation. Although the engineer was not born, Tesla is the hero of that remarkable novel. The people that Bulwer described drew light, power and human emotions from electricity.

After a half hour with Mr. Tesla any man who is suddenly asked to define electricity must answer:

Vibration.

And what is that? will naturally follow.

Vibration is life itself.

The inventor was in a sanguine mood, but did not go to the length of predicting immediate results of great scientific value. He conceded the possibility of projecting an electric disturbance as far as Mars, but evidently regarded with much greater favor the sending of power to ships in mid-ocean. John W Keely taught the world, in his clumsy way, twenty years ago, that vibrations develop mechanical energy; but Tesla, from accurately human data, has reasoned out the problem of starting on this earth's surface electric waves that will break upon the shores of other worlds. He says it can be done!

By disturbing the static conditions on this earth he also hopes to render possible the sending of messages of hope and encouragement to future Nansens and Andrees. By a series of stupendous etheric vibrations the French in communicated with from New York or Washington.

Light, we know, is transmitted on vibratory waves. The planets only shine by reflected light from the sun; in other words, the light must first travel to Mars or Jupiter, and thence back to us. In Tesla's opinion it is beyond all human possibility to construct a lamp strong enough to be seen on Mars; but the earth is a storehouse of energy that can be drawn on to any extent—making it easy to send electrical currents to any point without wires. He explained the theory upon which his device for telegraphing over the whole earth in the following simple simile:

"Suppose the earth to resemble a hollow rubber ball, filled with water," began Mr. Tesla. "At one place I have a tube, with a plunger, attached to the surface of this ball. If I press upon the plunger the water in the tube will be driven into the ball and every part will be expanded. If I withdraw the plunger the water follows it and every part of the ball will contract. Now, if I pierce the surface of that ball in several places and set up tubes and plungers at each place, these plungers will vibrate up and down in response to every movement that I may produce in the plunger of the first tube. An agitation in the centre of the ball, a series of vibrations in the whole body would occur. If I could then set the plunger in one of the tubes to vibrating in consonance with the vibrations I could burst the whole thing asunder."

In a non-technical way this indicates how Mr. Tesla proposes to set the whole static electricity of the earth in vibratory motion. The electric fluid is as incompressible as water, but its elasticity is remarkable. If crowded out at one point on the earth's surface it is absolutely sure to reappear elsewhere.

"What I have set out to do, I believe I have accomplished," said Mr. Tesla. "I spoke of my hopes when I addressed the Franklin Institute, of Philadelphia, in 1893, but I did not expect to see the end so near at so early a day. Just how far I can send these electric waves I know not. Accurate and very sensitive instruments will be required to demonstrate that point of the work. But when the proper vibratory impulse is met the response will be instantaneous."

Thus calmly does Mr. Tesla discourse regarding his plan to convert the Atlantic Ocean ferry into a trolley line! He declined to exhibit the machine to me, but he gave the following description:

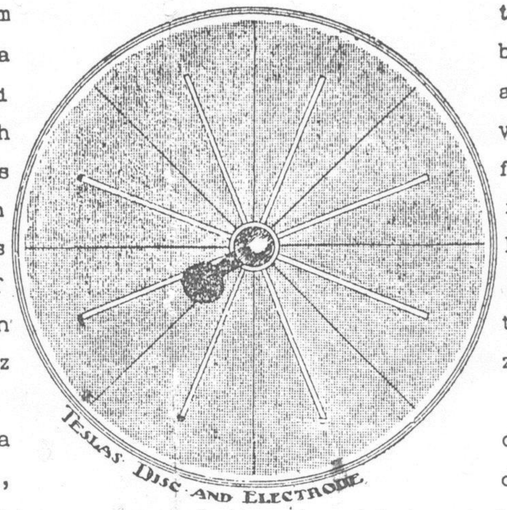
In a large darkened room is hung a black disk about eight feet across, and from the centre of this disk protrudes a brass electrode seven inches in diameter. When the current of high voltage is turned on the apartment is filled with crackling sounds, soon increasing into a succession of crashes. Bright and forked streaks of flame shoot eight feet toward the centre of the room, bursting into dazzling sparks at the vanishing point.

The spectacle, as described in the Journal, is appalling—weird, unnatural, dreadful. But Tesla says it is the

Possibilities with Mars.

"He conceded the possibility of projecting an electric disturbance as far as Mars, but evidently regarded with much greater favor the sending of power to ships in mid-ocean."

Will Toy with the Earth.



"Mr. Tesla proposes to set the whole static electricty of the earth in vibratory motion. The electric fluid is as incomprehensible as water, but its elasticity is remarkable. If crowded out at one point on the earth's surface, it is absolutely sure to reappear elsewhere."

TESLA'S MAGICAL DISC.

The Wondrous Machine by Which He Has Penetrated Nature's Secrets and Compels Her to Do His Bidding.

"He declined to exhibit the machine to me, but gave the following description:

"'In a darkened room is hung a black disk about eight fee across, and from the centre of thi disk protrudes a brass electrod seven inches in di ameter. When th current of high voltage is turne on the apartment is filled with crack ling sounds, soon increasing into succession of cras hes. Bright an forked streaks of flames shoot eigh feet toward the cen tre of the room bursting into daz zling sparks at th vaneshing point.'

"The Specta cle is appalling- wierd, unnatural, dreadful. But Tesl says it is the motive power and the thought transmitter of the nea future."

Tesla is quietly pursuing his fruitful labors, and, devoted as he is to the cause of science, remains undisturbed by journalistic sensationalism and consequent criticism of the uninformed. In this issue he again makes a particularly valuable and practical contribution to the important field which Lenard and Roentgen have opened up.

TESLA ON THE SOURCE OF ROENTGEN RAYS AND THE PRACTICAL CONSTRUCTION AND SAFE OPERATION OF LENARD TUBES.

To the Editor of Electrical Review:

I have for some time felt that a few indications in regard to the practical construction of Lenard tubes of improved designs, a great number of which I have recently exhibited before the New York Academy of Sciences (April 6, 1897), would be useful and timely, particularly as by their proper construction and use much of the danger attending the experimentation with the rays may be avoided. The simple precautions which I have suggested in my previous communications to your esteemed journal are seemingly disregarded, and cases of injury to patients are being almost daily reported, and in view of this only, were it for no other reason, the following lines, referring to this subject, would have been written before had not again pressing and unavoidable duties prevented me from doing so. A short and, I may say, most unwelcome interruption of the work which has been claiming my attention makes this now possible. However, as these opportunities are scarce, I will utilize the present to dwell in a few words on some other matters in connection with this subject, and particularly on a result of importance which I have reached some time ago by the aid of such a Lenard tube, and which, if I am correctly informed, I can only in part consider as my own, since it seems that practically it has been expressed in other words by Professor Roentgen in a recent communication to the Academy of Sciences of Berlin. The result alluded to has reference to the much disputed question of the source of the Roentgen rays. As will be remembered, in the first announcement of his discovery, Roentgen was of the opinion that the rays which affected the sensitive layer emanated from the fluorescent spot on the glass wall of the bulb; other scientific men next made the cathode responsible; still others the anode, while some thought that the rays were emitted solely from fluorescent powders or surfaces, and speculations, mostly unfounded, increased to such an extent that, despairingly, one would exclaim with the poet:

"O gluecklich wer noch hoffen kann,
Aus diesem Meer des Irrtums aufzutauchen!"

My own experiments led me to recognize that, regardless of the location, the chief source of these rays was the place of the *first* impact of the projected stream of particles within the bulb. This was merely a broad statement, of which that of Professor Roentgen was a special case, as in his first experiments the fluorescent spot on the glass wall was, incidentally, the place of the first impact of the cathodic stream. Investigations carried on up to the present day have only confirmed the correctness of the above opinion, and the place of the first collision of the stream of particles —be it an anode or independent impact body, the glass wall or an aluminum window—is still found to be the principal source of the rays. But, as will be seen presently, it is not the only source.

Since recording the above fact my efforts were directed to finding answers to the following questions: First, is it necessary that the impact body should be within the tube? Second, is it required that the obstacle in the path of the cathodic stream should be a solid or liquid? And, third, to what extent is the velocity of the stream necessary for the generation of and influence upon the character of the rays emitted?

In order to ascertain whether a body located outside of the tube and in the

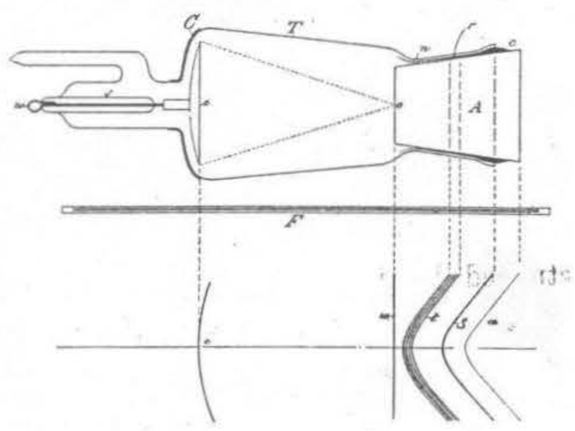

Fig. 1.—Illustrating an Experiment Revealing the Real Source of the Roentgen Rays.

path or in the direction of the stream of particles was capable of producing the same peculiar phenomena as an object located inside, it appeared necessary to first show that there is an actual penetration of the particles through the wall, or otherwise that the actions of the supposed streams, of whatever nature they might be, were sufficiently pronounced in the outer region close to the wall of the bulb as to produce some of the effects which are peculiar to a cathodic stream. It was not difficult to obtain with a properly prepared Lenard tube, having an exceedingly thin window, many and at first surprising evidences of this character. Some of these have already been pointed out, and it is thought sufficient to cite here one more which I have since observed. In the hollow aluminum cap A of a tube as shown in diagram Fig. 1, which will be described in detail, I placed a half-dollar silver piece, supporting it at a small distance from and parallel to the window or bottom of the cap by strips of mica in such a manner that it was not

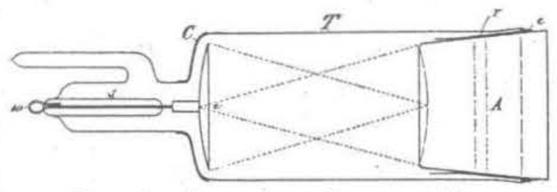

Fig. 2.—Improved Lenard Tube.

touching the metal of the tube, an air space being left all around it. Upon exciting the bulb for about 30 to 45 seconds by the secondary discharge of a powerful coil of a novel type now well known, it was found that the silver piece was rendered so hot as to actually scorch the hand; yet the aluminum window, which offered a very insignificant obstacle to the cathodic stream, was only moderately warmed. Thus it was shown that the silver alloy, owing to its density and thickness, took up most of the energy of the impact, being acted upon by the particles almost identically as if it had been inside of the bulb, and, what is more, indications were obtained, by observing the shadows, that it behaved like a second source of the rays, inasmuch as the outlines of the shadows, instead of being sharp and clear as when the half-dollar piece was removed, were dimmed. It was immaterial for the chief object of the inquiry to decide by more exact methods whether the cathodic particles actually penetrated the window, or whether a new and separate stream was projected from the outer side of the window. In my mind there exists not the least doubt that the former was the case, as in this respect I have been able to obtain numerous additional proofs, upon which I may dwell in the near future.

I next endeavored to ascertain whether it was necessary that the obstacle outside was, as in this case, a solid body, or a liquid, or broadly, a body of measurable dimensions, and it was in investigating in this direction that I came upon the important result to which I referred in the introductory statements of this communication. I namely observed rather accidentally, although I was following up a systematic inquiry, what is illustrated in diagram Fig. 1. The diagram shows a Lenard tube of

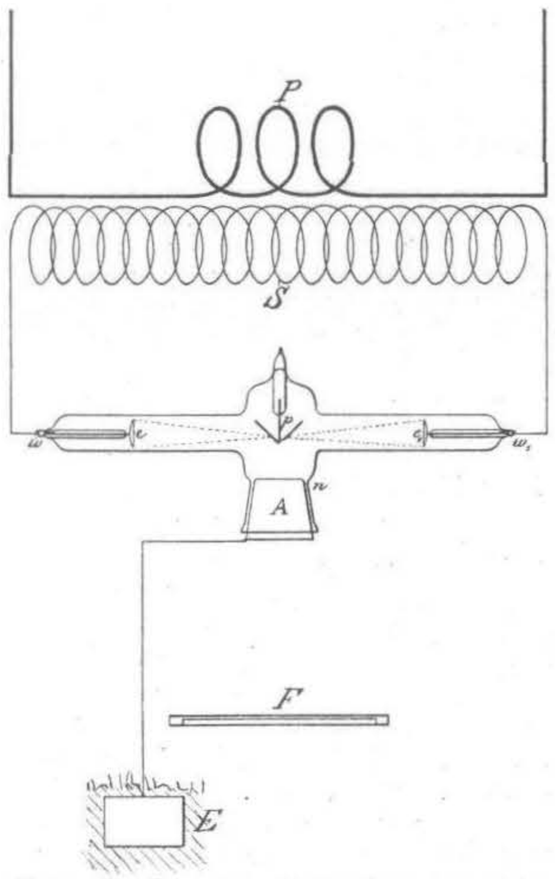

Fig. 3.—Illustrating Arrangement with Improved Double-Focus Tube for Reducing the Injurious Actions.

improved design, consisting of a tube T of thick glass tapering towards the open end, or neck *n*, into which is fitted an aluminum cap A, and a spherical cathode *e*, supported on a glass stem *s*, and platinum wire *w* sealed in the opposite end of the tube as usual. The aluminum cap A, as will be observed, is not in actual contact with the ground-glass wall, being held at a small distance from the latter by a narrow and continuous ring of tinfoil *r*. The outer space between the glass and the cap A is filled with cement *c*, in a manner which I shall later describe. F is a Roentgen screen such as is ordinarily used in making the observations.

Now, in looking upon the screen in the direction from F to T, the dark lines indicated on the lower part of the diagram were seen on the illuminated background. The curved line *e* and the straight line W were, of course, at once recognized as the outlines of the cathode *e* and the bottom of the cap A respectively, although, in consequence of a confusing optical illusion, they appeared much closer together than they actually were. For instance, if the distance between *e* and *o* was five inches, these lines would appear on the screen about two inches apart, as nearly as I could judge by the eye. This illusion may be easily explained and is quite unimportant, except that it might be of some moment to physicians to keep this fact in mind when making examinations with the screen as, owing to the above effect, which is sometimes exaggerated to a degree hard to believe, a completely erroneous idea of the distance of the various parts of the object under examination might be gained, to the detriment of the surgical operation. But while the lines *e* and W were easily accounted for, the curved lines *t*, *g*, *a* were at first puzzling. Soon, however, it was ascertained that the faint line *a* was the shadow of the edge of the aluminum cap, the much darker line *g* that of the rim of the glass tube T, and *t* the shadow of the tinfoil ring *r*. These shadows on the screen F clearly showed that the agency which affected the fluorescent material was proceeding from the space outside of the bulb towards the aluminum cap, and chiefly from the region through which the primary disturbances or streams emitted from the tube through the window were passing, which observation could not be explained in a more plausible manner than by assuming that the air and dust particles outside, in the path of the projected streams, afforded an obstacle to their passage and gave rise to impacts and collisions spreading through the air in all directions, thus producing continuously new sources of the rays. It is this fact which, in his recent communication before mentioned, Roentgen has brought out. So, at least, I have interpreted his reported statement that the rays emanate from the irradiated air. It now remains to be shown whether the air, from which carefully all foreign particles are removed, is capable of behaving as an impact body and source of the rays, in order to decide whether the generation of the latter is dependent on the presence in

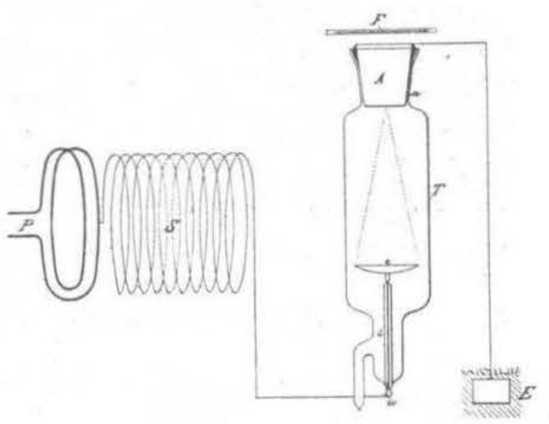

Fig. 4.—Illustrating Arrangement with a Lenard Tube for Safe Working at Close Range.

the air of impact particles of measurable dimensions. I have reasons to think so.

With the knowledge of this fact we are now able to form a more general

(Concluded on page 71.)

TESLA ON ROENTGEN RAYS.

(Concluded from page 67.)

idea of the process of generation of the radiations which have been discovered by Lenard and Roentgen. It may be comprised in the statement that the streams of minute material particles projected from an electrode with great velocity in encountering obstacles wherever they may be, within the bulb, in the air or other medium or in the sensitive layers themselves, give rise to rays or radiations possessing many of the properties of those known as light. If this physical process of generation of these rays is undoubtedly demonstrated as true, it will have most important consequences, as it will induce physicists to again critically examine many phenomena which are presently attributed to transverse ether waves, which may lead to a radical modification of existing views and theories in regard to these phenomena, if not as to their essence so, at least, as to the mode of their production.

My effort to arrive at an answer to the third of the above questions led me to the establishment, by actual photographs, of the close relationship which exists between the Lenard and Roentgen rays. The photographs bearing on this point were exhibited at a meeting of the New York Academy of Sciences—before referred to—April 6, 1897, but, unfortunately, owing to the shortness of my address, and concentration of thought on other matters, I omitted what was most important; namely, to describe the manner in which these photographs were obtained, an oversight which I was able to only partially repair the day following. I did, however, on that occasion illustrate and describe experiments, in which was shown the deflectibility of the Roentgen rays by a magnet, which establishes a still closer relationship, if not identity, of the rays named after these two discoverers. But the description of these experiments in detail, as well as of other investigations and results in harmony with and restricted to the subject I brought before that scientific body, will appear in a longer communication which I am slowly preparing.

To bring out clearly the significance of the photographs in question, I would recall that, in some of my previous contributions to scientific societies, I have endeavored to dispel a popular opinion before existing that the phenomena known as those of Crookes were dependent on and indicative of high vacua. With this object in view, I showed that phosphorescence and most of the phenomena in Crookes bulbs were producible at greater pressures of the gases in the bulbs by the use of much higher or more sudden electro-motive impulses. Having this well demonstrated fact before me, I prepared a tube in the manner described by Lenard in his first classical communication on this subject. The tube was exhausted to a moderate degree, either by chance or of necessity, and it was found that, when operated by an ordinary high-tension coil of a low rate of change in the current, no rays of any of the two kinds could be detected, even when the tube was so highly strained as to become very hot in a few moments. Now, I expected that, if the suddenness of the impulses through the bulb were sufficiently increased, rays would be emitted. To test this I employed a coil of a type which I have repeatedly described, in which the primary is operated by the discharges of a condenser. With such an instrument any desired suddenness of the impulses may be secured, there being practically no limit in this respect, as the energy accumulated in the condenser is the most violently explosive agent we know, and any potential or electrical pressure is obtainable. Indeed, I found that in increasing the suddenness of the electro-motive impulses through the tube—without, however, increasing, but rather diminishing the total energy conveyed to it—phosphorescence was observed and rays began to appear, first the feebler Lenard rays and later, by pushing the suddenness far enough, Roentgen rays of great intensity, which enabled me to obtain photographs showing the finest texture of the bones. Still, the same tube, when again operated with the ordinary coil of a low rate of change in the primary current, emitted practically no rays, even when, as before stated, much more energy, as judged from the heating, was passed through it. This experience, together with the fact that I have succeeded in producing by the use of immense electrical pressures, obtainable with certain apparatus designed for this express purpose, some impressions in free air, have led me to the conclusion that in lightning discharges Lenard and Roentgen rays must be generated at ordinary atmospheric pressure.

At this juncture I realize, by a perusal of the preceding lines, that my scientific interest has dominated the practical, and that the following remarks must be devoted to the primary object of this communication—that is, to giving some data for the construction to those engaged in the manufacture of the tubes and, perhaps, a few useful hints to practicing physicians who are dependent on such information. The foregoing was, nevertheless, not lost for this object, inasmuch as it has shown how much the result obtained depends on the proper construction of the instruments, for, with ordinary implements, most of the above observations could not have been made.

I have already described the form of tube illustrated in Fig. 1, and in Fig. 2 another still further improved design is shown. In this case the aluminum cap A, instead of having a straight bottom as before, is shaped spherically, the center of the sphere coinciding with that of the electrode *e*, which itself, as in Fig. 1, has its focus in the center of the window of cap A, as indicated by the dotted lines. The aluminum cap A has a tinfoil ring *r*, as that in Fig. 1, or else the metal of the cap is spun out on that place so as to afford a bearing of small surface between the metal and the glass. This is an important practical detail as, by making the bearing surface small, the pressure per unit of area is increased and a more perfect joint made. The ring *r* should be first spun out and then ground to fit the neck of the bulb. If a tinfoil ring is used instead, it may be cut out of one of the ordinary tinfoil caps obtainable in the market, care being taken that the ring is very smooth.

In Fig. 3 I have shown a modified design of tube which, as the two types before described, was comprised in the collection I exhibited. This, as will be observed, is a double-focus tube, with impact plates of iridium alloy and an aluminum cap A opposite the same. The tube is not shown because of any originality in design, but simply to illustrate a practical feature. It will be noted that the aluminum caps in the tubes described are fitted inside of the necks and not outside, as is frequently done. Long experience has demonstrated that it is practically impossible to maintain a high vacuum in a tube with an outside cap. The only way I have been able to do this in a fair measure is by cooling the cap by a jet of air, for instance, and observing the following precautions: The air jet is first turned on slightly and upon this the tube is excited. The current through the latter, and also the air pressure, are then gradually increased and brought to the normal working condition. Upon completing the experiment the air pressure and current through the tube are both gradually reduced and both so manipulated that no great differences in temperature result between the glass and aluminum cap. If these precautions are not observed the vacuum will be immediately impaired in consequence of the uneven expansion of the glass and metal.

With tubes, as these presently described, it is quite unnecessary to observe this precaution if proper care is taken in their preparation. In inserting the cap the latter is cooled down as low as it is deemed advisable without endangering the glass, and it is then gently pushed in the neck of the tube, taking care that it sets straight.

The two most important operations in the manufacture of such a tube are, however, the thinning down of the aluminum window and the sealing in of the cap. The metal of the latter may be one thirty-second or even one-sixteenth of an inch thick, and in such case the central portion may be thinned down by a countersink tool about one-fourth of an inch in diameter as far as it is possible without tearing the sheet. The further thinning down may then be done by hand with a scraping tool; and, finally, the metal should be gently beaten down so as to surely close the pores which might permit a slow leak. Instead of proceeding in this way I have employed a cap with a hole in the center, which I have closed with a sheet of pure aluminum a few thousandths of an inch thick, riveted to the cap by means of a washer of thick metal, but the results were not quite as satisfactory.

In sealing the cap I have adopted the following procedure: The tube is fastened on the pump in the proper position and exhausted until a permanent condition is reached. The degree of exhaustion is a measure of perfection of the joint. The leak is usually considerable, but this is not so serious a defect as might be thought. Heat is now gradually applied to the tube by means of a gas stove until a temperature up to about the boiling point of sealing wax is reached. The space between the cap and the glass is then filled with sealing wax of good quality; and, when the latter begins to boil, the temperature is reduced to allow its settling in the cavity. The heat is then again increased, and this process of heating and cooling is repeated several times until the entire cavity, upon reduction of the temperature, is found to be filled uniformly with the wax, all bubbles having disappeared. A little more wax is then put on the top and the exhaustion carried on for an hour or so, according to the capacity of the pump, by application of moderate heat much below the melting point of the wax.

A tube prepared in this manner will maintain the vacuum very well, and will last indefinitely. If not used for a few months, it may gradually lose the high vacuum, but it can be quickly worked up. However, if after long use it becomes necessary to clean the tube, this is easily done by gently warming it and taking off the cap. The cleaning may be done first with acid, then with highly diluted alkali, next with distilled water, and finally with pure rectified alcohol.

These tubes, when properly prepared, give impressions much sharper and reveal much more detail than those of ordinary make. It is important for the clearness of the impressions that the electrode should be properly shaped, and that the focus should be exactly in the center of the cap or slightly inside. In fitting in the cap, the distance from the electrode should be measured as exactly as possible. It should also be remarked that the thinner the window, the sharper are the impressions, but it is not advisable to make it too thin, as it is apt to melt in a point on turning on the current.

The above advantages are not the only ones which these tubes offer. They are also better adapted for purposes of examination by surgeons, particularly if used in the peculiar manner illustrated in diagrams Fig. 3 and Fig. 4, which are self-explanatory. It will be seen that in each of these the cap is connected to the ground. This decidedly diminishes the injurious action and enables also to take impressions with very short exposures of a few seconds only at close range, inasmuch as, during the operation of the bulb, one can easily touch the cap without any inconvenience, owing to the ground connection. The arrangement shown in Fig. 4 is particularly advantageous with a form of single terminal, which coil I have described on other occasions and which is diagramatically illustrated, P being the primary and S the secondary. In this instance the high-potential terminal is connected to the electrode, while the cap is grounded. The tube may be placed in the position indicated in the drawing, under the operating table and quite close, or even in contact with the body of the patient, if the impression requires only a few seconds as, for instance, in examining parts of the members. I have taken many impressions with such tubes and have observed no injurious action, but I would advise not to expose for longer than two or three minutes at very short distances. In this respect the experimenter should bear in mind what I have stated in previous communications. At all events it is certain that, in proceeding in the manner described, additional safety is obtained and the process of taking impressions much quickened. To cool the cap, a jet of air may be used, as before stated, or else a small quantity of water may be poured in the cap each time when an impression is taken. The water only slightly impairs the action of the tube, while it maintains the window at a safe temperature. I may add that the tubes are improved by providing back of the electrode a metallic coating C, shown in Fig. 3 and Fig. 4.

NIKOLA TESLA.

New York, August 9.

A NEW FORM OF INDUCTION COIL.

READ AT THE FOURTEENTH GENERAL MEETING OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS, ELIOT, ME., JULY 26–28, 1897, BY PROF. ELIHU THOMSON.

The induction coil presently to be described, it is believed, constitutes a new type employing the principle of a "substitute primary" or "secondary primary," which principle has been applied by me in a variety of ways.

The prime object of this coil is to permit the direct connection to circuits of considerable potential for obtaining energy for the production of high-potential discharges, like those of a Ruhmkorff coil for working Roentgen-ray vacuum tubes, and for such like purposes. The object, also, was to avoid the employment of banks of lamps or storage batteries, and to limit the energy consumed to only that amount required to work the coil itself. Furthermore, no larger condensers than those ordinarily used with an induction coil of equal capacity are needed, and no air-blast, while the coil as a whole is still available as an ordinary Ruhmkorff without change in its structure or connections.

To illustrate the principle, reference is made to Fig. 1, where *p n* represent connections to mains at, say, 110 volts difference of potential; I I is an iron wire core around which are wound two coils, one over the other, either of which may, of course, be the primary. The inner coil P in the figure is made the primary, and is wound with many turns of comparatively fine wire. For 110 volts it may have some thousands of turns and be wound with a wire safe for .5 to .75 ampere. The outside wire S may be coarse or fine. In the figure it is quite coarse and of relatively few turns, since it is assumed to give low potential and large current. The coil S is so proportioned as to be practically almost short-circuited at intervals by its load at B, which is three-cells of storage battery in series, for example. The object is assumed to be that the batteries are charged by transference of energy from coil P to S at low potential in S. The coil S should have ample copper so as to lower its internal resistance as much as possible; the resistance of the cells B should be low; and the average voltage of discharge of S much superior to the counter electro-motive force of B. Two synchronously revolving break-pieces, E, F, which may, in fact, be combined into one, are used; E is for governing the intervals of passage of current in coil P and connection of condenser C across the break or interruption periodically made between one terminal of P by a brush G and a metallic segment on E occupying a considerable arc on its periphery. Brush H connects to main *n*. Back of the main segment on E is a small condenser segment in continuous connection with one side or foil of the condenser, and the other side is connected to the other terminal of P, or that leading direct from line *p*. The contact maker and breaker F has a segment which is in continuous connection with one terminal of battery B to be charged, and which touches a stationary brush J, at or about the time of the break between brush G on the main segment of E. The battery B may have terminals by which it may furnish current while being charged.

Now let the break-wheels E and F be given rapid revolution, say, 10, 20 or 30 per second. The contact of brushes G and H with the main segment of E passes current for a certain considerable fraction of the revolution, at full line potential of 110 volts, through primary P. The current rises gradually during this period, and may at the end attain a value of one ampere, more or less. With slow revolution it would be limited by the resistance of P chiefly, but at rapid rates, the time constant of P acting as a self-induction, determines the ultimate value of current before breaking. Upon the break of brush G with the main segment it touches the condenser segment, which is thereby put across the break; but the circuit of S is also closed by contact of segment on F with brush J. The condenser receives only a small charge on account of the circuit of S having been closed. In fact, the break at G with main segment of E would be nearly sparkless without the condenser C, but what slight self-induction is not wiped out by the mutual induction of the currents in S and P is very easily taken care of.

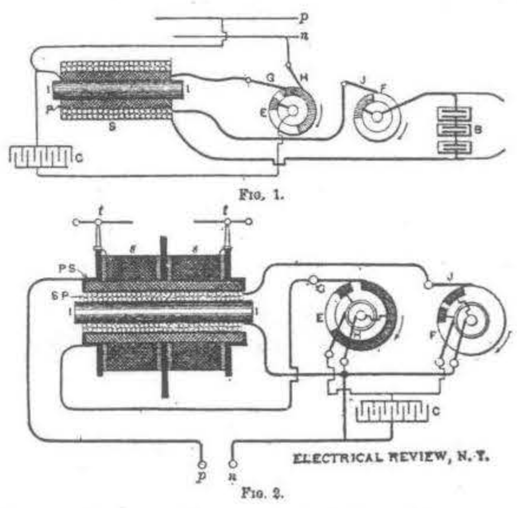

Fig. 1. Fig. 2.

PROF. ELIHU THOMSON'S NEW FORM OF INDUCTION COIL.

The magnetizing of the core I I or absorption of energy is by P, while delivery of energy is by S, acting as if nearly on a closed circuit. This condition, however, does not involve much waste of energy if the ohmic resistance of the circuit of S be low enough. Here, then, is a transfer of energy from one circuit to another while the currents are direct currents in each circuit. To insure this being the case in S, the time of contact of segment on F with brush J must be selected so as not to permit any reversal; i. e., the break of said segment with K must be timed to be made on the cessation of the first impulse or discharge from S. To do this an ammeter, responding to direct currents only, placed in the battery circuit or in the leads from S, will indicate a maximum direct current when the segment F is of proper extent, and less under other conditions.

With the principles of the above apparatus in mind it is easy to understand the action of my new form of induction coil, which may be described, briefly, as follows: The iron core I, Fig. 2, of the induction coil is wound with the ordinary coarse primary coil and terminals provided therefor. Then a coil of intermediate gauge, between the inner primary and the outer secondary, is wound. It is to be capable of being connected across a circuit of 110 volts as with coil P, Fig. 1. This coil is the true primary or energy supplying coil, but for convenience and saving of wire I prefer to connect it in as the under portion of the real secondary circuit. It thus becomes useful as a part of the secondary itself, and having several thousand turns adds a considerable fraction to the total potential of the secondary. The secondary is, as usual, of quite fine wire of many thousands of turns, well insulated throughout.

In Fig. 2 the coarse coil is marked S P, and the intermediate coil P S, while that outside is marked S. The functions of the coils S P and P S are to act as secondaries and primaries alternately. This is, in fact, an essential function of S P, but is only incidental to coil P S, having been connected into the secondary circuit S, whose terminals are at *t t*. The break-wheels E F are like those of Fig. 1, except that in F there is a much shorter main segment and a condenser segment following, as in E. There is no battery in the circuit of S P, but it is put on dead short-circuit at intervals, just at the time P S is broken. Coil P S receives current from line at *p n*, at 100 to 200 volts, or more. On the break of this circuit at brush G the ampere turns, so to speak, are shifted suddenly into circuit of S P, closed on itself by J F. The consequence is that even at slow breaks no spark occurs at the rupture of G E. As soon as the current has been fully established in S P on short circuit, and after brush Q has got entirely away from all metallic connections on E, the main segment of F breaks the circuit of S P, which is conveying a very heavy current at low potential. The condenser C is put instantly across the break, and the spark flies between terminals *t t*. In this way a coil of the size of a six-inch Ruhmkorff gives a torrent of six-inch sparks, with an average current from a 110-volt line of about one-half an ampere. A simple motor or clock-work may be used to drive the break-wheels E , which are made of fair diameter to insure accuracy in operation. The best results are only to be obtained when the proportioning of the parts is carefully done, and with a knowledge of the result to be obtained.

The discharges are indistinguishable from those of a similar Ruhmkorff. In fact, the coil described might be used with the same condenser C as an ordinary Ruhmkorff coil energized by batteries. In this case the terminals of the coil section P S are disconnected, brush J lifted and battery inserted between brush G and terminal of S P, which goes to J in Fig. 2. The break-wheel E or F, when run with low potentials, may be immersed in water in the usual way to facilitate sharp breaks, but the apparatus has been very successfully run, at full output, dry, or a little heavy oil on the break suffices. Also, the flux of current in S P may be made by a magnet to break its own circuit under water when the current has risen to a predetermined amount. In other words, it may be provided with the usual automatic break, damped or adjusted not to get into tremulous vibration. It will be seen from the above description that a new way of energizing an induction coil or other transforming apparatus has been embodied, and that it consists in the rapid substitution of secondary and primary functions in the coil S P.

Tesla's System of Energy Transmission to a Distance Without Wires.

In view of the many reports which are appearing in the sensational dailies about Tesla's work, it appears only justice to this earnest and modest worker that we should publish the following sensible statement reported in such a competent and carefully edited journal as the *Sun*, of this city. The statement is reported as follows in its evening issue of August 4:

Nikola Tesla this morning denied the report that he had announced the completion of his discovery of a method of telegraphy without wires. Occasional reports of the progress of the work had been published from time to time, he said. His experiments had been repeatedly shown in strict confidence to some of his personal friends, but the publication of them in any detail must have been a violation of confidence. As a matter of fact, no experiments were made at the laboratory yesterday. The inventor, however, was willing to give some account of his work up to the present time.

"In a lecture delivered about four years ago," he said, "before the National Electric Light Association, in St. Louis—that was in March, 1893—I explained a certain scheme for producing electrical disturbances with the object of transmitting intelligible messages, and even power, from place to place without the use of any wires.

"The principle is this: An electrical oscillator is connected by one of its terminals to earth, and another is led to an insulated object of considerable bulk. This object should preferably be at a great height, where the air is less dense and transmits more easily the disturbance.

"Such an apparatus is then exactly what in mechanics would be a suction pump. Periodically it draws electricity out and forces it again into the earth, thereby altering rhythmically the electrostatic potential in the earth as well as in the air.

"This scheme I had, as a matter of fact, conceived many years before. But I had previously lacked the courage to present it to the scientific world. At the time of the St. Louis lecture I had already seen such results that I gathered courage enough to announce the project seriously.

"Shortly afterward, on my return to this city, I actually demonstrated by means of an improved apparatus that I was indeed able to create a disturbance in the manner described in the lecture.

"In my pleasure and excitement at this success, I could not refrain from showing the first experiments to a few intimate friends. When, later, my laboratory burned down, and the first instrument with which I had succeeded in my demonstration, and which I valued above any other, was destroyed, it was no small consolation to me that a few men whom I hold in high esteem had seen the first evidence of my success. They were my friends. Of course, all the experiments that I have made to this day have been shown only in confidence and with the express understanding that no popular publication should be made of them until I had acquainted the scientific world with my results.

"It appeared several years ago that the result I aimed at would be very difficult, if not impossible, to attain. The method, nevertheless, as I have outlined it, is simple, involving merely the use of a properly constructed oscillator connected with the ground, and with an elevated object; also a sensitive and properly adjusted receiver at a distance, similarly connected with the ground, and with an object at a considerable height. For the purposes of this receiver, I consider a balloon most suitable.

"These disturbances with which I am experimenting are produced by methods and devices which I have been perfecting more recently, and from present results I do not consider it at all impracticable to obtain, if such were desired, electric sparks a mile in length. They could be readily secured by apparatus designed on these novel lines. I now obtain sparks as long as eight feet, and can produce local disturbances. What I affirm is that the disturbances in this city may be made perceptible in London or throughout the world.

"The voltage is very high—beyond computation. For a wild guess I should place the voltage at 50,000,000. I have stood in the course of the sparks, but I consider them dangerous.

"Scientific results are what I have been chiefly interested in. But there are many possibilities of turning the methods to practical use. For instance, if I wished to make a fortune I should only have to take out patents on methods for exploding torpedoes or powder magazines at a distance by means of electrical disturbances produced in this manner. But to dispel popular and erroneous opinions on this point, it is appropriate to say that, whereas, it is perfectly possible to ignite an explosive by a suitably arranged apparatus at a distance, yet this fact will not revolutionize warfare. The enemy could avail himself of similar methods with like results."

Interesting Information on Tesla Coil Experiments.

To the Editor of Electrical Review:

Since the publication in a previous number of the Electrical Review, of some suggestions I made to a subscriber of your journal relative to the construction of a Tesla coil, or high-frequency transformer, of small dimensions, a large number of inquiries have been addressed to me, which I have been unable to answer owing to lack of opportunity. As these inquiries have been made evidently by persons in possession of ordinary induction coils, of moderate power, I propose to help them in a measure by giving, through the medium of the Electrical Review, the benefit of my experience.

In the first place I desire to state that my results have been attained largely through the extreme kindness of Messrs. Tesla and Thomson, both of whom have been generous enough to respond to early correspondence on the subject of high-frequency coils.

Of course the best effects have been produced by specially constructed transformers. At the same time the ordinary induction coil, if it possess the efficiency claimed for it, in modern construction can be made to do good work in connection with a suitable condenser and high-frequency transformer. When properly built these small transformers make excellent exciters for the double-focus type X-ray tubes. The present suggestions are for a high-frequency transformer operated by ordinary induction coils from three-inch spark upward.

Fig. 1 shows the method of construction with an arrangement of winding different from that shown in my first communication. In the present type the primary winding is placed on the outside. A hollow wooden spool is provided, 12 inches in length, three inches in diameter, with the interior bored out to a diameter of two inches. If desired each end can be turned down one-half inch in width, and one-fourth inch in depth, to provide a position for two cheek blocks, sometimes to be employed with advantage, especially as resting feet for the coil. Two wooden washers are then turned with the outer diameter to fit the interior of the large spool, and these washers have a central opening one and one-half inch in diameter. Through these washers is inserted a central wooden spool turned to fit 13 inches in length, and on this inner spool the secondary winding is placed. A brass binding post screwed into each end of the inner spool serves to give outlet to the secondary winding, and is of some advantage as a permanent connection for the secondary winding when it is desired to experiment much with different primaries, and it becomes necessary to handle the coil much.

From 20 to 25 turns of No. 8 heavily insulated wire is wound on the outer surface, and approximately 250 turns of double silk covered No. 26 to No. 28 wire is wound in one layer, on the inner spool. This gives a ratio of 10 to 1, in transformation, but as Tesla has said, this ratio may be even much greater when the condenser is discharged through the primary. I have found that any estimate is liable to be far from the truth, for the secondary discharge, varying as it does with different conditions at the spark gap, is hard to estimate. My experience has been that different induction coils require different condenser capacities, due probably to the fact that the resistance of the different secondaries, and consequently the quantity output of the coils used, varied. Generally speaking, a condenser made of a plate of good glass, and having a tinfoil surface of about 50 to 90 square inches on each side, is sufficient. With such a condenser and winding as given, energized by a coil giving three to five-inch spark, the terminals of the high-frequency coil give a fairly heavy stream of sparks about three inches in length. I have found, however, that the spark length of a high-frequency transformer does not always measure its efficiency. For instance, one induction coil of larger spark rating — 10 inches — with slightly different condenser capacity, gave high-frequency streams, four inches between terminals of high-frequency coil, while the snapping spark similar to that given by the ordinary coil, scarcely exceeded one inch in length. Yet this particular high-frequency coil has been the best energizer of tubes that I have tried. It was evident that the frequency was great, due, as I afterwards discovered, to a primary winding of very heavy wire and few turns. With insufficient education in these matters, progress can be made only by incessant experiment, and the coil I submit for the benefit of my amateur friends is one which can be readily taken out of the oil bath necessary for its efficient operation, and experimental windings can easily be substituted for those here given. The spark gap and condenser connections are shown in the sketch. Fig. 3 shows a completed coil for high-frequency work, constructed by me.

With this form of coil, intelligently operated, many of Tesla's beautiful experiments are readily made, besides those which may occur—as they surely will—to the experimenter. Two years of high-frequency experimenting has been one of my chief pleasures and a never failing source of entertainment to friends. The full measure of satisfaction was attained, however, when the double focus tube came into the market and I found my high-frequency coil ample for X-ray work.

Lord Kelvin.

Lord and Lady Kelvin arrived in New York city on the "Campania" last Friday en route to the meeting of the British Association for the Advancement of Science, which begins at Toronto, Ont., on August 18. Aside from being one of the most remarkable scientific men of the century, Lord Kelvin gives evidence of his great vitality in making, at the age of 73, a transatlantic voyage to attend the sessions of a scientific body. He was born at Belfast, Ireland, in June, 1824. His father, Dr. James Thomson, was at that time lecturer on mathematics at the Royal Academical Institute at Belfast, but he removed with his family to Glasgow on receiving an appointment to the professorship of mathematics in the university there. Lord Kelvin's writings are voluminous, and he is a member of many societies, both at home and abroad. He has borne the title of Lord Kelvin since 1892. He has been president of the mathematical and physical section of the British Association five times, and in 1890 he succeeded Sir George Gabriel Stokes, Bart., as president of the Royal Society.

On his arrival in New York Lord Kelvin was met by a number of newspaper men, to whom he said:

"This is my second visit to America. I have not missed a meeting of the Royal Society in more than 40 years, and I have come now to attend the meeting in Toronto. I was here before when the meeting was at Montreal in 1884. We shall leave New York in the morning and go to Niagara Falls. There I shall inspect the great electric power plant. From there we go to Toronto. After the meeting closes we may go to Vancouver, simply to see the country. In that event our stay will cover considerable time. In any event the date of my return is uncertain."

Lord Kelvin said that he had come across the ocean largely to observe, but that he should read a paper at the meeting of the association. He expressed much interest in some of the latest developments in electrical science in this country, such as Mr. Tesla's scheme for telegraphing without wires, and the use of the third rail for transmitting electric power for traction purposes directly and without feeder wires, as is done between Berlin and Hartford, Ct.

"I have not received information regarding Mr. Tesla's methods," said Lord Kelvin, "which is definite enough to enable me speak about them, but I have no doubt we shall hear more of this at the meeting."

In regard to the recently opened garbage destructor works at Shoreditch, England, Lord Kelvin said:

"It is only six weeks since the works were opened, but they have proved themselves to be a great success. Ten tons of 'dust' are equal, we calculate, to one ton of coal for steam making. Enough energy is now obtained to operate the municipal electric lighting plant, and so long as 'dust' is obtainable not an ounce of coal need be used. Whatever dust or refuse is collected has combustible qualities, and is therefore available."

In speaking of Lord Kelvin last week, Mr. Tesla expressed himself as follows:

"His mathematical essays on electricity, magnetism and heat stand almost alone, veritable monuments. The practical public can better appreciate a part of what he has done when I say that for the past 50 years we have been depending on instruments invented by him for the measurement of a great many quantities, and it is impossible to estimate the benefits to science which have come from his instruments, which even now are used in every scientific laboratory in the world. He has given us the perfected mariner's compass, and just imagine what this has done for navigation and commerce; and in ocean telegraphy he has given us the delicate instruments which are now used for recording messages under all seas. If Lord Kelvin were a young man, we might express admiration for his achievements, but his age has almost given sanctity to the eminence of his position."

ROENTGEN RAYS

ON THE SOURCE OF ROENTGEN RAYS AND THE PRACTICAL CONSTRUCTION AND SAFE OPERATION OF LENARD TUBES.[1]

BY NIKOLA TESLA.

AS will be remembered, in the first announcement of his discovery, Röntgen was of the opinion that the rays which affected the sensitive layer emanated from the fluorescent spot on the glass wall of the bulb; other scientific men next made the cathode responsible; still others the anode, while some thought that the rays were emitted solely from fluorescent powders or surfaces. My own experiments led me to recognize that, regardless of the location, the chief source of these rays was the place of the first impact of the projected stream of particles within the bulb. This was merely a broad statement, of which that of Prof. Röntgen was a special case, as in his first experiments the fluorescent spot on the glass wall was, incidentally, the place of the first impact of the cathodic stream. Investigations carried on up to the present day have only confirmed the correctness of the above opinion, and the place of the first collision of the stream of particles—be it an anode or independent impact body, the glass wall or an aluminum window—is still found to be the principal source of the rays. But, as will be seen presently, it is not the only source.

Since recording the above fact my efforts were directed to finding answers to the following questions: First, is it necessary that the impact body should be within the tube? Second, is it required that the obstacle in the path of the cathodic stream should be a solid or liquid? And, third, to what extent is the velocity of the stream necessary for the generation of and influence upon the character of the rays emitted?

In order to ascertain whether a body located outside of the

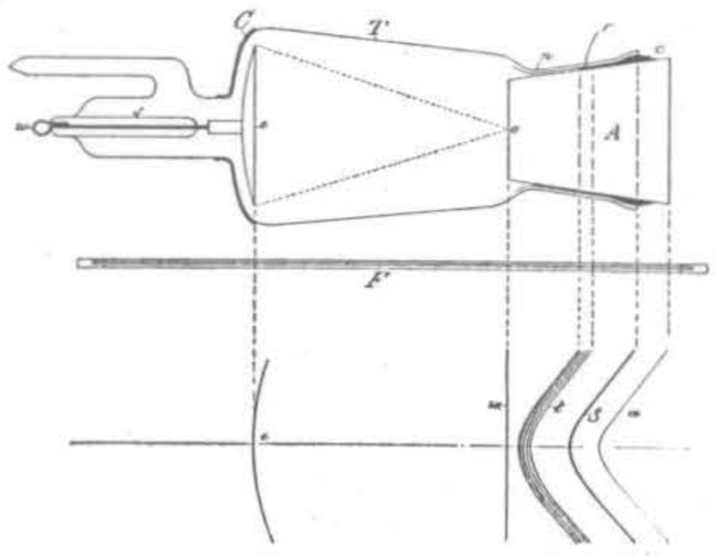

FIG. 1.

tube and in the path or in the direction of the stream of particles was capable of producing the same peculiar phenomena as an object located inside, it appeared necessary to first show that there is an actual penetration of the particles through the wall, or otherwise that the actions of the supposed streams, of whatever nature they might be, were sufficiently pronounced in the outer region close to the wall of the bulb as to produce some of the effects which are peculiar to a cathodic stream. It was not difficult to obtain with a properly prepared Lenard tube, having an exceedingly thin window, many and at first surprising evidences of this character. Some of these have already been pointed out, and it is thought sufficient to cite here one more which I have since observed. In the hollow aluminum cap, A, of a tube, as shown in diagram Fig. 1, which will be described in detail, I placed a half-dollar silver piece, supporting it at a small distance from and parallel to the window or bottom of the cap by strips of mica in such a manner that it was not touching the metal of the tube, an air space being left all around it. Upon exciting the bulb for about 30 to 45 seconds by the secondary discharge of a powerful coil of a novel type now well known, it was found that the silver piece was rendered so hot as to actually scorch the hand; yet the aluminum window, which offered a very insignificant obstacle to the cathodic stream, was only moderately warmed. Thus it was shown that the silver alloy, owing to its density and thickness, took up most of the energy of the impact, being acted upon by the particles almost identically as if it had been inside of the bulb, and, what is more, indications were obtained, by observing the shadows, that it behaved like a second source of the rays, inasmuch as the outlines of the shadows, instead of being sharp and clear as when the half-dollar piece was removed, were dimmed. It was immaterial for the chief object of the inquiry to decide by more exact methods whether the cathodic particles actually penetrated the window or whether a new and separate stream was projected from the outer side of the window. In my mind there exists not the least doubt that the former was the case, as in this respect I have been able to obtain numerous additional proofs.

I next endeavored to ascertain whether it was necessary that the obstacle outside was, as in this case, a solid body, or a liquid, or broadly, a body of measurable dimensions. I observed accidentally what is illustrated in Fig. 1. The diagram shows a Lenard tube of improved design, consisting of a tube, T, of thick glass tapering toward the open end, or neck, n, into which is fitted an aluminum cap, A, and a spherical cathode, e, supported on a glass stem, s, and platinum wire, w, sealed in the opposite end of the tube as usual. The aluminum cap, A, as will be observed, is not in actual contact with the ground glass wall, being held at a small distance from the latter by a narrow and continuous ring of tinfoil, r. The outer space between the glass and the cap, A, is filled with cement, c, in a manner described below. F is a Röntgen screen such as is ordinarily used in making the observations.

Now, in looking upon the screen in the direction from F to T, the dark lines indicated on the lower part of the diagram were seen on the illuminated background. The curved line, e, and the straight line, w, were, of course, at once recognized as the outlines of the cathode, e, and the bottom of the cap, A, respectively, although, in consequence of a confusing optical illusion, they appeared much closer together than they actually were. For instance, if the distance between e and o was 5 inches, these lines would appear on the screen about 2 inches apart, as nearly as I could judge by the eye. This illusion may be easily explained and is quite unimportant, except that it might be of some moment to physicians to keep this fact in mind when making examinations with the screen as, owing to the above effect, which is sometimes exaggerated to a degree hard to believe, a completely erroneous idea of the distance of the various parts of the object under examination might be gained, to the detriment of the surgical operation. But while the lines, e and w, were easily accounted for, the curved lines, t, g, a, were at first puzzling. Soon, however, it was ascertained that the faint line, a, was the shadow of the edge of the aluminum cap, the much darker line, g, that of the rim of the glass tube, T, and t the shadow of the tinfoil ring, r. These shadows on the screen, F, clearly showed that the agency which affected the fluorescent material was proceeding from the space outside of the bulb towards the aluminum cap, and chiefly from the region through which the primary disturbances or streams emitted from the tube through the window were passing, which observation could not be explained in a more plausible manner than by assuming that the air and dust particles outside, in the path of the projected streams, afforded an obstacle to their passage and gave rise to impacts and collisions spreading through the air in all directions, thus producing continuously new sources of the rays. It is this fact which, in his recent communication before mentioned, Röntgen has brought out. So, at least, I have interpreted his reported statement that the rays emanate from the irradiated air. It now remains to be shown whether the air, from which all foreign particles are carefully removed, is capable of behaving as an impact body and source of the rays, in order to decide whether the generation of the latter is dependent on the presence in the air of impact particles of measurable dimensions. I have reasons to think so.

With the knowledge of this fact we are now able to form a more general idea of the process of generation of the radiations which have been discovered by Lenard and Röntgen. It may be comprised in the statement that the streams of minute material particles projected from an electrode with great velocity in encountering obstacles wherever they may be, within the bulb, in the air or other medium or in the sensitive layers themselves, give rise to rays or radiations possessing many of the properties of those known as light. If this physical process of generation of these rays is undoubtedly demonstrated as true, it will have most important consequences, as it will induce physicists to again critically examine many phenomena which are at present attributed to transverse ether waves, which may lead to a radical modification of existing views and theories in regard to these phenomena, if not as to their essence, so, at least, as to the mode of their production.

[1] From The Electrical Review.

My effort to arrive at an answer to the third of the above questions led me to the establishment, by actual photographs, of the close relationship which exists between the Lenard and Röntgen rays. I prepared a tube in the manner described by Lenard in his first classical communication on this subject. The tube was exhausted to a moderate degree, either by chance or of necessity, and it was found that, when operated by an ordinary high-tension coil of a low rate of change in the current, no rays of any of the two kinds could be detected, even when the tube was so highly strained as to become very hot in a few moments. Now I expected that, if the suddenness of the impulses through the bulb were sufficiently increased, rays would be emitted. To test this I employed a coil of a type which I have repeatedly described, in which the primary is operated by the discharges of a condenser. With such an instrument any desired suddenness of the impulses may be secured, there being practically no limit in this respect, as the energy accumulated in the condenser is the most violently explosive agent we know, and any potential or electrical pressure is obtainable. Indeed, I found that in increasing the suddenness of the electromotive impulses through the tube—without, however, increasing, but rather diminishing the total energy conveyed to it—phosphorescence was observed and rays began to appear, first the feebler Lenard rays and later, by pushing the suddenness far enough, Röntgen rays of great intensity, which enabled me to obtain photographs showing the finest texture of the bones. Still, the same tube, when again operated with the ordinary coil of a low rate of change in the primary current, emitted practically no rays, even when, as before stated, much more energy, as judged from the heating, was passed through it. This experience, together with the fact that I have succeeded in producing by the use of immense electrical pressures, obtainable with certain apparatus designed for this express purpose, some impressions in free air, have led me to the conclusion that in lightning discharges Lenard and Röntgen rays must be generated at ordinary atmospheric pressure.

I have already described the form of tube illustrated in Fig. 1, and in Fig. 2 another still further improved design is shown. In this case the aluminum cap, A, instead of having a straight bottom as before, is shaped spherically, the center of the sphere coinciding with that of the electrode, e, which itself, as in Fig. 1, has its focus in the center of the window of cap, A, as indicated by the dotted lines. The aluminum cap, A, has a tinfoil ring, r, as that in Fig. 1, or else the metal of the cap is spun out on that place so as to afford a bearing of small surface between the metal and the glass. This is an important practical detail as, by making the bearing surface small, the pressure per unit of area is increased and a more perfect joint made. The ring, r, should be first spun out and then ground to fit the neck of the bulb. If a tinfoil ring is used instead, it may be cut out of one of the ordinary tinfoil caps obtainable in the market, care being taken that the ring is very smooth.

In Fig. 3 I have shown a modified design of tube. This, as will be observed, is a double focus tube, with impact plates or iridium alloy and an aluminum cap, A, opposite the same. It will be noted that the aluminum caps in the tubes described are fitted inside of the necks and not outside, as is frequently done. Long experience has demonstrated that it is practically impossible to maintain a high vacuum in a tube with an outside cap. The only way I have been able to do this in a fair measure is by cooling the cap by a jet of air, for instance, and observing the following precautions: The air jet is first turned on slightly and upon this the tube is excited. The current through the latter, and also the air pressure, are then gradually increased and brought to the normal working condition. Upon completing the experiment the air pressure and current through the tube are both gradually reduced and both so manipulated that no great differences in temperature result between the glass and aluminum cap. If these precautions are not observed the vacuum will be immediately impaired in consequence of the uneven expansion of the glass and metal.

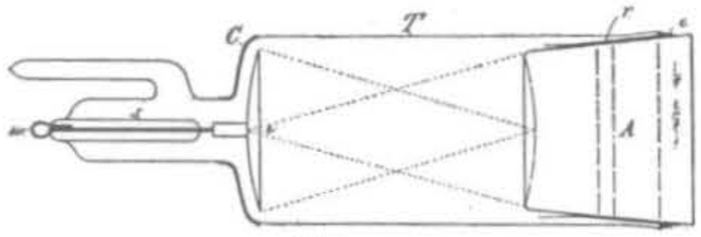

FIG. 2.

With tubes, as those described, it is quite unnecessary to observe this precaution if proper care is taken in their preparation. In inserting the cap the latter is cooled down as low as it is deemed advisable without endangering the glass, and it is then gently pushed in the neck of the tube, taking care that it sets straight.

The two most important operations in the manufacture of such a tube are, however, the thinning down of the aluminum window and the sealing in of the cap. The metal of the latter

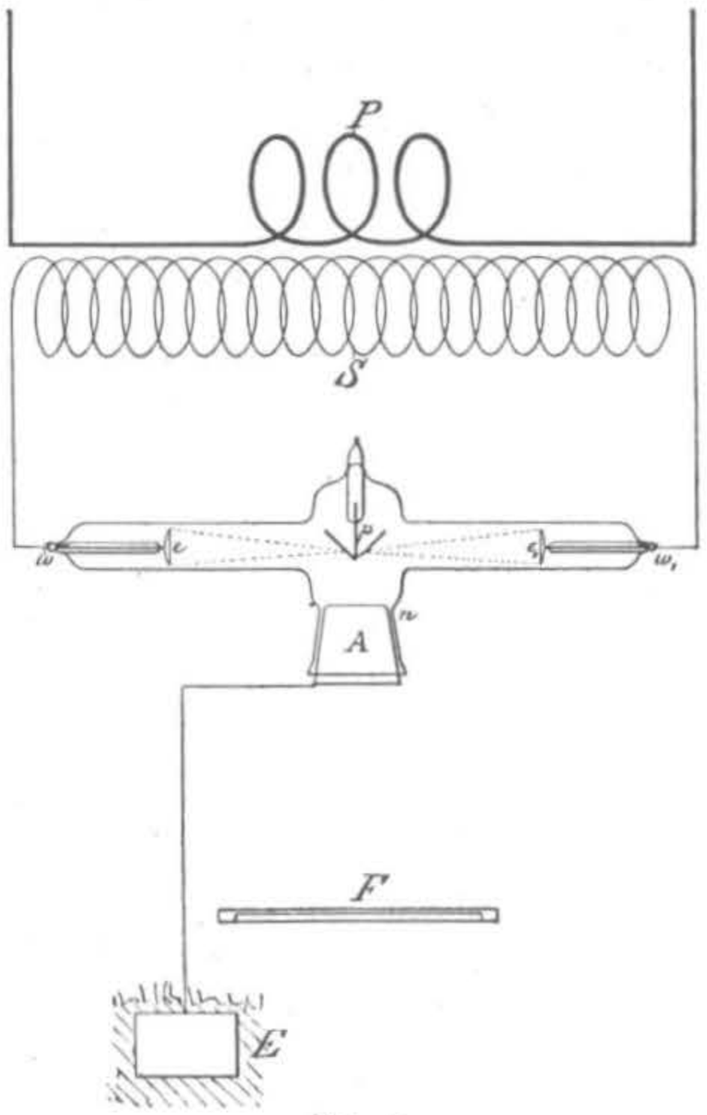

FIG. 3.

may be 1-32d or even 1-16th of an inch thick, and in such case the central portion may be thinned down by a countersink tool about ¼th of an inch in diameter as far as it is possible without tearing the sheet. The further thinning down may then be done by hand with a scraping tool; and, finally, the metal should be gently beaten down so as to surely close the pores which might permit a slow leak. Instead of proceeding in this way I have employed a cap with a hole in the center, which I have closed with a sheet of pure aluminum a few thousandths of an inch thick, riveted to the cap by means of a washer of thick metal, but the results were not quite as satisfactory.

In sealing the cap I have adopted the following procedure: The tube is fastened on the pump in the proper position and exhausted until a permanent condition is reached. The degree of exhaustion is a measure of perfection of the joint. The leak is usually considerable, but this is not so serious a defect as might be thought. Heat is now gradually applied to the tube by means of a gas stove until a temperature up to about the boiling point of sealing wax is reached. The space between the cap and the glass is then filled with sealing wax of good quality; and, when the latter begins to boil, the temperature is reduced to allow its settling in the cavity. The heat is then again increased, and this process of heating and cooling is repeated several times until the entire cavity, upon reduction of the temperature, is found to be filled uniformly with the wax, all bubbles having disappeared. A little more wax is then put on the top and the exhaustion carried on for an hour or so, according to the capacity of the pump, by application of moderate heat much below the melting point of the wax.

A tube prepared in this manner will maintain the vacuum very well, and will last indefinitely. If not used for a few months, it may gradually lose the high vacuum, but it can be quickly worked up. However, if after long use it becomes necessary to clean the tube, this is easily done by gently warming it and taking off the cap. The cleaning may be done first with acid, then with highly diluted alkali, next with distilled water, and finally with pure rectified alcohol.

These tubes, when properly prepared, give impressions much sharper and reveal much more detail than those of ordinary make. It is important for the clearness of the impressions that the electrode should be properly shaped, and that the focus should be exactly in the center of the cap or slightly inside. In fitting in the cap, the distance from the electrode should be measured as exactly as possible. It should also be remarked that the thinner the window, the sharper are the impressions, but it is not advisable to make it too thin, as it

is apt to melt in a point on turning on the current.

The above advantages are not the only ones which these tubes offer. They are also better adapted for purposes of examination by surgeons, particularly if used in the peculiar manner illustrated in diagrams, Fig. 3 and Fig. 4, which are self-explanatory. It will be seen that in each of these the cap is connected to the ground. This decidedly diminishes the injurious action and enables also to take impressions with very short exposures of a few seconds only at close range, inasmuch as, during the operation of the bulb, one can easily touch the cap without any inconvenience, owing to the ground connection. The arrangement shown in Fig. 4 is particularly advantageous with a form of single terminal, which coil is diagramatically illustrated, P being the primary and S the secondary. In this instance the high-potential terminal is con-

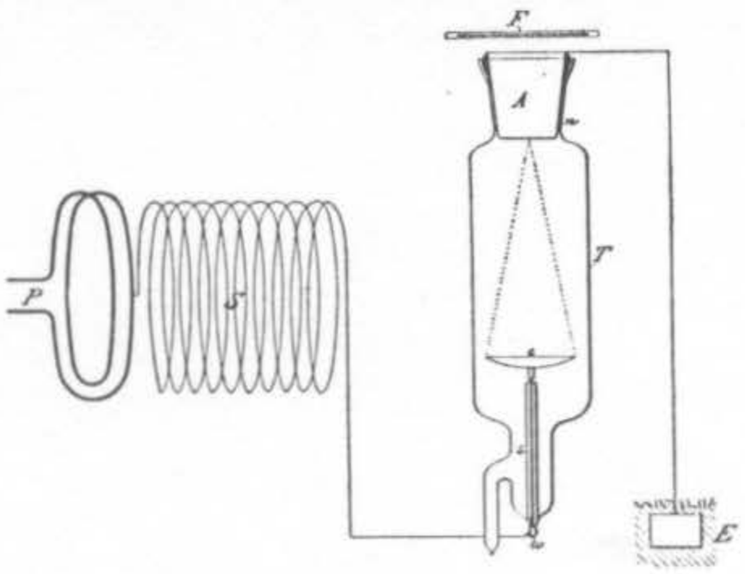

FIG. 4.

nected to the electrode, while the cap is grounded. The tube may be placed in the position indicated in the drawing, under the operating table and quite close, or even in contact with the body of the patient, if the impression requires only a few seconds as, for instance, in examining parts of the members. I have taken many impressions with such tubes and have observed no injurious action, but I would advise not to expose for longer than two or three minutes at very short distances. In this respect the experimenter should bear in mind what I have stated in previous communications. At all events it is certain that, in proceeding in the manner described, additional safety is obtained and the process of taking impressions much quickened. To cool the cap, a jet of air may be used, as before stated, or else a small quantity of water may be poured in the cap each time when an impression is taken. The water only slightly impairs the action of the tube, while it maintains the window at a safe temperature. I may add that the tubes are improved by providing back of the electrode a metallic coating, C, shown in Fig. 3 and Fig. 4.

NOTES.

Tesla Electrifies the Earth.—It is queer that the American inventors cannot dispense with sensational interviews. We sometimes are inclined to doubt whether an untechnical interviewer is always at fault. Thus the New York *Journal* announces the completion of Mr. Tesla's work for the transmission of messages from one point to another on the earth without the aid of wires. To give an idea of the high potential currents used in this work, he showed the interviewer a large disc, from the centre of which protruded a spherical electrode shooting forth long streams of ethereal flame. Mr. Tesla stated that the electrical disturbance thus created was felt throughout the globe.

TESLA, MARVEL OF THE WORLD.

Life, Habits and Philosophy of the Scientist.

SPENDS $15 FOR A MEAL.

He Has Never Married Because He Believes that a Woman Would Interfere with His Work.

NEW YORK, Aug. 20.—The name of Nicola Tesla has again flashed around the earth. He is the foremost man in the world. No human being has ever reached the pinnacle upon which he stands to-day.

Almost coincident with the announcement that he has solved the great problem upon which he has been at work for nearly seven years, comes the news that an Italian youth, Guglielmo Marconi, has discovered the means of telegraphing without wires.

The scientific world acknowledges the value of Marconi's invention. It admits its practical use. The same men who honor Marconi worship Tesla. Marconi has explained, and his methods are easily grasped. Tesla has simply said that he has accomplished his great work, and they believe.

Years ago those recognized as masters admitted that Tesla had no peer in abstract electrical research. To-day the most scientific, the farthest advanced, look upon him with rapt admiring eyes. That which he says he has accomplished seems like the dream of an intoxicated god. The most brilliant and wonderful flights of imagination become feeble and pitiful beside Tesla's facts.

When the young man announced publicly, about five years ago, that he believed the time would come when he would be able to transmit electrical vibration without wires, it was looked upon as a dream in nowise to be taken seriously.

The dream has become a reality. If any man knows the secret of the invenion by which the results have been accomplished he has guarded it closely. Tesla has given his word that it is so. The suspicious scientific world that demands convincing proof has taken his assertion, accepted it as a demonstrated fact.

The discovery of Marconi is admittedly one possessing enormous practical value. But it does not compare with the achievements of Tesla. Telegraphy is an unimportant factor in the great scheme. It is the transmission of power that is the vital principle.

With his machine he can disturb the electrical conditions of the earth, and make the electrostatic force do his will.

As he told one writer, he hopes to make Niagara Falls drive mills in New England, send ships across the sea, and transmit thought or information to the uttermost parts of the earth.

As to the working out of the mechanical part of the problem Tesla gives no information. It is a mere detail in his mind, something that any able electrical engineer can do. It is a trifle with which he has not time to bother.

The achievement carries with it another that has been more talked about, the making of light without wires. Tesla has produced a light that has all the brilliancy and qualities of sunlight. And it can be made cheaper than the ordinary electric light.

These latest wonders he has worked arouse an intense interest in the personality of the man. It is in keeping with his work.

TESLA'S EARLY LIFE.

The early facts of his life are well enough known. He was born in Smiljan, a village of perhaps forty houses, in Lika, on the borderland region of Austro-Hungary, of the Serbian race, which has maintained an unceasing struggle with Turkey for freedom. In his native language there are a hundred words for knife, and only one for mercy.

His father was an eloquent clergyman in the Greek Church, in which a younger brother is now a recognized force. His mother possessed extraordinary mechanical skill.

Nicola was intended for the priesthood. He passed four years in the public school at Gospich and three years in the Real Skule. Then he was sent to Carstatt, Croatia, where he spent three years in the Higher Real School, graduating in 1873.

He devoted himself to electricity and magnetism. His father consented to his taking a scientific course, and he entered the Polytechnic School at Gratz.

He was not yet 20 when he told his professor that it was possible to operate a dynamo without commutator or brushes, and he was laughed at as a foolish boy. But the time came when he made the rotating field principle an accomplished fact.

From Gratz he went to Prague and Budapesth to study languages, and to broadly qualify himself for his profession. He entered the Government telegraph department. Afterward he went to Paris, searching for more knowledge. He connected himself with an electric lighting concern.

It was while he was in Paris, in 1882, that he perfected the rotating field principle, which has had a profound influence upon dynamo electrical machinery. He purposed giving his discovery to the world. But wise business men, who learned of its value, urged him to first secure a patent. Tesla had no thought of a patent.

Americans whom he met in Paris urged him to come to this country. He acted swiftly. The day he arrived in the United States Tesla went to work in Edison's laboratory.

Afterward he became associated with different companies, which placed his inventions upon the market, for Tesla has made many which only electricians know about.

It was a little more than seven years ago that he established a laboratory in South Fifth avenue, in New York, and devoted himself to that research and experiment that is his joy and ambition.

HIS PERSONAL APPEARANCE.

These bald facts give little hint of the man himself. So far as personal appearance goes no one can look upon him without feeling his force. He is more than six feet tall and very slender. Yet he possesses great physical power. His hands are large, his thumbs abnormally long, and this is a sign of great intelligence. His hair is black and straight, a deep, shining black. He brushes it sharply from over his ears, so that it makes a little ridge with serrated edges.

His cheekbones are high and prominent, the mark of the Sclav; his skin is like marble that age has given the first searing of yellow. His eyes are blue, deeply set, and they burn like balls of fire. Those weird flashes of light he makes with his instrument seem also to shoot from them. His head is wedge-shaped. His chin is almost a point.

So much for the appearance of the man. Never was a human being filled with loftier ideals. Never did a man labor so unceasingly, so earnestly, so unselfishly for the benefit of his race. Tesla is not rich. He does not trouble himself about money. Had he chosen to follow in the footsteps of Edison he could be, perhaps, the richest man in the world, and Tesla is just 40 years old.

Tesla equipped himself with the best technical education that Europe and America could furnish. He mastered all that the men who had gone before him had accomplished. And all the while he reasoned for himself.

Nothing of importance that Tesla has discovered has been an accident. For a quarter of a century he has lived with his whole consciousness near the bosom of nature. He has wrested her secrets from her. He has learned the source of her power. Now he has harnessed it that man may be happier and better.

To the layman Tesla's life seems to be bound up in vibrations. Three or four years ago electricians declared that 300 a second was the limit. Tesla announced that he was sure he could obtain 30,000,000 vibrations a second. Already he has secured 50,000,000, and the end is far off. These figures show the relative position of Tesla and other electrical scientists.

The daily life of this man has been the same, practically, ever since he has been in New York. He lives in the Gerlach, a very quiet family hotel, in 27th street, between Broadway and Sixth avenue. He starts for his laboratory before 9 o'clock in the morning. All day long he lives in his weird uncanny world, reaching forth to capture new power to gain fresh knowledge.

NICOLA TESLA, THE WONDER WORKER.

No stranger ever sees him at his work. No one knows of his assistants. At rare intervals he presents some experiments in his laboratory, and there is no sacrifice that thousands of people would not make to gain admission to these.

Usually he works until 6 o'clock, but he may stay later. The absence of natural light does not trouble him. Tesla makes sunlight in his workshop.

At exactly 8 o'clock he enters the Waldorf. He is attired in irreproachable evening clothes. In the winter time he never wears an evening jacket, but always the coat with tails.

PAYS $15 FOR HIS DINNER.

He walks directly to a table in the farthest corner of the palm garden, which is reserved for him. He carries two or three newspapers in his hands, and one of these he perches before him.

No gourmet who dines at the Waldorf can order a better dinner than Tesla. It is an elaborate dinner of many courses. He drinks a fine Burgundy and a fine champagne, a quart of one and a pint of the other. His dinner costs Tesla never less than $15, and seldom more. It is practically the only meal he eats during the day. He never tips the waiter or the man who takes care of his hat and coat less than a dollar.

He finishes his dinner at exactly 10 o'clock, and leaves his hotel, either to go to his rooms to study or to return to his laboratory to work through the night.

Two or three times a week he will go to a barber shop. He demands that the towels and covering on the chair be changed, and does not object to the barber using the common mug and brush. He insists upon having his head rubbed for nearly half an hour.

These are the only occasions when Tesla appears in public. Perhaps two or three times a year some one may dine with him. He is a bold man who will dine with Tesla. If he has any sense at all he will realize that he can give the scientist not the slightest title of information about anything that interests him. And he cannot understand about what Tesla is talking for more than two minutes at a time. For this marvelous mind lives in a realm so weird and so awful that the ordinary intelligence draws back affrighted.

Tesla is, above all things, a serious man, undoubtedly the most serious man in New York. Yet he has a keen sense of humor and the most beautiful manners. He is the most genuinely modest of men. He knows no jealousy. He has never decried the accomplishments of another, never refused credit.

When he talks you listen. You do not know what he is saying, but it enthralls you. You feel the importance without understanding the meaning. He speaks the perfect English of a highly educated foreigner, without accent and with precision. He speaks six or eight languages equally well.

He speaks constantly about electrostatic force, that mighty power which he has chained at last. And this he has explained.

"Electrostatic force is that which governs the motion of the atoms," he said when he was asked about it. "It is the force which causes them to collide and develop the life-sustaining energy of heat and light, and which causes them to aggregate in an infinite variety of ways, according to Nature's fanciful designs, and form all these wondrous structures we see around us. It is, in fact, if our present views be true, the most important force for us to consider in Nature."

WHY HE HAS NOT MARRIED.

Tesla has never married, and it is not likely that he ever shall. His father and mother are both dead. His brothers are in his native land. Tesla is an American citizen. It is not likely that any child shall bear his name in this country. He has elected to devote his whole life to his work, and for this reason he is denied the love and companionship of a good woman. And this, too, he has explained.

"I believe that a writer or a musician should marry. They gain inspiration that leads to finer achievement.

"But an inventor has so intense a nature, with so much in it of wild, passionate quality that, in giving himself to a woman, he would give up everything, and so take everything from his chosen field. It is a pity, too; sometimes we feel so lonely."

But the inventor who succeeds has his recompense, and this also has Tesla spoken about.

"In my student days I have known what it was to pass forty-eight hours at a stretch at a gaming table, undergoing intense emotion, that which most people believe is the strongest that can be known, but it is tame and insipid compared with that sublime moment when you see the labor of weeks fructify in a successful experiment that proves your theories."

Many times has Nicola Tesla known that supreme happiness. And he is likely to know it often again. It is impossible that his life work can be finished at 40. It would seem that his powers are only reaching their maturity.

No man has ever occupied the place that he has, for he is not only an uncrowned king of science, he is not only the deepest, more original investigator; he is a real discoverer of wonderful forces, and inventor of the harness to control them, and, in addition to all these things, he is a seer as well. And only the ignorant have courage to scoff at him.

FRANKLIN CHESTER.

ELECTRICITY DURING THE LAST FIVE YEARS.

BY FRANZ BENDT.

TRANSLATED FOR "THE CHAUTAUQUAN" FROM THE GERMAN "UEBER LAND UND MEER."

IT is mostly through its practical results that a science appeals to the general public for anything more than a casual attention. This fact is nowhere more noticeable than in electricity, which has loaded humanity with gifts and in a comparatively short time has revolutionized customs and business so that the present era not unjustly has been called "the age of electricity." The term is doubly appropriate because, as all signs indicate, we are not at the end but only just at the beginning of the electrical epoch. Moreover, it should be noted, the wonderful and mysterious manner in which the electrical forces are manifested have thoroughly aroused astonishment, even in adepts, and a thirst for knowledge in the laity.

In glancing over the many practical acquisitions of the young science one gets the impression that for its years it has developed strongly and powerfully, if also disproportionately. Yet many branches of the electrical science have broadened out into mighty industries. Its practical side, electrotechnics, already has been divided into two parts, the weak current and the strong current technics, and the exponents of these two parts belong to different classes of vocations hotly rivaling each other.

A brief forecast of the history of the science will help us to appreciate its development during the last five years.

The oldest branch of the new technic does service in propagating news. It is now about seventy years that its electric spark has carried messages across oceans and over wide continents. The amount of lines and conducting wires connected with them is at the present time something imposing, and not less so is the growth that both have shown from year to year. Altogether the wires would reach about five times from the earth to the moon.

Yet more marvelous than the development of telegraphy is the development of long-distance speaking, or telephoning, already a dangerous rival to telegraphy. We are about to enjoy an extension in both lines of culture here on German soil. At the present time there are in the German Empire 93,768.46 miles of lines and 440,682.44 miles of conducting wires to convey written and spoken messages. The number of telegraph stations here is 28,281. Especially significant is the growth in the number of city telephone stations; during the last year their number has increased from 109,960 to 125,810.

The technical improvement in this region

is evidenced by the development of new telephone lines to connect cities. The longest line in Germany is found between Berlin and Memel, extending over the remarkable distance of 621.37 miles. The great distance cannot influence the audibility, for the hearing qualities are excellent. During the preliminary experiments for the laying of these connections, the experts at the German imperial post arrived at the important judgment that this line might be lengthened about threefold without injury. If they succeed in establishing communication over such a long distance, the feat will place German telephone engineers at the head of their profession, for telephonic transmission over 1864 miles never before has been accomplished except by way of experiment.

The sea cable also is a modern development, and to its possibilities, too, there is no limit. At present experts are engaged in the task of laying its conducting wires through the great ocean. Then, with the perfection of this gigantic plan, one can send a despatch around the whole world in a moment. The circuit will be complete.

While the weak current technics has consumed almost two thirds of a century in her upbuilding, her younger sister, the strong current technics, in a comparatively short time has grown into a giant. What about five years ago was mere project now is actual fact. We need mention only the extension within this time of the electrical railway.

The special problem of strong current technics was, how practically to work out methods for transmitting power. They arrived at a definite solution of this problem in the year 1891, at the electrical exposition in Frankfort on the Main, when they succeeded in leading from Lauffen on the Neckar to the exposition city their current, by means of the electric motive conductor. Since then, the hopes which were built on this solution have for the most part been realized.

One of the greatest of these outcomes, that already is much talked of, we admire in the plant for transmitting power from Niagara Falls. Of the 5,000,000 horse-power which these greatest falls of the world exert every minute, 15,000 are diverted and put to use through a region fifteen and one half miles in radius. Buffalo, for instance, which lies within the circumference of this circle, owes its light and its business power to its electrical career at Niagara Falls.

On German soil, too, and especially in the Rhine regions, similar plants at this moment are in progress of building. By means of powerful turbines they aim to draw from the Rhine about 10,500 horse-power and to send them, by means of an electric motor, to cities and factories in all directions within a radius of twelve and one half miles.

It is obvious that power transmitted in such quantities can be sold cheap. Already its price has caused a depreciation of about thirty per cent in steam machinery. Carefully planned improvements and centralization in such an industrial district are the best methods to increase the wealth of a country and to add to the prosperity of its inhabitants. The industries of the upper Rhine, for example, previously enjoyed only a mere existence, because their life element, coal, had become exhausted. The electrical current which the new plant will send out will be able, without doubt, to convert the Rhine region establishments into places of business activity.

Already modern methods of power-transmission are beginning to make their way even into that conservative branch of industry, agriculture. Lately at Dietrichshagen, in the vicinity of Rostock, in experiments before the representatives of the Prussian ministry of agriculture, it was demonstrated clearly, time and again, that in this business one could work more cheaply by the use of mechanical than of animal power. The significance of this is plain to be seen when it is considered that in the cultivation of the soil in Germany there are employed about 2,500,000 horses and 500,000 draught oxen. According to the reckoning of most competent business people, German farmers could aggregate a yearly saving of 210,000,000 marks, or $49,980,000, by the general use of mechan-

ical power. The experiments at Dietrichshagen led to the conclusion that by the use of electrical power-transmission and its application in electrical plows one could cut down expenses fifty per cent. The conclusion would take on a still more favorable appearance if this power, always ready for work, should find application to other purposes, such as running sugar factories, and the farmer should utilize for the production of electric currents the energy that nature places at his disposal in the form of falling or flowing streams.

In the large cities, too, they already use the electric current very effectively in the trades. The electric stations which were set up there for the generation of light also furnish currents for power, and a considerable number of working establishments have furnished their machines with it at a comparatively small cost.

Since this has been done the mighty electric current has stood at the service of the investigator as well as the tradesman everywhere, and great strides have been made in the application of the remarkable power. Thus within a few years new scientific results have developed which, such as electrochemics, for instance, have influenced the authorities to establish special chairs of learning in the high schools. Electrochemics has arisen from the union of electricity with chemistry. Until shortly ago the combination and separation of substances was effected by a comparatively weak current at a low temperature. A world of new phenomena opened to the investigators when they attacked the physical world with powerful currents and the previously unheard-of high temperatures. These multitudinous scientific conquests are made applicable through the methods of power-transmission to industrial uses, and prove valuable acquisitions to all manufactories.

One of the most fortunate discoverers in the realm of electrochemics, whose results are peculiarly adapted to rouse interest in wide circles, is Henry Moissan of Paris. With the force of the current he conquered fluorin, which most stubbornly of all the elements has resisted isolation, and presented it, free of all combinations, to the eye of the investigator—the first time it ever was seen in a free state. In his electric oven he crystalized coal to diamonds, and gold, copper, and resisting graphite were neglected and melted down into the form of little scales. These and similar experiments give an important idea of the almost creative power that the strong current lends humanity over material.

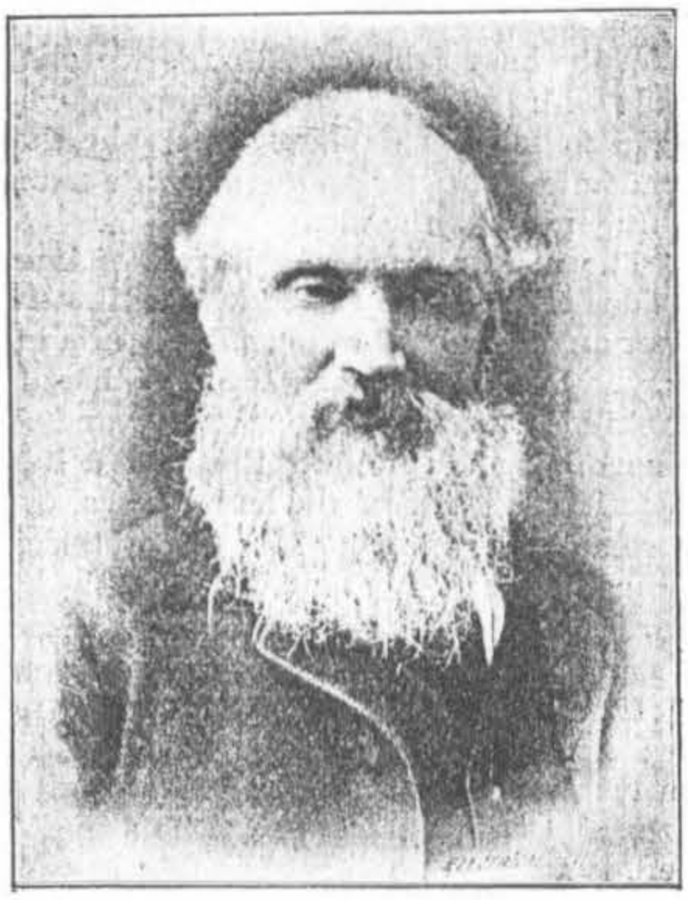
Besides such new knowledge, electrochemics has ripened the prominent practical results and has placed others nearer attainment. The extraction of the far-famed aluminum from clay takes place almost immediately under the influence of the powerful current. In like manner soda is formed from kitchen salt almost without expense if you take into account the value of the important second product. Electricity has been used successfully also to purify streams and rivers and to free them effectively from the death germs most inimical to humanity, such as cholera, typhus, malaria, etc.

Such wonderful properties explain why among the laity so often the question arises, What is electricity? Yet a few years ago a physicist would have had to stand abashed, for he knew no more of the mysterious sphinx than the questioner. Now the question can be answered, if not wholly, at least in part.

During the departing century natural philosophers have arrived at the knowledge that light and radiating heat are caused by swinging motions of a fine substance called ether. That electrical phenomena demanded a similar explanation was undoubted by every intelligent physicist; but the remarkable form of energy stubbornly refused to divulge its secret. The German physicist Heinrich Hertz first lifted the veil and showed that electricity spread out into space in waves 39.37 inches (a meter) long. This finally led to the proof that all force was expressed in the form of the billowy movements of ether. The only difference between light, radiating heat, and electricity in appearance is in the length of their respective waves.

On the theoretical judgment that electrical waves roll out into space, Nikola

Tesla built up his experiments, which afford interesting glimpses into the future development of electrotechnics. Only consider what an advantage would be gained, if, without intervening wires, verbal or written messages could be sent over the wide world, if, without cables, currents could be conducted, lamps fed, and especially if electrical energy could be made to go in whatever place one desired. To make that possible is no longer the wish of a fruitless fancy, but already has been partly realized. Thus Tesla has made tubes a meter long light up brightly without connecting them anywhere, and Preece in London has telegraphed several miles through sea water without any cable.



In order to excite the remarkable light tube Tesla makes use of a peculiar machine, which conducts the so-called alternating current at a high speed of alternations. With this he made observations on wonderful phenomena. It is pretty generally known that alternating currents are dangerous; in fact they already have cost many human lives. Through the use of an ordinary machine for alternating currents, all organic life may be annihilated. But the immeasurably stronger and faster alternating Tesla current does no harm whatever to animals and people by passing through them. For instance it was found that dogs subjected to a current that made 4,500 alternations in a second were not disturbed, while an equally strong current of 120 alternations killed them. By further experiments on animals Professor Houston arrived at the general knowledge that with the increase of alternations—from a certain limit up—the danger from the currents diminishes and the effect even becomes beneficial. When the number of alternations is increased until they equal those of the waves of ether, which brings down the sunlight, they are able to exert on the surface of the body the same beneficial effects as ether. In fact Tesla has set out to use his current for remedial purposes.

Only shortly ago Roentgen's marvelous discovery gave us a new outlook on the phenomena and results of nature's forces. So great an impression has it made upon us all that it is almost unnecessary to dwell on the peculiar X-rays, invisible in themselves, that expose to view the interior of opaque bodies, and on the practical results to which already they have given place and which are yet to grow out of them. These things have been set forth at length in the journals during the last year, and for months have occupied whole columns of the newspapers. Yet we here may mention the greatest theoretical importance of the Roentgen discovery. It has shown that the X-rays are manifested through the wave motions of ether and that these waves are the smallest that ever yet have been observed.

SCIENCE

AN EMINENT VISITING SCIENTIST.

LORD KELVIN, better known as Sir William Thomson, for he was sixty-eight years old and had many years of scientific eminence behind him when he was raised to the English peerage in 1892, arrived in New York recently, on his way to the meeting of the British Association in Toronto. He was met, of course, by a number of reporters, and said the usual polite things in the resulting interviews. More interesting than these is the opinion of the great English scientist expressed by Nikola Tesla, as reported by James Creelman for the New York *Journal*. Said Mr. Tesla:

LORD KELVIN.

By courtesy of *The Electrical Review*.

"One of the reasons why I do not like to speak of Lord Kelvin is that I can not find words to express my admiration for the genius of this remarkable man, and my gratitude for what he has done for humanity at large, and for those who, like myself, are following some of the paths he has opened. He occupies a unique position in the scientific world, not only by reason of his achievements, but also by the fact that he has been active and productive during a period seldom allotted to workers in scientific fields. Usually the efforts of the mind prematurely consume the man. But in a few cases, occurring now and then in a century, an exceptionally gifted and vigorous personality appears and leaves an impression which lasts for ages. Lord Kelvin is such a man. But not only is this true of him, but he has also, what few great scientific men have had, a lovable nature, which years have only broadened and intensified.

"His mathematical essays on electricity, magnetism, and heat almost stand alone, veritable monuments. The practical public can better appreciate a part of what he has done when I say that for the past fifty years we have been depending on instruments invented by him for the measurement of a great many quantities, and it is impossible to estimate the benefits to science which have come from his instruments, which even now are used in every scientific laboratory in the world. He has given us the perfected mariner's compass, and just imagine what this has done for navigation and commerce; and in ocean telegraphy he has given us the delicate instruments which are now used for recording messages under all the seas.

"If he were a young man, we might express admiration for his achievement, but his age has almost given sanctity to the eminence of his position."

This is Lord Kelvin's second visit to America, as he was here in 1884, at the Montreal meeting of the British Association. He read a paper at the recent Toronto meeting.

"WE recorded last spring," says *Science*, "the sale of a great auk's egg for £294. Tho the subject has, perhaps, no greater scientific interest than that of the sale of a rare postage-stamp, it may be noticed that another of the eggs, slightly cracked, has been sold in London for £168. The purchaser, Mr. Middlebrook, has now three specimens in his collection."

The Sunday Magazine.

MAN MAY BE MADE TO LIVE 1,000 YEARS.

Prof. Virchow's Splendid Vision of a New Race of Methuselahs.

How the Physically Perfect Man Might Be Bred.

Nearly 4,000 Centenarians Now Living in the United States.

CAN man be made to live forever?

If, by careful living, men can reach the age of one hundred years, why cannot life be prolonged still further?

Science is holding out the hope that the prophecy of Scripture may be fulfilled—that man's last enemy, Death, may be vanquished and human life be prolonged indefinitely.

The remarkable statements made by Prof. Virchow and Nicola Tesla, which are printed on this page, point directly to the possible restoration of the marvellous human age limits recorded in the Old Testament, when the patriarchs, like Methuselah and Noah, lived nearly one thousand years. What man has done in former ages he may do again. He may even transcend it, for man's knowledge of the mechanism of his own body, of its chemical constitution and processes, and of all the diseases that assail it, is incalculably greater now than in the days before the deluge.

Prof. Virchow's recent declaration is startling indeed. He told the International Congress at Moscow a few days ago, in substance that he believed the last secret of life, how to keep life alive and defend it against the assaults of disease effectively and for an indefinite length of time, extending over centuries, would be discovered within the life-time of many members of that Congress.

This is a sublimely grand vision—man storming the mysterious citadel of his own existence, robbing the King of Terrors of his crown, and renewing his youth at will from century to century by the application of his own knowledge of life's inmost secrets.

Not only does Virchow declare his belief in the solution of the problem of keeping human life alive by arresting the processes that now destroy it within a little more than thirty-three years, on an average, and within a century at the most, but Tesla indicates how it will be done. The microbe is the enemy to be destroyed. The destruction of the microbe in all its forms is already being planned and plotted for in all the scientific laboratories of the world.

When the detection of all the disease-breeding bacilli is made easy and certain—and that will be done within a few years—Tesla tells us that the rest will be simply the work of each individual man and woman. The intermarriage of the physically perfect will, in Tesla's judgment, provided the perfect types of humanity thus married observe strictly the laws of health, result in producing a race of men who "will live and retain their faculties for centuries."

That human life may be prolonged very far beyond the limit of years now accepted as usual and inevitable is not indeed a matter of speculation. The average length of human life has already been notably increased within the past thirty years. The death rates of all civilized countries has been going steadily down. Fewer people died per thousand this year in New York City, for example, than died here in 1887. The same is true of London, of Paris, of Berlin and Vienna. Sanitary precautions, health laws, hygienic discoveries of various kinds have done this.

And while the mass of people are living longer on the average, it is remarkable how frequently more than centenarians are reported as having just died in different parts of the world. To live to be one hundred years old is no longer to be distinguished. Especially is the United States a centenarian country. Human century plants are fast becoming commonplace individuals in the land.

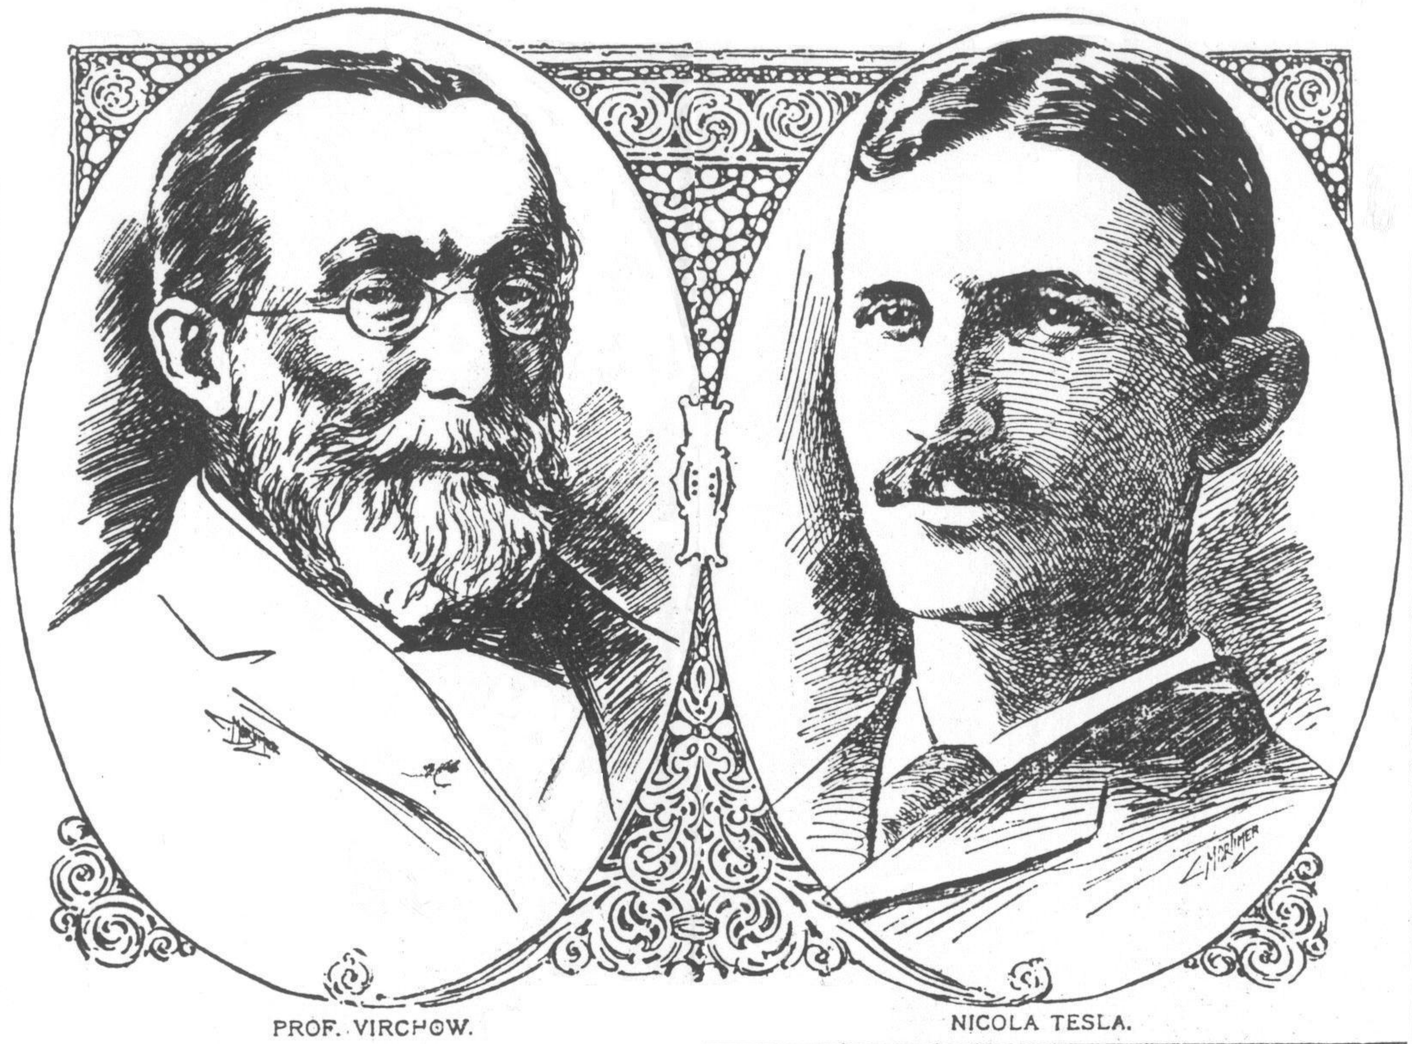
4,000 AMERICAN CENTENARIANS.

The census of 1890 disclosed the fact that nearly 4,000 persons were living in the United States, every one of whom was more than one hundred years old. In Massachusetts alone there were, in the ten years ending with 1890, 203 deaths reported of persons who had all lived more than a century. That showed the one-hundred-year limit of life to be already attained in that State by one in every 1,300 of its population. Iowa reported 500 persons living in the same year at ages above ninety years, and twenty-one persons who had passed their one hundredth birthday.

The British Registrar-General's returns show that in 1891 twenty-one persons were living in London aged upward of one hundred years each. Haller, a famous statistician, collected the figures on this subject for all England a few years ago, and within its boundaries he found authentic records of 1,000 persons who had lived from 100 to 110 years, 60 persons who had scored between 110 and 120 years, 29 who had lived from 120 to 130 years, 15 who had reached ages from 130 to 140 years, 6 who had attained ages from 140 to 150 years, and 1 person who had actually celebrated the 169th anniversary of his birth.

Already, then, we are living in a time when one hundred years is proved to be an easily attainable age, provided the candidate for centenarian honors is of sound hereditary constitution and observes the rules that prolong life.

What Virchow and Tesla hold out to us as a possible scientific realization of the near future is that, with perfected means for the detection of the slightest assault by their microbic enemies upon the blood and tissues of the human body, and men and women willing to live on strictly hygienic principles and bring children into the world, life may be indefinitely prolonged.



Virchow has declared that all life comes from the cell. No living man has studied more deeply the phenomena of life—its beginning, its growth, its culmination and its final decay and death. John Hunter, his celebrated forerunner in this field of inquiry, closed his researches by saying, "Every living thing comes from an egg." Virchow says: "All life comes from a cell."

Everything that lives, whether it be a plant, a tree or an animal, begins its life in a cell, and is built up of cells, each separate cell having a distinct life of its own. "I have been able," says Virchow in a lecture before the Royal Society of England, "to demonstrate the existence of cells in those parts where their presence appeared most doubtful—in bone and connective tissues, and have been able to give utterance to the dictum, omnis cellula a cellula, (every little living cell came from a pre-existing, living cell). The cell is the seat and vehicle of disease, the seat and carrier also of individual life. It possesses the property of irritability, and the changes in its substance, providing these do not of themselves destroy life, produce local disease."

From this demonstration it follows that if Virchow's latest prophecy comes true, and the principle of cell life is finally discovered, man will know how to "keep life alive" by reinforcing it with new life, just as a declining fire is reinforced with new fuel. The life-time of an approximately perfect human body, bred from previous approximately perfect human organizations, may then be extended, at first from periods of from twenty to fifty years, beyond the 100 years already frequently attained.

Then, as the careful reproduction of approximately perfect men and women proceeds, each successive generation will approach more nearly to perfection—with sounder vital organs, purer blood, stronger bones, and a physical equipment in every respect more durable.

(Continued on Page 26.)

PROF. VIRCHOW. NICOLA TESLA.

Nicola Tesla Says Perfected Men Might Live for Centuries.

All Life Is From a Cell and All Death From Microbes.

The Classic Types of the Sculptors Can Be Surpassed.

TESLA SAYS MEN MAY YET LIVE FOR CENTURIES.

"THERE is absolutely no doubt in my mind that the latent power fully exists in man to greatly prolong the average length of his life by the exercise of extraordinary care and the proper utilization of the various instruments which science, day by day, is placing at his disposal. A large proportion of the people who die nowadays before reaching what is commonly called old age can trace the cause of their death to the fact that microbes of every kind are allowed by them to enter their bodies through the swallowing of microbe-laden water and food and through the inspiration of microbe-laden air. How many people are really careful to-day about the water they drink, the food they swallow and the air they breathe? And how many millions of people would be careful if they knew the difference between microbe-laden food and air and those which are really pure?

"Now, instead of whole armies of us plunging into the disgraceful and contemptible task of killing each other in battle, instead of thousands of our master minds spending all their lives in the invention and construction of some terrible machines to kill other human beings, why should not all of us join hands together and shoulder to shoulder turn all our physical and mental energies to killing and warding off all our common enemies and dangers as men? I refer to the perils that are all about us, that threaten us in the air we breathe, the water we drink and the food we consume.

"Is it not strange and shameful that human beings, creatures in the highest state of development in this world, beings with such immense powers of thought and action, the masters of the globe, should be absolutely at the mercy of our unseen foes, that we should not know whether a swallow of food or drink brings us joy and life or pain and death?

"The economical production of high-frequency currents of electricity, which is now an accomplished fact, enables us to generate easily and in large quantities ozone for the disinfection of the water and the air, while certain novel radiations recently discovered give hope of finding effective remedies against ills of microbic origin which have hitherto withstood all efforts of the physician.

"Let the whole world turn against our real foe—disease. Then, with the certain discovery of hundreds of such secrets as the Roentgen rays in their various forms, and countless other means of detecting the presence of bacilli and microbes in the blood, the disordered conditions of the tissues and vital parts, with the legal intermarriage of only such as are physically perfect down to the smallest detail of tissue, blood and bone, and with the proper observance of the laws of health, it is by no means too much to expect that man can ultimately prolong the average length of his life to one hundred years. I believe we are learning to live more intelligently every year. It is very gratifying, for one thing, to find that children are being brought up more carefully than ever before. I believe that with the most careful scientific marriage a race of men and women may in time be developed in which individuals will live and retain their faculties for centuries."

VIRCHOW BELIEVES THE KEY TO LIFE WILL BE FOUND.

"LIFE has no other origin than life itself, and this is one of the great truths which the labors of pathologists and biologists of the present century have established beyond the possibility of a doubt. If the life that is taken from life is taken from a highly-developed life so will be the life that is taken. My earnest hope and belief is that the final mystery of life, the key to life, the principle which keeps life alive, will be solved by the biologists and pathologists before all the members of the present Congress are dead."—Prof. Virchow to the International Congress at Moscow, Aug. 19, 1897.

A PERFECT WOMAN'S PROPORTIONS.	
Height	5 ft. 6 inches.
Width of neck	4 inches.
Width of shoulders	14 inches.
Width of chest between the arms	8 inches.
Fullest width of waist	10½ inches.
Width of hips at front	13 inches.
Front width of leg just above the knee	11 inches.
Front width of calf	11 inches.
Front width of ankle	2½ inches.
Weight	140 pounds.

A PERFECT MAN'S PROPORTIONS.	
Height	6 ft. 2½ inches.
Girth of chest	46 inches.
Girth of waist	38 inches.
Length of upper leg	17 inches.
Length of lower leg	14½ inches.
Largest girth of thigh	2[illegible] inches.
Girth of calf	16 inches.
Length of arm	26 inches.
Weight	190 pounds.

EMINENT SCIENTISTS DECLARE THAT THERE IS NO LIMIT TO THE LIFE OF HUMAN BEINGS.

(Continued from Page 25.)

In this way the perfected men and women of the coming age, foreseen by Virchow and Tesla, will be born with a much longer lease of life to begin with—built to live 150 years.

Assume that these perfected types of human life avoid all disease-inducing habits and practices, live temperately in all things, make no drafts of folly on their stock of vital energy, and call to the protection [illegible]ore of life all the resources of the latest scientific [illegible]veries. Koch and his school have shown how all malignant disease proceeds from bacilli. Diphtheria, typhus, cholera, the plague, consumption and all the other dragons that destroy human life are simply so many species of bacilli.

THE NEW SEARCHLIGHT.

The X ray permits the inmost secrets of the body to be undovered. With its aid the first appearance of the assailing microbe will be easily signalled. Under its searching light the earliest symptom of functional disturbance will be apparent. And every physician knows that men die by thousands daily simply because their internal maladies were not discovered in time to make resistance successful.

"All life is from a cell," cries Virchow. "All death is from a bacillus," cries Koch. To discover how the life principle of the cell may be fed and renewed is one-half of the problem of making men live three, four, five or ten times as many years as they do now. Virchow believes that half of it will be solved within the lives of many men now living.

The other half of the problem is how to detect and destroy the attacking bacillus and thus baffle death. And half of that half-problem is already solved. Those who are familiar with the results reached by expert horticulturists in the perfecting of plants by careful selection of seeds, so that marvellously beautiful flowers have been at length evolved from continually improving growths, will easily believe that whenever men and women in any considerable number choose to enter the marriage relation with the studied purpose of producing more perfect types of humanity, startling results will be gained. If they and their children and their children's children shall continue to blend the science of health with the sentiment of love, the result, in the course of time, would surely be the appearance of a distinctly higher and nobler order of men and women of such splendid stature and perfectly proportioned bodies as would surpass the loftiest conceptions of human strength, symmetry of limb and beauty of face, which the sculptor's inspired chisel has embodied in the marbled gods.

POSSIBILITIES OF SCIENTIFIC PARENTAGE.

The lesson of the scientific methods of stock raising by which cows and sheep, stronger, larger-limbed and longer-lived that our fathers ever saw, and horses capable of speed performances such as they would have said were beyond the bounds of possibility, are all hints in the same direction.

To state the problem in arithmetical shape: If Thomas Parr lived 152 years, his lifetime stretching across three centuries, from the fifteenth to the seventeenth, in an age that was unsanitary and unscientific, when the hundred and one aids to long life and defenses against disease and death which are at our service to-day were unknown and undreamed of, how long might a human life of strength originally equal to Parr's, derived from several generations of constantly perfecting human types, be made to last, when Virchow's promise has been realized and the principle of reinforcing life has been discovered on the one hand, and Koch's promise or immunity from microbes has been fulfilled on the other?

Clearly, if Parr, in the darkness and ignorance of the fifteenth and sixteenth centuries, the days of the Great Plague, when pestilence stalked the earth unchallenged, was able to achieve 152 years, the perfected man of the twentieth century of light and science may be expected to easily reach 200 years, and advance by natural stages of improvement, until the man who lives 500 years will be no more celebrated than Thomas Parr is now.

SULLIVAN'S DEFECT AS A PHYSICAL MODEL.

The process of improving the human type by reproducing it from the most perfect types, the improved types in their turn peopling the world with yet more nearly perfect types, will have as its natural starting point the most ideal type of the physical man of which we now have knowledge.

This is a matter of proportionate measurements, which the authorities on the human form have definitely laid down. The figure of the most ideal man yet developed—a foreshadowing of the perfected man who is coming—is shown on this page. It is adapted from the famous statue of "The Boxer," by the sculptor Donoghue. It was modelled, as to the body, from John L. Sullivan in his best form. But the legs are not those of Sullivan.

Dr. Oliver Wendell Holmes, who inspected Sullivan about that time, and whose anatomical learning was second to that of no man of his time, pronounced him to be a model of form—except as to his legs. They were too small. The legs were modelled, strange to say, from those of a bantam-weight boxer, who weighed sixty pounds less than Sullivan—Johnny Murphy—long known as Harvard's favorite boxing instructor.

IDEAL MEASUREMENTS.

The measurements of Corbett at twenty-seven years of age may be cited as those of one of the approximately best human physiques living to-day. Standing 6 feet 1 inch in his bare feet, he weighed 185 pounds. His neck measured 17 inches, his chest 38 inches, expanding to 42¼ inches; his waist 33 inches, his thighs 21 inches, his calves 14½ inches, his arms outstretched gave 6 feet 2 inches from finger-tips to finger-tips, his biceps measured 14½ inches, his forearm 11½ inches, his wrist 6¼ inches; his glove size was 8, his hat size 7½ and his shoe size 8. Yet he was not precisely proportioned.

It is doubtful if any man living exactly meets all the measurements that make a perfectly proportioned man. Somewhere in his make-up there is a defect, a surplus inch or an inch lacking. We shall have to wait for the perfectly proportioned man until the visions of Virchow and Koch and Tesla are all fulfilled, and the production of higher types from high types, and higher yet from the higher thus created, and so on, has culminated in the man and woman filled with health, proof against disease, of exactly proportionate measurements, and possessing the secret of keeping life alive, fitted to live for four or five centuries.

THE LATEST ANTI-GERM DISCOVERIES.

Within the past fortnight two new scientific appliances have been announced which will make it easier for the coming man to grow proof against microbes and measure his years by hundreds. Dr. Robert Xavier Glering, of Baltimore, has found a way of using X rays so as to obtain photographic pictures, not merely of the bones of the body, but of every tissue in the body, in detail—all its muscles, interior organs, blood vessels and nerves. No symptom of disease can evade this photographic test. Dr. Robert L. Watkins, of this city, at the same time announces the invention of what he calls the micromotoscope. With this instrument, a combination of the microscope and the vitascope, the presence of any bacilli in the blood can, he asserts, be unerringly detected. Such inventions herald the age when disease will not be cured, but prevented.

Dr. Howard Lilienthal, of No. 111 Madison Avenue, consulting physician to Mount Sinai Hospital, discussing Virchow's prophecy says: "Any new apparatus or method which will enable physicians to discover the presence of curable diseases earlier than the present methods do, will undoubtedly result in the prolongation of human life. Still, it is rather too early to decide the amount of good done to medicine by the newly announced apparatus of Dr. Glering, of Baltimore, and Dr. Watkins, of this city. We should wait a little to see if they are really practical. I do believe, however, that it is only a question of a few years when science will place in the hands of man appliances like the X ray which will enable him to prolong his own life for no inconsiderable period.

"Only last week I was reading a book of Gould's and was simply astounded to find in its pages a long list of men and women who had been known by the author to have lived to the ages of 150 and 175 years. Certainly if the people mentioned by Gould could live to the age of 175 without the aid of such scientific appliances as the X ray it is only reasonable to expect that others can live just as long, if not longer, if they have placed in their hands the apparatus without number which are sure to be discovered in the years to come.

"It will no doubt surprise the world at large to learn that Virchow, the greatest living authority on all medical matters, and who is President of the International Association of Surgeons, which has just concluded its big congress at Moscow, is reported by the Medical Record to have said in his address to that body that he firmly believes the time will come when man will learn the key to prolonging life, and that he (Virchow) is inclined to believe that as soon as the twentieth century that one great secret of life will be laid bare by the men of science."

WHAT DR. CYRUS EDSON THINKS.

Dr. Cyrus Edson says: "While I believe that microbes are not such an unmixed evil, in that they serve to kill out the physically and mentally weak, I believe, nevertheless, that the discovery of such appliances as those attributed to Glering and Watkins, if they can ever become practical, will be the means of lengthening human life enormously.

"I think that Tesla goes to rather an extreme and looks too far into the future when he says that men can ultimately live so long, but I do believe, also, that in a few generations a large number of appliances will be discovered, each of which, doing its little share, will serve to place it within man's reach to lengthen his life by fifty years, or even more. But when I say this I want it understood that the appliances can serve to lengthen the lives of those only, and none others, who will devote themselves from the beginning to strictly sober, temperate lives, entirely free from the vices which are now so common.

"Even at the present day any physician can enormously lengthen the life of any physically perfect man who will agree to abstain entirely from intemperate and vicious habits. The difficulty is to find the man who is willing to sacrifice his inclination for vice to his mere wish to live a long life. But, given a man and woman who are willing to devote themselves to such purely hygienic lives, and whom these appliances show to be minutely physically and mentally perfect, their offspring will be healthier than the average man, and consequently longer lived."

A WOMAN PHYSICIAN'S THOUGHT.

Dr. Donohue, the clever woman physician-director of the New York Hospital for Women, at No. 213 West Fifty-fourth street, and who is a daughter of the late celebrated athlete, Capt. Donohue, of Newburg, says:

"The mere discovery of these various appliances like the X-rays, and those of Drs. Glering and Watkins, if they are practical, will unquestionably give the medical man better opportunity of locating and diagnosing diseases of all kinds. But these discoveries for the locating of diseases will not in themselves so materially serve to lengthen human life. If we will set to work and, after perfecting apparatus to detect disease in such obscure and little known places, invent means of curing the diseases we have so cleverly located, then unquestionably the man who leads a temperate, non-vicious life can prolong that life indefinitely.

"If we could make it possible to allow only the intermarriage of such persons as are shown by these means to be really physically perfect, down to the smallest detail of tissue and blood, then it is more than likely that by ages and ages of breeding men who led hygienic lives, descended from physically perfect men who had also led hygienic lives, we might produce a race that might live double, treble and possibly a hundredfold more years than the average man of this present time."

E. B. Foote, M. D., of No. 130 Lexington avenue, who is the author of several well-known works of medical interest, says: "I certainly agree with Mr. Tesla when he says that human life can ultimately be prolonged indefinitely. For the past fifty years all of our large cities have been devoting enormous sums of money to the construction of proper drainage and other public sanitation, and, as everybody now knows, the death-rate in our large cities at the present day is strikingly smaller than it ever has been in all medical history.

"This shows conclusively that man has the power within him to prolong his own life. If it were possible to have fifteen or twenty generations of men live strictly temperate lives, with the total abandonment of vicious habits, and abstinence from coffee, tea, tobacco and alcohol, together with the marriage of only such women as the newest appliances of X-rays and other scientific discoveries would show to be physically perfect, even to the absence of microbes of any disease in the blood and tissues, then I believe that the last man of the line would compare favorably in age with Methuselah and the other famous old men of Biblical tradition. The trouble will be to find the men to live such purely scientifically perfect lives."

DR. KUHN BELIEVES IT.

Dr. F. W. Kuhn, head surgeon of the Eastern District Hospital, Brooklyn, says: "Man's life is rendered extinct when the germs and microbes in his body succeed in getting the upper hand. If man can utilize science in locating these germs and killing them off, unquestionably even the men of our own generation can prolong their own lives by a number of years.

"If the old men of Biblical note could live for such long years I do not see any good reason why men of the present and the centuries to come could not live a great deal longer than sixty, eighty or ninety years. While, of course, microbes existed in the time of Methuselah and the other patriarchs, I believe that their number was so infinitesimally small that men were entirely free from contamination by them, and thus were able to live to such great ages. But with the continual increase in the number of microbes and the consequent increase of the number swallowed by man in his food, water and the air he breathes, the more desperate has been the battle of his vital parts with these hostile germs, and consequently the earlier has been his consignment to the grave. Invent appliances to destroy these myriads of microbes and you invent means to prolong man's life, and the more thorough the character of the appliances invented the more nearly will the men of the future approach in age the years of the patriarchs the Bible tells about."

These opinions of representative physicians show that Virchow's and Tesla's prophecies of a coming race that will possess the secret of renewing life, defying disease and living through many centuries are well within the bounds of possibility.

A SUMMARY OF ROENTGEN RAY THEORIES.—I.

BY A. VOSMAER AND F. L. ORTT.

(Electrical Research Laboratory, The Hague, Holland.)

THE most important question whether Röntgen rays are to be considered as falling into the domain of light, or whether they are something else, has occupied so many minds, that the literature on this subject has grown enormously; but is it settled yet whether they are transversal waves of very small wave-length, or longitudinal waves, or vortex motion of the ether, or longitudinal impulses, or due to electromagnetic dispersion, or radiant matter? Having read so many theories, with so many supporters and opposers, one gets puzzled what to believe. Not a small part of the confusion is caused by the number of contradictory experiments; and no wonder at this, the question being, in fact, of the utmost complication—that is to say, not only as to the nature of the rays themselves, but also the way in which to get them. Being engaged in the study of silent electric discharges, it was rather in our line to consider the question of cathodic, as well as of our anodic, discharges. Thus we arrived at a conclusion about the nature of Röntgen rays, which explains a great deal, though we must confess that certain assumptions have to be made. This is not an attempt to explain this most difficult problem, but to suggest an hypothesis that is most nearly in accordance with experiments, so far as they go.

We consider Röntgen rays to be nothing but discharged cathode rays, and will now test this hypothesis by seeing how it will explain some of the most striking experiments and facts. As a matter of fact, cathode rays are deflected by a magnet; they obey the law of attraction of a current by a magnet; i. e., they behave as a current or stream of negatively charged particles. These negative particles impinge upon the glass wall of the tube, which, as is well known, possesses a strong positive (external) charge. Is there anything strange in the idea that those particles may lose their charge when in contact with the positive charged wall, and proceed on their way as discharged particles? These discharged particles cannot be, and are not, attracted by a magnet; why should they be? Hence the essential difference between cathode and Röntgen rays is explained. Röntgen rays would thus discharge a negatively or positively charged body, as a matter of course, since any electrified body, struck by neutral particles, always loses its charge.

Now let us consider some important details; in the first place, with regard to the focus tube. Some people do not accept the property of being reflected as possessed by the Röntgen rays. It seems to us that the experiments of Tesla with his T-tube, allowing him to take simultaneously a sciagraph from reflected and from rays that have passed through different plates of metal, are conclusive in this respect; but they prove that the total amount of reflection varies not very much for the least and for the best reflectors; the maximum result obtained with zinc (platinum does not seem to have been tested) was only 3 per cent. Probably platinum will give a higher percentage of reflected rays; but even then it does not sufficiently account for the large difference of efficiency of the ordinary and the focus tube. According to our theory the real cause of the high efficiency of the focus tube lies in the fact that the cathode rays strike on an actual anode, instead of upon an anode by induction.

This, so far, is not new. To quote Lodge, in an article written some time ago: "Hence, undoubtedly the X-rays do not start from cathode, or from anything attached to it, but do start from a surface upon which the cathode rays strike, whether it be an actual anode or only an anti-cathodic surface; best, however, if it be an actual anode."

Röntgen and Rowland had discovered the same thing. According to our theory, it is evident that the negatively charged particles can lose their charge sooner and more completely when they strike an actual anode, than when they strike an anode by induction (of greater surface, and thus of smaller density). Everybody will agree with Prof. Peckham, where he says that the discharge-tube is a resonator for its coil, and when the coil and tube are properly attuned the maximum effect is obtained. We should say, when the discharging capacity of the surface struck by the cathode rays can keep time with the vibrations of the intermittent current or stream of charged particles, the most intense Röntgen rays will be obtained. If discharging—or, better to say, neutralizing—of the waves of negative particles from the cathode be not synchronous with their impinging upon the focus or wall, they cannot lose all their charge, and will proceed either as particles with a minute negative charge, or with a minute positive charge, or perhaps mixed with neutral parts. The result will be feebler Röntgen rays, and, according to the preponderance of the one or the other particles, these rays will discharge an electrified body and give it charge according to its own charge. Borgmann found that a negatively charged plate, when exposed to Röntgen rays, lost its charge to become positively charged; when the plate was positively charged, it lost part of its charge. Righi found just the contrary; a positively charged plate lost its charge to end with a negative charge. Porter, and nearly all other experimenters, found in all cases a complete loss.

We could explain these differences by admitting that neither Borgmann nor Righi had pure Röntgen rays, but had them mixed with positive and negative rays, respectively. We consider Porter's $X_1X_2X_3$ rays and Lenard's gamut of rays of more and less magnetic deflectibility, as Röntgen rays of less and more purity, i. e., neutrality. The more perfectly the negative charge has been taken away by the anode—without, however, imparting a positive charge instead—the more intense the Röntgen rays will be, and the stronger penetrating power they will possess. It is hardly necessary to say that it must be very difficult to obtain perfectly neutral rays; this end will obviously only be attained when the whole system of generating—current, frequency, self-induction, capacity, vacuum, size and form of tube, and all the rest—be in true harmony with one another; and to realize this, means no small thing to do in practice.

We do not venture to say that our theory explains everything, but we do think it explains much; we do not ignore the fact that it is difficult to understand how the Crookes' radiant matter could pass through the glass wall as discharged matter, but the theory of ether motion also presents difficulties. Experiments on the Lenard rays passing as charged particles through aluminum, are described in "Nature," of May 27 (p. 93). Why should the etheric disturbance in the air answer so closely to the vacuum in the tube? Why should the rays, if they be ether vibrations, which in any case must be of so short a wave-length that the well known properties of light do not show, make any difference whether they are obliged to pass through one or the other metal or material? If the intermolecular space be of any influence on them, one should expect refraction in those materials that show greater resistance to the rays passing.

The strongest proof for our theory is Lafay's experiment, where he found that Röntgen rays, passed through a negatively charged leaf of silver, can again be deflected by a magnet, and in the same direction as the cathode rays in the tube; and when the leaf was positively charged, in the opposite direction. That means that neutral, non-deflectible rays, after recharging, become again sensitive to the magnet; the deflection being absolutely in accordance with electromagnetic laws of attraction and repulsion. Unfortunately this experiment, repeated by Lodge, has not been confirmed by him; but it is easy to understand that recharging, just like discharging, is no simple thing to accomplish.

(Our next issue will contain a review of the theory of Messrs. Vosmaer and Ortt.—Eds. E. E.)

[1]From London Nature

AN INTERESTING REVIEW OF X-RAY PRACTICE.

Gold Foil Screen Described by Mr. Elliott Woods.

MANY IMPORTANT EXPERIMENTS INSTRUCTIVE TO THE SURGEON AND THE MANUFACTURER OF X-RAY APPARATUS—THE AUTHOR BELIEVES THAT THE DANGER FROM THE RAYS IS EXAGGERATED, AND STATES THAT THEY ARE HARMLESS UNDER THE PRECAUTIONS ANNOUNCED — BATH OF HIGH-FREQUENCY CURRENTS BENEFICIAL FOR X-RAY BURNS—TESLA'S VALUABLE WORK IN THIS NEW FIELD.

To the Editor of Electrical Review:

Some publicity has been given by the daily press to an alleged discovery made by me of a method of making the X ray harmless. In a local paper of this date considerable importance has been attached to an accidental chat with a reporter, and this so-called discovery magnified to a considerable degree. Now, to be exact and at the same time to aid, if possible, in the study of the X-ray phenomena, particularly in the application of the rays to surgical studies, I desire to correct these press reports to a considerable extent and state what really has been done.

First, nothing has been accomplished that is not the result, directly, of Mr. Tesla's already published results; and my experiments are merely modifications of his methods. Mr. Tesla utilizes aluminum sheet or gauze. I use gold leaf, such as gilders use, and this only because aluminum sheet was not to be had in the city.

My experiments having brought me in contact with a number of surgeons in the city, who desired to note the condition of injured bones which had been treated by them, I felt a natural anxiety that the patients they presented for examination should not suffer from the much-heralded results of a continued exposure to rays generated by a powerful apparatus. Previous to the publication of Mr. Tesla's article, wherein he details his experiments with tubes of platinum and aluminum anodes, and aluminum sheet or gauze earth connected, I had contented myself with brief exposures, both for photographic and visual purposes. I deemed this precaution necessary, for accounts were numerous of the effect of the rays and the patients were timid. On the other hand, from the date of Roentgen's announcement, I have exposed my person freely, both in experimenting and for exhibition purposes, and as yet have failed to receive the slightest injury. The tubes used are the most powerful obtainable, excited by various coils and high-frequency apparatus. I will return to this later.

In the course of an examination made on the foot of a patient, to locate a broken needle, I placed the tube about 12 inches from the foot, and was surprised to note, after putting the tube into action, that a tolerably heavy spark could be drawn from the bottom of the foot. In frequent shifting of the foot, necessary to properly examine and sketch the position of the small piece of needle, the patient complained of the unpleasant feeling caused by the spark, but I learned that a "hot feeling," which he mentioned early in the examination, subsided when I held his foot in my hand. It was evident that the foot in this case was the outlet for a considerable charge of electricity which the patient had been able to accumulate from the tube and wires, because of his well insulated position on the reclining-table used, and that he was relieved by the additional condenser added when I connected my body to his. Taking note of the two facts obtained in this examination, and remembering Mr. Tesla's work with the aluminum screen, I carried on some experiments with the only metal sheet I had which was sufficiently transparent, and that was gold foil. I prepared a screen about 10 by 10 inches, and of cardboard, putting on it a temporary coating of gold foil. When not connected to earth, a considerable spark could be obtained from it, which spark entirely ceased, of course, when the foil was earth connected. Placing the hand of a volunteer assistant behind this foil screen, properly connected, no spark was secured. I gave my hand generous exposure under the screen and no ill effects have been noted. Placing the screen close to the tube so that my face could be brought within six inches, I failed to note the heating sensation which I nearly always feel when exhibiting my skull without the screen. Here I wish to remark that my cheek and that portion of the body between the shoulder blades are the only portions of the body which take note of this effect. Now, it would seem that whatever danger symptoms lurk in the rays, all are effectually stopped by an earth-connected screen of this kind and one made of gold leaf on cardboard is nearly transparent on account of the thinness of the metal leaf. In fact, I have failed to find any absorption produced by it on the platinum-barium screen. There might be more shown when using less powerful tubes, but with those used by me the absorption is inappreciable. There are no special claims for this "discovery" as published. To Tesla belongs everything that attaches to it, being as it is a modification of his method. I hope, however, that experimenters will not fail to try *thoroughly* the gold leaf or other thin leaf metal, which is inexpensive, readily procurable when aluminum may not be. This type of screen, while it has proved its security, as a makeshift, in the cases where it has been used by me, may not prove safe in other cases.

I hope every one who utilizes the X-rays for more than exhibition purposes merely will study these screening effects of leaf metal, and give surgeons who desire to install suitable apparatus relief from their fears, for these fears seem to be widespread, and patients are at the present day more fearful of the ray than of the knife. In any event, I would warn the handlers of powerful apparatus to take heed of the first sensation of heat when spoken of by the patient. It is likely to be the first sign of dissolution of tissue. While patients are apt, as a result of report, to be timid, it would be well to state frankly to them the possible sensations which might be felt and ask them to control their imagination sufficiently well to give their actual sensations.

Different persons appear to differ in their sensations when under the influence of a copious generation of the rays. Some are affected at the eyelids. Some feel the sensations of an electric discharge; while others state that their hands or faces are bombarded by invisible dust. These various sensations are worth consideration. They lead me to an opinion that the majority of persons, by reason of bodily state of health, are immune, at least to ordinary exposures. Some, according to my experience, are extremely sensitive, and it would be well for operating surgeons to take carefully into account the nervous condition of the patient.

A nervous person—and by that I mean one naturally so—is a fit subject for the metal screen. Some tissues of the body appear to be more susceptible than others. Particularly does this appear to be the case with the tissues of the head. I can always experience that "hot sensation" in the head, and in that portion of the body between the shoulders, when I exhibit my heart on the screen. Other parts of my body are not susceptible. The sensations, when experienced, are unmistakable, and a sensible patient can readily give his operating surgeon the note of warning. The surgeon should know his apparatus thoroughly, and content himself with brief exposures; and here I would suggest, out of experience, that before a powerful apparatus is used, every means should be resorted to in becoming acquainted, not only with the coil used to excite the tube, but the tube also.

A coil excited by a battery, while ample for ordinary exhibitions, is apt to fluctuate in its output by reason of the fall in the exciting current. It is advisable, when the coil is to be used for surgical operations, that it be excited by a motor-generator giving a constant current and voltage, and operated by an electric lighting circuit. It is essential that the tube for such operations be of the very best adjustable vacuum type, for then the surgeon can be assured of a constancy in the generation and penetrating power of the rays. With these tubes the vacuum can be adjusted so that the rays may not, in cases of examination of the limbs, be of themselves dangerous. When adjusted for examination of the trunk, and the vacuum being maintained high to obtain great penetration, and a high voltage used in the exciting apparatus, the metal screen should be interposed. It is the indiscriminate, careless handling of the exciting apparatus that is responsible largely for accidents. The surgeon would never handle the lance except by the best and well studied method. The X-ray tube is worthy of the same study and careful manipulation.

By far the best exciting apparatus, either direct or high frequency (which can sometimes be charged by a direct-current coil), is that operated from a lighting circuit. The inconstancy of current is largely avoided and the vacuum of the tube having been adjusted can be readily maintained. This is of safe and great importance in surgical operations; and while I do not wish to cast slander on coils operated by batteries, I have found that it is hard to obtain these important items from a battery-driven coil. Confidence in your tube and coil and knowledge that the current and voltage will remain practically constant is a factor of safety to the patient.

I now beg to call the attention of surgeons to so-called burns produced by X rays. Their features are well known. The persistence against ordinary remedies, I believe, is now admitted. Some time ago I read in an article copied from the foreign press that high-frequency currents were found beneficial treatment. When, by exhibiting my skull, I experience the heating sensation mentioned before, I generally give my affected cheek a bath of high-frequency currents, from *one* terminal of the high-frequency coil. If a surgeon have a case of injury from the rays, let him try this remedy if he can find such a coil in the neighborhood. I do not say it will cure, but rather ask a trial of it; and if I may be permitted to wander from the subject a trifle, I would add to try these high-frequency currents for fresh colds, weakness of voice, and general affections of the throat, remembering that the application should be made with the hand, laying it on the throat *first*, then connecting the operating surgeon's body to *one* terminal of a weakly excited, high-frequency coil. These coils are prolific generators of ozone. Excite the coil and let the patient inhale the ozone from either a funnel and tube held over the discharge, or by getting his mouth conveniently near. If an inhaling funnel is used, it should be of rubber to prevent shock, and the patient should be allowed to use it to suit the sensitive state of the affected membranes.

From a careful study of the effects of X rays on the tissue I am led to theorize that it is an electrical decomposition of the tissue, which can be prevented by the use of the metal screen. In treating a case of burn already produced, with high frequency currents, it would be well to use a spray discharge, avoiding carefully the spark which is apt to pass if the electrode is brought too near. I would suggest the spray of the static machine. But the main thing

is to make the X ray harmless, and whether we believe with Tesla that the rays are projections of material particles, or whether they are mere electric waves, the virus—if I may so term it—seems to be extracted when we force them to pass through a metal screen. These carriers of decomposition, in whatever form we may choose to look upon them as possessing, become apparently harmless after such a passage. The surgeon knows the utility of the X ray, but many are fearful of the effect. Manufacturers of X-ray apparatus should, by all means, further their own interests by giving competent instruction to purchasers, based on the experience of users, and particularly on the splendid investigations of Tesla, which have been published. It would be good policy for colleges to train surgeons in the manipulation of apparatus, and the subject would hardly fail of interest where so much benefit is involved and some dangers due to carelessness to be avoided.

I am inclined to believe from my personal experience that the dangers are greatly exaggerated. I am more inclined to lay bad experiences, already in evidence, to bodily conditions. I hope to experiment on this feature for the benefit of surgeons. I earnestly hope that experiences may be noted by surgeons in the handling of the rays on persons of various temperaments and that they be published in the proper journals.

In any event, it appears that X rays are harmless under the precautions named. ELLIOTT WOODS.

Washington, D. C., Sept 6.

HAVE CONTROL OF TESLA'S INVENTIONS

The Kings County Electric Company Will Revolutionize Things

IN THE ELECTRICAL WORLD.

Three Brooklynites Who Are Deeply Interested in the New Enterprise—A Plan Which, It Is Hoped, Will Result in the Manufacture of Electricity at Such a Low Rate That Present Conditions Will Be All Upset—D. O. Mills, ex-Governor Flower and Vice President Hobart Interested In the Venture. Power for Metropolitan Surface and L Roads One of the Prizes the New Company Has In View—A Great Project.

Brooklyn will shortly be the scene of one of the greatest scientific and industrial battles of the age. The breastworks and fortifications are already being built. The genius of Tesla is to try conclusions with the wisdom and experience of Edison. This great struggle for supremacy in science and finance will have its seat of war right in Brooklyn, though its outposts will spread throughout this state and into Jersey. Just how far it will eventually extend its lines no one can at present say, for that lies principally in the outcome of the battle that is now beginning in this city. In other words the Edison Electric Company has a rival in the field whose strength will probably soon be felt. The Edison people have an inkling of what is about to take place, but they pretend to look upon it as not very important. In Montague street the Kings County Electric Light and Power Company have established an office in the second floor of the recently rebuilt and improved building next to the Real Estate Exchange. By the general public little is known of this concern. The employes there refuse to even give the names of the officers of the company and direct all inquirers to see A. M. Young. A. M. Young has no particular hour of arriving at the office nor of departing—and even if caught by questioners he is a little less communicative, if possible, than the clerks. It is said on good authority, however, that Bridge President William Berri, Seth L. Keeney and Felix Campbell, president of the People's Trust Company, are much interested in the new company. Mr. Berri, when questioned about the enterprise by an Eagle reporter, said:

"It is a very big scheme and one in which Mr. Keeney and I are very much interested, but we cannot say just at present just what is in the project. It is a great enterprise, with lots of money in it, but for many reasons its intentions cannot be told now."

Felix Campbell shook his head when interviewed and said: "Yes, there is such a company organized and I have been told of it, but I have been away and do not know who is behind it."

Mr. Julian Fairchild, president of the Kings County Trust Company, who is a director of the Edison Company, said:

"We know the intentions of the Kings County Electric Light and Power Company, and if they think they work in secret they are mistaken. Perhaps we would fear their power if we did not know that the men whom we believed at first were in it are not. We have investigated and find that J. Pierpont Morgan and D. O. Mills are not behind it with their capital, and Governor Flower is the biggest man they have."

The company as it now stands, it is understood, will put into actual practice and work the inventions of Nikola Tresla, upon which he has been working for years and which have been brought to a practical industrial basis within the last year. Vice President Hobart, it is understood, with two other prominent financiers of New Jersey, will take hold of the enterprise in that state.

Ex-Governor Roswell P. Flower and Messrs. Morgan and Mills will represent New York City and the state, while Messrs, Berri, Campbell and Keeney will see to the work in Brooklyn that has already been commenced. Behind these men will stand the genius of Tesla and their wealth will bring out the result of inventions that he has already demonstrated in a more or less forcible degree.

Ostensibly the presidetn of the new company is Charles Cooper. It was he who secured the franchise for the electric plant in this city and it is said that he was at first more than willing to sell it for somewhere in the neighborhood of $50,000. But he did not then realize the possibilities that lay behind this franchise and they have grown to such an extent that Mr. Cooper, it is now stated, would not dispose of this franchise or his holdings in the company for $600,000 cash. Mr. Cooper is the man who pushed the gas combination through to a successful climax. Mr. A. M. Young is the business manager of the concern and is pushing forward the work in Brooklyn.

The first demonstration on the part of the company that they meant business and big business was the purchase of a piece of property on the East River that involved an expenditure of half a million dollars. It was the block running from East River to John street, between Bridge and Gold. In the first transaction the Kings County Electric Light Company bought from Squibb & Sons, the chemists, for $185,000, the chemical plant situated on Gold and Johns streets, running down to the river front, with a frontage of 185 feet on East River and John street and a depth of 475 feet. It has several brick buildings upon it at present. This is the first piece of property owned by the company and with the exception of the big piece of land bought by the Squibbs adjoining it it is the only considerable waterfront that is not controlled by the warehouse combination. It is here that the first plant will be built and it is an excellent site, for the coal may be easily and cheaply brought to the works and there are many other advantages coming from the water front obtained. Fifty miles of subway have already been laid by the company, and it is now said that just as soon as the power plant is ready fully a hundred miles of wire will be ready to receive the electric current and the big fight will be on in earnest.

President Berri said that no bonds would be offered and no shares sold at large and that the company was already fully organized and backed by well equipped men in the financial world. The company admits, through the president, that the Tesla inventions and his new systems are controlled by them. How much this means cannot be fully stated until the company chooses to make all its plans public, but it may be said that Tesla has long been at work upon the problem of transmitting power of high voltage to any distance without the expensive loss that is a part of the systems now in use. Mr. Tesla came to America with the idea of entering a field where inventive genius would be appreciated and had in his mind then the problem which he is said to have to a great measure solved. He worked for a time under Edison, for whom he has the greatest admiration. But soon the pupil became too great for the master and he left him to joint a company to make and sell an arc lighting system based on some of his inventions in that branch of art and which had in them the then unworked theory of the alternating current which Tesla had experimented upon successfully in Paris. So full was he of the wonderful possibilities in his surprising discoveries that he was for publishing then abroad, but he was induced by friends to put his inventions and discoveries to the test through interested capital, which was soon obtained. A suggestion of what is about to be disclosed through the company now formed may be had from an address made by Tesla in May, 1891, before the American Institute of Electrical Engineers in New York, in which he spoke of the possibilities of alternating currents and the transmission of high potential currents. He stated then a step had been made in the advance of electrical lighting and power giving.

"But there is a possibility of obtaining energy not only in the form of light, but motive power," said Mr. Tesla, "and energy of any other form in some more direct way from the medium. The time will be when this will be accomplished and the time has come when one may utter such words before an enlightened audience without being considered a visionary. The mere contemplation of these possibilities expands our minds, strengthens our hopes and fills our hearts with supreme delight."

And this man who spoke so enthusiastically then of the discovery he was on the eve of making some time later spoke of the progress he had made in the distribution of light and power in these words:

"I am led to believe now that in our future distribution of electrical energy by currents of very high tension, liquid insulation will be used. The cost is a great drawback, but if we employ an oil as an insulator the distribution of electrical energy with something like 100,000 volts, and even more, becomes, at least, with higher frequencies, so easy that it could hardly be called an engineering feat. With oil insulation and alternate current motors, transmission of power can be effected with safety and upon an industrial basis at distances of as much as a thousand miles."

That was several years ago, and it is now stated that this modern genius has worked out his theory to a practical basis and Edison will meet a foe worthy of him in his own field. It is said that the railroads of this city, the Brooklyn Heights, the elevated roads and all the transportation lines will be enabled to sell their plants or dispose of them to the new company and obtain all their power from the plant that will work wih the inventions of Tesla. D. O. Mills, it is said, has satisfied himself of the practicability of the scheme and, with his interests in metropolitan railroad companies, is anxious to have it put to the test.

MAY SUPPLY RAILROADS.

New Tesla Electric Company Has Made Them Propositions.

COST TO BE MUCH REDUCED.

After the Eagle Was Published Last Night the Promoters of the New Enterprise Were Deluged With Applications for Stock From Would-Be Investors — Machinery Involving New Ideas to Be Built.

Further information in regard to the Kings County Electric Light and Power Company shows that this new factor in Brooklyn's industrial world is more important that was at first believed. The account in the Eagle created considerable interest in financial and business circles and only a short time after the paper was on the street the demand for stock in the new company began and the offices of the concern were burdened with applications for information. It should be said right here for the benefit of would be investors, that every cent of stock has been contributed and shares cannot be cought at any price, according to the statement of those in authority. As stated before, Mr. Cooper is nominally the president at present, but in about ten days the directors of the company will elect the officers and in six months the concern will, it is said, be at work supplying power and light, for which they already have more orders than they can possibly take care of for some time.

All the local railroads are greatly interested in the outcome of the new electric company's experiments here and it is more than possible that every one of them will be supplied with power by the new company. Negotiations to this effect have been conducted with Presidents Rossiter, Johnson, Heins and Sullivan of the trolley roads and also with Presidents Uhlmann and Jourdan of the Brooklyn and Kings County Elevated Companies, which are to change their motive power to electricity this fall. One of the largest holders in the new electrical company said to-day that all of the railroad presidents had considered the scheme with favor and if the Tesla inventions prove to be all that is claimed for them and the prices are as low as promised, it is assured that the entire local railroad system will be operated by power from the Kings County Company.

If this is accomplished it is the present intention of the trolley roads to sell their present power houses to the new electrical company. This will give the new company a plant of sufficient capacity to supply all Brooklyn with electricity.

The electricians say that the machinery of the new company is the finest ever manufactured and that the plant has cost less than half what would have been paid for it ten years ago, as all iron work and machinery of every kind is at its lowest just at this time. The electricty will be produced by the newly invented machinery at half the expenditure with the old method. It will only cost half as much to lay the mains as it did a few years ago and added to this is the enormous advantage that Tesla's inventions give the concern, as it is now known that the electrical genius has devised a means of transmitting a current without loss to any distance, and the company can as well supply power to the outer fringes of Greater New York as easily as to a business house half a block away. This means that the greatest problem in electric power has been solved.

The power house, which will take up all the grounds on the river front to John street and from Gold to Bridge, a piece of property, 185x475 feet, will be equipped, it is said, with the finest machinery ever manufactured and a condenser will be included so that water may be obtained directly from the river. Coal can easily be brought in barge loads and deposited on the docks of the company. As soon as the project was started the demand for power was immediate and, as has been stated, even with the new inventions of multiplying, producing and carrying capacity, it will not be possible to meet these demands until new power houses have been erected. New plants will be established in South Brooklyn and along the water front as rapidly as possible.

Just who will be the officers of the new company is not at present known. While Messrs. Kecney, Campbell and Berri are the heaviest holders in Brooklyn there are many other men of the city interested in the new company and all, of course, will have a say in the naming of the men who will take active control of its affairs. Vice President Hobart, ex-Governor Flower and other men who were mentioned in the article of yesterday will, of course, have an active interest in the Brooklyn as well as other ends of the work. Men of financial and business importance from other states are heavily interested and the company is already established on a firm financial basis and has behind it men who will not hesitate to advance its advantages by the expenditure of almost any amount of money called for by the active managers.

The advantage of having a power house established in a central position has already been recognized by the dispensers of electrical force and that is why the Edison and other big establishments have their plants as nearly as possible to the center of business localities where the demand lies. In transmitting power to railroads the idea has been advanced and is being put into practice of having central dispensing stations along the line. But even then a considerable loss has been suffered in sending the power to the stations and all along the line. Tesla's new system will do away with this loss. With this fact known the active interest of ex-Governor Flower and D. O. Mills, as well as other big railroad men of the vicinity is doubly important, as it will probably be a question of time, and no considerable time, when all the railroads of the metropolitan district will be getting their power directly from the plants of the new company.

This morning it was learned by an Eagle reporter that the first business of the company would not be competitive but would be in an entirely new field in Brooklyn and New York. It is certain, however, that electric lighting and power dispensing will not be monopolized in this vicinity within a few months from now. The first idea of the new company was to supply the new demand created every day by new industries and it was with that intention that Charles Cooper obtained his franchise. The control of the Tesla patents, however, and the advantages obtained through the genius of the inventor soon developed new possibilities that wholly outgrew the original intentions of Mr. Cooper and the capitalists behind him. The Cooper company has been continued for convenience until the directors of the concern deem it advisable to elect its regular officers and begin business upon the large scale that is now possible.

"There is no mystery about it," one of the interested men said this morning. "It is a pure business venture with certain details that the directors do not deem it necessary to immediately disclose. While the publication of the plans of the company could not possibly injure it in any way, it would be of no benefit to us. We do not care to boom the company. That fact is apparent when it is said that not a bit of stock could be obtained by any one and we would not reveal the advantages we possess for that purpose. The Eagle's article created something like a sensation and that was just what we did not want to happen. All the money we want is now invested, and we would rather go right ahead in a regular business way with our work. In ten days, perhaps, the details of the organization may be published in the report of the company and then any information desired in regard to the general work of the company may be obtained, but we have no desire to publish any facts at present for purely business reasons. The Eagle's article, however, was correct except that it really did not give more than an idea of the magnitude of the concern."

The New York Herald September 23, 1897

LIGHT COMPANY'S EXTENSIVE PLANS.

It Contemplates Rivalry of the Edison Concerns, Using Nicola Tesla's Inventions.

SITE BOUGHT FOR A PLANT.

William Berri Interested and Perhaps J. P. Morgan and Former Governor Flower.

MR. HOBART ALSO MENTIONED.

The Kings County Electric Light and Power Company has established an office in Montague street, Brooklyn, and proposes to be a business rival to the Edison Electric Company. Among the Brooklyn men interested in the new concern are President Berri, of the Bridge Trustees; Seth L. Keeney and Felix Campbell, president of the People's Trust Company. Mr. Berri admitted yesterday that he and the other men named were interested in the venture, but he refused to give any details.

Julien D. Fairchild, president of the Kings County Trust Company, who is a director in the Edison Company, said that he was well aware of the plans of the rival company, but did not fear its power. He said that J. Pierpont Morgan and D. O. Mills were not behind it, and that former Governor Roswell P. Flower was the largest financial backer.

It is understood that the new company will adopt the devices and discoveries of Nicola Tesla. In this State the business of the company will be handled by Messrs. J. P. Morgan and D. O. Mills, while Vice President Hobart will be one of the financial backers in the State of New Jersey.

Charles Cooper is said to be the president of the new company. He obtained the franchise for the electric plant and he is said to have been more than ready to sell it at one time for $50,000. Now, report says, he holds it to be worth $600,000.

The company has purchased the block fronting on the East River and John street, from Bridge to Gold streets, Brooklyn, at a cost of $500,000. This is about the only large piece of water front property not controlled by the Warehouse Trust, and it is here the first plant of the company is to be erected.

Fifty miles of subway have been laid, and by the time the plant is ready it is expected to have one hundred miles of wire ready for operation.

Mr. Berri said that neither the bonds nor stock of the company would be sold at large. There is no secret made of the intention to adopt Tesla's discoveries. He has been long at work on the problem of transmitting high voltage power without the losses that now exist. He is said to have solved this difficulty by means of a liquid insulator.

Scribner's Magazine October 1897

ABOUT THE WORLD

vibrations on the Herz radiator principle, with a rapidity of 225,000,000 vibrations per second, these waves seem to be carried through the ether, if unobstructed by material obstacles, equally in all directions, and his delicate receiver has no difficulty in receiving and recording them across the Bristol Channel. The feat is possible only in places where an unobstructed expanse of ether interposes between the transmitting and receiving instruments.

The idea of wireless telegraphy is no new one. Men have been thinking of it almost ever since the Morse inventions came to the world. The astonishing Mr. Edison had his try, and abandoned the attempt for more immediately promising work. Aside from the young Italian, Marconi, Nikola Tesla has the most ambitious projects in this direction and, indeed, Mr. Tesla contemplates the possibility of an even vaster feat, for he believes he can transmit electrical power without wires. Should he accomplish such a thing, the bounds of electrical utility will be extended more radically than by any other discovery the world has seen. Mr. Tesla is not yet ready to publish the details of his experiments, but he has explained to interviewers that it is the static electricity of the earth which he will exploit in furnishing the power necessary for his wireless transmission. He has already sent signals via the earth current to and fro through a distance of twenty miles, and announces unhesitatingly that he shall in time be able to telegraph without wires to any part of the earth's surface.

Tesla used a striking and simple simile in explaining how he intended to disturb and capture the earth's electricity. He said to his interviewer: "Suppose the whole earth to be like a hollow rubber ball filled with water, and at one place I have a tube attached to this, with a plunger in the tube. If I press upon the plunger the water in the tube will be driven into the rubber ball, and as the water is practically incompressible, every part of the surface of the ball will be expanded. If I withdraw the plunger, the water follows it and every part of the ball will contract. Now, if I pierce the surface of the ball several times and set tubes and plungers at each place, the plungers in these will vibrate up and down in answer to every movement which I may produce in the plunger of the first tube. If I were to produce an explosion in the centre of the body of water in the ball, this would set up a

IN these days the layman is apt to protect himself in a cloak of *blasé* acquiescence from the ever-fresh demands upon his mental powers made by mechanical wonders. But the most fatigued and agnostic intelligence will scarcely fail to respond to the proposal of the electrical "wizards" to telegraph from one part of the earth's surface to another without the use of wires. In Europe, a young electrician named Marconi has actually succeeded in transmitting and receiving messages through a distance of nine miles, with no connection between the sending and receiving instruments save that furnished by the circumambient ether. Marconi has found that when a transmitting instrument—which is so simple in its elements that one is tempted to describe it in detail—is made to utter electrical

series of vibrations in the whole body. If I could then set the plunger in one of the tubes to vibrating in consonance with the vibrations of the water, in a little while and with the use of a very little energy, I could burst the whole thing asunder."

In the same way, Mr. Tesla proposes, with a comparatively small power uttered in vibrations of marvellous rapidity, to urge into action the terrestrial current. The inventor thinks it possible that his machine when perfected may be set up, one in each great centre of civilization, to flash the news of the day's or hour's history immediately to all the other cities of the world; and stepping for a sentence out of the realms of the workaday world, he offers a prophecy that any communication we may have with other stars will certainly be by such a method—a prophecy which has all the picturesque and imaginative charm to be desired, together with an unusual quality of prudence and safety.

MARCONI TELEGRAPHY.

In July, experiments with this system were made at Spezzia by a Commission of the Royal Italian Fleet, assisted by the inventor. The results, of which the following is an abstract, are reported in the *Rev. Marittima* :—

A transmitter, and a receiver for controlling purposes, were set up on land ; a second receiver being placed on board ship. In one experiment the ship lay at anchor, in another the ship steamed away from, or approached, the telegraphing station on shore. The results obtained were :—1. Under favourable atmospheric conditions, *i.e.*, in the absence of electric strain in the air, messages were successfully transmitted from land to the ship in motion, over a distance of 8·9 nautical miles (10·5 miles). 2. The presence of electric strain in the atmopshere made the reading of messages by the Marconi apparatus impossible. 3. It was found, also, that the intervention of mountains, islands, or headlands between the transmitter and the receiver made the reading of the messages impossible. 4. The intervention of masts or chimneys, or the like, was also found to considerably reduce the distance at which messages could be distinctly read ; for example, if the receiver was fixed abaft the ship, and the ship was steaming directly toward the sending station on shore, the distinctness of the messages was considerably reduced.

The account given by Mr. Marconi, in an interview published by the *Dailg Chronicle*, is somewhat more sanguine. He says :—

I sent messages from the Arsenal of San Bartolomeo and the *San Martino*, an armour-clad fighting ship, completely armed and cruising in the open sea 12 miles distant from the fortress. My receiver was hidden in the cabin, under the guns, under the engines, in fact, anywhere on board, so long as the vertical wire conductor remained exposed. No matter where the receiver was, it "ticked" out the message in due course. I used conductors 90 feet high to procure this result, and am now preparing a receiver to take a message from a distance of 40 miles. The fact of the message being sent to a vessel which was practically one mass of metal made no difference. In Rome, to communicate to houses I had a conductor 3 feet high. For the transmission of signals across the Bristol Channel it was 100 feet high, but it is difficult to say off hand how far the question of distance is determined by the height of the conductor. You see I got signals to a greater distance at Spezia with a conductor 10 feet less in height. The induction coil used in Italy was much less powerful, as the signals were obtained by a 6-inch spark worked by a small portable battery of eight volts. This disproves the statement of certain scientists who have declared that my results have only been secured by the employment of a large amount of battery power.

In the *Chronicle* interview Mr. Marconi defends his invention against the charges of want of novelty which have very freely been brought against it. He claims that he has greatly improved the Branly coherer, and invented for it the electro-magnetic tapper, a claim which has been questioned by Lodge. But we think there can be no doubt that Marconi is the true and first inventor of the elevated electrodes on the receiver and transmitter, and this detail appears to have contributed more to extend the possible distance of telegraphy by electric waves than anything that has been discovered since the time of Hertz and Branly. In the interview above referred to, Mr. Marconi insists on this point, saying :—

I think, too, that my invention deserves all the protection it has secured, for what I have really discovered is this, that by bringing one pole of the transmitter and one pole of the receiver in contact with the earth, and joining the other poles of the instruments to vertical conductors of sultable height, I can send a message 12 miles with an amount of battery power that would not obtain any effect at all, even at 100 yards, if used by the Branly, Lodge, or Righi apparatus.

No doubt the Law Courts will some day be asked to settle the differences between the rival claimants for the invention of wireless telegraphy. In the meantime the heated discussions on the subject which are appearing in some of our contemporaries appear to be futile.

M. Del Proposto gives the following mathematical theory of the working of the Marconi apparatus. Since the transmitter and receiver in the Marconi system are connected by induction, the efficiency and range of the apparatus can be determined by a consideration of the coefficient of mutual induction.

Cœteris paribus the current induced in the receiver is proportional to this coefficient, which is given by the expression

$$\mathrm{M} = \int\int \frac{ds\ ds^1 \cos\varepsilon}{r} \qquad (1)$$

in which ds and ds^1 are elements of the two circuits, ε the angle between them, and r their distance apart. In the Marconi apparatus with vertical wires (taken as parallel) $\varepsilon = 0$, r = constant, the expression becomes

$$\mathrm{M} = \frac{h^2}{r} \qquad (2)$$

h being the height of the wires. Equation (1) is reduced to equation (2) if, at any instant, the current has the same sign at every part of each apparatus, an admission which cannot, however, be made *a priori*. According to (2) the range of an apparatus of given sensibility will be proportional to the square of the height of the vertical wires. But it must not be forgotten that in increasing the length of the vertical wires, we increase their self-induction and their capacity. This, in accordance with the formula

$$\mathrm{T} = \frac{\pi\sqrt{c\,\mathrm{L}}}{v}$$

(v = the velocity of light, T = duration of an oscillation) will reduce the frequency of the oscillations. The decrease of the range due to diminished frequency may be compensated by increasing the original current, *i.e.*, the energy of the discharge.

The electromagnetic force is horizontal if the wires of the apparatus are vertical ; consequently the transmission by the Marconi apparatus will not be disturbed by horizontal con-

ductors, such as telegraph and telephone wires. But vertical conductors may cause serious disturbances in the transmission; Hertz indeed has shown that a frame of parallel wires suitably arranged in relation to the waves may stop them. If two receivers are placed at considerably different distances, the nearest receiver may absorb so much of the energy of the electric waves that it will be impossible to produce any effect on the more distant instrument. The electromagnetic waves are propagated in every direction, and if these waves encounter conductors capable of acting as receivers (and all conductors can do so to a certain extent), the transmission between the two instruments will be seriously interfered with.

Reflectors are not likely to be successfully used with the Marconi apparatus. Hertz found that reflectors were useless with waves 7 m. in length, and the Marconi waves are much longer than this. Before reflectors can be successfully used, it will be necessary to reduce very considerably the length of the waves, but these reflectors will have to be very large, comparable in dimensions, in fact, with the vertical wire.

The propagation in every direction is the principal objection to the Marconi system. Multiple reception of messages may, to a certain extent, be obviated by tuning, but it would always be easy to bring any receiver into tune by trial.

MR. TESLA ON HIGH SPEED ELECTRIC RAILROADING.

In an interview with a New York Journal reporter Mr. Tesla gives his views on high speed railroading. He says:

"The projectors of the road to be operated by means of the alternating current evidently realize what a vast undertaking they are entering into, as is indicated by their capitalization. First of all, it is not only practicable, but easy of perfection. The question of great speed will be greatly controlled by the quality of the track and the running gear on the cars. Properly constructed tracks, on level country, will permit a rate of speed as high as 150 miles an hour, and perhaps 200, as its stated by the president of the company, but it is certain that 100 miles an hour can be made with safety.

"So far as any personal discomfort is concerned, it is my impression that without curves and heavy grades such as are found on surface roads, the flight of a train traveling 100 miles an hour would not be any more unpleasant than one traveling 60. An air line road built eight feet above the ground, with no obstructions, and perfected running gear and heavy tracks, would cover the distance between here and Chicago easily in nine hours, and mail and light freight could even travel at the 150 mile rate.

"The venture is a big one—large enough, I should say, for the government to handle. It will revolutionize railroad travel and work great changes in commerce between cities wide apart.

"The popular impression that the speed is too great amounts to nothing. Balloonists have gone 150 miles an hour, and so far as a question of velocity is concerned, it depends upon the machinery and the excellence of the track. The human frame can stand the trip just as easily as at half that speed.

"If the General Electric Company has offered to sign a contract to equip the road I am satisfied that all the petty obstructions have been carefully investigated, and that the promoters mean business. Either the General Electric Company or the Westinghouse can supply the power if others will supply the capital. So far as the alternating current is concerned, it will supply the speed."

LORD KELVIN SAILS FOR HOME.

Lord and Lady Kelvin sailed on the "Campania" for England last Saturday morning after a visit of nearly three months in the United States and Canada. He left delighted with his American visit, stating that he had made notes enough of new ideas to keep him thinking all the rest of his life, and expressed quite an interest in the wonderful development of electric traction. Before sailing, Lord Kelvin made two visits to Tesla's laboratory in New York city, where some new scientific results were shown to him. Lord Kelvin is respected and loved by every electrical and scientific worker in the United States, and all wish him a pleasant return voyage and many years of continued usefulness at Glasgow University.

CORRESPONDENCE.

"Wireless Telegraphy."

In your interesting article on this subject in your issue for the 8th inst., you say: "We think there can be no doubt that Marconi is the true and first inventor of the elevated electrodes on the receiver and transmitter."

In a book entitled "The Inventions, Researches and Writings of Nikola Tesla," published early in 1894, pages 346—9, will be found much interesting matter with regard to what is therein termed "the transmission of intelligible signals, or perhaps even power, to any distance without the use of wires." In particular, an arrangement of transmitter and receiver, each connected with one terminal to earth, and with the other terminal to an insulated body of large surface, shown in a diagram as elevated above the earth, is suggested for the purpose of what is indexed as "telegraphy without wires."

Without in any way desiring to detract from the credit that is due to Mr. Marconi for the results that he has obtained, I think that it is only fair to Mr. Tesla that attention should be called to the above.

A. A. C. Swinton.

Cambridge Philosophical Society - Proceedings

(1) *Electrical Oscillations in Wires.* By Mr H. C. POCKLINGTON, St John's College.

1. In this paper are discussed some problems relating to the propagation of electrical oscillations along wires. The wire is always supposed to be a perfect conductor, and to have a circular cross-section, the diameter of which is small compared with the other dimensions of the system. We have therefore to solve the equations $\nabla^2(P, Q, R) = V^2 \frac{d^2}{dt^2}(P, Q, R)$, conv. $(P, Q, R) = 0$, with the further condition that at the surface of the wire the vector (P, Q, R) is perpendicular to the surface. The method of solution used is to start with the simplest solution of the general equations and by adding an infinite number of such solutions together to obtain one of sufficient generality. The arbitrary function which represents the infinite number of arbitrary constants introduced into this last solution is then found from an equation deduced from the surface condition. This last part of the work is conducted by means of approximations.

2. The simplest solution of the general equations, that corresponding to the solution $\phi = 1/r$ of the equation $\nabla^2\phi = 0$, is given by the formulae*

$$P = \frac{d^2\Pi}{dx\,dz},\quad Q = \frac{d^2\Pi}{dy\,dz},\quad R = \frac{d^2\Pi}{dz^2} + \alpha^2\Pi,\ \text{where}\ \Pi = e^{\iota\alpha r}e^{\iota pt}/r,$$

in which $2\pi/p$ is the period of the disturbance, and $2\pi/\alpha\,(= 2\pi V/p)$ the wave-length corresponding in free ether to this period. This result can be expressed in words as follows. The electric force due to an elementary Hertzian oscillation with the element of length ds as axis, is compounded of two forces; the first of these is derived from a potential function $-\frac{d\Pi}{ds}$, and the second is a force $\alpha^2\Pi$ parallel to ds. This system of forces satisfies the equations of propagation of electric force everywhere excepting at the element ds. If we place an infinite number of such elements consecutively so as to form a curve, of which ds will then be an elementary arc, and attribute varying strengths λ to them, we shall obtain a system of forces which satisfies the equations of propagation everywhere except on the curve. The resulting system of forces is

$$(P, Q, R) = -\left(\frac{d}{dx}, \frac{d}{dy}, \frac{d}{dz}\right)\int ds\lambda\frac{d\Pi}{ds} + \alpha^2\int ds\,(l, m, n)\,\lambda\Pi.$$

* Hertz, *Wied. Ann.* 1889, vol. 36, p. 4; *Electrical Waves* (tr. Jones), p. 140.

If the curve is either closed or has its extremities at infinity, this is equivalent to

$$(P, Q, R) = \left(\frac{d}{dx}, \frac{d}{dy}, \frac{d}{dz}\right)\int ds\frac{d\lambda}{ds}\Pi + \alpha^2\int ds\,(l, m, n)\,\lambda\Pi \ldots(1).$$

This is a general solution containing an arbitrary function λ.

3. It now remains to consider the equation derived from the surface conditions. At a point at a small distance ϵ from the curve we have, neglecting all terms that are not large,

$$\int ds\,\Pi\frac{d\lambda}{ds} = -2\frac{d\lambda}{ds}\log\epsilon\,.\,e^{\iota pt},$$

and similarly for $\int ds\,l\lambda\Pi$, etc., so that, to this order of approximation,

$$P = -\left\{2\frac{d}{dx}\frac{d\lambda}{ds}\log\epsilon - 2\alpha^2 l\lambda\log\epsilon\right\}e^{\iota pt},$$

and similarly for Q and R.

The component of force along the wire therefore is, to this order,

$$-2\left(\frac{d^2\lambda}{ds^2} + \alpha^2\lambda\right)\log\epsilon\,.\,e^{\iota pt}.$$

The force tangential to the cross-section of the wire $= 0$ to this order. Hence the system of forces given by (1) is a solution of the problem (to this order) provided that

$$\frac{d^2\lambda}{ds^2} + \alpha^2\lambda = 0\ \text{ or }\ \lambda = e^{\iota\alpha s},$$

and the disturbance is propagated along the wire with velocity V and without diminution of amplitude. This is only what might have been expected from a knowledge of what happens in the case of a straight wire; for if in our case we take the electrical forces to be finite near the wire, at a finite distance they are zero.

4. It is clear that in order to obtain results of much interest we must approximate more closely. We will now consider the equations obtained by neglecting only small quantities of the first and higher orders.

As given by (1) the force at any point on the wire tangential to the axis is the same for all points on the same cross-section, and contains two terms, one containing $\log\epsilon$, the other finite. The force tangential to the cross-section is finite and varies for a given value of s as the cosine of some azimuth angle.

Suppose now that we shift the curve formed by the Hertzian elements through a small distance of the second order. The effect is to change the value of the component tangential to the cross-section by a finite amount which varies as the cosine of some azimuth angle, and that parallel to the axis of the wire by an amount of the first order of small quantities.

By making such a shift of appropriate magnitude and direction at every point, we can therefore eliminate the component tangential to the cross-section. At the same time, the component parallel to the wire is unaltered (to our order). Hence we may still derive the surface condition from (1) by taking the integration along the axis of the wire.

The condition thus obtained is

$$0 = \frac{d}{ds}\int ds\,\frac{d\lambda}{ds}\,\Pi + \alpha^2\{l\int ds\, l\lambda\Pi + m\int ds\, m\lambda\Pi + n\int ds\, n\lambda\Pi\}\ldots(2).$$

5. *Circular Ring.* The simplest case that we can consider is that of a circular ring. Let the radius of the ring be a, the radius of the wire ϵ as before, and let the axis of symmetry be chosen as the axis of z. We shall assume $\lambda = A\cos r\phi$, where ϕ defines a point on the axis of the wire. This assumption will be justified later.

At the point (ϖ, θ, z)

$$\int ds\,\frac{d\lambda}{ds}\,\Pi = -rA\int_0^{2\pi} d\phi\,\Pi\sin r\phi$$

$$= -rA\int_0^{2\pi} d\phi\,\Pi_0(\sin r\theta\cos r\phi + \cos r\theta\sin r\phi)\,e^{\iota pt},$$

where Π_0 is the value that Π takes when ϕ is put for $(\theta-\phi)$ and 0 for t, and is thus a function of ϕ, ϖ, z only,

$$= -2rAe^{\iota pt}\sin r\theta\int_0^{\pi} d\phi\,\Pi_0\cos r\phi;$$

$$\int ds\, l\lambda\Pi = -A\int_0^{2\pi} a\,d\phi\,\Pi\cos\phi\cos r\phi$$

$$= Aae^{\iota pt}\left[\cos(r+1)\theta\int_0^{\pi} d\phi\,\Pi_0\cos(r+1)\phi\right.$$

$$\left. + \cos(r-1)\theta\int_0^{\pi} d\phi\,\Pi_0\cos(r-1)\phi\right],$$

as above; and $\int ds\, n\lambda\Pi = 0.$

Hence (2) becomes

$$0 = \left[-2rA\,\frac{r\cos r\theta}{a}\int_0^{\pi} d\phi\,\Pi_0\cos r\phi\right.$$

$$\left. + \alpha^2 Aa\cos r\theta\int_0^{\pi} d\phi\,\Pi_0\{\cos(r+1)\phi + \cos(r-1)\phi\}\right]e^{\iota pt},$$

or
$$\int_0^{\pi} d\phi\,\Pi_0\cos r\phi\,(r^2 - \alpha^2 a^2\cos\phi) = 0 \ldots\ldots\ldots\ldots(3),$$

the disappearance of θ justifying the assumption made as to the form of λ. In this equation for finding α we may give to ϖ and z in Π_0 any values which correspond to a point on the surface of the wire. The simplest values are $\varpi = a+\epsilon$, $z=0$, and these should therefore be chosen.

6. The special case $r=1$, which corresponds to the fundamental node of the wire, is that of the most interest and will be investigated in detail.

In this case, (3) becomes on substituting for Π_0 its value (when $z=0$),

$$\int_0^{\pi} d\phi\,\frac{e^{\iota\alpha\sqrt{a^2-2a\varpi\cos\phi+\varpi^2}}}{\sqrt{a^2-2a\varpi\cos\phi+\varpi^2}}\{\cos\phi - \tfrac{1}{2}\alpha^2a^2(1+\cos 2\phi)\} = 0,$$

or, putting $\varpi = a+\epsilon$,

$$\int_0^{\pi} d\phi\,\frac{\frac{1}{2}\alpha^2a^2 - \cos\phi + \frac{1}{2}\alpha^2a^2\cos 2\phi}{\sqrt{2a(a+\epsilon)(1-\cos\phi)+\epsilon^2}}$$

$$+\int_0^{\pi} d\phi\,\frac{e^{2\iota\alpha a\sin\frac{1}{2}\phi}-1}{2a\sin\frac{1}{2}\phi}(\tfrac{1}{2}\alpha^2a^2 - \cos\phi + \tfrac{1}{2}\alpha^2a^2\cos 2\phi) = 0\ldots(4),$$

where in the second integral ϵ has been put $=0$, since we are neglecting small quantities.

The first integral in (4) is, calling $2\alpha a = x$, $\log\frac{8a}{\epsilon} = L$, and neglecting small quantities,

$$\frac{1}{a}\left\{2 - \frac{x^2}{3} + \left(\frac{x^2}{4} - 1\right)L\right\}$$

The second integral is, putting $\phi/2 = \psi$,

$$\int_0^{\frac{\pi}{2}} d\psi\,\frac{e^{\iota x\sin\psi}-1}{\sin\psi}\left\{\frac{x^2}{8a}(1+\cos 4\psi) - \frac{1}{a}\cos 2\psi\right\}$$

$$= \iota\int_0^{\frac{\pi}{2}} d\psi\,\frac{\sin(x\sin\psi)}{\sin\psi}\left\{\frac{x^2}{8a}(1+\cos 4\psi) - \frac{1}{a}\cos 2\psi\right\}$$

$$+\int_0^{\frac{\pi}{2}} d\psi\,\frac{\cos(x\sin\psi)-1}{\sin\psi}\left\{\frac{x^2}{8a}(1+\cos 4\psi) - \frac{1}{a}\cos 2\psi\right\}\ldots(5).$$

Now, n being an integer,

$$\frac{2}{\pi}\int_0^{\frac{\pi}{2}} d\psi \cos 2n\psi \cos(x\sin\psi) = J_{2n}(x),$$

$$\frac{2}{\pi}\int_0^{\frac{\pi}{2}} d\psi \cos 2n\psi \frac{\sin(x\sin\psi)}{\sin\psi} = \int_0^x dx\, J_{2n}(x)$$

$$= -2\left[J_{2n-1}(x) + J_{2n-3}(x) + \ldots + J_1(x)\right] + \int_0^x dx\, J_0(x).$$

Therefore the first integral in (5) is

$$\frac{\iota\pi}{2a}\left\{-\frac{x^2}{4}J_3(x) + \left(2-\frac{x^2}{4}\right)J_1(x) + \left(\frac{x^2}{4}-1\right)\int_0^x dx J_0(x)\right\},$$

and (4) becomes, on re-arrangement and multiplication by a,

$$\left(\frac{x^2}{4}-1\right)L = \frac{x^2}{3} - 2 - \frac{\iota\pi}{2}\left\{-\frac{x^2}{4}J_3(x) + \left(2-\frac{x^2}{4}\right)J_1(x) + \left(\frac{x^2}{4}-1\right)\int_0^x dx\, J_0(x)\right\}$$

$$-\left\{\frac{x^2}{8}\int_0^{\frac{\pi}{2}} d\psi \frac{\cos(x\sin\psi)-1}{\sin\psi}(1-2\cos 2\psi+\cos 4\psi)\right.$$

$$\left.+\left(\frac{x^2}{4}-1\right)\int_0^{\frac{\pi}{2}} d\psi \frac{\cos(x\sin\psi)-1}{\sin\psi}\cos 2\psi\right\} \ldots(6).$$

This equation gives x and thence α with an error of the order of ϵ/a. It can only be solved by trial. If however ϵ is so small that errors of the order of $1/L^2$ can be neglected, we may use an approximate solution of the above. A first approximation is $x^2=4$ or $x=2$. A second is obtained by putting $x=2$ on the right-hand side of (6). This gives

$$\left(\frac{x^2}{4}-1\right)L = \cdot 485 - \cdot 703\iota,$$

so that

$$\alpha = \frac{1}{a}\{1 + (\cdot 243 - \cdot 351\iota)/L\}.$$

Hence the period of the oscillation is equal to the time required for a free wave to traverse a distance equal to the circumference of the circle multiplied by $1-\cdot 243/L$, and the ratio of the amplitudes of consecutive vibrations is $1 : e^{-2\cdot 21/L}$ or $1 : 1-2\cdot 21/L$. It is easy to verify from first principles that the decrease in amplitude of the vibrations is of this order.

7. *Induced Vibrations in a Ring.* We will now consider the case of a ring upon which plane waves are incident in a direction parallel to the axis of the ring.

Let the coordinate axes be chosen as before, and let the incident vibration be given by

$$P = R = 0, \quad Q = Ae^{\iota\alpha z}e^{\iota pt}.$$

The tangential force at the point θ due to this wave together with a disturbance induced in the wire of the fundamental mode and magnitude B, is to be equated to zero, giving

$$0 = Ae^{\iota pt}\cos\theta - 2Be^{\iota pt}\frac{\cos\theta}{a}\int_0^{\pi} d\phi\, \Pi_0 \cos\phi\,(1-\alpha^2a^2\cos\phi).$$

If we neglect ϵ/a in comparison with unity, this becomes, as in § 6,

$$0 = A + \frac{2B}{a^2}\left[\left\{2-\frac{x^2}{3}+\left(\frac{x^2}{4}-1\right)L\right\}\right.$$

$$+\frac{\iota\pi}{2}\left\{-\frac{x^2}{4}J_3(x)+\left(2-\frac{x^2}{4}\right)J_1(x)+\left(\frac{x^2}{4}-1\right)\int_0^x dx J_0(x)\right\}$$

$$+\frac{x^2}{8}\int_0^{\frac{\pi}{2}} d\psi \frac{\cos(x\sin\psi)-1}{\sin\psi}(1-2\cos 2\psi+\cos 4\psi)$$

$$\left.+\left(\frac{x^2}{4}-1\right)\int_0^{\frac{\pi}{2}} d\psi \frac{\cos(x\sin\psi)-1}{\sin\psi}\cos 2\psi\right].$$

Unless $x=2$, this gives

$$B = \frac{2Aa^2}{(4-x^2)L},$$

so that in general the induced vibration is small, and the thinner the wire the smaller the induced vibration. The phase is the same as or opposite to that of the electric displacement in the plane of the ring due to the incident wave: If, however, $x = 2 = 2+\xi$, where ξ is small, we may put $x=2$ in all the terms not involving L, and get

$$B = \frac{Aa^2}{-2L\xi + \cdot 970 - 1\cdot 055\iota}.$$

The maximum amplitude of the induced vibration is obtained when $2L\xi = \cdot 970$, or $\alpha = x/2a = \{1+\cdot 243/L\}/a$, i.e. when the period of the incident wave is the same as the free period of the ring; the amplitude then is $\cdot 948Aa^2$, and the phase is in quadrature

with that of the wave. It is noteworthy that the amplitude of the induced vibration is independent of the thickness of the wire. If the incident wave is not proceeding in a direction perpendicular to the ring, the problem can still be solved by a method similar to the above. The vibrations induced in the ring will however not be confined to the fundamental, but will include vibrations of all modes.

8. *Helix.* We will now consider the case of vibrations propagated along an infinite wire wound into a uniform helix. Let the equations of the axis of the wire be $x = a\cos\phi$, $y = a\sin\phi$, $z = a\phi\tan\omega$. We shall assume $\lambda = Ae^{\iota\beta\phi}$. This assumption is justified later. The value of the force tangential to the wire at the point (ϖ, θ, z) is $e^{\iota\beta\theta}$ times that at the point $(\varpi, \theta, z - a\theta\tan\omega)$. Hence (2) gives

$$0 = Ae^{\iota pt}\left[\left(\frac{d}{ds}\right)_{\theta=0} e^{\iota\beta\theta}\int_{-\infty}^{\infty} d\phi\,\iota\beta e^{\iota\beta\phi}\Pi_0 + \alpha^2\left\{\cos\omega\int_{-\infty}^{\infty} d\phi\, a\cos\phi e^{\iota\beta\phi}\Pi_0 + \sin\omega\int_{-\infty}^{\infty} d\phi\, a\tan\omega e^{\iota\beta\phi}\Pi_0\right\}\right],$$

where Π_0 is the value that Π takes when $t = 0$ and ϕ is put for $\phi - \theta$.

Hence $$0 = \int_{-\infty}^{\infty} d\phi\, e^{\iota\beta\phi}\,(\alpha^2a^2\tan^2\omega - \beta^2 + \alpha^2a^2\cos\phi)\,\Pi_0 \ldots(7).$$

In obtaining this equation small quantities only have been neglected. If however ϵ/a is very small, we may in this equation neglect all finite quantities in comparison with those of the order of $\log\epsilon/a$. In this case we may with advantage find an approximate value of the right-hand side of (7).

Assuming κ any finite quantity, and neglecting terms that are finite, the right-hand side of (7) is

$$\int_{-\infty}^{-\kappa} d\phi\, e^{\iota\beta\phi}\,\frac{e^{-\iota a a}\phi\tan\omega}{-a\phi\tan\omega}\{\alpha^2a^2\tan^2\omega - \beta^2 + \alpha^2a^2\cos\phi\}$$

$$+\int_{-\kappa}^{\kappa} d\phi\,\frac{\alpha^2a^2\sec^2\omega - \beta^2}{\sqrt{2a\,(a+\epsilon)(1-\cos\phi) + a^2\phi^2\tan^2\omega + \epsilon^2}}$$

$$+\int_{\kappa}^{\infty} d\phi\, e^{\iota\beta\phi}\,\frac{e^{\iota a a\phi\tan\omega}}{a\phi\tan\omega}\{\alpha^2a^2\tan^2\omega - \beta^2 + \alpha^2a^2\cos\phi\}.$$

The second integral is, neglecting finite quantities,

$$-2\,(\alpha^2a^2\sec^2\omega - \beta^2)\,\frac{\cos\omega}{a}\log\epsilon.$$

The first and last can be reduced to sums of integrals of the form $\int_{\kappa}^{\infty} d\phi\,\frac{e^{-\gamma\phi}}{\phi}$. This integral* is $-\log\gamma$ to our order, and thus the first and last integrals give

$$\frac{1}{a\tan\omega}\,[(\alpha^2a^2\tan^2\omega - \beta^2)\log(\alpha^2a^2\tan^2\omega - \beta^2)$$

$$+\tfrac{1}{2}\alpha^2a^2\log\{(1+\beta+\alpha a\tan\omega)(1-\beta+\alpha a\tan\omega)(1+\beta-\alpha a\tan\omega)(1-\beta-\alpha a\tan\omega)\}],$$

and therefore the approximate form of (7) is

$$2\,(\alpha^2a^2\sec^2\omega - \beta^2)\sin\omega\log\epsilon = (\alpha^2a^2\tan^2\omega - \beta^2)\log(\alpha^2a^2\tan^2\omega - \beta^2)$$

$$+\tfrac{1}{2}\alpha^2a^2\log\{(1+\beta+\alpha a\tan\omega)(1-\beta+\alpha a\tan\omega)(1+\beta-\alpha a\tan\omega)(1-\beta-\alpha a\tan\omega)\}\ldots(8).$$

Several cases may occur. (i) In general, if α is not small, the only term of importance is that on the left, so that

$$\alpha^2a^2\sec^2\omega - \beta^2 = 0, \text{ or } \beta = \alpha a\sec\omega,$$

and the velocity of propagation measured along the wire is

$$\frac{p}{\beta}a\sec\omega = \frac{p}{\alpha} = V,$$

the same result as that obtained in the case of a circle.

(ii) If however α and β are small, the first term on the right is also of importance. If α and β are so small that $\log\epsilon$ can be neglected in comparison with $\log(\alpha^2a^2\tan^2\omega - \beta^2)$, i.e. if the product of the wave-length of the disturbance into the radius of the wire is very large compared with the square of the radius of the helix, we have $\alpha^2a^2\tan^2\omega - \beta^2 = 0$, or $\beta = \alpha a\tan\omega$, and the velocity of propagation measured along the wire is

$$\frac{p}{\beta}a\sec\omega = \frac{p}{\alpha}\operatorname{cosec}\omega = V\operatorname{cosec}\omega,$$

so that the disturbance is propagated with a velocity V measured along the axis of the helix.

If α and β are small, but not so small that $\log\epsilon$ can be neglected, i.e. if the product of the wave-length into the radius of the wire is comparable with the radius of the helix, the velocity of propagation has an intermediate value†. It is easy to see that a like result does not follow if we try to make $(\alpha^2a^2\tan^2\omega - \beta^2)$ small without making α and β small.

* J. W. L. Glaisher, *Phil. Trans.*, 1870, p. 369.

† Hertz, *Wied. Ann.* 1889, vol. 36, p. 21; *Electrical Waves* (tr. Jones), p. 158, has proved experimentally that this is the case.

(iii) If one of the factors, e.g. the last, of the term under the second log sign be small we have, since α and β cannot then both be small,

$$2(\alpha^2 a^2 \sec^2\omega - \beta^2)\sin\omega \log\epsilon = \tfrac{1}{2}\alpha^2 a^2 \log(1-\beta-\alpha a\tan\omega).$$

In this case we must have $\beta < \alpha a \sec\omega$, so that the velocity of propagation measured along the wire must be greater than V. There is however no superior limit to the value that it may have. There is an inferior limit to α. Hence for periods which are not greater than a certain value, there are two velocities of propagation along the wire, one $= V$ given by (i), the other, $> V$, given by (iii).

No other cases arise by making α and β great, since we must then recur to (7), as (8) does not then hold; and here if α and β are great, we simply have $\alpha^2 a^2 \sec^2\omega - \beta^2 = 0$, the case considered in (i).

This paper is printed in the *Transactions,* Vol. XVI. Part III.

(3) *Reduction of a certain Multiple Integral.* By ARTHUR BLACK. Communicated by Professor M. J. M. HILL, M.A., Sc.D., F.R.S.

This paper is printed in the *Transactions,* Vol. XVI. Part III.

(4) *On the Gamma Function.* By Mr H. F. BAKER.

The Gamma Function could be defined for real values of x by the conditions (i) that $\Gamma(1)=1$, (ii) that $\Gamma(x+1)=x\Gamma(x)$, (iii) that, for a fixed finite h, as x tends to $+\infty$, the difference

$$\frac{\Gamma'(x+h)}{\Gamma(x+h)} - \frac{\Gamma'(x)}{\Gamma(x)}$$

tends always to zero. The condition (iii) was well known, being deducible from the result

$$\frac{\Gamma'(x)}{\Gamma(x)} - \log x = \int_0^\infty [e^{-xt} - (1+t)^{-x}]\frac{dt}{t},$$

and was of suitable character for a definition; it was desirable however to deduce it immediately from the equation

$$\Gamma(x) = \int_0^\infty e^{-t}t^{x-1}dt;$$

this note dealt with such a deduction.

The New York Herald October 31, 1897

ELECTRICAL CURE FOR SKIN DISEASE.

Nikola Tesla Envelops the Human Body in Luminous Flame with Wondrous Results.

Announcement of a Curious Discovery

NIKOLA TESLA is now in the midst of intricate electrical experiments which promise most valuable hygienic results, so soon as he declares himself ready to put his recently acquired knowledge into practical operation, for the ridding of the human skin of all extraneous matter, including parasites of every nature, whether they are virulent disease germs or not.

These experiments have been conducted by Mr. Tesla for some time within the secret precincts of his laboratory, and all of the matters involved, from the first inception to the last experiment, have received most careful consideration, and a number of times in his published writings he has hinted at what he believed and what he expected to accomplish, but only incidentally, and in a manner that has made his readers anxious to know just what it is he expects to do and how he intends to accomplish it.

Mr. Tesla was found in his laboratory yesterday, with head and hands full of matters electrical, as usual, and when spoken to of the interest his hints and suggestions of what he was doing had aroused he hesitated for a moment before answering.

Then, as a foundation, the electrician explained that it is a fundamental electrical law, well known, that two bodies charged with the same kind of electricity, either positive or negative, repel each other; that if a body be charged with electricity from a static machine the electricity accumulates on its surface.

"Now," continued Mr. Tesla, "if there are small bodies of the minutest weight on that electrically charged surface; and if they are conductors capable of taking electricity, they will also become charged with the same kind of electricity that the surface has received. What is the result under the law of repulsion? There is a force at work between them and the surface, which strongly tends to part the two, and the particles are thrown off, frequently with great force. In fact, this force can be increased to pressure of any desired magnitude. Just the form of apparatus I am using, and which accomplishes this thing, I must keep secret for a time yet.

"This repulsion under the pressure I have referred to is increased the more under the law that governs it, for if a given electrical pressure is doubled the repulsion is increased fourfold, and even more than this, on account of another law, because electricity preferably accumulates on points, and an extremely small body is practically a point. So the normal accumulation on the surface referred to—say it is of brass—is exceeded by the accumulation on the small bodies that may be on that surface.

"I have found ways of producing all degrees of pressure; even to a degree that approaches more or less to that of lightning; and the repulsion exerted on the small particles—when a body is charged with such a tremendous pressure—is so great as to actually tear asunder not only the firmly adhering small objects, but the very particles of the metal on which they rest. Now, for an illustration, if a brass ball is painted with bronze paint—which is conducting—the whole of the paint is almost thrown away when the pressure is turned

"But further. You know how firmly bronze paint adheres when it has dried. It requires great force to tear it away, but under the pressure I refer to not only is the bronze torn from the brass surface, but the hard brass itself is subjected to such a pressure that its particles are torn asunder, scattered with great force and thrown away, not only to distances measured by feet, but measured by miles. Keep up the action, and finally the entire solid brass ball would be carried away, but ages would be required to accomplish this result with the present apparatus, because of the smallness of the particles. Still, if the pressure was sufficiently great—as in the case of a lightning stroke—the brass ball could be destroyed in an infinitesimal period of tin e.

"Now we will see what all of this leads up to. I know that the scientific fact of the result described is accomplished, and we will consider its application to the human body in cases of skin disorders or any disorders that may arise from the skin being attacked by disease germs or parasites of any sort. Since small particles on a body can be thrown from it by the means I have told you of, it is thinkable or even very probable that a human body may in this way rid itself of any extraneous particles that may be on it, and as the disease germs, if any, would be among these particles, the possibility and practicability of such treatment naturally suggests itself.

"I have tried experiments in line with this suggestion and have reached most remarkable and startling results, that impress me as being of great value. They will be continued and their actual value positively ascertained before the method is unqualifiedly recommended.

"By means of my apparatus I have applied an electrical current from a static machine so as to agitate the air surrounding a human subject in a most extreme and remarkable manner. The startling effect was to make the person when operated on in a darkened room appear to be clouded in a haze of luminous mist.

"The electrical pressure not only violently agitated the air around the body, but the repelling force threw off all particles with such violence that their extremely rapid motion through the atmosphere caused a friction that consumed them, and for the fraction of a second making them luminous, so much so as to cause them to appear like myriads of infinitisimal meteors shooting in all directions away from the repelling body.

"I have gone far enough with these experiments to suggest the possibility of completely enveloping the human body in an actual sheet of flame, without injury to either the skin or the nerves.

POWER TRANSMISSION

TESLA'S HIGH POTENTIAL TRANSFORMER.

IN his experiments involving high potentials Mr. Nikola Tesla has for some time past made use of a special form of induction coil, and in a recent patent issued to him he describes several forms specially adapted to be used in connection with a system of high potential power transmission. To accomplish the desired object Mr. Tesla employs an induction coil or transformer in which the primary and secondary coils are wound in such manner that the convolutions of the conductor of the latter will be farther removed from the primary as the liability of injury from the effects of potential increases, the terminal or point of highest potential being the most remote, and so that between adjacent convolutions there shall be the least possible difference of potential.

The type of coil in which the last named features are present is the flat spiral, and this form Mr. Tesla generally employs, winding the primary on the outside of the secondary and taking off the current from the latter at the center or inner end of the spiral.

In constructing his improved transformers Mr. Tesla employs a length of secondary which is approximately one-quarter of the wave length of the electrical disturbance in the circuit including the secondary coil, based on the velocity of propagation of electrical disturbances through such circuit, or, in general, of such length that the potential at the terminal of the secondary which is the more remote from the primary shall be at its maximum. In using these coils the inventor connects one end of the secondary, or that in proximity to the primary, to earth, and in order to more effectually provide against injury to persons or to the apparatus he also connects it with the primary.

The accompanying diagram, Fig. 1, illustrates the plan of winding and connection employed in constructing the improved coils and the manner of using them for the transmission of energy over long distances.

A designates a core, which may be magnetic, around which the coil B is wound in spiral form. C is the primary, which is wound around in proximity to the secondary. One terminal of the latter will be at the center of the spiral coil, and from this the current is taken to line. The other terminal of the secondary is connected to earth and also to the primary.

When two coils are used in a transmission system in which the currents are raised to a high potential and then reconverted to a lower potential, the receiving transformer will be

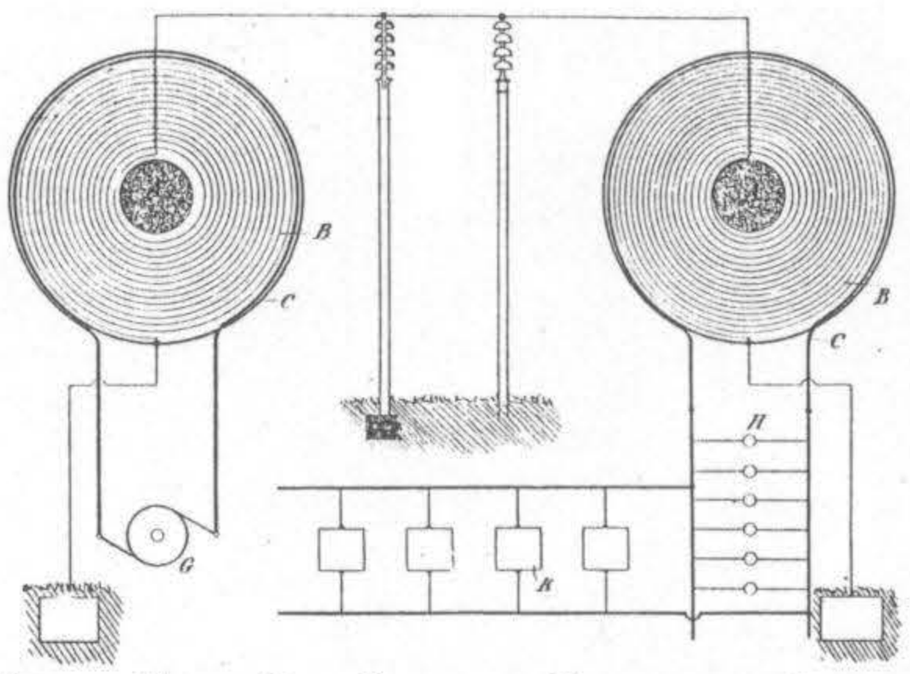

FIG. 1.—TESLA HIGH POTENTIAL TRANSMISSION SYSTEM.

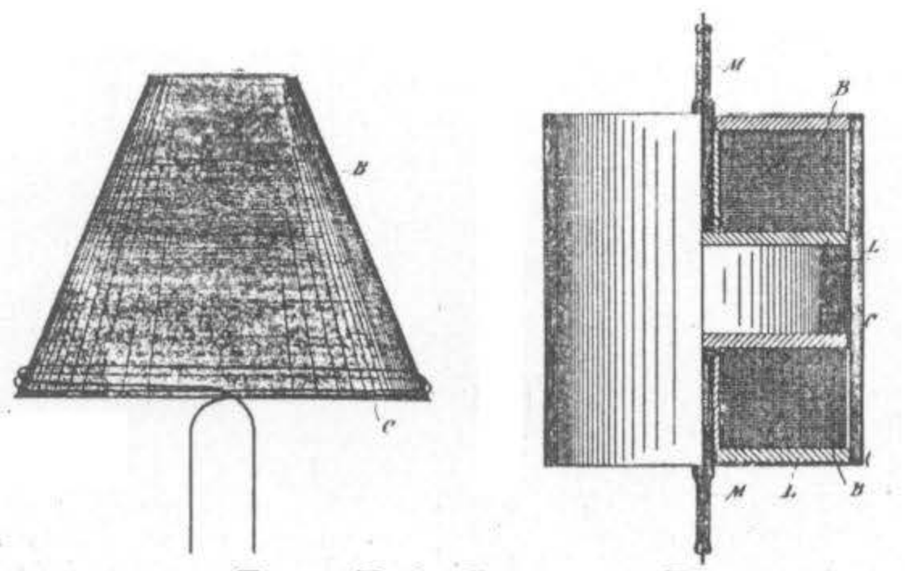
constructed and connected in the same manner as the first—that is to say, the inner or center end of what corresponds to the secondary of the first will be connected to line and the other end to earth and to the local circuit or that which corresponds to the primary of the first. In such case also the line wire should be supported in such manner as to avoid loss by the current jumping from line to objects in its vicinity and in contact with earth—as, for example, by means of long insulators, mounted, preferably, on metal poles, so that in case of leakage from the line it will pass harmlessly to earth. In Fig. 1, where such a system is illustrated, a dynamo G is rep-

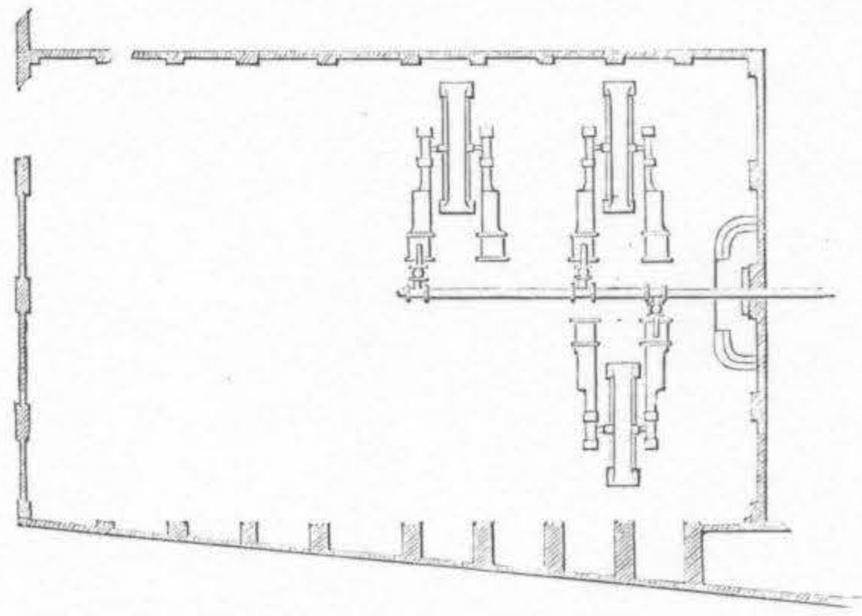


resented as supplying the primary of the sending or "step-up" transformer and lamps H and motors K are shown as connected with the corresponding circuit of the receiving or "step-down" transformer.

Instead of winding the coils in the form of a flat spiral the secondary may be wound on a support in the shape of a frustum of a cone and the primary wound around its base, as shown in Fig. 2.

In practice for apparatus designed for ordinary usage the coil is usually constructed on the plan illustrated in Fig. 3. In this figure L L are spools of insulating material upon which the secondary is wound—in the present case, however, in two sections, so as to constitute really two secondaries. The primary C is a spirally-wound flat strip surrounding both secondaries B. The inner terminals of the secondaries are led out through tubes of insulating material M, while the other or outside terminals are connected with the primary.

The length of the secondary coil B or of each secondary coil when two are used, as in Fig. 3, is, as before stated, approximately one-quarter of the wave length of the electrical disturbance in the secondary circuit, based on the velocity of propagation of the electrical disturbance through the coil itself and the circuit with which it is designed to be used—that is to say, if the rate at which a current traverses the circuit, including the coil, be 185,000 miles per second, then a frequency of 925 per second would maintain 925 stationary waves in a circuit 185,000 miles long, and each wave length would be 200 miles in length. For such a frequency Mr. Tesla would use a secondary 50 miles in length, so that at one terminal the potential would be zero and at the other maximum.

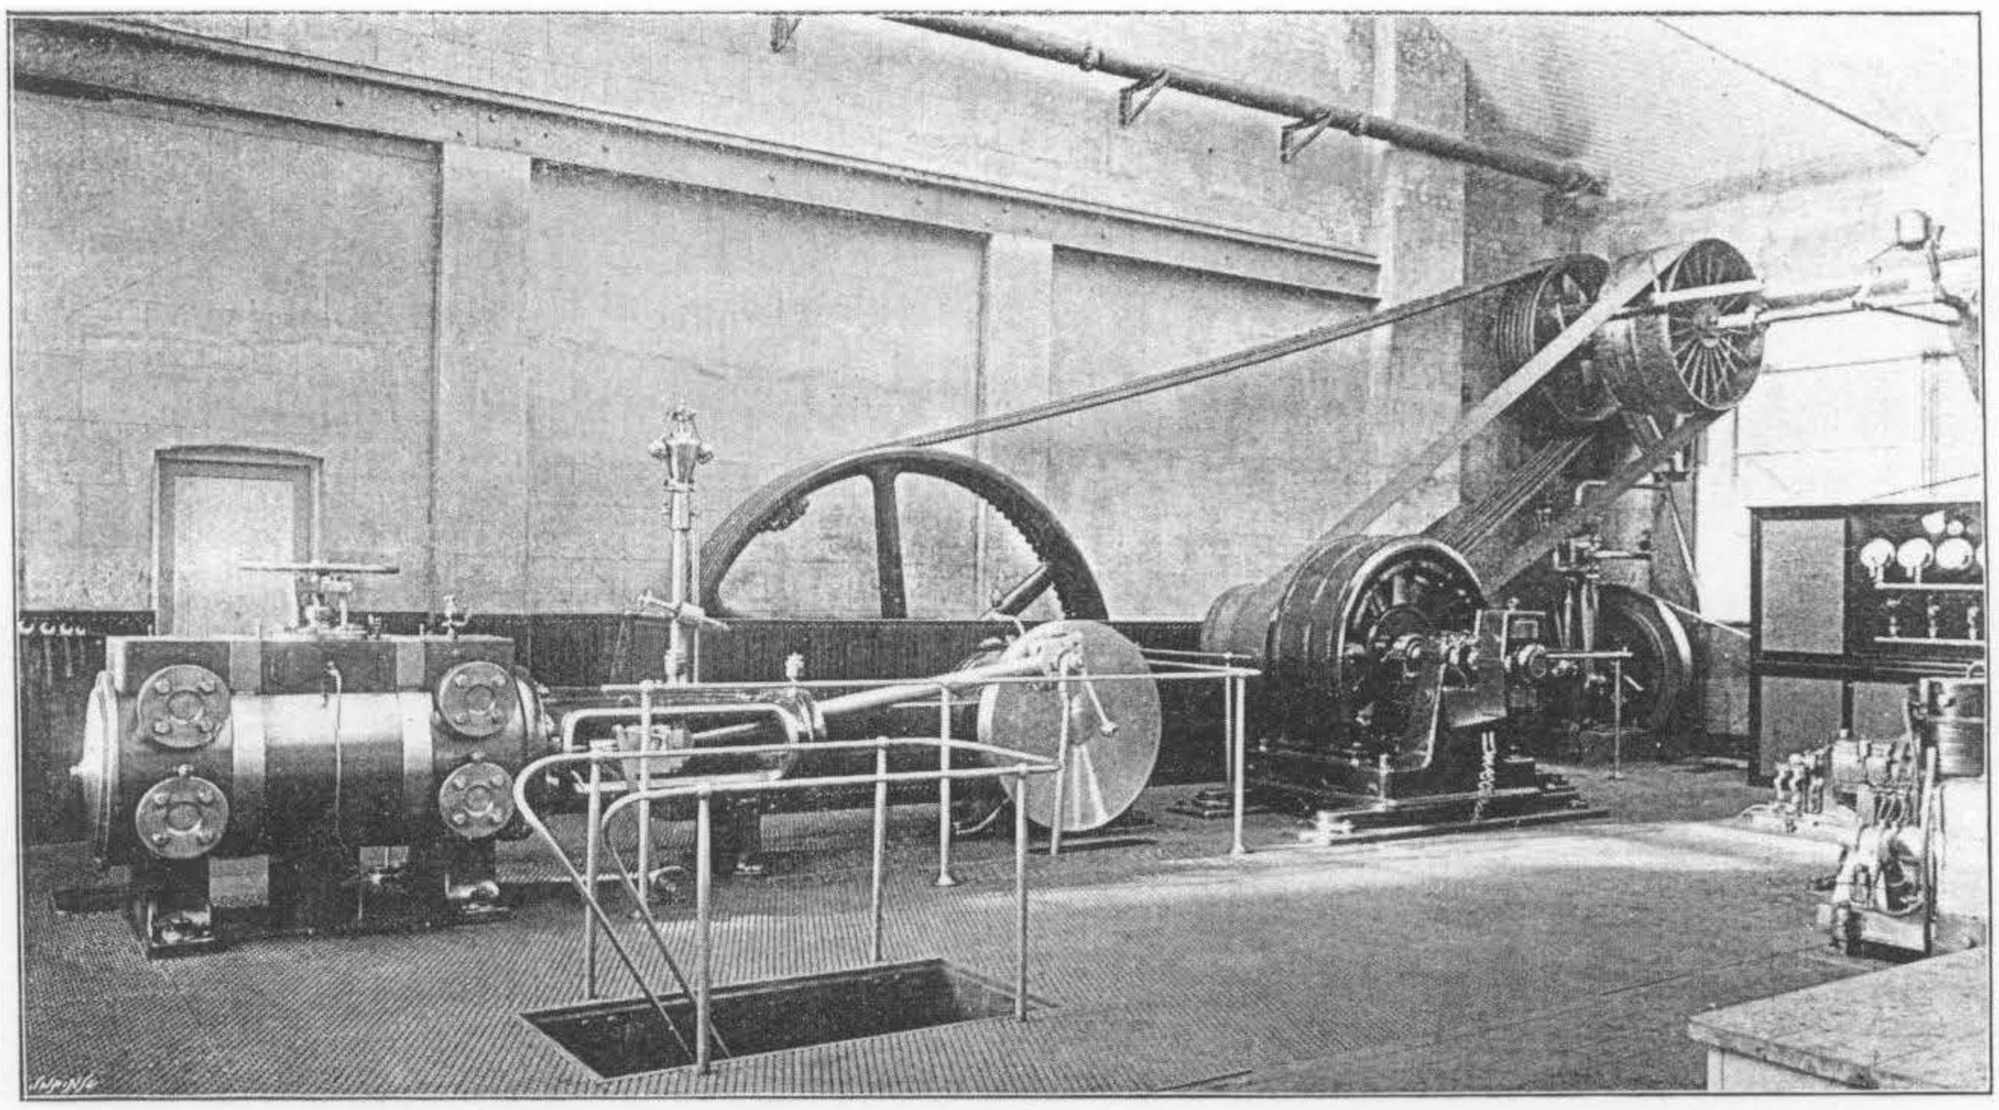


Coils of this character, according to Mr. Tesla, have several

FIGS. 2 AND 3.—TESLA HIGH POTENTIAL TRANSFORMERS.

important advantages. As the potential increases with the number of turns the difference of potential between adjacent turns is comparatively small, and hence a very high potential, impracticable with ordinary coils, may be successfully maintained. As the secondary is electrically connected with the primary the latter will be at substantially the same potential as the adjacent portions of the secondary, so that there will be no tendency for sparks to jump from one to the other and destroy the insulation. Moreover, as both primary and secondary are grounded and the line-terminal of the coil carried and protected to a point remote from the apparatus the danger of a discharge through the body of a person handling or approaching the apparatus is reduced to a minimum.

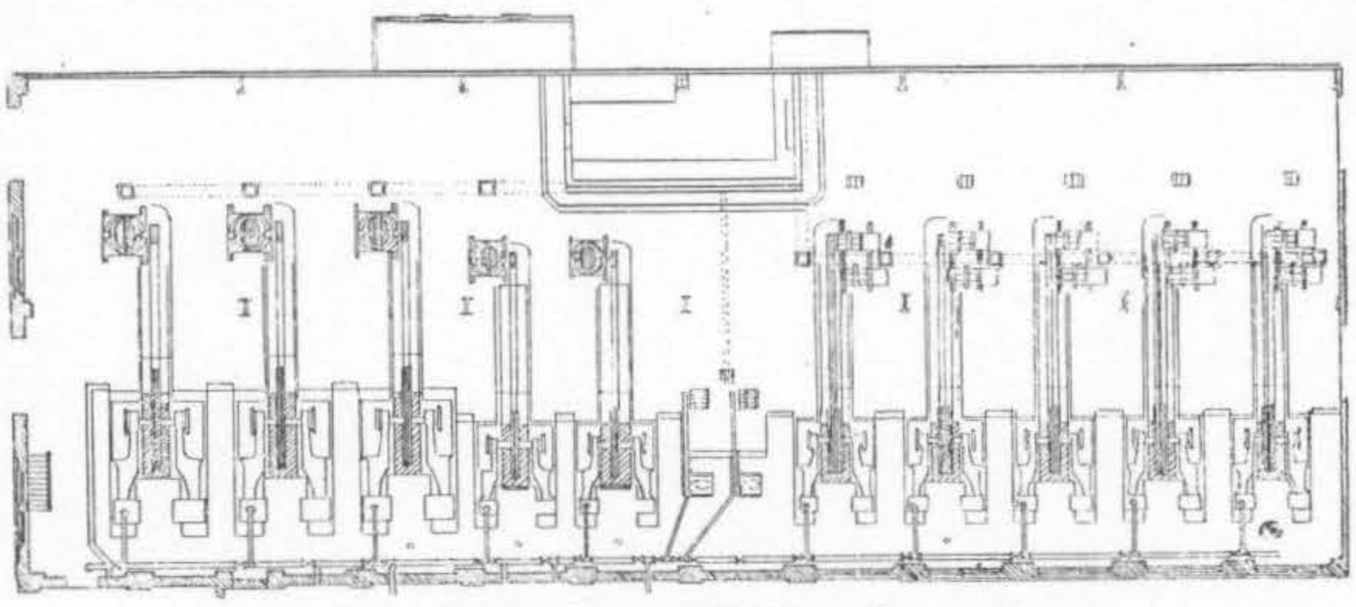
from multiphase machinery. As a concession to this opinion, it may be pointed out that in some of the Continental stations where multiphase plant is employed, the three-phase current is merely transmitted to distant points, and there utilised to drive continuous current machinery. This does not, however, obtain in every case, for at Baden, Milan, and a large number of other places on the Continent, multiphase current is being supplied direct to both motors and lamps without causing, as far as we can learn,



Direct Coupled Plant, Capacity of 660 Units (see p. 661).

THE INTRODUCTION OF MULTIPHASE WORK IN THE UNITED KINGDOM.

The question as to why multiphase work has not been more generally adopted in this country is one that must have occurred to many. It is generally conceded that a large measure of success has attended the systems that have been laid down in different parts of the European Continent and America, and these systems have been examined and duly praised from time to time by English engineers. At the same time there was—and, no doubt, there still remains—a feeling that there were certain limitations in a multiphase system. A commonly-expressed opinion was that though a multiphase system might show distinct advantages when used solely for power purposes, certain complications would arise if an attempt were made to do both lighting and driving any complications. At Baden, Messrs. Brown, Boveri's shops are being driven from the town supply, which is on the two-phase system, and a considerable amount of lighting is being done, indeed the power required for lighting is about equal to that required for motive power purposes.

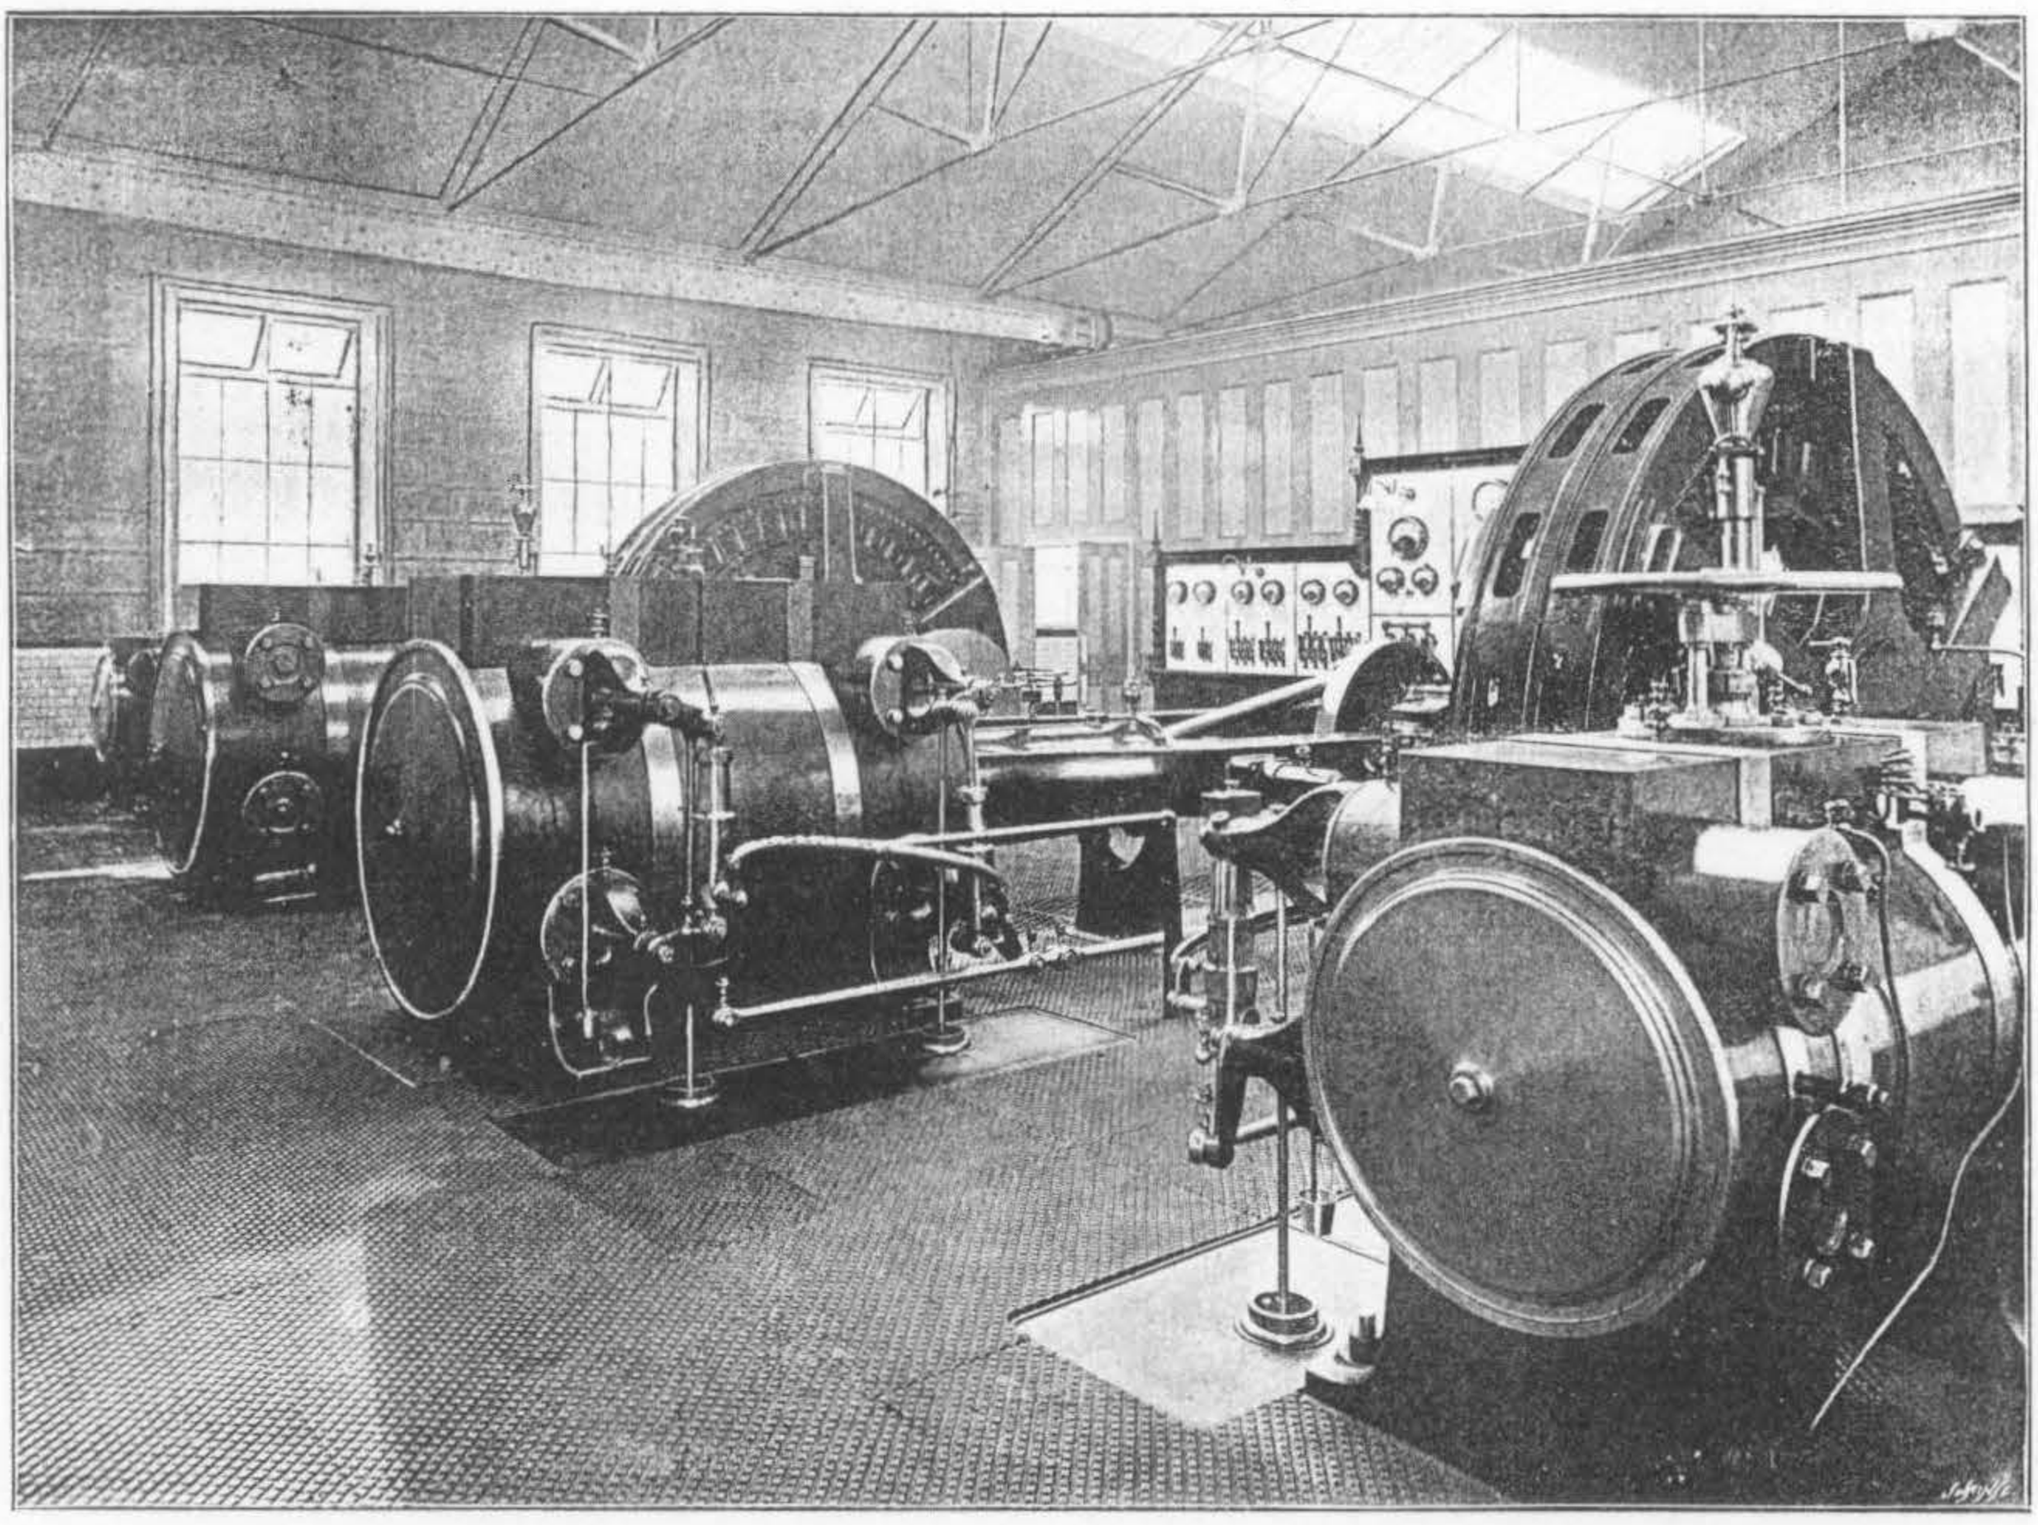


In spite of the reluctance of English engineers to take up multiphase work, it has been held that for some purposes the induction motor is most desirable. As was said some time ago in these columns:* "Now that the commutatorless motor is perfected in the form of single-phase, two-phase, and three-phase induction motors, these somewhat lame devices (enclosing motors and brushes) are not likely to be perpetuated. The only motor for fiery mains is the induction motor. They can be started with sufficient torque for all practical purposes, and are absolutely sparkless, and, in reality, much safer to handle than continuous current motors. This last claim for induction motors is generally overlooked, but

Single Engine Driving 80 kw. Generator at Messrs. Richardson & Sons.

* Rankin Kennedy, Electrical Review, Vol. 39, September 11th, 1896.

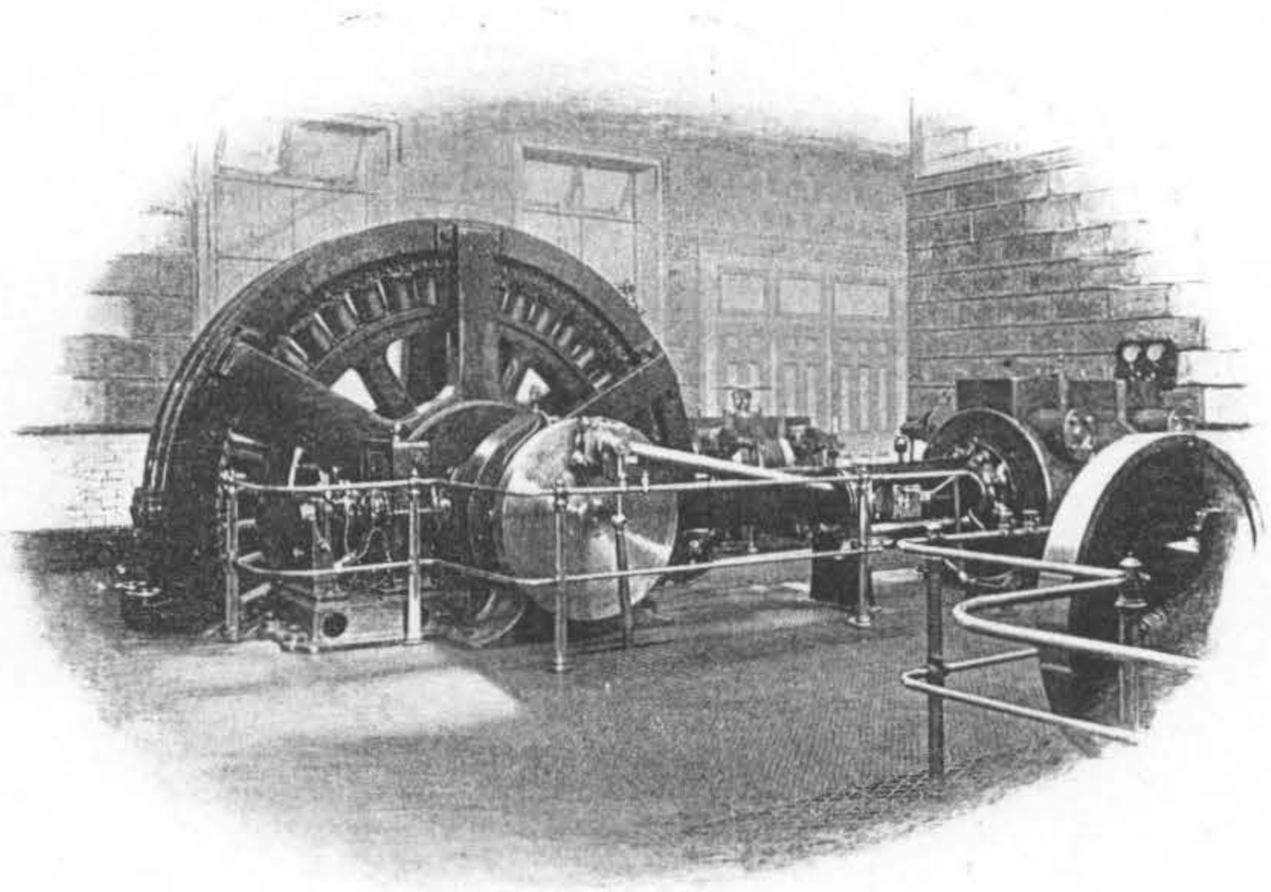
from the facilities offered in transforming the alternating currents used in induction motors, we can work them at much lower electric pressures than the continuous motor; for in order to run the continuous motor with wires at any reasonably low cost, we must use 300 to 700 volts right up to the motor. We cannot transform down to 100 or 50 volts as we can with the induction motor. Using the induction motor, we can transmit a large power at very small loss through thin wires to a long distance, and then still be able to apply a low pressure to the motor."



Rope Driven Plant, 650 Units Capacity.
(See page 661.)

The foregoing advantages were in all probability appreciated by most electrical engineers, but before there could be much extension of the induction motor, it was necessary to satisfy English engineers on one point, and that was, How do we stand in regard to patent rights? It must be confessed that the position has been an unsatisfactory one, and we can hardly accuse the reputed owners of the patents of unduly advertising their rights. There seemed to be insuperable difficulties in the way of obtaining authoritative information as to what were the patents, or to what extent they governed the three-phase motor. On all hands the question was raised, but as no satisfactory reply could be given, manufacturers, for the most part, gave up all idea of entering into the manufacturing of multiphase motors, and it is this difficulty, more than all others, that has retarded their introduction into this country. One of the most definite opinions given on the subject was that of Mr. Rankin Kennedy, which appeared in these columns,* to the effect that:—"There are some good and valid patents concerning the various 'improvements' on polyphase motors, but it is extremely doubtful whether any one, or more of them, can be held as a master patent controlling the whole of the polyphase motor business."

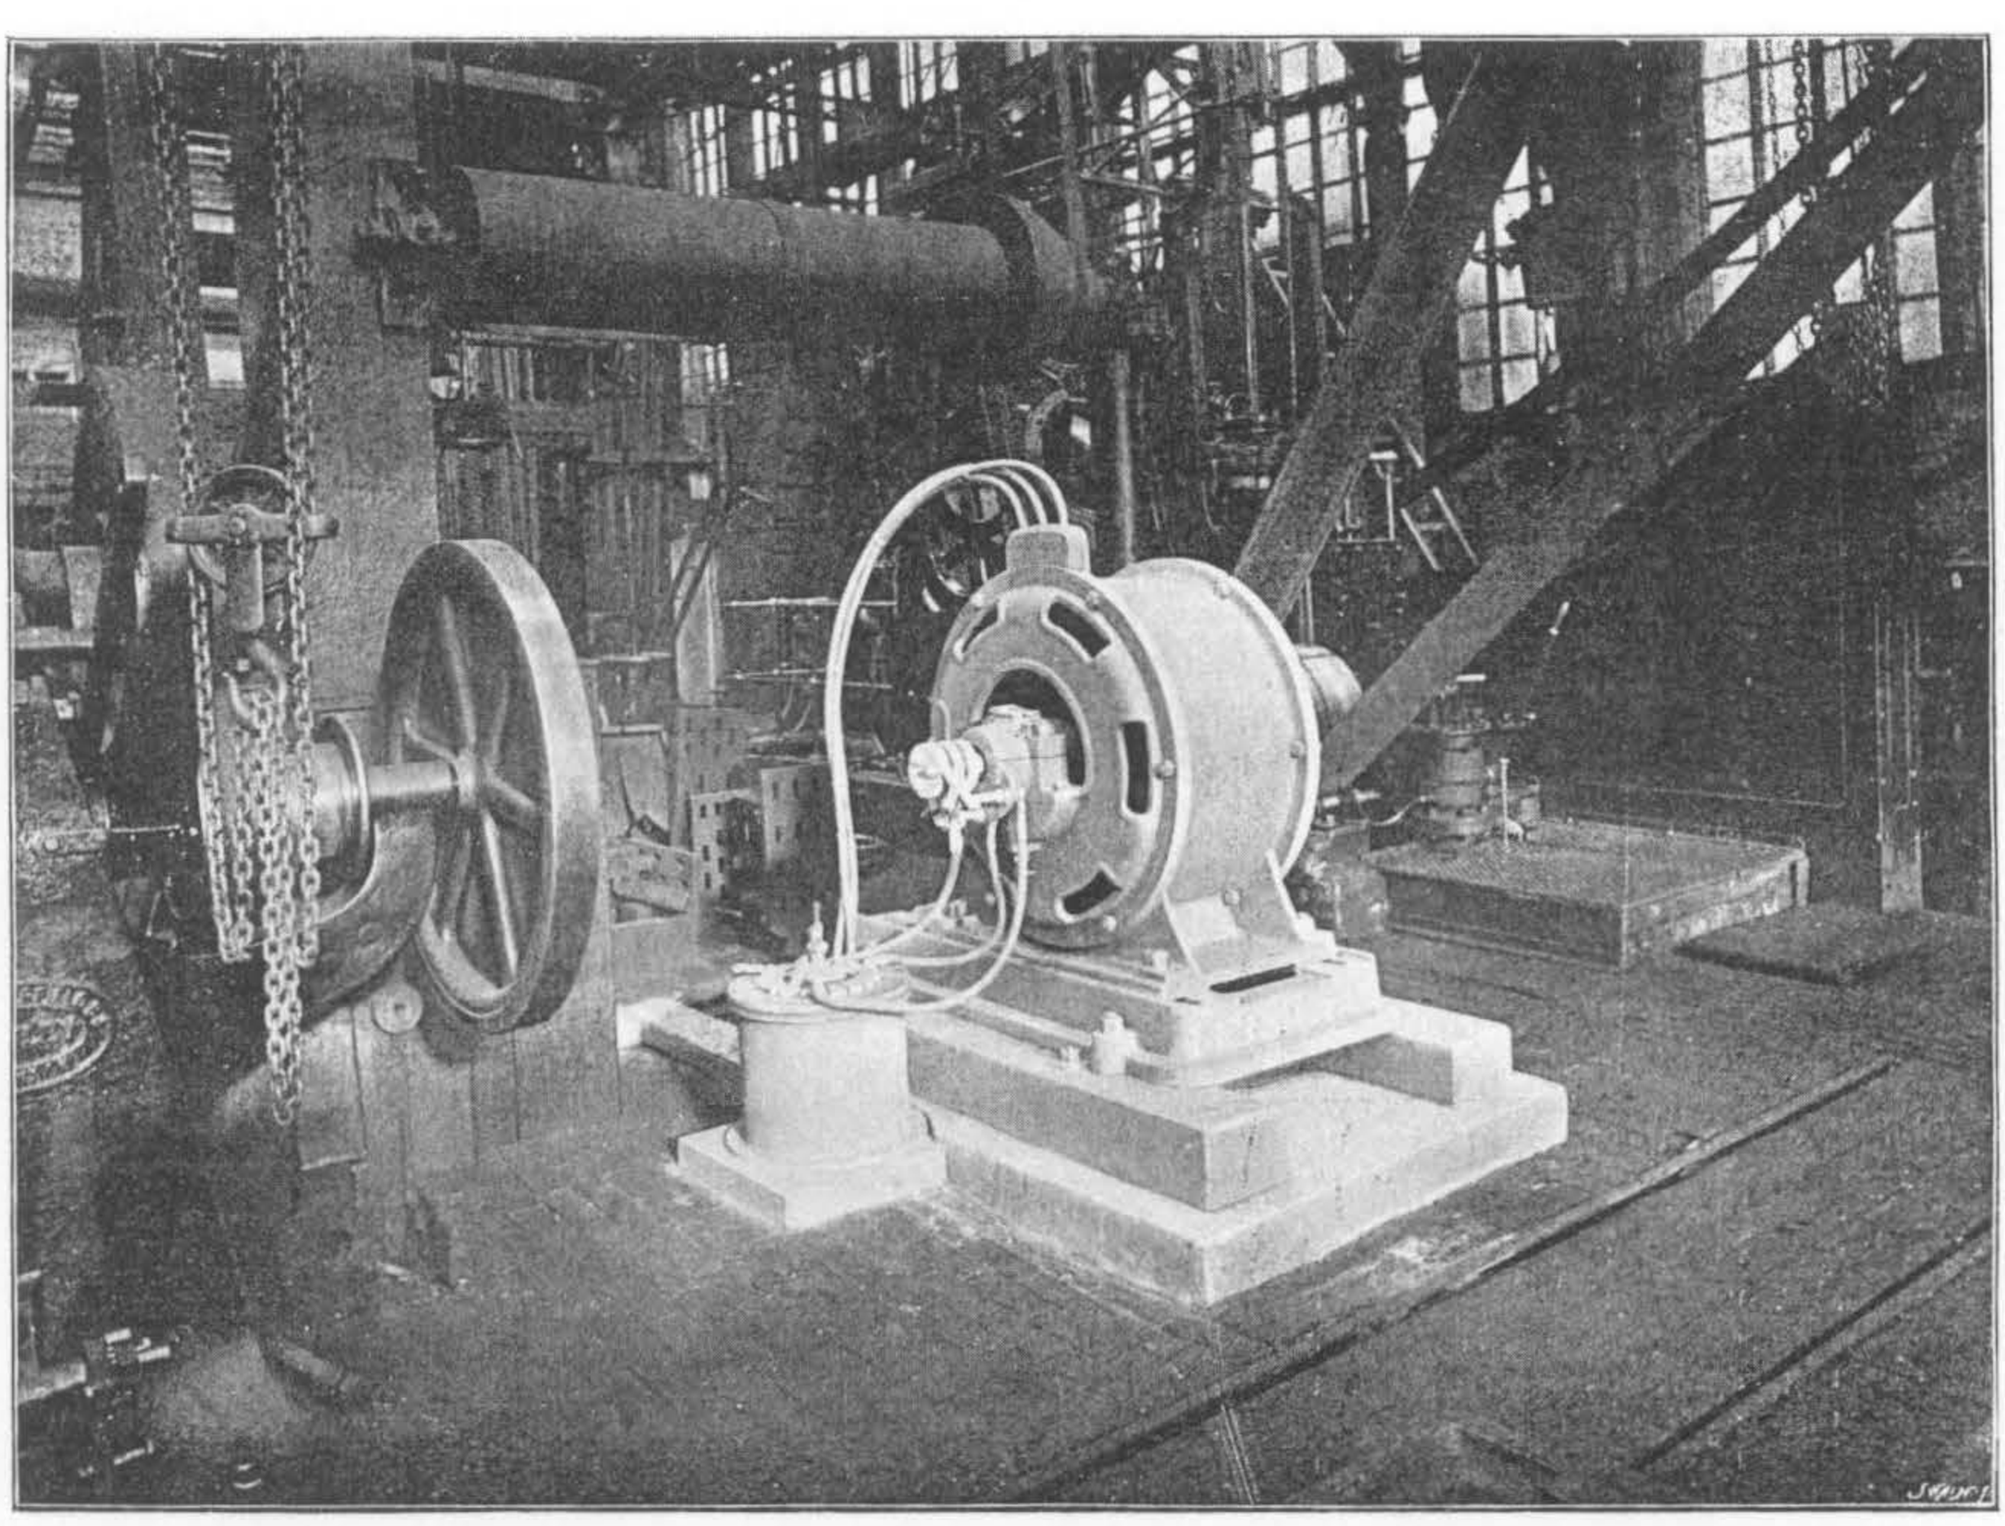
Considering, therefore, the delicacy of the whole question, the announcement that Messrs. Thomas Richardson & Sons, of Hartlepool, in conjunction with Messrs. Brown Boveri, had made arrangements to manufacture multiphase machinery in this country was naturally of considerable interest.



We have recently learned how Messrs. Richardson & Sons came to add so interesting a department to their extensive engineering business, and it will be entertaining to recount how the multiphase motor question was approached by them. Sir Thomas Richardson has long been impressed with the value of electrical driving, and he has for some years been a staunch adherent of the system. In order to obtain a comprehensive knowledge of the various methods of electrical transmission over short distances, Sir Thomas Richardson and Mr. D. B. Morison visited the Continent, and the result of their investigations was to establish in their minds the marked superiority of multiphase methods. When they sought, however, to introduce

General View of Multiphase Generators at Messrs. Richardson & Sons.

* Electrical Review, Vol. 39, p. 496.

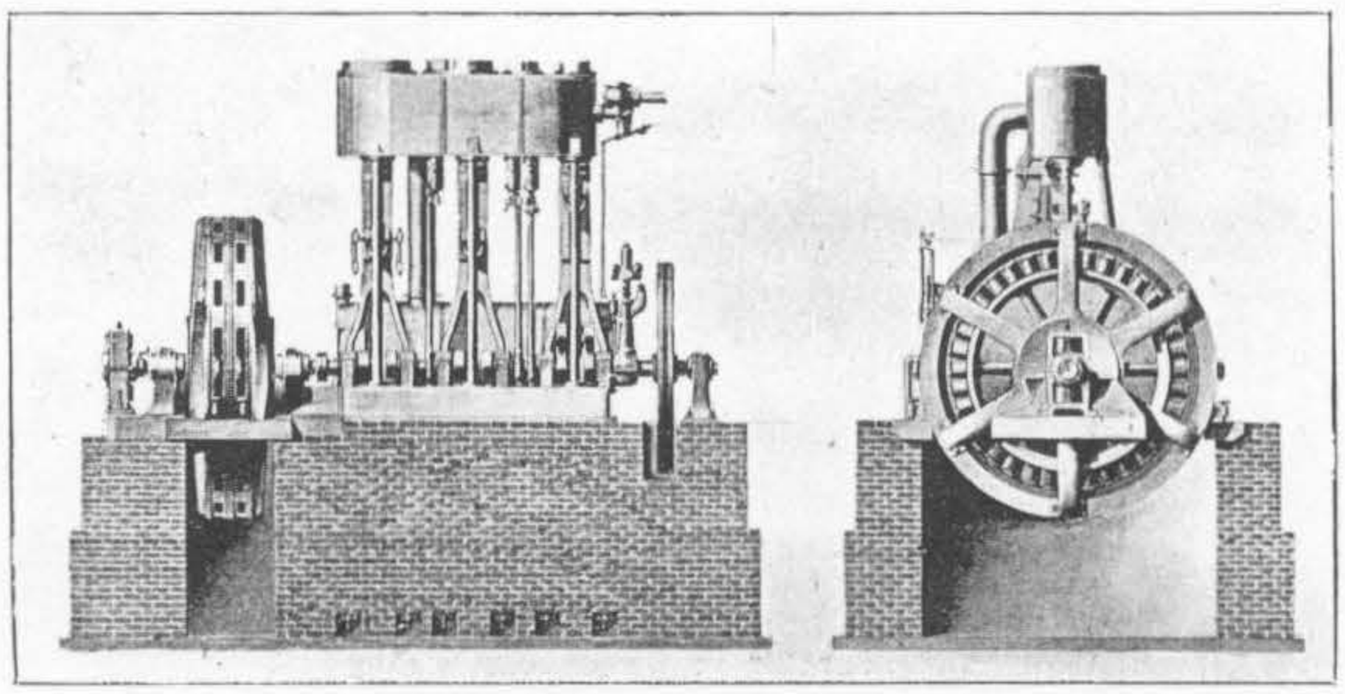


three-phase working into their own works, they were immediately confronted with the patent question; but not to be turned aside by an obstacle of this nature, they sought legal assistance, and went into the whole question of the patent rights for induction motors in this country. The result of their somewhat elaborate investigations was to satisfy themselves that the Tesla patent really covered the ground, and so convinced were they of this fact, that negotiations were immediately commenced with the Tesla Company for a license to use and manufacture multiphase motors. The preliminary negotiations were most unpromising, however, and when pressure was brought to bear on the Tesla Company, the patent rights were transferred to the Westinghouse Company. Difficulties again arose, but ultimately satisfactory arrangements were completed.

Multiphase Generator at Messrs. Richardson & Sons.

Whatever difference of opinion there may be on the legal aspects of the question, Messrs. Richardson & Sons are to be heartily congratulated on arriving at one solution of an apparently intricate problem. They have not only cleared the air of the mystery that surrounded the ownership of the induction motor; they have laid down a plant for multiphase working on a sufficiently large scale to demonstrate the simplicity and economy of the system. It will be admitted, from the illustrations of the generating plant, that Messrs. Richardson & Sons have provided a model station, and for arrangement and soundness of design we do not think that this country has anything superior to show.

Without taking into consideration this latest addition to multiphase systems, we suppose, at the outside, there are not more than four or five in the United Kingdom, and these are

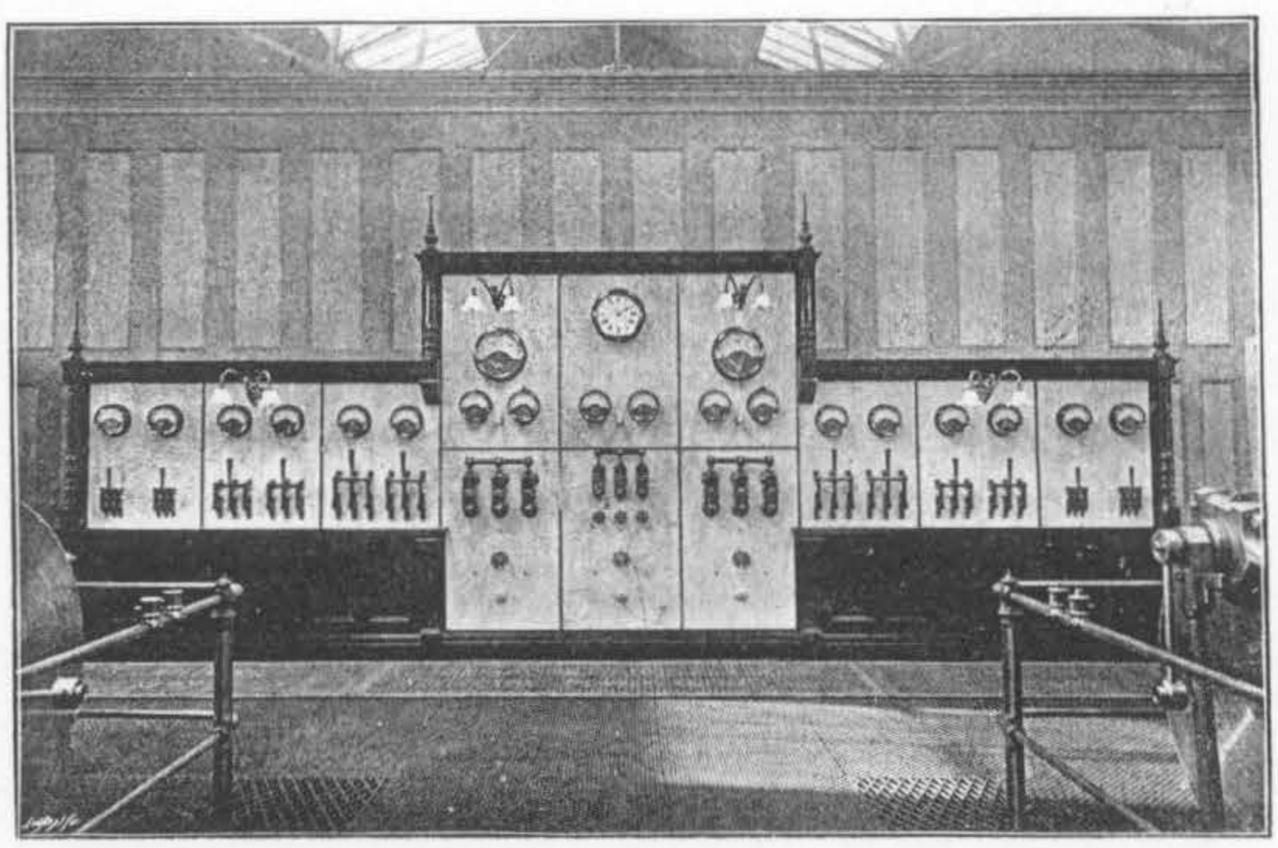


Multiphase Motor Driving Shafting at Messrs. Richardson & Sons.

The position then at the present moment with regard to three-phase patents in this country, and, of course, it must be remembered that the present position has been arrived at without the intervention of the Courts, is that it is necessary to obtain a license from the Westinghouse Company.

only of moderate size. There is a small one at Glasgow of 100 horse-power, and another of about 130 H.P. in Edinburgh, in both of which cases "Brown's" machinery is employed; in addition, there is the one at the Liverpool Grain Warehouses, which was recently described in these

columns, and probably there are one or two others on a small scale.



The plant, which has been laid down by Messrs. Richardson and Sons, aggregates about 1,250 H.P. There are at the present moment, as will be seen from the illustration, two large fly-wheel generators driven by horizontal compound engines, and a smaller machine of 80 kw. driven by a single engine, which is intended for night shifts. Each of the fly-wheel generators is capable of absorbing 420 brake H.P., which is the full output of the engines. The generators supply three-phase current to motors placed at different parts of the works. The plant is located in a well-designed building, the interior of which is lined with terra cotta coloured plaster, which helps to give a pleasing appearance to the station. The steam raising plant consists of two marine type boilers, generating steam at 160 lbs.

Messrs. Richardson & Sons' Direct Coupled Vertical Engine and Multiphase Generator.

The fly-wheel generators run at a speed of 125 revolutions, and generate three-phase currents at a tension of 200 volts between each terminal, and at a frequency of about 41 per second.

The rotating part of these machines consist of the fly-wheel of the engines, on the circumference of which are fixed the poles of the field magnet system. The winding of these poles consists of a spiral of copper strip, wound up on edge, the several convolutions of strip being insulated from the neighbouring turns by layers of varnished paper. This rotating field magnet revolves within the fixed armature. The laminated iron core of the armature is securely held in a cast-iron frame, the whole being divided into two parts for convenience and handling. This ring-shaped armature is supported in position on two star shaped cast-iron frames, which in turn are carried centrally on trunnion rings, bolted to the frame of the engines.

Multiphase Switchboard at Messrs. Richardson & Sons.

The armature, when in position, is thus like a wheel, capable of being rotated round the trunnion ring mentioned above.

The turning moment exercised on the armature by the rotating field magnet when the machine is doing work, is taken up on small bed-plates on the ground level at the outer circumference of the armature.

These bed-plates are so arranged that, on loosening the tightening screws (seen on the photograph at the circumference of the armature), part of the bed-plate can be slipped out of its place, which allows the armature to be rotated, there being then sufficient clearance for the screws and their bosses to pass through the embrace of these bed-plates.

The advantages claimed for this mode of construction are firstly, the possibility of carrying the armature absolutely centrally with regard to the rotating part, and secondly, that it allows easy access to any part of the armature for cleaning or possible repair, without making the pit in which the armature is situated so large as would otherwise be required.

The simplicity of the switchboard, as evidenced by the illustration, is one of the most noteworthy features of this plant. It is made up of three larger and six smaller marble panels, the larger ones being for the generators and the smaller ones for the feeders. One great point about the board is that the back is quite open, and access can be obtained to it from the adjoining room. Connections are brought from the dynamos by means of flat strips carried in tunnels, and the strip is continued along the back of the board, the size decreasing as the end of the feeder connections is reached. The fuses are fixed at the back of the board. Each panel carries a three-point switch and a voltmeter and ammeter, large dial ammeters easily read from all parts of the room indicating the total output of the plant. The mains throughout the works are carried in underground tunnels and supported on porcelain insulators.

The synchronising arrangements are simplicity itself, a pair of 200-volt incandescent lamps being used for each machine. No artificial load being used, no difficulty whatever is found in using any combination of the three machines in parallel.

Thirteen motors are installed in the shops; the sum of the powers of these machines is just over 500 H.P., five of them are 65 H.P. machines, the others vary in size down to 10 H.P.

A motor of 20 B.H.P. drives the pattern shop, and it is interesting to observe that this motor has repeatedly been tested to double its working load. This motor drives from a floor above the wood-working shop, the motors in all other cases being fixed on the floor and driving upwards. The illustration which we give shows one of the motors driving the whole of one of the engineering shops, thus supplanting an old beam engine, which is situated just behind the motor.

The "Brown" multiphase motor is too well known to need further description. The windings of the fixed part of the motor which are traversed by the main current are carried through tunnels in the laminated iron. These tunnels are insulated with layers of varnished paper, which has been found a very satisfactory insulator for all tensions.

The rotating part of the large motors is also wound with a multiphase winding, the three ends of which are brought out to sliding contact rings on the shaft At starting, a three-branch resistance is inserted between these rings, to regulate the current at starting in the same manner as in a continuous current machine.

As a point in favour of the economies already effected at Messrs. Richardson & Sons by the introduction of the multiphase plant, it is worth noting that it is expected that the

fly-wheel generators will supply power for the whole of the works, which hitherto has necessitated the use of *ten boilers*.

It is very evident that considerable interest is being taken in multiphase transmission, and at the present moment Messrs. Richardson & Sons have orders in hand for multiphase plant equivalent to 1,500 H.P. The type of combined plant which is being recommended is shown in the annexed sketch, and consists of a triple expansion engine of the vertical type, coupled direct to a three-phase generator. We trust that every success will attend the courageous efforts of Messrs. Richardson's to introduce multiphase machinery into this country.

Mr. Charles F. Higgins, formerly chief assistant to Brown, Boveri & Co., is superintending the electrical department at Messrs. Richardsons. It may be mentioned that Mr. Higgins has been intimately concerned in the introduction of multiphase machinery into this country, and has supervised the erection of all the "Brown" multiphase plant including the small plants at Glasgow and Edinburgh. Messrs. Geipel & Lange, of 68, Victoria Street, are the London agents for Messrs. Richardson & Sons.

TELEGRAPHY WITHOUT WIRES.

The following intelligent summary of the present status of the problem of telegraphy is condensed from a recent editorial utterance of the *Scientific American*, and will be found of interest :

Nikola Tesla has lately announced that he has completed his wireless telegraph to such an extent as to permit of telegraphy through the earth for a distance of twenty miles or more, and his experiments satisfy him of the feasibility of wireless telegraphy on a much more extended scale. In fact, he aims at nothing less than the establishment of a system of telegraphy that shall include the whole earth, and by which items of news may be distributed from one political or commercial center to every other such center throughout the world. This, Mr. Tesla claims, is possible without the interference of one set of signals with another.

He has constructed and tested both transmitting and receiving apparatus, and has found that a surprisingly small expenditure of energy is required. It is impossible, at this writing, to secure details of the apparatus, but it is known that he utilizes the static equilibrium of the earth. This he disturbs at one point, making signals which can be distinguished at one or more distant points.

In his earlier experiments in high frequency currents Mr. Tesla attained a frequency of 10,000 per second ; now 2,000,000 oscillations per second is not deemed extraordinary. It is said that the success of the system is assured, but he will not come before the public until every detail is completed. It is understood that the transmission of power from place to place by means of a similar system is contemplated.

While Mr. Tesla has been wrestling with this great problem in this country, Mr. Marconi, a young Anglo-Italian, has been working on the same line in England under the direction of Mr. Preece. It is reported that Mr. Preece has succeeded in telegraphing with certainty and sufficient rapidity from Penarth to Weston-super-Mare, a distance across the water of seven or eight miles, without wires, and it is believed that this distance can be greatly extended.

It is said by *The Engineer* that the apparatus devised by Marconi is extremely ingenious, and has for its object the getting out of the Hertzian vibrations sufficient work for telegraphic purposes. The apparatus comprises a transmitter and receiver. The former consists mainly of a small Ruhmkorff induction coil excited by a couple of battery cells. The secondary or high tension wires terminate each in a metallic ball. Between the two balls is placed a cubical box containing oil. In the opposite sides of the box are fixed two brass balls, oil-tight, so that one-half of each ball is in the oil in the box and the other half outside of the box. The balls do not touch. The whole arrangement has been designed by an Italian professor, Righi. On sending a a current through the induction coil, Hertzian vibrations are set up in the balls and communicated to the ether. The oil has a peculiar effect, acting as a species of brake, the rapidity of the wave vibrations being only about one-half of that stated by Dr. Lodge. These vibrations are then given off into space all around in every direction. So far as known, nothing save metals appears to be opaque to them, and here, therefore, we have an analogy with the Röentgen ray.

Marconi's receiver consists of a tube about ¼ inch in diameter and 3 inches long, in which are two silver plugs terminating in wires, the ends of which are soldered to the silver plugs. The wires are fused into the glass. The tube is exhausted to a near approach to absolute vacuum. The faces of the two silver plugs are very close to each other, and the space between is filled up with an impalpable metallic dust. On the nature of this dust much depends. It must suffice to say that there are in it three constituents, one of which is nickel. Under ordinary conditions this powder will not conduct electricity, save feebly. Its resistance is very high. If a Hertzian ray falls on the little tube, the dust is polarized like the filings in a Hughes test tube, and the powder becomes a conductor. It will be seen at once that we have here a make and break which can be acted on from a distance, and an ordinary Morse sounder does the rest. But matters, after all, are not quite so simple. It is easy to dispatch into space Hertzian waves at intervals corresponding to dots and dashes, but the powder in the receiver, once polarized, remains polarized. To get over this obstacle, a tiny hammer is so arranged that, the moment a current passes through the tube, the hammer taps the side of the tube and depolarizes the powder ready for the next signal.

There is nothing in common between ethereal or wireless telegraphy and telegraphy by induction; the phenomena are wholly distinct. The Hertzian radiance is akin to light, and the polarization of the powder in the receiver finds its analogue in the molecular change which is wrought by light in a sensitized plate.

Wireless Telegraphy.

There are two errors in connection with wireless telegraphy that are being constantly repeated, viz., that Marconi has done nothing new, and that the British Post Office neglected the work of Dr. Oliver Lodge and took up that of Marconi. When such a statement is reiterated by so eminent an authority as Prof. Silvanus Thompson, one feels constrained to enter some protest. At a lecture on "Signalling without Wires," recently delivered at the London Institution, Prof. Thompson, after very properly extolling the magnificent work of Hertz and Lodge, asked what had Marconi done? Nothing new! But surely before Marconi came to this country there had been no serious attempts at signalling over considerable distances. We presume if either Dr. Lodge, or even Mr. Tesla, had thought they were so near such striking results, they would have been unceasing in their efforts to carry the experiments a little further than they did. Moreover, we feel sure that if Dr. Lodge had brought something definite before the British Postal authorities they would have taken up his discovery as readily as they did Marconi's. At the same time, whatever may be the commercial future of systems of signalling across space, its development may be said to be due to the minds of many.

The New York Herald December 19, 1897

CHRISTMAS UPON ADRIATIC'S SHORES.

—As Recalled by—

NIKOLA TESLA.

NIKOLA TESLA does not often speak at length about himself or his wonderful electrical inventions, but he sat and talked for an hour or two the other day with a friend about Christmas in the province of Lika, which is a part of the Austro-Hungarian empire and lies close to the Adriatic Sea, near Herzigovina, Dalmatia and Bosina. Tesla passed much of his boyhood in Smiljan, a town of Lika, where his father was pastor of a Greek church, but went from there while yet a boy.

"Christmas festivities in my country," said Mr. Tesla, "differ much from Christmas festivities here, yet there are many similarities, too. We begin the celebration on the day before Christmas by fasting. We do not altogether abstain, being privileged to eat freely of fish and all vegetable foods, but we may partake of no flesh meats, nor milk, nor eggs. This day is devoted largely to reflection, and its observance lasts until late on Christmas Eve.

"We rise very early in my country on Christmas morning—as early as three o'clock at the latest—to go to church and hear mass. All the morning until eleven o'clock is given over to religious services of one sort or another, and but little if any food is taken until that hour. By that time, however, every one is hungry, and a liberal luncheon is eaten, no discrimination being made against the heartiest food.

"Every one in my country is fond of coffee, which is generally drunk in large cups, with cream or milk. We may drink coffee on the day before Christmas, but without milk only, and as we are allowed to resume the use of milk in coffee on the day itself, you may be sure we then indulge freely in the delicious drink. After this breakfast, the gentlemen are served with liquors and little cakes.

The Christmas Dinner.

"The Christmas dinner comes later in the day, and I assure you it is always a meal to remember. No, we do not serve turkey there as the chief dish, and I am not sure that I can name any dish that may properly be said to take the turkey's place, unless it be roasted pig.

"I do not remember a Christmas dinner without a roasted pig in my country. The pig selected is always very young and small, and is roasted entire after dressing, the cooking being attended to with great care and prolonged until the skin is crisp and crackling. Besides the Christmas pig there are many other dishes served on the great Christmas festival—all the good things, in fact, that can be devised, the same as in America; and every one eats as heartily as possible, another point in which the people of my country and Americans are alike.

"There is always a Christmas tree wherever there are children in my country, and the good house mothers and fathers prepare and decorate them with much loving care, to the great delight of the little ones. There are always present a-plenty on the trees, of course, but, even so, gift giving is not so much a feature of the holiday time here as there.

"The stockings are not hung up on Christmas eve, as here, in my country, but on St. Nicholas Day, which falls some days earlier than Christmas. In America the festival of St. Nicholas, or Santa Claus, and Christmas seem to be combined, but there they are kept separate, and the children have two days of holiday rejoicing and frolic in place of one.

"As a matter of fact, they have more than that, since the observance of Christmas itself lasts two or three days after the day itself, during all which time the greatest jollity prevails, and family reunions are held. There is much visiting back and forth, and seasonable greetings fill the air.

"But sometimes," continued the electrician musingly, as if thinking of other days, "the reunions are not held, and the visiting exists in the wishes of the people only. That is when the deep snows come.

A Land of Mighty Snows.

"For you must know," he went on, "that my country is not only cold in the winter, but subject at times to great snowfalls, the like of which I have never seen in the New World—snowfalls so deep that a man's head would be far below the level of the light and feathery substance in many places; snowfalls that are often accompanied by wild, fierce winds, piling the flakes up into enormous drifts in some places and sweeping the rock bound soil clean in others; snowfalls that it is not well to encounter unless shelter is near, and that have buried many a human victim beneath a milk white death mantle.

"Not all these terrible storms come in the winter season, either, as I have excellent cause to remember. My country is high above the sea level, my home was two thousand feet and more straight up from the tide, and many there be who live one, two, almost three thousand feet higher."

TESLA'S LATEST ADVANCES IN VACUUM-TUBE LIGHTING.

APPLICATION OF TUBES OF HIGH ILLUMINATING POWER TO PHOTOGRAPHY AND OTHER PURPOSES.

To the Editor of Electrical Review:

A few years ago I began a series of experiments with a view of ascertaining the applicability of the light emitted by phosphorescent vacuum tubes to ordinary photography. The results soon showed that, even with a tube giving no more light than the equivalent of one half of a candle, objects could be easily photographed with exposures of a few minutes, and the time could be reduced at will by pushing the tube to a high candle-power. Photographs of persons were likewise obtained at that time and, if I am not mistaken, these were the first likenesses produced with this kind of illumination. However, a number of facts, not pertaining to the subject presently considered, were observed in the course of these experiments which, had they been immediately published, might have materially hastened important scientific developments which have taken place since. To dwell on these and other experimental results obtained at that time, more extensively at the first opportunity, is one of my good resolutions for the coming year. A calamity, unfortunately, interrupted my labors for a short period, but as soon as I was able I took up again the thread of the investigation, which was not only interesting in connection with the principal object in view, but was also useful in many other respects. So, for instance, in making observations as to the efficiency or any peculiarity of the vacuum tubes, the photographic plate was found to be an excellent means of comparison, note being taken of the distance and time of exposure, character of the phosphorescent body, degree of rarefaction and other such particulars of moment.

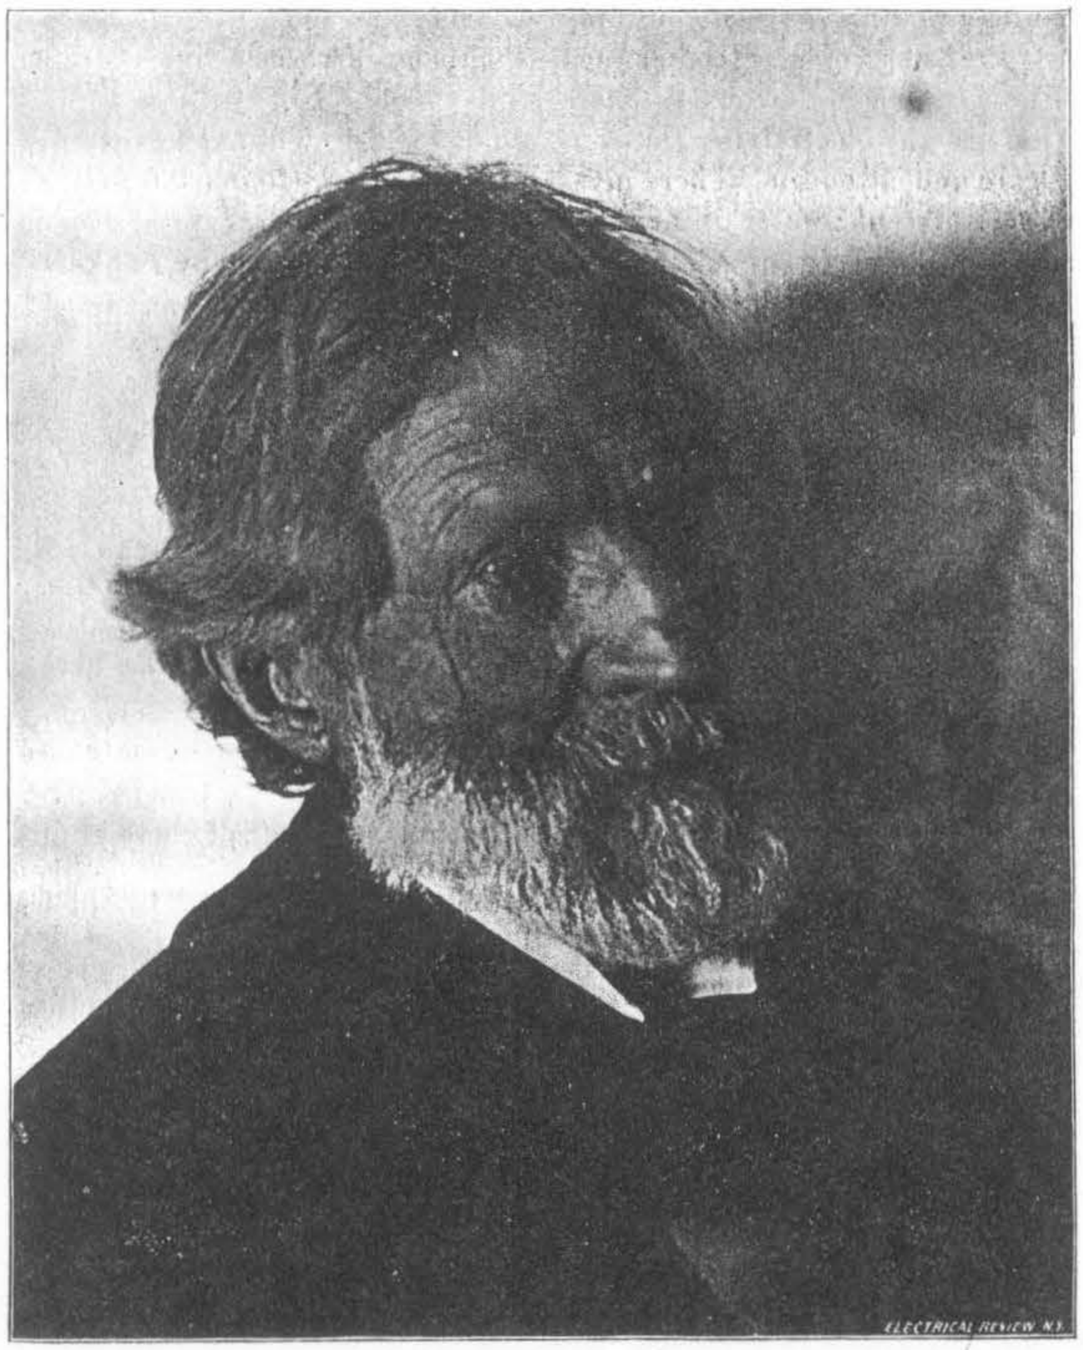


Fig. 1.—"Tesla's Latest Advances in Vacuum-Tube Lighting." Photograph Made by the Light of a Single Vacuum Tube, at a Distance of Five Feet; Exposure, Five Seconds.

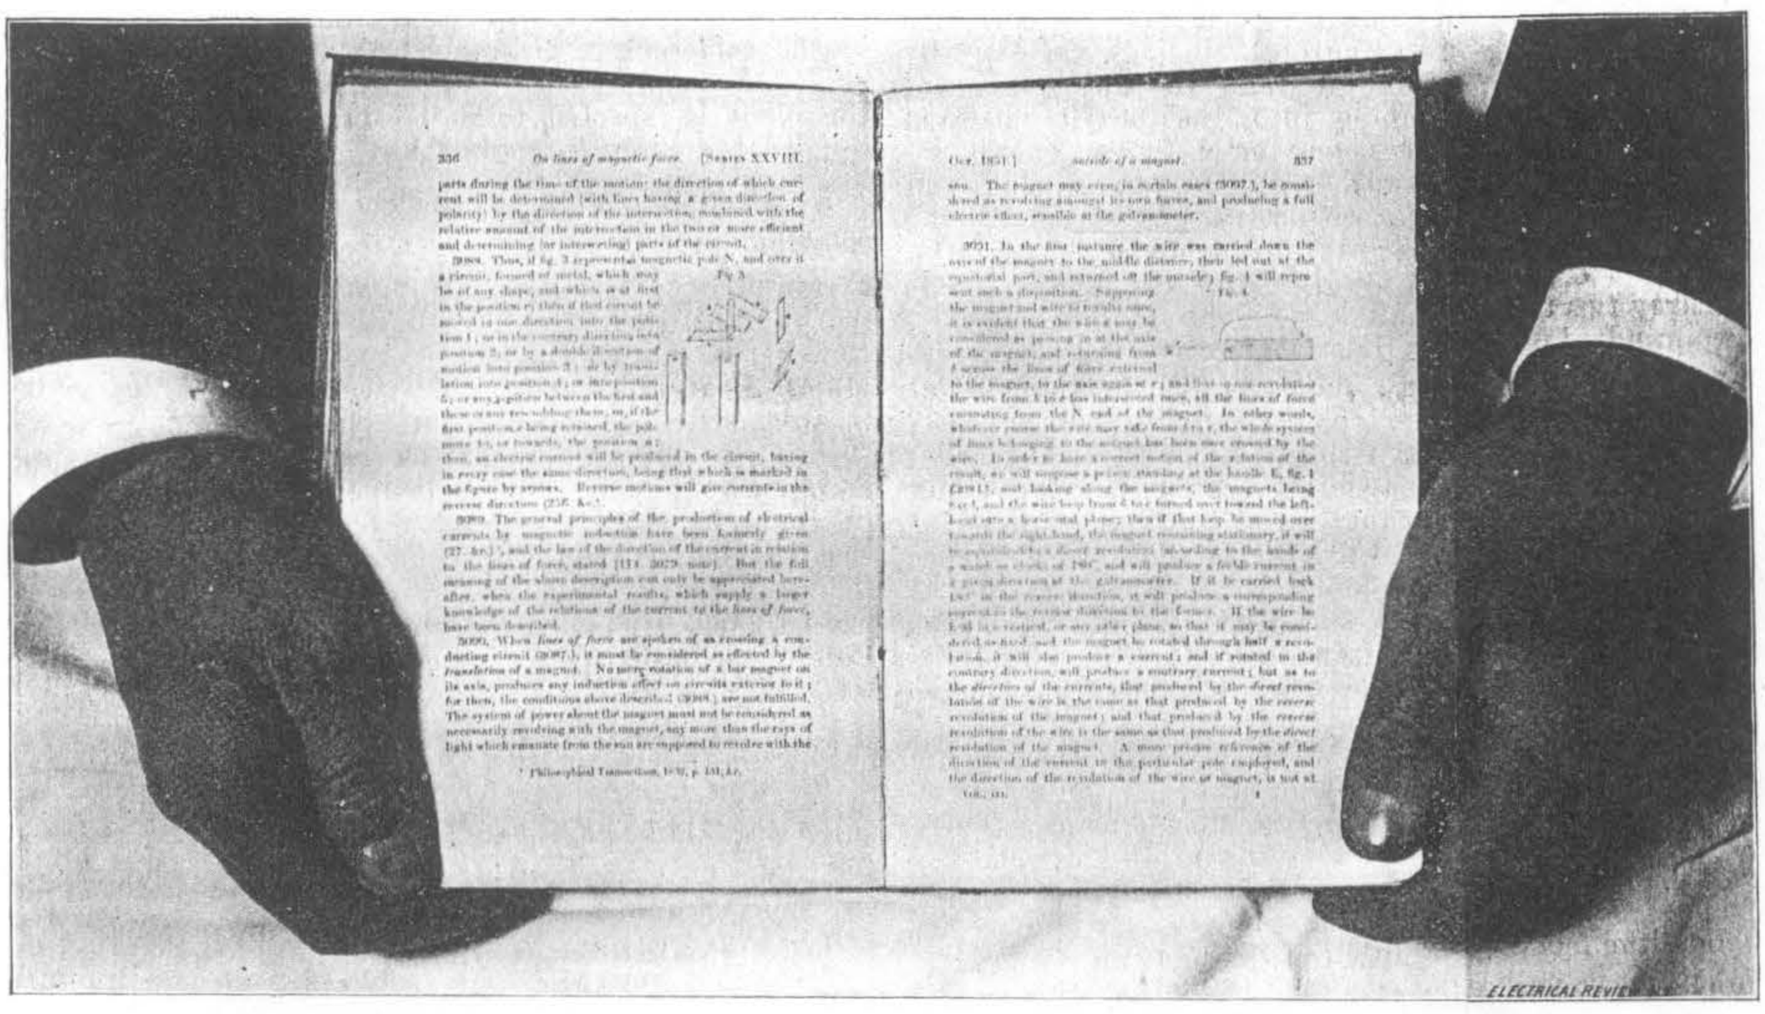

Fig. 2.—"Tesla's Latest Advances in Vacuum-Tube Lighting."—Two Historical Pages Photographed by the Light of a Single Vacuum Tube at a Distance of Four Feet; Exposure Two Seconds.

A rather curious feature in the photographs obtained with tubes of moderate illuminating power, as a few candles, was that the lights and shadows came out remarkably strong, as when very short exposures are made by flashlight, but the outlines were not sharp and practically no detail was visible. By producing tubes of much greater candle-power, a notable improvement in this respect was effected, and this advance prompted me to further efforts in this direction, which finally resulted in the production of a tube of an illuminating power equal to that of hundreds, and even thousands, of ordinary vacuum tubes. What is more, I believe that I am far from having attained the limit in the amount of light producible, and believe that this method of illumination will be eventually employed for light-house purposes. This probably will be considered the oddest and most unlooked-for development of the vacuum tube.

Simultaneously with this progress a corresponding improvement was made in the efficiency of the light produced. A few words on this point might not be amiss, considering that a popular and erroneous opinion still exists in regard to the power consumed by vacuum tubes lighted by ordinary means. So deeply rooted is this opinion which, I will frankly confess, I myself have shared for a long time, that, shortly after my own first efforts, Sir David Solomons and Messrs. Pike & Harris undertook to introduce in England such tubes on a large scale in competition with the incandescent system of lighting. The enterprise, which was commented on in the technical periodicals, was commendable enough, but it was not difficult to foretell its fate; for although the high-frequency currents obtained from the alternator yielded better economical results than interrupted currents, and although they were obtained in a convenient and fairly economical manner, still the efficiency of the whole system was necessarily too small for competition with incandescent lamps. The reasons for the great power consumption, which may often be as much as 10 times that taking place in incandescent

lamps for an equivalent amount of light, are not far to seek. A vacuum tube, particularly if it be very large, offers an immense radiating surface, and is capable of giving off a great amount of energy without rising perceptibly in temperature. What still increases the dissipation of energy is the high temperature of the rarefied gas. Generally it is supposed that the particles are not brought to a high temperature, but a calculation from the amount of the energy consumed during a given period of time, and the amount of matter contained in the tube, leads to results which would seem to indicate that, of all the means at disposal for bringing a small amount of matter to a high temperature, the vacuum tube is the most effective. This observation may lead to valuable uses of such tubes in astronomical researches, and a line of experiment to this end was suggested to me recently by Dr. Geo. E. Hale, of the Yerkes Observatory. As compared with these disadvantages the incandescent lamp, crude and inefficient as it undoubtedly is, possesses vastly superior features. These difficulties have been recognized by me early, and my efforts during the past few years have been directed towards overcoming these defects and have finally resulted in material advances, so that I find it possible to obtain from a tube of a volume not much greater than that of a bulb of an incandescent lamp, about the same amount of light produced by the latter, without the tube becoming overheated, which is sure to take place under ordinary conditions. Both of these improvements, the increase of candle-power as well as degree of efficiency, have been achieved by gradual perfection of the means of producing economically harmonical electrical vibrations of extreme rapidity. The fundamental principle involved is now well known, and it only remains to describe the features of the system in detail, a duty with which I expect to be able to comply soon, this being another one of my good resolutions.

FIG. 3.—"TESLA'S LATEST ADVANCES IN VACUUM TUBES."—PHOTOGRAPH OF THE EXPERIMENTER'S HAND MADE BY THE LIGHT OF A SINGLE IMPROVED VACUUM TUBE OF 1,000 CANDLES. EXPOSURE TWO SECONDS; DISTANCE FROM THE TUBE FOUR FEET.

The purpose of the present communication is chiefly to give an idea in how far the object here aimed at was obtained. The photographs shown were taken by a tube having a radiating surface of about two hundred square inches. The frequency of the oscillations, which were obtained from an Edison direct-current supply circuit, I estimated to be about two million a second. The illuminating power of the tube approximated about one thousand candles, and the exposures ranged from two to five seconds, the distance of the object being four to five feet from the tube. It might be asked why, with so high an illuminating power, the exposures should not be instantaneous. I would not undertake to satisfactorily answer this question, which was put to me recently by a scientific man, whose visit to my laboratory I still vividly recollect. Likenesses can, of course, be obtained with instantaneous exposures, but it has been found preferable to expose longer and at a greater distance from the tube. The results so far obtained would make it appear that this kind of light will be of great value in photography, not only because of the fineness of the lines, but also because the artist will be able to exactly adjust the conditions in every experiment so as to secure the best result, which is impossible with ordinary light. He will thus be made entirely independent of daylight, and will be able to carry on his work at any hour, night or day. It might also be of value to the painter, though its use for such purposes I still consider problematical.

I anticipate that much detail will naturally be lost in the reproductions through the half-tone process and press work, however good, but I hope that enough will be shown to demonstrate the advantageous features of this light in photography and its practical usefulness in this art.

In conclusion, I wish to thank Mr. R. L. Newman for kindly consenting to the use of his photograph.

NIKOLA TESLA.
New York, Jan. 3.

ROENTGEN-RAY NOTES.

BY WILLIAM ROLLINS.

X—SCATTERED ROENTGEN RAYS.

In a previous note I said the wave length depended on the potential and degree of exhaustion in the tube; a low potential and vacuum giving waves of such length as to make strong contrasts between bones and soft tissues in the human body; a high vacuum and potential giving less contrast, because the shorter waves generated went through the bones also. When we wished to see through greater thickness and yet have marked contrast, I recommended increasing the amperage, thus keeping the wave length unchanged, but increasing the amount of light, and stated that this did not much change the relative transparencies within the limits of an ordinary apparatus. It is the object of the present note to show why there is any change in the relative transparencies. In attempting to use ordinary light with one of my X-ray cameras, made to find stones in the bladder, I so enclosed a 20,000-candle-power arc that no light could escape into the room except through a small hole directed toward the abdomen. Though this light came through the tissues, it was too scattered to show structure, and this is naturally what happens with Roentgen rays, though in a less degree, because of their shorter wave length.

If we generate these waves of such a length as to lose all detail in the soft tissues we may still have the bones very dark by contrast. If we try to make the bones lighter by increasing the amperage, keeping the potential the same to prevent altering the wave length, we can make them very bright, if we have a big condenser and discharge it rapidly, but the brightness is due to scattered light and we do not see any more of their structure. If we want more details in the bones we must develop waves of shorter wave length, and when we have done this by increasing the potential and the vacuum we can make the bones as bright as before and yet see their structure, because the light is less scattered. Now, if we increase the amperage as before we make them still lighter and lose the structure, because we are using enough light to come through the denser parts, but being scattered light it shows no detail.

XI—MAKING THE COOLED ANODE OF OTHER METALS THAN PLATINUM.

In describing the A-W-L Roentgen-ray tube, I mentioned the cost of the platinum as a possible objection, and promised to describe a method of reducing the expense. In some experiments to determine what metal was best for that part of the anode receiving the cathode discharge, I used a brass anode, the only platinum being a short tube where it was sealed into the glass. As Kirmayer & Oelling, who make my tubes, find no difficulty in this construction, I see no present reason why it may not be employed. By soldering different metals to the end of these anodes, I have tried to determine which was best to use as a target in a reflecting focus tube. Tubes work so differently that it is difficult to compare them; and, to overcome this, I have arranged the metals to be tested around the periphery of an iron disk, which, being revolved by a magnet, enables me to bring any one quickly in position to receive the cathode discharge. Even then it is difficult to determine the relative values; but at present platinum seems well adapted to the purpose.

XII—BURNING FROM A VACUUM TUBE NOT GENERATING ROENTGEN RAYS. (TESLA'S SCREEN.)

Mr. Tesla long ago told us how to prevent burning, and, as his statements are always facts of nature, no proof is required to support them. I simply approach his fact from another point of view. I exhausted a tube to such a degree that no Roentgen light could be produced with the potential I employed, the discharge going around the tube. By exposing my hand it was severely burned. Yet, I have frequently exposed the same hand for 50 hours in a single month to a tube in which powerful Roentgen light was being generated, using the Tesla grounded aluminun screen, without producing any greater effect than slight redness and roughness of the skin. Cases of burning are not infrequent, and patients are nervous under examination, because they have known some one who has been burned. If a few physicians were sued for malpractice this would be immediately stopped, for there is no surer incentive to knowledge than to make ignorance and incredulity costly.

The Brooklyn Eagle January 6, 1898

TESLA'S NEW TUBES.

The Light an Excellent Substitute for Daylight.

Nicola Tesla, the noted electrician, has invented a new light after a long time spent in experiments. Tesla says that by using large vacuum tubes the light will be so powerful that photographs can be taken as easily at night as in the day. This light will also be used for lighthouse purposes and he predicts that colors may be distinguishable. At present Tesla declines to discuss his discovery, but he says he hopes to provide a light strong enough to pierce the densest fog. Accompanying some photographs which Mr. Tesla sent to the Electrical Review showing the result of his discovery was a letter which describes the experiments as follows:

The photographs shown were taken by a tube having a radiating surface of about 200 square inches. The frequency of the oscillations, which were obtained from an Edison direct current supply circuit, I estimated to be about 2,000,000 a second. The illuminating power of the tube approximated about 1,000 candles, and the exposures ranged from two to five seconds, the distance of the object being four to five feet from the tube. It might be asked why, with so high an illuminating power, the exposures should not be instantaneous. I would not undertake to satisfactorily answer this question, which was put to me recently by a scientific man, whose visit to my laboratory I still vividly recollect.

Likenesses can, of course, be obtained with instantaneous exposures, but it has been found preferable to expose longer and at a greater distance from the tube. The results so far obtained would make it appear that this kind of light will be of great value in photography, not only because of the fineness of the lines, but also because the artist will be able to exactly adjust the conditions in every experiment, so as to secure the best result, which is impossible with ordinary light. He will thus be made entirely independent of daylight and will be able to carry on his work at any hour, night or day. It might, also, be of value to the painter, though its use for such purposes I still consider problematical.

NIKOLA TESLA'S NEW PHOTOGRAPHY.

This Picture Was Reproduced from a Photograph Made by the Light of a Single Vacuum Tube, at a Distance of Five Feet, Exposure Five Seconds.

EQUAL TO SUNLIGHT.

Tesla with His Perfected Vacuum Takes Photographs as Well by Night as by Day.

NO MORE "FLASH" PICTURES

Powerful Rays Reveal Every Line in the Subject Photographed with Startling Distinctness.

TO ILLUMINE LIGHTHOUSES.

Nikola Tesla, the well known electrician, announces an important discovery to-day in the Electrical Review. He says that he has perfected vacuum tubes of such high illuminating power that they may be used in lighthouses, and that they will enable the photographer to work by night as well as by day. He even suggests that by means of this light the painter may be able to distinguish colors as well at night as he can by the clear, soft light of day.

The result which Mr. Tesla has attained represents several years of patient experimenting. His work was somewhat retarded by the burning of his laboratory in 1895. He is not ready yet to describe his invention in detail. He promises to do soon. He always speaks in a conservative way of his discoveries. I called yesterday at his laboratory. His bearing was one of great elation.

"It is of more importance," he said, "to discover new principles, to find out scientific facts, than to invent mere appliances."

LIGHT AS OF NOONDAY.

The results which Mr. Tesla has attained have been achieved by the use of his vacuum tubes and his oscillator. The light which he is able to produce by this means is as bright as that of the noonday sun. By its use every line of the object photographed may be made to stand out clearly and distinctly.

Mr. Tesla has taken several photographs by this light, which are reproduced in the Electrical Review. I saw the original photographs yesterday at the office of the publication. Half tone engraving cannot begin to do justice to the extreme clearness and delicacy of these photographs. It is possible to give only a suggestion of the clearness of the original in a picture such as is used for the purpose of newspaper illustration. The accompanying portrait is from one of the half tones. The original photograph was made under the light of a single vacuum tube at a distance of five feet, with an exposure of five seconds.

A STARTLING EFFECT.

Every wrinkle in the face of the man is clearly shown. The hairs of the beard and the eyelashes are distinct. The effect is almost startling. The face seems to stand out from the paper. This photograph was taken, too, without the discomfort to the subject which attends the use of the flashlight.

The most remarkable photograph is that of the hand of Tesla. It was made by the light of a single improved vacuum tube of one thousand candle power, at a distance of four feet, after an exposure of two seconds. The lines of the hand stand forth so clearly that the palmist may read them with the greatest care. Every detail is reproduced with microscopic accuracy. The veins of the wrists and the fine lines upon the cuticle are faithfully shown. The texture of the inventor's coat is shown in several inches of the sleeve and the linen threads of the cuff are almost distinct. The shadows about the wrists and fingers give the impression that you are looking at a hand of flesh and blood.

Another photograph is that of an open book upon electricity, supported by two hands. This was done by a vacuum tube, at a distance of four feet, with an exposure of two seconds.

PICTURES PRAISED.

Nicola Tesla Commends the Effort of the Herald in Telegraphing Sketches of Shaw Trial.

OTHER PAPERS SURPRISED.

George Palmer, Head of the Journal Art Department, Says a Distinct Advance Has Been Made.

PUBLIC MUCH INTERESTED.

The enterprise of the HERALD in presenting to its readers telegraphed pictures illustrating the trial of Eli Shaw at Camden, N. J., was much praised yesterday by experts and by the public. For years there have been experiments looking toward the transmission of pictures by wire. The HERALD has been the first to make a practical application of a much discussed process to the purposes of newspaper illustration. The directors of the art departments of the various newspapers were deeply interested, and some of them spoke highly of the distinct advance which the HERALD has made in newspaper illustration.

Nicola Tesla, the distinguished scientist, who has made exhaustive researches in the realm of electricity, was deeply interested in the HERALD'S pictures. He was seen yesterday afternoon at his laboratory, at No. 46 East Houston street.

MR. TESLA'S COMMENDATION.

"I would say in a general way," he said, "that, of course, the HERALD'S efforts are very commendable. As long as we have journals which are willing to expend sums of money for such experiments, inventions will progress.

"The fundamental principles of these transmissions of characters and pictures to a distance over a wire [redacted] back, and may be really traced to Caselli, an Italian who many years ago availed himself of the electro-chemical principle for this purpose. Numerous attempts have been made since, with more or less success, and the fundamental idea has been carried out in many ways by various inventors. Edison, I believe, was one of the most arduous workers in this field, and produced an interesting device in the form of a pen for transmitting characters.

"Professor Gray, however, made a notable step in advance by perfecting his telautograph, which is now in practical use. With this instrument characters and sketches can be readily transmitted over a wire to great distances. There is no doubt that Bell's telephone, Edison's phonograph and the telautograph of Gray have all helped to bring about these last improvements.

"But if I am correctly informed I think that the honor of having successfully transmitted such pictures with devices such as the HERALD describes belongs to Mr. N. S. Amstutz, a young engineer of Cleveland, who has to my knowledge worked indefatigably on this task for a number of years. I have in my possession some samples which he gave me two years ago, which are altogether remarkable. However, Mr. Amstutz's invention was described in periodicals almost three years ago, and of these I may cite the Scientific American, April 6, 1895, which I happen to find. I would not attempt to criticise the invention described in the HERALD, as I have not followed the development of the art in its minute details.

IT IS A DISTINCT ADVANCE.

"The HERALD has made a distinct advance," said George Palmer, the head of the art department of the New York Journal. "The pictures of the Shaw trial are the most practicable thing in the line of sending pictures by wire which I have ever seen. Any fair minded man, upon being shown these pictures and having been assured that they were absolutely authentic, could not for a moment that they mean an important step in newspaper illustration. I am glad to see the HERALD make a success of the process.

"I would make the criticism that at present it seems difficult to get the delicate shades of expression. Of course, the process may be greatly improved. In the pictures of Norcross and Cox, the jurors in the Shaw case, I notice that the men have strong features. I should like to see the process tried with the faces of women and children. It seems to me that in transmitting pictures of scenes and diagrams that this process will prove of great utility.

"I am greatly interested in the matter, because for years I have been following the experiments."

M. C. Ernsberger, the director of the art department of the New York Tribune, said yesterday afternoon that the HERALD had shown great enterprise and had added a valuable factor to the art of newspaper illustration.

MR. TESLA'S ANNOUNCEMENT.

Mr. Tesla makes his announcement in a letter to the editor of the Electrical Review. In speaking of his experiments in photography he says:—

The photographs shown were taken by a tube having a radiating surface of about two hundred square inches. The frequency of the oscillations, which were obtained from an Edison direct-current supply circuit, I estimated to be about two million a second. The illuminating power of the tube approximated about one thousand candles, and the exposures ranged from two to five seconds, the distance of the object being four to five feet from the tube. It might be asked why, with so high an illuminating power, the exposures should not be instantaneous. I would not undertake to satisfactorily answer this question, which was put to me recently by a scientific man, whose visit to my laboratory I still vividly recollect.

Likenesses can, of course, be obtained with instantaneous exposures, but it has been found preferable to expose longer and at a greater distance from the tube. The results so far obtained would make it appear that this kind of light will be of great value in photography, not only because of the fineness of the lines, but also because the artist will be able to exactly adjust the conditions in every experiment so as to secure the best result, which is impossible with ordinary light. He will thus be made entirely independent of daylight and will be able to carry on his work at any hour, night or day. It might also be of value to the painter, though its use for such purposes I still consider problematical.

TO PIERCE FOGS.

Another development of Mr. Tesla's vacuum tube, which will prove of incalculable value concerns lighthouses. It is well known that it is difficult to secure a light which will penetrate fog. It is believed that light from the vacuum tube will eventually be used for this purpose. It is likely that practical experiments will soon be made in some lighthouse on this coast for the purpose of demonstrating the practicability of Mr. Tesla's invention.

"By producing tubes of much greater candle power," says Mr. Tesla in his letter, speaking of progress in electric lighting, "a notable improvement in this respect was effected, and this advance prompted me to further efforts in this direction, which finally resulted in the production of a tube of an illuminating power equal to that of hundreds, and even thousands, of ordinary vacuum tubes. What is more, I believe that I am far from having attained the limit in the amount of light producible, and believe that this method of illumination will be eventually empoyed for lighthouse purposes. This probably will be considered the oddest and most unlooked for development of the vacuum tube."

Mr. Tesla also says in his letter that he finds that from an ordinary vacuum tube, not much greater in volume than an ordinary incandescent lamp, about the same amount of light is produced as from the incandescent lamp without any overheating.

The New York Times January 6, 1898

NEW LIGHT IN PHOTOGRAPHY.

Nikola Tesla Develops Vacuum Tubes to Make Pictures Regardless of the Sun.

The art of photography will hereafter be independent of sunlight and will be relieved of the inconvenience and discomfort of the flashlight if Nikola Tesla's claims for his latest development of the vacuum tubes are well founded. Illuminating power for lighthouses will also be enormously increased if his discovery is successful.

The Electrical Review of to-day prints an article on the new application of the tube and reproduces photographs taken by the new light, as evidence that sunlight may not only be dispensed with, but is excelled by the intensity of the vacuum rays. It is likely that experiments in the application of the light to lighthouses will soon be made.

The Review says editorially that this particular application is the oddest and most unlooked for development of the vacuum tube, and is evidently deeply impressed with its value.

Mr. Tesla last night declined to discuss his discovery, saying that more time than he could then spare would be required to explain it.

The New York Tribune January 7, 1898

TESLA'S VACUUM TUBE LIGHT.

HE HAS MADE NOTABLE PROGRESS IN IMPROVING IT.

A brief, but interesting announcement was made by Nikola Tesla this week in regard to the advances effected by him in a line of experiment in which he has been engaged for several years. The two forms of electric lamp now in common use employ, respectively, the incandescence of an inclosed filament and the arc produced at a gap in a circuit. The mode of illumination which Mr. Tesla has sought to develop is the agitation of the particles of a highly rarefied gas in a so-called "vacuum tube."

That particular form of apparatus, in the hands of Geissler, Crookes and other physicists, emitted only a faint luminosity. Röntgen discovered that it also gave birth to a powerful, but utterly invisible, radiance. But Tesla has now multiplied the brilliancy of the visible light several hundred times, perhaps several thousand times. "The Electrical Review," his chosen mouthpiéce among the technical papers, printed a letter from the great investigator yesterday, in which he said that he believes that he is even yet "far from having attained the limit in the amount of light producible, and believes that this method of illumination will be eventually employed for lighthouses."

The more immediate application which Mr. Tesla proposes for his light, however, is to photography, to which it is admirably suited by its intensity, penetrating power and the facility with which it may be regulated. His letter is accompanied by three photographs to illustrate this point. A vacuum tube of about one thousand candle-power afforded the light for these pictures, and it was placed at a distance of about four or five feet from the objects represented. An exposure of from two to five seconds was deemed preferable to instantaneous work.

The agitation of the gaseous particles remaining in the vacuum tube is caused by creating oscillations of extreme frequency and abruptness in the electrical current which does the work. Mr. Tesla has long been famous on both sides of the Atlantic for his researches into the possibility of exciting such waves, and for his varied methods of doing so. His "discharger" and his "oscillator," already well known to electricians, are only two of the forms of apparatus which he has tried. Mr. Tesla admitted to a Tribune reporter yesterday that it was by means of his oscillator that he had achieved his recent successes in vacuum-tube lighting. He estimates the frequency of the electrical vibrations in these experiments at about two million per second. But the collisions and bombardment resulting from this shaking up of the confined gaseous particles gave rise, he thought, to ether waves, both of the same frequency as those of sunlight and of still higher frequencies.

The great inventor maintains a gracious but tantalizing reserve at present when asked as to the amount of energy (measured by watts) which he consumes per candle-power, but manifests much secret satisfaction with this phase of the subject.

Electrical Progress.

Nicola Tesla's New Engine.

Tesla says that coal will not play so important a part in producing the power of the earth as wood does now, and shows an invention of his in the experimental stage, about which he declares that there is no possibility of its failure. He declares that the apparatus is so simple that the least learned in mechanics can comprehend it, and if it were fully described others might seize his idea, patent it, and control a blessing which he intends shall be a free gift to the world. This is so extraordinary, so totally at variance with established customs, that it is almost as unbelievable as the discovery itself.

In the center of a large room with a glass roof Tesla will place a huge cylinder of thick glass on a bed of asbestos, supported by a firm stone pedestal placed in the center of the room. The circle will be laid lengthwise, and will be surrounded by a circle of mirrors covered with asbestos coats to refract the rays of the sun into the glass cylinder. The cylinder will always be kept full of water, which will have been treated by a secret chemical process, which Tesla claims to have devised, and which, he says, is the only complicated part of the discovery. All day long, while the sun shines, its rays will be refracted into the glass cylinder. The chemical treatment makes the water easily susceptible to heat, and in a little while the vaporizing begins. The steam thus in the cylinder is carried to a steam engine of the ordinary description. The engine in turn will generate electricity, which will be stored and transmitted by cables to the factory and the home. The power house will store sufficient electricity to meet all demands during the time that the sun does shine, although it may be clouded over for weeks at a time. "Most people will contend that the plan to harness the rays of the sun and make them operate the machinery of man, and to give light and heat, is the idle fancy of a dreamer," said Tesla. "I would indeed be surprised if they were to contend otherwise. There has never yet been proposed a single great scientific enterprise that has not at first been met with ridicule and laughed at as something beyond the bounds of possibility. Every one will remember the days of horse cars, when electric street railways were first talked about as possibilities. The suggestions of cars running along the streets without horses in front of them was laughed at. But now people have trolley cars running in villages where, a few years ago, horse cars were considered too expensive, and they pay no more attention to the marvel they witness every day than they do to an express wagon rumbling along the same street. It will be the same with the motive power generated by harnessing the rays of the sun. The first two months that the generating stations are in operation they will be places of intense interest, but after that people will think no more about them, except as places of business. They will regard them as little as they do gas tanks, electric light plants or water reservoirs. They will simply suggest monthly or quarterly bills, such as they now pay for water or gas, except that the bills will be much smaller. I do not care at this time to go into details. I have not yet begun the practical part of the work. I wish to have the experimental part so completed that no one can stick a pin into it. But I will say that the results so far achieved are all that I could desire, and they place all possibility of a failure beyond the shadow of a doubt. I am certain that the new apparatus will come into speedy and general use. Its cost is so insignificant that it cannot be ignored. After the apparatus has been placed in any station there is absolutely no expense in running it for years, except the salaries of engineers and the small cost of the wear and tear of the apparatus, which will be eventually anything but expensive. The whole business will be so simply arranged that there will be no probability of its breaking down; but even if it should happen that one station would be useless for a short time, the immense amount of electricity always at hand—for it will cost practically no more to generate 5000 volts than to generate so many million volts—will bridge over the difficulty. There would be nothing to prevent the generation of a whole year's supply in case of an accident in the generating machinery. There is nothing unnatural in the proposition to have the sun drive the machinery of the earth and, indirectly, to heat and light the planet at night as well as by day. It is a great deal less artificial than for men to delve down into the bowels of the earth at so much trouble and loss of life in order to get a few handfuls of coal to run an engine a short time and then to make spasmodic return trips for more. As to the proposition to have each city look after the heating and lighting of the homes of its inhabitants, there is nothing more extraordinary about it than the present system of cities supplying water pipes and sewers and private companies supplying steam heat, gas light, electric light and motive power." All of which has been said before.

THOS. A. EDISON JR. is credited with announcing that he can photograph thought. Nicola Tesla tells a New York paper that he has "harnessed the rays of the sun" and will compel them to operate machinery and give light and heat. This invention is still in the experimental stage, but he declares that there is not a possibility of its failure. He has discovered a method of producing steam from the rays of the sun. The steam runs a steam engine which generates electricity. It is probable the dailies have distorted the utterances of these electricians, who usually let results attest the worth of their efforts.

HIGH ELECTROMOTIVE FORCE.

PROF. JOHN TROWBRIDGE.

I have lately perfected a large plant for the study of the discharges of electricity through gases which I believe is more extended, and on a larger scale, than any at present in existence ; and I have obtained some results with it, especially in the subject of high electromotive force, which throw light upon many mooted points. The source of electricity which produces the electrical discharges is obtained from ten thousand storage cells. From these cells I obtain very approximately twenty thousand volts, and by means of a peculiar apparatus called Planté's rheostatic machine, I am enabled to obtain over one million volts—which enables me to experiment with powerful discharges in air, more than four feet in length.

By the employment of storage cells in the subject of the discharges of electricity through gases, one can form a fair estimate of the amount of energy that is employed to produce the desired effects—for instance, the X rays ; while with the use of electrical machines or induction coils and transformers it is extremely difficult, if not impossible, to form an accurate estimate. Fig. 1 is an illustration of the type of cells of which the battery consists. Each cell is composed of a test tube 5½ inches long and ¾ of an inch internal diameter containing two strips of lead which are separated from each other by rubber bands and are immersed in dilute sulphuric acid. The surfaces of the lead strips are roughened by a mechanical device, and the cells are charged in multiple circuit by means of a dynamo machine. When the cells are properly formed, each one gives two volts and has an internal resistance of one-quarter of an ohm. The problem of insulating these cells was a serious one ; but it was practically solved by mounting the cells in sets of threes, in holes bored in a block of wood which had been carefully boiled in paraffine. The mechanician of the laboratory, Mr. George Thompson, devised a simple switch board which enables me to throw the cells into multiple or into series—to use the entire ten thousand, or suitable portions of this number. The battery gives eight amperes of current with twenty thousand volts, and this amount of energy is amply sufficient to kill a man. By accident an operator received the shock from only one thousand of the cells and was badly shocked and burned. It is prudent therefore in experimenting with this battery to use rubber gloves, even in throwing the switches, and it is recommended to employ only one hand covered with a rubber glove and to keep the other hand in a pocket.

I had at first intended to use this large battery in the study of electrical discharges through Crookes tubes, but I speedily found that X rays could not be excited by a difference of potential represented by twenty thousand volts. I found that at least one hundred thousand volts were necessary to produce them strongly, and I, therefore, resolved to construct a Planté rheostatic machine. This machine is simply an apparatus by means of which Leyden jars are first charged in parallel and are then discharged in series or by cascade. That is, all the inside coatings of the jars are connected to the negative terminal of the ten thousand cells, and all the outside coatings are connected to the positive terminal of the cells. When the cells are charged, the inside of one Leyden jar is connected to the outside of the next, and so on. In this way a very high electromotive force can be obtained. I use sixty Leyden jars in the form of plates of glass 15 × 18 inches coated on both sides with tinfoil. Starting with twenty thousand volts, I can exalt this to one million two hundred thousand volts. The accompanying illustration (Fig. 2) shows the Planté machine. The mechanician of the laboratory has introduced a notable improvement in the apparatus of Planté. Instead of a revolving commutator such as was used by the latter, Mr. Thompson employed lever arms, by means of which the jars were first charged in parallel and then discharged in series. It was found that the apparatus designed by Planté could not be used for higher voltages than one or two thousand without serious error and loss. By means of this apparatus I can study electrical discharges at least four feet in length—of great body—which are produced by an electromotive force of one million two hundred thousand volts. This apparatus possesses the great advantage that it enables one to obtain a fairly exact measure of such high voltage. When we reflect that the trolley car employs only

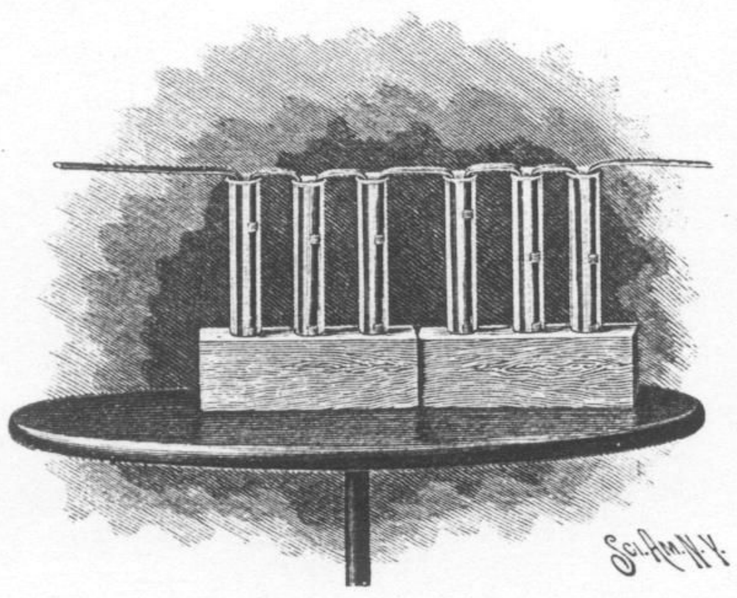

Fig. 1.—THE CELLS.

five hundred volts, and in the system of transmission of power from Niagara Falls it is proposed to use only ten thousand volts, it is evident that the effects produced by voltages of over a million must be of great scientific interest.

The study of such high electromotive forces immediately showed that previous estimates of the electromotive force necessary to produce a spark of a certain length were highly erroneous. For instance, Heydeweiler, a German investigator, believes that Prof. Elihu Thomson's statement, that a spark of five feet in length which he produced required a voltage of five hundred thousand, is very wide of the mark, and Heydeweiler maintains that one hundred thousand would be nearer the truth. I find that even Prof. Thomson's estimate must be more than doubled. Experiments with my apparatus show conclusively that the length of the electric spark between points separated by more than one inch varies directly with the electromotive force. A spark forty-eight to fifty inches in length requires an electromotive force of one million two hundred thousand volts, and a discharge of lightning one mile long would therefore require the enormous number of over one hundred million volts. In reflecting upon the development of such enormous energy in the air we can understand why telephone bells ring during a thunder storm ; why subsidiary sparks occur in networks of wires ; and why telegraphic messages are interrupted. The world beneath the thunderstorm throbs and pulsates with the oscillatory discharges of lightning.

One of the most interesting results of my study of powerful disruptive discharges is the discovery that such discharges will pass through glass tubes which are exhausted to such a high degree that they are said to contain a vacuum ; for the eight-inch spark of a Ruhmkorff coil prefers to jump around the tube to passing through the extremely rarefied space in the interior of the tube. Such tubes, however, are brilliantly lighted by a difference of potential of a million volts and readily show the X rays, and exhibit the skeleton of the hand in a fluoroscope. The so-called brush discharge from the positive terminal of the Planté machine extends visibly to a distance of over a foot. If the hand is exposed to this brush, it produces the well known X ray burn, such as various investigators have received in taking photographs of the skeletons of their hands, or in testing the condition of Crookes tubes by exposing their hands before a fluoroscope. The skin of the hand becomes irritable and turns a bright red color, especially after exposure to cold winds.

This result interested me greatly; for it proved that the so-called X ray burn could be produced by the brush discharge of very high electromotive force. The extent of the influence of this powerful brush discharge is very great. For instance, photographic plates in a plate holder carefully insulated from the ground and covered with a plate of glass half an inch in thickness show the inductive action of the brush discharge from the positive terminal, which is distant at least a foot. These inductive effects are manifested by star-shaped figures on a photographic plate. They are surrounded by dark clouds. When the burn on the back of one's hand produced by such brush discharges is examined by a microscope, similar centers of disturbance (in this case points of inflammation) are seen. Although the Leyden jars of my machine are carefully insulated on supports of vulcanite which are mounted on dry wood, which in turn is supported on rubber, I can obtain a discharge of more than two feet in length when I bring a point connected to the steam pipes to the neighborhood of one terminal of the machine. The other terminal of the machine is carefully insulated. This experiment shows conclusively that it is of no use to insulate lightning rods. My experiments thus far show that no vacuum which I can produce can resist the discharges which are caused by one million volts. It now becomes an interesting question whether there exists mechanical or chemical means by which a so-called vacuum can be produced which will resist such discharges.

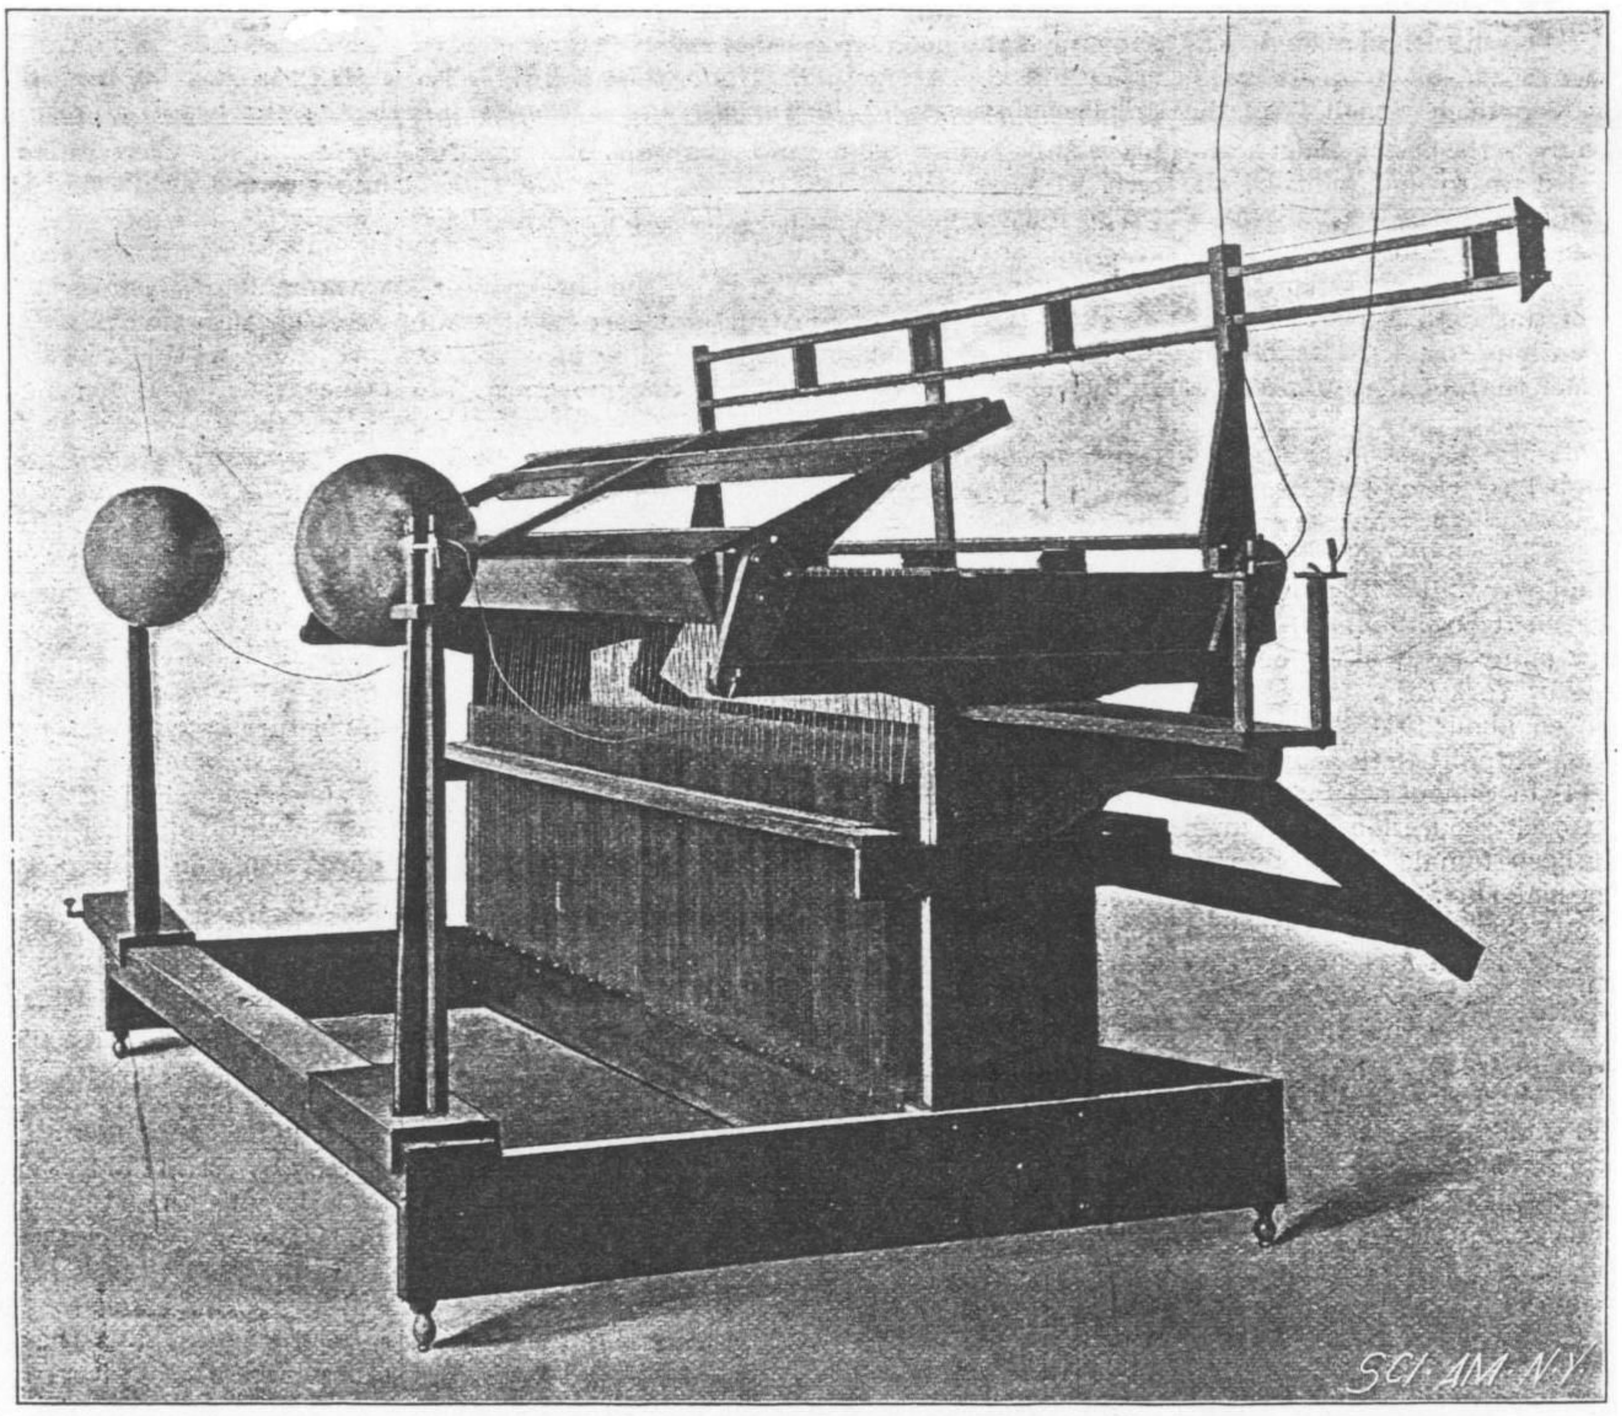

Fig. 2.—PLANTÉ RHEOSTATIC MACHINE.

The New York Herald January 16, 1898

NIKOLA TESLA'S HAND SEEN BY A PALMIST.

FROM A PHOTOGRAPH BY VACUUM TUBE LIGHT.

A photograph of the left hand of Nikola Tesla has been submitted to a professional palmist, and he, without knowing to whom the hand belonged, tells what his art teaches him of the original. Mr. Tesla photographed his own hand last week by means of light from his wonderful perfected vacuum tubes, and he kindly consented that the picture should be submitted for a "reading."

The picture, without marks or other indications as to whose hand it was, was submitted to Sir Henry Onequi, who was not given any intimation as to the identity of his subject. Here is what he says, and the reader may draw his own conclusions:—

By Sir Henry Onequi, Palmist.

THIS palm indicates a person who has a remarkable amount of will power and a great deal of energy. The head line would indicate a very shrewd and active mind; a person who could be capable of becoming a great leader, while the heart line would indicate a remarkable degree of love. Great feeling and great duration is shown by the life line, although this line, being the one line running toward the Mount of Mercury, would indicate that the person should be quite a philosopher.

The line of Venus being so strongly developed would indicate a great lover of the opposite sex, although the head line seems to hold this in check. We find that the person would be liable to suffer the latter part of life through heart trouble, which may be quite severe.

The fate line would indicate great success, but as I only have one hand to read from these statements are subject to a change, because I have not the other hand to verify them. Travels are shown very distinctly. That the person should be one who would be very just and honorable in all dealings is shown. He is one who could not be driven one step, but could be led by kindness to the extremes through life.

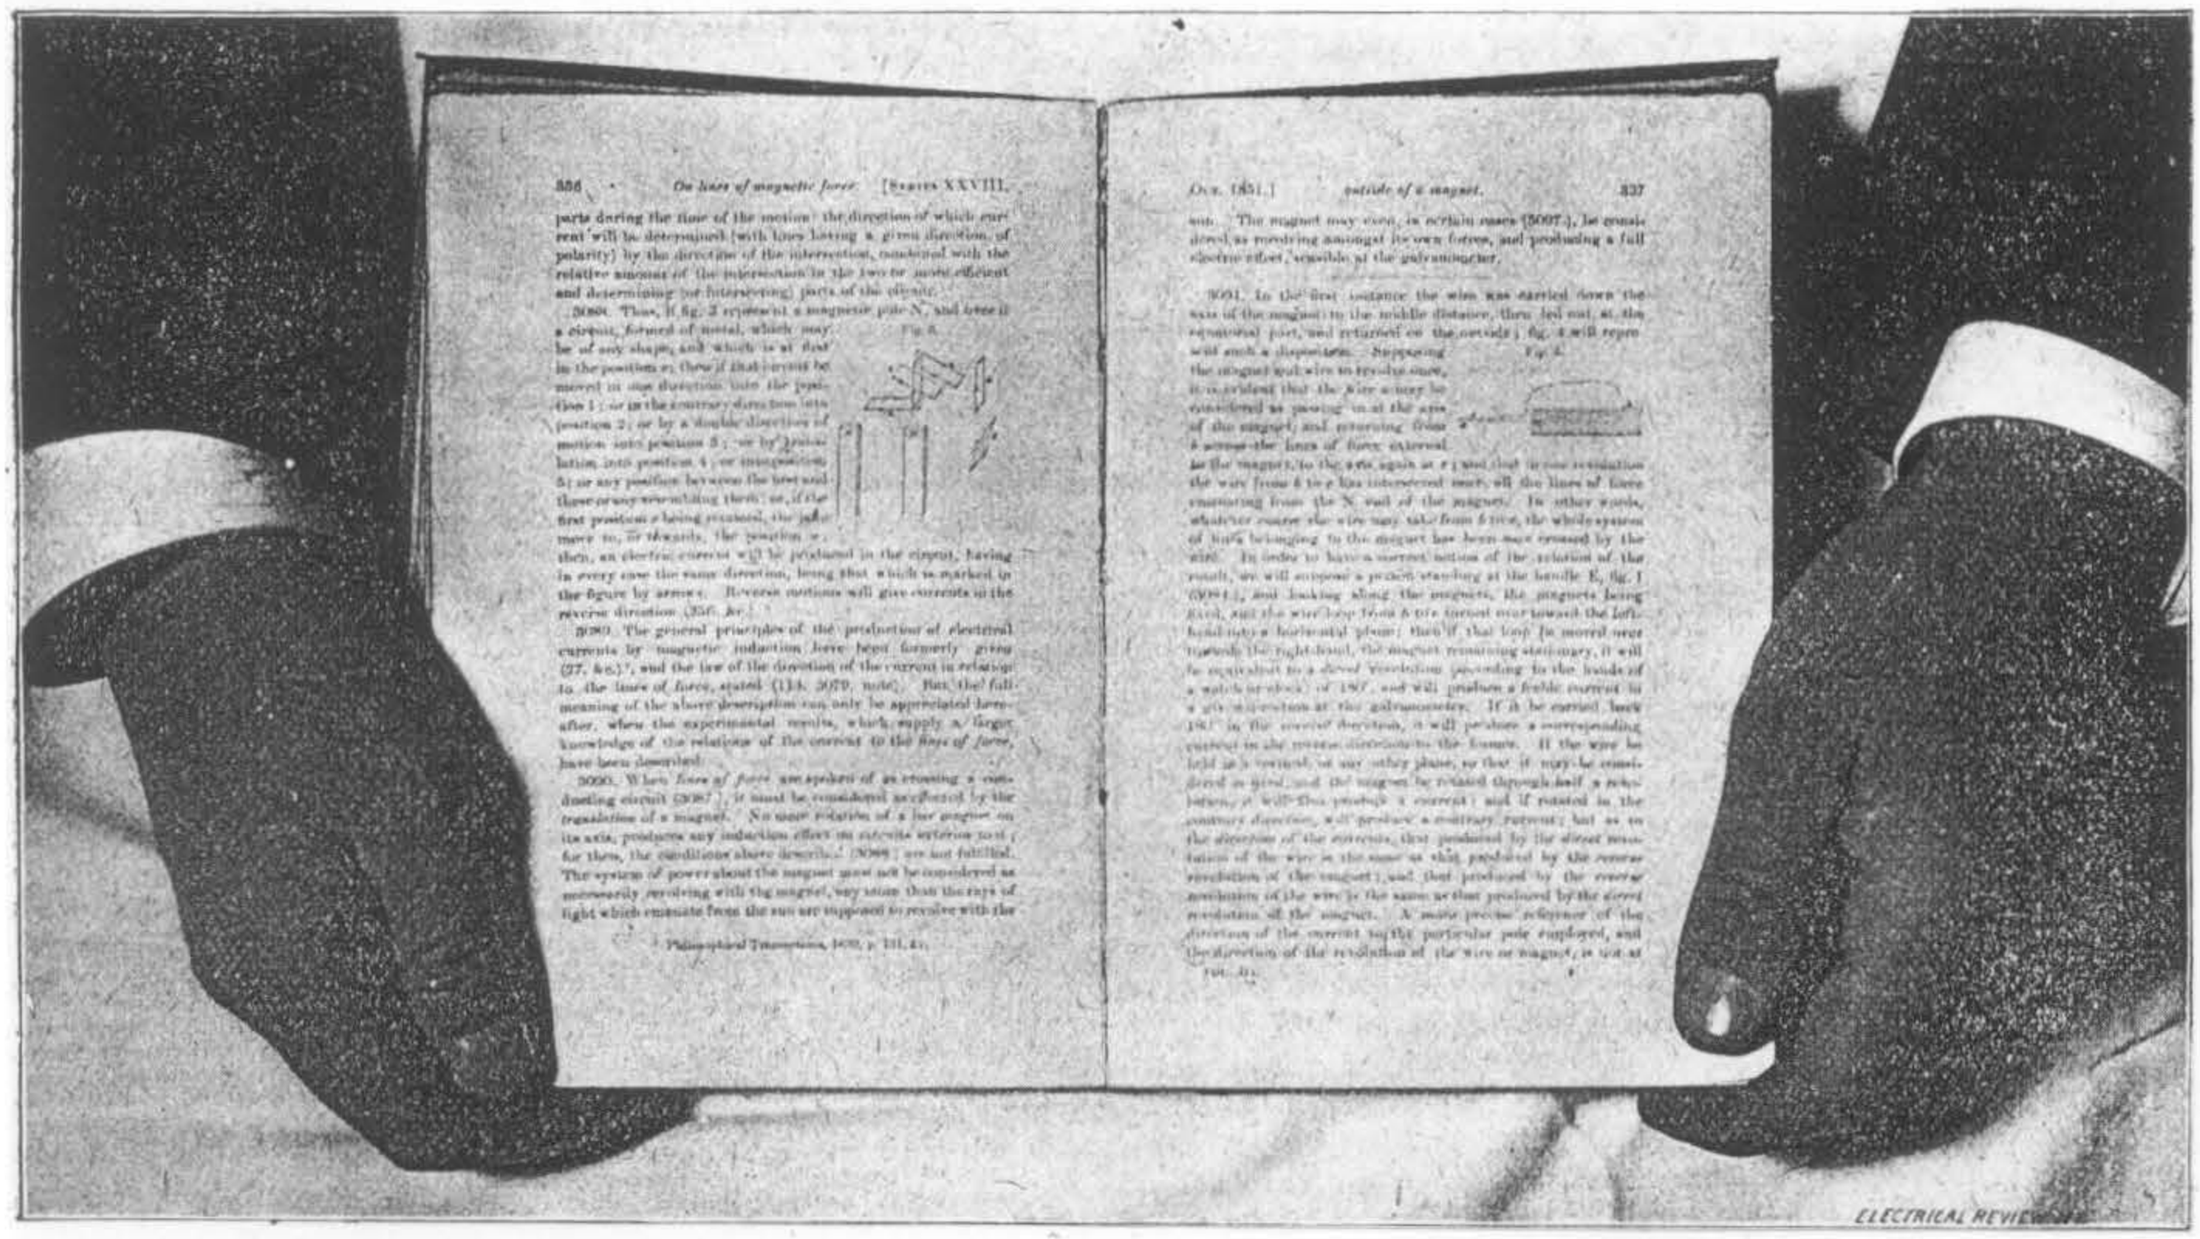
The hand also indicates a great many changes to be brought about, and it looks as if these changes were brought about through the influence of others. The palm indicates that the person would make great success in financial affairs, although there is shown one very heavy loss.

There should be two marriages in life. Domestic relations should be very happy. One heavy loss by fire is indicated by the cross. One great gain, brought about through personal perseverance and will power, is shown, which is to be of great satisfaction. The person should have one great gain through a change made in the latter part of life.

This person would not be one to be trifled with, should be a great lover of justice and make success as an orator.

I would be pleased to see the other hand to verify these statements.

PHOTOGRAPH OF THE PALM OF NIKOLA TESLA



SCIENTIFIC

The Use of Vacuum-tube Lighting in Photography

NIKOLA TESLA, in the *Electrical Review*, New York. Condensed for PUBLIC OPINION

A few years ago I began a series of experiments with a view of ascertaining the applicability of the light emitted by phosphorescent vacuum tubes to ordinary photography. The results soon showed that, even with a tube giving no more light than the equivalent of one-half of a candle, objects could be easily photographed with exposures of a few minutes, and the time could be reduced at will by pushing the tube to a high candle-power. Photographs of persons were likewise obtained at that time and, if I am not mistaken, these were the first likenesses produced with this kind of illumination. A rather curious feature in the photographs obtained with tubes of moderate illuminating power was that the lights and shadows came out remarkably strong, as when very short exposures are made by flashlight, but the outlines were not sharp and practically no detail was visible. By producing tubes of much greater candle-power, a notable improvement in this respect was effected, and this advance prompted me to further efforts in this direction, which finally resulted in the production of a tube of an illuminating power equal to that of hundreds, and even thousands, of ordinary vacuum tubes. What is more, I believe that I am far from having attained the limit in the amount of light producible, and believe that this method of illumination will be eventually employed for lighthouse purposes. This probably will be considered the oddest and most unlooked-for development of the vacuum tube.

The purpose of the present communication is chiefly to give an idea in how far the object here aimed at was obtained. The photographs were taken by a tube having a radiating surface of about two hundred square inches. The frequency of the oscillations, which were obtained from an Edison direct-current supply circuit, I estimated to be about two million a second. The illuminating power of the tube approximated about one thousand candles, and the exposures ranged from two to five seconds, the distance of the object being four to five feet from the tube. It might be asked why, with so high an illuminating power, the exposures should not be instantaneous. I would not undertake to satisfactorily answer this question, which was put to me recently by a scientific man. Likenesses can, of course, be obtained with instantaneous exposures, but it has been found preferable to expose longer and at a greater distance from the tube. The results so far obtained would make it appear that this kind of light will be of great value in photography, not only because of the fineness of the lines, but also because the artist will be able to exactly adjust the conditions in every experiment so as to secure the best result, which is impossible with ordinary light. He will thus be made entirely independent of daylight, and will be able to carry on his work at any hour, night or day. It might also be of value to the painter, though its use for such purposes I still consider problematical.

PHOTOGRAPHED BY THE LIGHT OF A SINGLE VACUUM TUBR AT A DISTANCE OF FOUR FEET; EXPOSURE TWO SECONDS.—*Electrical Review.*

Teslaic.—In the issue of the New York *Electrical Review* for Jan. 5 is a communication by Mr. Nikola Tesla. He has added his latest advances in vacuum-tube lighting. We are only restrained from giving his communication in full because of the photographs which illustrate it. To reproduce these would detract from their clearness. The author refers to his experiments of a few years ago, which were for a time laid aside, but examples of figures are given with tubes of moderate illuminating power, whereas he is enabled to produce tubes of much greater candle-power—in fact, illuminating power equal to that of hundreds and even thousands of ordinary vacuum tubes; and he says "What is more, I believe that I am far from having attained the limit in the amount of light producible, and believe that this method of illumination will be eventually employed for lighthouse purposes. This probably will be considered the oddest and most unlooked-for development of the vacuum tube." He points out that at the time of his previous experiments an endeavour was made to introduce vacuum-tube lighting into this country. He thought it was bound to fail, as indeed it did. The power consumption was very large for the amount of light produced. The reason of this, he says, is not far to seek. "A vacuum tube, particularly if it be very large, offers an immense radiating surface, and is capable of giving off a great amount of energy without rising perceptibly in temperature. What still increases the dissipation of energy is the high temperature of the rarefied gas. Generally it is supposed that the particles are not brought to a high temperature, but a calculation from the amount of the energy consumed during a given period of time, and the amount of matter contained in the tube, leads to results which would seem to indicate that, of all the means at disposal for bringing a small amount of matter to a high temperature, the vacuum tube is the most effective. . . . As compared with these disadvantages, the incandescent lamp, crude and inefficient as it undoubtedly is, possesses vastly superior features. These difficulties have been recognised by me early, and my efforts during the past few years have been directed towards overcoming these defects, and have finally resulted in material advances, so that I find it possible to obtain from a tube of a volume not much greater than that of a bulb of an incandescent lamp about the same amount of light produced by the latter, without the tube becoming overheated, which is sure to take place under ordinary conditions. Both of these improvements, the increase of candle-power as well as degree of efficiency, have been achieved by gradual perfection of the means of producing economically harmonical electrical vibrations of extreme rapidity." Mr. Tesla tells us that his experiments have been made from an Edison direct-current supply circuit, and the frequency he estimates it about 2,000,000 a second. The illuminating power of the tube approximated to about 1,000 c.p.

SCIENCE AND INVENTION.

VACUUM-TUBE LIGHTING AGAIN.

SOME time ago, as readers of THE LITERARY DIGEST will remember, we heard a great deal about methods of lighting with vacuum-tubes caused to glow by means of the electric discharge. It was abundantly proved at the time that such light is

Courtesy of *The Electrical Review.*

TESLA'S HAND.

easily produced and that it is very soft, white, and pleasant, but its production has not yet been put on a commercial basis. In *The Electrical Review* (January 5) Nikola Tesla, who has long

experimented in this direction, gives some of the reasons why glow-tube lighting has not yet been financially successful, and predicts that it will soon be used widely for photography, if for no other purpose. Says Mr. Tesla:

"The reasons for the great power consumption, which may often be as much as ten times that taking place in incandescent lamps for an equivalent amount of light, are not far to seek. A vacuum-tube, particularly if it be very large, offers an immense radiating surface, and is capable of giving off a great amount of energy without rising perceptibly in temperature. What still increases the dissipation of energy is the high temperature of the rarefied gas. Generally it is supposed that the particles are not brought to a high temperature, but a calculation from the amount of the energy consumed during a given period of time, and the amount of matter contained in the tube, lead to results which would seem to indicate that, of all the means at disposal for bringing a small amount of matter to a high temperature, the vacuum-tube is the most effective. . . . As compared with these disadvantages the incandescent lamp, crude and inefficient as it undoubtedly is, possesses vastly superior features. These difficulties have been recognized by me early, and my efforts during the past few years have been directed toward overcoming these defects, and have finally resulted in material advances, so that I find it possible to obtain from a tube of a volume not much greater than that of a bulb of an incandescent lamp about the same amount of light produced by the latter, without the tube becoming overheated, which is sure to take place under ordinary conditions. Both of these improvements, the increase of candle-power as well as degree of efficiency, have been achieved by gradual perfection of the means of producing economically harmonical electrical vibrations of extreme rapidity."

The photographs taken by Mr. Tesla with his light were, he tells us, from a tube with a radiating surface of about 200 square inches, energized by a current having about two million oscillations in a second. The candle-power of the light was about 1,000, and exposures varied from 2 to 5 seconds, at a distance of 4 to 5 feet, this being found more satisfactory than instantaneous exposures close to the tube. Mr. Tesla concludes:

"The results so far obtained would make it appear that this kind of light will be of great value in photography, not only because of the fineness of the lines, but also because the artist will be able exactly to adjust the conditions in every experiment so as to secure the best result, which is impossible with ordinary light. He will thus be made entirely independent of daylight, and will be able to carry on his work at any hour, night or day. It might also be of value to the painter, tho its use for such purposes I still consider problematical."

An Imperial Electrical Inventor.

THE career of American electric street railway apparatus in Germany may be destined to be a short and merry one, for the news has come very circumstantially of late that the Emperor himself proposes to invent a new electrical car for Berlin, and, if for Berlin, then for all Germany. A few years back, Prince Henry, the Emperor's brother, repeated all the sensational Tesla experiments with currents of high voltage and high frequency, and not many months ago we noted the fact in these columns that the Emperor, the Prince and some high army officers were taking a special electrical course. This all goes to confirm the rumor. We are sure his majesty can help the electric railway art materially, for it has been said that he has a rolling eye of genius just like Edison's; although we have never seen Mr. Edison roll his eye, unless a wink is included in the expression. But what worries us is that we don't see where the Emperor is to get the time; he is so busy. There is Turkey to be patronized; Greece to be snubbed; Russia to be flattered; France to be flouted; England to be insulted, and China to be cut up, all of which he is giving personal attention to, conscientiously. But his majesty is also otherwise engaged, in oratory, music, art, the drama, yachting and a few other diversions. Now the success of such railway inventors as Sprague and Short has come from pretty close attention to one thing. It is true that Tesla dines at Delmonico's; that Edward Weston delights in his big naphtha launch, his camera or his telescope; that Elihu Thomson and Steinmetz persist in scorching on their beloved bicycles; but, after all, their one serious thought and aim in life is electrical investigation and invention. We are sorry that so far as the Emperor's character has interpreted itself to us, his great genius lacks concentration. This is electricity's loss, but we may all just as well make up our minds to stand it. If there is one constant element in the case, it is the Emperor's inconstancy; and he will soon be forgetting that electric car for a balloon, a gun, a picture or a navy.

NICOLA TESLA SEES NO DANGER TO LABOR IN THE INCREASE OF MACHINERY AND ELECTRICAL PROGRESS.

The Poor Have Been Benefitted More Than the Rich by Inventions and Discoveries of Labor-Saving Means, Asserts This Great Practical Scientist in Answer to a Labor Leader's Questions.

NICOLA TESLA.

THE old question of the effect of inventions and improved machinery upon the labor market is again receiving a good deal of attention, in view of the strike in the cotton mills and the wonderful developments of electrical science. The latter, in particular has already demonstrated that it can greatly diminish the labor-cost of modern production.

Any change in the condition of one industry affects in some degree the conditions of other industries the world over. If the harnessing of electricity has lessened the demand for certain kinds of labor in the same way that it has unquestionably lowered the price of horses in cities where they formerly drew street cars, it may not be unreasonable to inquire whether it has had and will have an effect upon labor in other lines.

Mr. Edison's inventions have affected several classes of artisans and large numbers of laborers as well. So have Mr. Tesla's. These and other men of genius are ardently toiling with brain and hand to add to the mechanical means of industrial production. The shackling of Niagara may be followed by the exacting of a tribute of labor from the ocean, the utilization of its constant undulation for the generating of electricity and the driving of machinery.

Henry Weissman, who was long the head of the national organization of American bankers, is one of the best known. He has become rather more conservative since he was known as a star orator of the San Francisco "sand lots" in the 80's. Mr. Weissman commands the confidence of workingmen. He was largely instrumental in bringing about the passage of laws in the East compelling sanitary improvements in the conduct of the baking business. His knowledge of the conditions and needs of labor has been acquired through years of practical study.

Mr. Weissman has drawn up for the Sunday Post-Dispatch a series of questions and submitted them to Nicola Tesla. They cover the whole topic of wages as affected by invention, and Mr. Tesla's answers will be read with interest by every student of labor problems:

1. Is it your opinion that labor-saving machinery benefits workingmen or workingwomen in general?

1. Certainly it is. The whole tendency of mechanical progress is to make life easier and more enjoyable for the whole of mankind. It does not benefit any class or classes to the exclusion of other classes. It indeed brings things within the reach of the many that formerly could be had only by the few. It lights our public streets, for instance, as well as the parlors of the aristocrat once were lighted. It has made a 100-mile excursion of as little cost as a stage-coach ride of 20 miles in the old days. It has lessened the price of flour—in fact, of nearly every manufactured thing. And it brings the products of foreign countries to the doors of the poor at so moderate an expense that from many of them they are no more debarred to the extent of their needs than is the man of millions.

2. If that has lessened the cost of articles is the workman benefited?

2. I suppose you mean that other conditions may overbalance that kind of benefit. What conditions?

3. Is it not true that while invention and discovery have increased the catalogue of the things that are within the reach of the laboring man and his family, the disproportion between the need of the laboring class and the luxury of the unproductive rich has also increased? In other words, of the added profit from production which is obtained from the use of labor-saving devices, does not the capitalist and the rich consumer get a share greatly out of proportion to the increased agency of capital in production?

3. That query goes so far into the domain of political economy, pure and simple, that I should feel much hesitation in attempting to answer it scientifically, as alone it should be answered. That would necessarily bring into review everything that affects the relations and co-operation of labor and capital. I am disposed to think that laws of natural adjustment in the social economy have not been altered by the fact that many very remarkable, very useful and consequently very lucrative inventions have been made. The principle of supply and demand is still at the bottom of the economic system. The power of self-indulgence, of wants or of self-satisfaction of needs, as the case may be, is dependent upon the purchasing power of the individual, which again is nothing more or less, as regards the laborer, than the earning power. This again must be referred to the demand for one's services, which is more or less qualified by the degree or the absence or presence of competition.

If in some directions the effect of improved devices has been in a measure to lessen the demand for workmen (numerically, I mean), it has also constantly tended to cheapen the average livelihood. You must consider, too, a fact that is commonly lost sight of—that after all the main distinction between the lives of the very rich and those of the moderately thrifty poor, aside from the possession of leisure and the ability to dispose of their time, is the elegance in which the former may indulge. Now, very little has come to pass in many years to cheapen what, strictly speaking, may be called elegance. Pictures, statuary, fine carvings, rich hangings, rare rugs, all these and many other things of aristocratic or curious value are proportionately dearer to-day, as compared with the general cost of living, than ever they were. It is so with the service in the rich man's household. He pays thousands for the salary of a cook and even of a private secretary, where his prototype paid some paltry hundreds. Analyze the matter thoroughly and I think you will find that the material possessions which most distinguish the rich from the poor have shared very little, if at all, in the general depreciation of prices. On the other hand, it is acknowledged that the general trend of wages for the past 12 years or more has been upward.

4. Has not labor-saving machinery lessened the market for labor?

4. In one sense I will answer that query in the negative. The march of invention has increased the demand for intelligent labor by creating new and ever-widening fields for it. It has enlarged very greatly the aggregate rewards of labor. It has established for the laboring man an incentive for the improvement of his mental faculties, such as was never given him before. He knows that trained intelligence, coupled with mechanical skill, offers him the best chance of advancement. It must be remembered, too, that shortened hours of labor were not thought of until manufacturing by swift machinery became the controlling fact in industrial life.

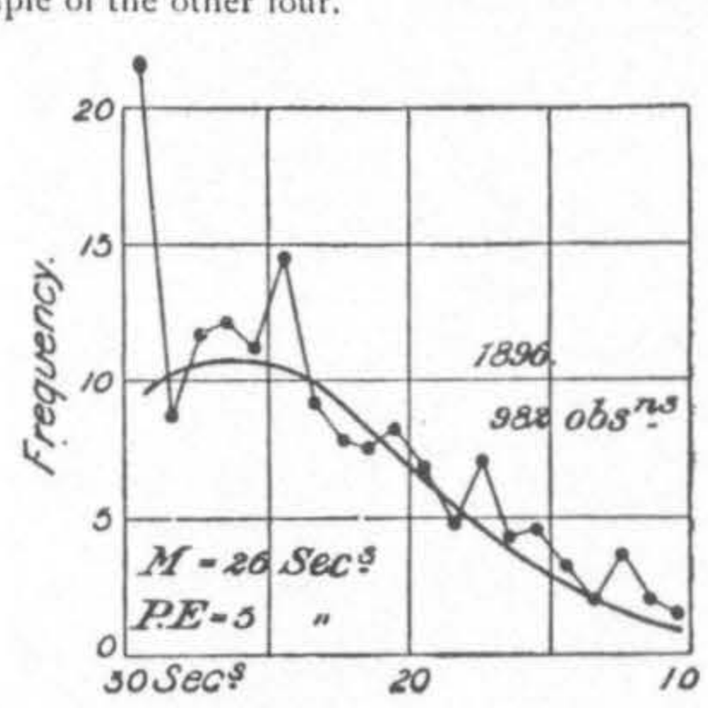
The new employments that have been provided by inventive talent are agreeable and interesting, besides prompting more surely to self-improvement than the old. Electricity is the one great force for the future service of man. It is the ultimate force, and the end of its development may not be foreseen. The transition states of labor that may be in part caused by the industrial revolutions that are due to it are not to be put permanently to its charge. Rather to the charge of the slow intellect of the man which did not sooner realize that nature might offer him such help. If there are incidental ups and downs of labor we must not allow them to obscure to our vision the steadily increasing average of progress in labor's condition. If in the new employments there are fewer places for the mere laborer than in the old, it must be remembered that the new employments draw to them men from the ranks of the mere laborers who before had no such prospect of betterment. Electricity may in this sense be likened to the magnet which selects the grains or flakes of valuable metal from the heap of neglected screenings from the mine.

As the hitherto unregarded intelligences advance the men who are left in the ranks of common labor will find themselves less crowded. Thus there will be a compensation for common or the less skilled labor.

No. I do not think that any alarmist theory based upon the increase of labor-saving machinery will stand the test of logic for a moment.

SOCIETIES AND ACADEMIES.

LONDON.



Royal Society, December 13, 1897.—"An Examination into the Registered Speeds of American Trotting Horses, with Remarks on their Value as Hereditary Data." By Francis Galton, D.C.L., F.R.S.

It is strange that the huge sums spent on the breeding of pedigree stock, whether of horses, cattle, or other animals, should not give rise to systematic publications of authentic records in a form suitable for scientific inquiry into the laws of heredity. An almost solitary exception to the disregard shown by breeders and owners, of exact measurements for publication in stud books, exists in the United States with respect to the measured speed of "trotters" and "pacers" under defined conditions. The performance of one mile by a trotter, harnessed to a two-wheeled vehicle, carrying a weight of not less than 150 lbs. inclusive of the driver, in 2 minutes 30 seconds qualifies him for entry in the "Trotting Register," giving him, as it were, a pass-degree into a class of horses whose several utmost speeds or "records" are there published.

The system of timing was first put into practice more than fifty years ago, and has since been developed and improved. In 1892 a considerable change was made in the conditions by the introduction of bicycle wheels with pneumatic tyres, which produced a gain of speed, the amount of which is much discussed, but which a prevalent opinion rates at 5 seconds in the mile. Thenceforward the records are comparable on nearly equal terms. All trotting performances up to the 2′ 30″ standard are registered in the large and closely printed volumes of "Wallace's Year Book," published under the authority of the American Trotting Association. Vols. viii.–xii. refer to the years 1892-6, and it is from the entries in these that the following remarks are based.

The object of my inquiry was to test the suitability of these trotting (and pacing) records for investigations into the laws of heredity. I had to determine whether the observations fell into a tolerably smooth curve; and, if so, whether that curve was a tolerable approach to the normal curve of frequency. In the latter event the observations would fall into line with numerous anthropometric and other measures which have been often discussed, and which, when treated by methods in which the arithmetic mean is employed, yield results that accord with observed facts.

I had 5705 extracts made from the entries published in the Year Books for the five years 1892–6. It was tedious work, and I thought it unnecessary to repeat it to check the results, being satisfied after some examination that they were quite accurate enough for general conclusions. They were arranged in columns; the first to the left contained entries of all observations recorded as 2′ 29·0″, 29¼″, 29½″, or 29¾″; that is of all under 2′ 30″ down to 2′ 29″ inclusive. The second column referred to 2′ 28″·0, 28″¼, 28″½, and 28″¾, and so on with the rest. These were then reduced to percentages and diagrams were drawn from them, of which the following, for the year 1896, is one; it will serve as a fair sample of the other four.

If divided by the eye into imaginary columns corresponding to those in the tables, the point representing the sum of the observations of 2′ 29″·0′, 29″¼, 29″½ and 29″¾ will be found in the middle of the first imaginary column, that is to say it stands vertically above the point that lies half way between 29 and 30 on the scale along the base. The dots are connected by thin lines to show the trace or curve of the observations. The smooth curves are those of normal frequency, calculated from the values of the mean (M) and of the probable error (P.E.), which are given in the diagrams.

Leaving aside for the moment the strange pinnacle that rises on the extreme left of every diagram, we see that the traces of the rest of the observations run very roughly, but not intolerably so. In each diagram they seem to be disposed about a fundamentally smooth curve. Considering the smallness of the interval, namely, only one second, that separates the observations assigned to each pair of successive columns, together with the experience derived from other kinds of statistical curves, it seems to me that the run of the observations is good enough to certify their general trustworthiness. As regards the pinnacle it is different matter, and is one which when beginning work, as

did, on the 1892 entries only, was very perplexing. However, by persevering with the other years, it became increasingly plain that the pinnacle was a false maximum; in 1896 it was certain that the true maximum lay well within the portion of the curve included in the diagram. The explanation of the pinnacle then became obvious[1]; it was that the tolerance granted to those horses who failed by only a little to qualify themselves, was extended considerably beyond the quarter second for which I was prepared. The cases of 2′ 30·0″ were few; they do not appear in the diagram, but their addition would be quite insufficient to remove the difficulty. If the pinnacle were distributed among *two* adjacent columns outside and to the left of the diagram it would smooth away the incongruity, so I suspect that cases of "under 2′ 32″ and down to 2′ 30″" are habitually rated at a trifle less than 2′ 30″. Consequently I had no hesitation in wholly disregarding the entries that helped to make the pinnacle, namely, the whole of those contained in the first column to the left in every one of the diagrams. The course thereupon became clear and straightforward. I estimated the position of the mean value for each year, from inspection of the curve of that year, allowing myself to be somewhat biassed in estimating its point of culmination by the curves of the adjacent years; similarly as to the probable error. Now that the curves are drawn, I see that somewhat better fits might have been made, but they are close enough to show the existence of a fair amount of correspondence between the observed values and those calculated according to the law of normal frequency. It is near enough to remove hesitation in working with the arithmetic mean.

I now come to the fundamental purpose of this memoir, which is to point out the existence in the registers of the American Trotting Association, of a store of material most valuable to inquirers into the laws of heredity, which accumulates and increases in value year by year. But it seems to me hardly worth while to discuss hereditary influence on speed in horses, unless the records of at least their sires and of their dams, and those of each of their four grandparents, as well as their own record, are all known. Even in this case (according, at least, to my own theory) one quarter of the hereditary influences are unknown and have to be inferred. It is practically impossible to make an adequate collection of the names of horses who fulfil the above conditions out of the entries in the "Trotting Register," each search requiring many cross references and occupying a long time, while the number of futile searches before attaining a success is great. On the other hand, the breeders and possessors of these notably bred horses must be familiar with the required facts, and would assuredly be delighted to have them known. There need, therefore, be little difficulty in obtaining materials for the much desired table. In the meantime I am sending circulars to the chief breeders in America, in hopes of making a start.

The great need for genealogical data of an exact numerical kind, by those who prosecute inquiries into the laws of heredity, is the justification that I offer for submitting these remarks to the Royal Society.

Physical Society, January 21.—Mr. Shelford Bidwell, President, in the chair.—Prof. Fitzgerald exhibited some photographs by Mr. Preston in illustration of the Zeeman effect, for various cases, including those of iron, cadmium, zinc, and sodium. These photographs and the method of obtaining them have already been described. The cause of doubling is now attributed by Prof. Fitzgerald to absorption by the surrounding vapour. In a particular case he examined a double line that exists in one of the photographs. Under the polariser the two lines are at first distinctly seen; but when the polariser is turned, a thin line appears in the middle, and this central line is, therefore, circularly polarised in a direction opposite to that of the outer pair of lines. The reason for the appearance of doubling in the first position of the polariser is that the central line is there completely absorbed out by the surrounding vapour.—Prof. Oliver Lodge then gave a communication concerning his work on "Electric Signalling without Connecting-wires." From the nature of the oscillatory disturbances emanating from any of the customary forms of Hertz vibrator, syntony has hitherto been only very partially available as a means for discriminating between receivers. There is in fact so rapid a decrease in the amplitude of the vibrations that almost any receiver can respond to some extent. Discrimination by syntony is possible with magnetic systems of space telegraphy where the magnetic energy much exceeds the electric, *i.e.* as between two separated inductive coils; and by the use of such coils, appropriately applied, the author has been able to attain fair syntony even with true Hertz waves, *i.e.* he has constructed spark-gap oscillators, with sufficient persistence of vibration, and syntonised resonators. The "coherer" principle can be applied to either a purely magnetic or to the Hertzian system. It was first used by Prof. Lodge in devising lightning-guards, and afterwards in his magnetic system of telegraphy by inductive circuits, each in series with a Leyden-jar; a pair of knobs in near contact, or other over-flow gap, being provided in the receiving apparatus. This was the first meaning of a "coherer" in the electrical sense as used by Prof. Lodge. It referred to a *single* contact between two metal knobs. The term has since been extended by others to the filings-tube of M. Branly, and some confusion has arisen, for M. Branly does not consider that simple coherence and break explains fully the behaviour of his instrument. Prof. Lodge is disposed to agree, for he finds that the resistance of almost any form of coherer varies in rough proportion to the received impulses, and that there are other peculiarities (to be mentioned later). He is, therefore, inclined to think that the action cannot after all be entirely explained as due to mere "welding," but that there is something more to be learnt about it. The sensitiveness of a coherer depends upon the number of loose contacts; it is a maximum for a single contact, *i.e.* for a needle-point lightly touching a steel spring. With this sensitive coherer, hardly any "tapping-back" is required for decoherence, but it wants delicate treatment when properly adjusted, and the greatest current through it should not approach a milliampere. On the other hand, a Branly tube rather improves under rough treatment; in such a tube the author prefers to use iron filings in the best possible vacuum; brass, too, is very good, but rather less easy to manage. Aluminium is thoroughly bad, and gold, for an opposite reason, will not work—its surface is too clean. Points, or small surfaces for making contact with the filings, are better than large surfaces. The usual method of connecting the coherer across the gap of an ordinary Hertz receiver, in parallel with the telegraph instrument and battery, has the unavoidable objection that they shunt away part of the received oscillations. With the syntonic receiver of Prof. Lodge, which contains no gap, but a closed wire coil instead, this difficulty no longer exists; for the coherer can now be in series with the detecting instrument, and in so far as these obstruct the oscillations they may be shunted out in various ways, as the author describes. The main feature of his new syntonised vibrators is this self-inductance coil, whose function it is to prolong the duration of the oscillations, and thereby to render syntony possible. Although such a coil acts disadvantageously in so far as it possesses resistance, the resistance does not increase so fast as the self-induction. The coil should consist of thick copper of highest conductivity, and it should have maximum inductance for given resistance. For similar reasons, the capacity-areas should also be of highest conductivity, their dimensions should increase outwards from the spark-gap, as triangles. The receiver must have no gap, it should be accurately bridged over when a transmitter is used as receiver. The limit of speed of response depends upon the telegraphic instrument. Dr. Muirhead adapted a siphon-recorder to the purpose, because it is one of the quickest responders; he arranged it so that it could be used with intermittent currents direct. Under these intermittent impulses the siphon trembles; and instead of the ordinary siphon-signals, the slip is marked with dots and dashes. Constant mechanical tremor is usually employed for decoherence, but the author finds that decoherence can be brought about by electrical means, without any mechanical tremor, by connecting the coherer momentarily to a circuit less effective as a collector than that of the proper capacity-areas of the syntonised receiver. The battery and galvanometer detector-circuit may be used for this purpose, the coherer being momentarily connected to it, and while so connected letting it experience an impulse from a distance. Prof. Lodge has designed a revolving commutator by means of which the coherer can be rapidly changed over from the resonating circuit to the instru-

[1] I should like to take the opportunity afforded by the appearance of an abstract of my memoir in NATURE to correct a questionable suspicion, namely, that the pinnacles in the diagrams are due to tolerance shown towards horses who failed by a very little to qualify for the much-coveted rank of standard trotters. I am assured on excellent authority that the strict conditions of timing make this impossible (among other reasons there are three timers). On the other hand, there is a vast competition *just* to pass the 2′ 30″ limit; and when a horse has done so, his owner often does not care to train him for racing, but rather to utilise him at once for breeding or other purposes. The question is too complicated to discuss here at length. Suffice it that the 2′ 29″ to 2′ 30″ records are not homogeneous with the rest, and should be discarded as I proposed.—F. G.

ment-circuit, and finally to the "tapping-back" apparatus. A coherer is more sensitive when thus isolated and exposed to the full influence of the received oscillations; the subsequent detection of the effect by altered connections is very convenient for laboratory measurements. A diagram of a series of plotted measurements showed that the resistance of an undisturbed filings-tube is approximately a direct function of the intensity of the received stimulus, whether successive stimuli increased or decreased in strength. This electrical process of "tapping-back" is to be depended upon, but the process long continued fatigues the tube until a mechanical shake is employed to restore it. Large size apparatus made by Dr. Muirhead for actual distant syntonic work was exhibited, and means were shown for protecting and isolating the coherer when its receiving areas were being used as emitters; also a switch used for changing at one moment all the connections from "sending" to "receiving." Prof. Threlfall said he had come to the same conclusion as Prof. Lodge as to the advisability of diminishing the number of contact-points in the coherer. He had endeavoured to produce longer and more persistent waves, and thus to set afield greater effective energy. It was desirable to keep the waves as parallel as possible. He thought there was some probability that the wave-fronts could be altered and rendered more conformable by a process of diffraction. Mr. Rutherford also had found it best to work with long waves. He fully appreciated the advantage of increasing the capacity of the oscillator by extending the surface of the metallic plates. Mr. Campbell-Swinton asked whether experiments had been made to verify Hertz results as to the influence of reflectors behind oscillators and receivers. He had found them disadvantageous. A single wire behind either apparatus seemed partially to annul the effect. He also asked whether Prof. Lodge had observed the extraordinary sensitiveness of coherers to small changes of current in neighbouring circuits. Prof. Lodge, in reply, said he had observed the sensitiveness to slight sudden variations of current referred to by Mr. Campbell Swinton; for instance, when electric lamps were switched on or off. The effect of mirrors had been studied by Prof. Fitzgerald. They required to be of large dimensions as compared to the oscillator and receiver, otherwise the true reflections were not obtained. Dr. Silvanus Thompson afterwards exhibited a Tesla oscillator. This apparatus is intended to replace the two induction coils and spark-gap arrangements used by Mr. Tesla for high frequency experiments. It consists of an induction coil with a separate self-inductance coil in the primary circuit. This self-inductance coil is also used as an electromagnet for the separate interrupter of the primary circuit. A condenser is connected between one end of the primary coil and one terminal of the interrupter, so as to include both of them between its terminals. The primary is a single turn of copper strip, six inches wide. The secondary is one layer of thick wire; each turn separated from the next by an air space. The supply current, about half an ampere, may be taken from the electric-light mains at almost any voltage from 50 to 200, direct or alternating. Prof. Lodge said it would work quite well at 10 volts. He pointed out also that if the straight discharge-rods at the spark-gap were free to slide, the discharge drove them back into their sockets. Prof. Fitzgerald said it was stated at Toronto that the spark was broken at the interrupter when the condenser was charged, and that by the time the condenser was ready to discharge, the contact at the interrupter had been made again. It seemed to him that the condenser discharges and surgings must take place at a rate far higher than the period of the mechanical movement of the interrupter. The condenser charges and discharges were very rapid. It was not what is ordinarily called the "time constant" that was involved, for that only referred to constant voltage. Here the voltage was changing very rapidly indeed. Prof. Herschel asked if such an apparatus was suitable for work with Röntgen rays. Dr. Thompson, in reply, congratulated Mr. Tesla upon the perfect working and compactness of his invention. The present form was not suited for Röntgen ray experiments, but Mr. Tesla had designed a special coil that was excellent for that purpose. —The President proposed votes of thanks, and the meeting was adjourned until February 11.

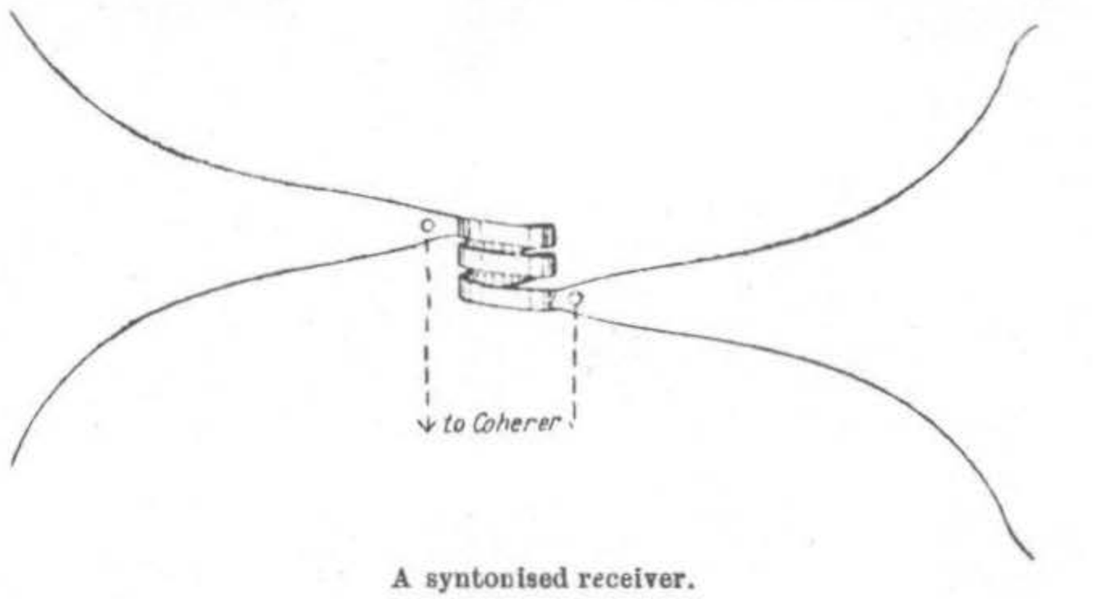
Academy of Sciences, January 24.—M. Wolf in the chair. —On the reduction of some double integrals, and on a new invariant in the theory of algebraic surfaces, by M. Émile Picard.—Addition to a preceding note on the Zeeman effect, by M. A Cornu. Some results of measurements showing that the magnitude of the separation produced increases with the refrangibility of the ray.—On the conditions of formation of alkaline carbides, and the carbides of magnesium and of the alkaline earths, by M. Henri Moissan. Metallic potassium, if left for a long time in acetylene, slowly but completely decomposes the gas giving hydrogen and C_2HK. Sodium gives a similar compound when sealed up with liquid acetylene, and this C_2HNa, heated in a vacuum, gives up pure acetylene, leaving sodium carbide C_2Na_2 behind; at a red heat this is decomposed into carbon and sodium. The potassium compound behaves similarly, neither sodium, potassium, nor magnesium carbides being able to exist at the temperature of the electric furnace.—Histological mechanism of cicatrisation; on true immediate reunion, by M. L. Ranvier. In wounds caused by cutting the cornea of the rabbit, two modes of closing up of the tissue can be noted, an immediate synaptic joining, and a true immediate joining, the former due to the cuts being filled with epithelial cells arising from the neighbouring epithelium, and the latter noticeable only in wounds forty-eight hours after the incision had been made, and where, owing to the lips of the cut happening to touch, no epithelial cells had penetrated.—The enlargement of the right auricle of the heart during inspiration demonstrated by radioscopy, by M. Ch. Bouchard.—On the fourth voyage of the *Princesse-Alice*, by S.A.S. Albert I., Prince of Monaco. The chief work was done on the western coast of Morocco, round Madeira and the Azores, and comprised sounding operations, together with zoological study of the fauna of the Princesse-Alice bank. A chart of this bank accompanies the paper.—Remarks by M. Edmond Perrier on his work on animal colonies and the formation of organisms.—Shooting-stars in the months of November and December 1897, observed at Basse-Terre (Guadeloupe), by M. Ch. Duprat.—On the development of uniform or holomorphic functions in any field, by M. Paul Painlevé.—On the types of increase and on complete functions, by M. Émile Borel.—On systems of partial differential equations analogous to equations of the first order, by M. Jules Beudon.—On the geometry of magnetic fields and of motion with two degrees of freedom in a plane or on a sphere, by M. René de Saussure.—Law of deformation of commercial metals, by M. Marcel Brillouin. A mathematical expression is given which includes all the known facts regarding permanent changes of shape in metals.—On an interference spectroscope, by MM. Ch. Fabry and A. Perot. The method consists in observing rings produced by transmission through a layer of air contained between two perfectly parallel silvered glass faces. Full details of the adjustments necessary are given in the present paper.—On the part played by diffraction in the effects produced with gratings, by M. Ch. Féry.—Study of chemical and physical equilibria by the osmotic method, by M. A. Ponsot.—On the law of mixture of gases by M. Paul Sacerdote, giving the experimental results of mixing equal volumes of gases. The observed changes of pressure for a mixture of nitrous oxide and carbon dioxide, and of the latter gas with sulphur dioxide, are compared with those deduced from the densities by M. Leduc. The results of the two methods are in general agreement.—On the separation of thorium and the cerite earths, by MM. G. Wyrouboff and A. Verneuil.—The method proposed is based upon the fact that in a mixture of nitrates of the rare earths, as free as possible from excess of acid, heating with excess of hydrogen peroxide to 60° completely precipitates all the thoria in the solution.—Hydramides and the isomeric glyoxalidines, by M. Marcel Delépine. A thermochemical paper.—Researches on ouabaïne, by M. Arnaud.—Synthesis of terebic acid, by M. E. E. Blaise.—Manufacture of acetone oil, in particular of methyl-ethyl-ketone, by means of the liquors from the desuintage of wool, by MM. A. and P. Buisine. The calcium salts of the mixture of fatty acids obtained from wool is submitted to dry distillation. The resulting liquid yields on fractionation 60 per cent. of methyl-ethyl-ketone. —On the estimation of gastric juice, by M. L. Cordier. The free acid is converted into lithium chloride by treatment with lithium carbonate, and this separated from the sodium chloride by extracting the incinerated residue with a mixture of equal parts of absolute alcohol and dry ether, in which the lithium chloride only is soluble.—Ergographical experiments for measuring the maximum power of a muscle regularly stretched, by MM. André Broca and Charles Richet.—The fungus *Sporotrichum globuliferum*, by M. Trabut.—On the anhydrous calcium sulphate produced by the complete dehydration of gypsum, by M. A. Lacroix. The dehydration of gypsum gives rise to a calcium sulphate dimorphous with anhydrite, probably triclinic. When the drying was not quite carried to completion another form of crystal was observed, possibly $2CaSO_4.H_2O$.—On the Callovian of Woëvre, by M. René Nicklès.—On the third international ascent of experimental balloons, by M. Ed. Stelling. Two ascents were made, one with two observers, the other balloon carrying self-registering instruments only. The temperature variation with the height is given in full.

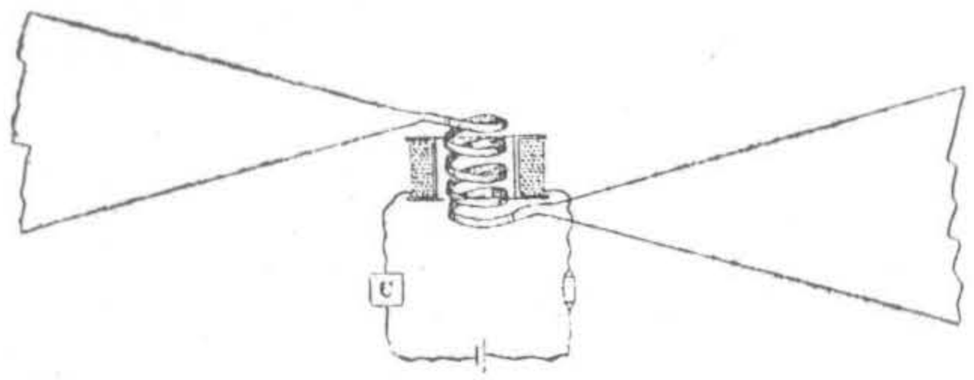


PHYSICAL SOCIETY.

[The illustrations given herewith were made from sketches kindly lent us by Dr. Oliver Lodge, and are explained by their footnotes. They are not referred to in the text of the official report.—Ed. *E. E.*]

At the ordinary meeting held on Jan. 21, 1898, Mr. Shelford Bidwell, president, in the chair,

Prof. Fitzgerald exhibited some photographs by Mr. Preston in illustration of the Zeeman effect for various cases, including those of iron, cadmium, zinc, and sodium. These photographs and the method of obtaining them have already been described. The cause of doubling is now attributed by Prof. Fitzgerald to absorption by the surrounding vapour. In a particular case he examined a double line that exists in one of the photographs. Under the polariser the two lines are at first distinctly seen, but when the polariser is turned, a thin line appears in the middle, and this central line is therefore circularly polarised in a direction opposite to that of the outer pair of lines. The reason for the appearance of doubling in the first position of the polariser is that the central line is there completely absorbed out by the surrounding vapour.



Prof. Oliver J. Lodge then gave a communication concerning his work on "**Electric Signalling without Connecting Wires.**" From the nature of the oscillatory disturbances emanating from any of the customary forms of Hertz vibrator, syntony has hitherto been only very partially available as a means for discriminating between receivers. There is, in fact, so rapid a decrease in the amplitude of the vibrations that almost any receiver can respond to some extent. Discrimination by syntony is possible with magnetic systems of space telegraphy where the

process of "tapping back" is to be depended upon, but the process long continued fatigues the tube until a mechanical shake is employed to restore it. Large-size apparatus made by Dr. Muirhead for actual distant syntonic work was exhibited, and means were shown for protecting and isolating the coherer when its receiving areas were being used as emitters; also a switch used for changing at one moment all the connections from "sending" to "receiving."

A long-distance sending and receiving station. The insulated metal roof is used as the capacity area, with all its parts well connected up to discharging rod.

Prof. Threlfall said he had come to the same conclusion as Prof. Lodge as to the advisability of diminishing the number of contact points in the coherer. He had endeavoured to produce longer and more persistent waves, and thus to set afield greater effective energy. It was desirable to keep the waves as parallel as possible. He thought there was some probability that the wave fronts could be altered and rendered more conformable by a process of diffraction.

Mr. Rutherford also had found it best to work with long waves. He fully appreciated the advantage of increasing the capacity of the oscillator by extending the surface of the metallic plates.

Mr. Campbell-Swinton asked whether experiments had been made to verify Hertz results as to the influence of reflectors behind oscillators and receivers. He had found them disadvantageous. A single wire behind either apparatus seemed partially

to annul the effect. He also asked whether Prof. Lodge had observed the extraordinary sensitiveness of coherers to small changes of current in neighbouring circuits.

Prof. Lodge, in reply, said he had observed the sensitiveness to slight sudden variations of current referred to by Mr. Campbell-Swinton—for instance, when electric lamps were switched on or off. The effect of mirrors had been studied by Prof. Fitzgerald. They required to be of large dimensions as compared to the oscillator and receiver, otherwise the true reflections were not obtained.

Dr. Silvanus Thompson afterwards exhibited a Tesla oscillator. This apparatus is intended to replace the two induction coils and spark-gap arrangements used by Mr. Tesla for high-frequency experiments. It consists of an induction coil with a separate self-inductance coil in the primary circuit. This self-inductance coil is also used as an electromagnet for the separate interrupter of the primary circuit. A condenser is connected between one end of the primary coil and one terminal of the interrupter, so as to include both of them between its terminals. The primary is a single turn of copper strip, 6in. wide. The secondary is one layer of thick wire; each turn separated from the next by an air space. The supply current, about half an ampere, may be taken from the electric light mains at almost any voltage from 50 to 200, direct or alternating.

Prof. Lodge said it would work quite well at 10 volts. He pointed out also that if the straight discharge rods at the spark gap were free to slide, the discharge drove them back into their sockets.

Prof. Fitzgerald said it was stated at Toronto that the spark was broken at the interrupter when the condenser was charged, and that by the time the condenser was ready to discharge the contact at the interrupter had been made again. It seemed to him that the condenser discharges and surgings must take place at a rate far higher than the period of the mechanical movement of the interrupter. The condenser charges and discharges were very rapid. It was not what is ordinarily called the "time constant" that was involved for that only referred to constant voltage. Here the voltage was changing very rapidly indeed.

Prof. Herschel asked if such an apparatus was suitable for work with Röntgen rays.

Dr. Thompson, in reply, congratulated Mr. Tesla upon the perfect working and compactness of his invention. The present form was not suited for Röntgen-ray experiments with the ordinary focussing tubes, but Mr. Tesla had designed a special tube which gave most excellent results with the coil.

The **President** proposed votes of thanks, and the meeting was adjourned until Feb. 11.

THE PHYSICAL SOCIETY.

AT the meeting of the Physical Society, held on January 21, Mr. Shelford Bidwell, President, in the chair, Professor Fitzgerald exhibited some photographs by Mr. Preston in illustration of the Zeeman effect, for various cases, including those of iron, cadmium, zinc, and sodium. These photographs and the method of obtaining them have already been described. The cause of doubling is now attributed by Professor Fitzgerald to absorption by the surrounding vapour. In a particular case he examined a double line that exists in one of the photographs. Under the polariser the two lines are at first distinctly seen; but when the polariser is turned, a thin line appears in the middle, and this central line is, therefore, circularly polarised in a direction opposite to that of the outer pair of lines. The reason for the appearance of doubling in the first position of the polariser is that the central line is there completely absorbed out by the surrounding vapour.

Professor Oliver Lodze then gave a communication concerning his work on "*Electric Signalling without Connecting-wires.*" From the nature of the oscillatory disturbances emanating from any of the customary forms of Hertz vibrator, syntony has hitherto been only very partially available as a means for discriminating between receivers. There is, in fact, so rapid a decrease in the amplitude of the virations that almost any receiver can respond to some extent. Discrimination by syntony is possible with magnetic systems of space telegraphy where the magnetic energy much exceeds the electric, *i.e.*, as between two separated inductive coils; and by the use of such coils, appropriately applied, the author has been able to obtain fair syntony even with true Hertz waves, *i.e.*, he has constructed spark-gap oscillators, with sufficient persistence of vibration and syntonised resonators. The "coherer" principle can be applied to either a purely magnetic or to the Hertzian system. It was first used by Professor Lodge in devising lightning-guards, and afterwards in his magnetic system of telegraphy by inductive

circuits, each in series with a Leyden jar; a pair of knobs in rear contact, or other overflow gap, being provided in the receiving apparatus. This was the first meaning of a "coherer" in the electrical sense, as used by Professor Lodge. It referred to a single contact between two metal knobs. The term has since been extended by others to the filings-tube of M. Branly, and some confusion has arisen, for M. Branly does not consider that simple coherence and break explains fully the behaviour of his instrument. Professor Lodge is disposed to agree, for he finds that the resistance of almost any form of coherer varies in rough proportion to the received impulses, and that there are other peculiarities (to be mentioned later); he is, therefore, inclined to think that the action cannot, after all, be entirely explained as due to mere "welding," but that there is something more to be learnt about it. The sensitiveness of a coherer depends upon the number of loose contacts; it is a maximum for a single contact, *i.e.*, for a needle-point lightly touching a steel spring. With this sensitive coherer, hardly any "tapping-back" is required for decoherence, but it wants delicate treatment when properly adjusted, and the greatest current through it should not approach a milliampere. On the other hand, a Branly tube rather improves under rough treatment; in such a tube the author prefers to use iron filings in the best possible vacuum; brass, too, is very good, but rather less easy to manage. Aluminium is thoroughly bad; and gold, for an opposite reason, will not work; its surface is too clean. Points, or small surfaces for making contact with the filings, are better than large surfaces. The usual method of connecting the coherer across the gap of an ordinary Hertz receiver, in parallel with the telegraph instrument and battery, has the unavoidable objection that they shunt away part of the received oscillations. With the syntonic receiver of Professor Lodge, which contains no gap, but a closed wire coil instead, the difficulty no longer exists: for the coherer can now be in series with the detecting instrument, and in so far as these obstruct the oscillations they may be shunted out in various ways, as the author describes. The main feature of his new syntonised vibrators is this self-inductance coil, whose function it is to prolong the duration of the oscillations, and thereby to render syntony possible. Although such a coil acts disadvantageously in so far as it possesses resistance, the resistance does not increase so fast as the self-induction. The coil should consist of thick copper of highest conductivity, and it should have maximum inductance for given resistance. For similar reasons, the capacity-areas should also be of highest conductivity, their dimensions should increase outwards from the spark-gap, as triangles. The receiver must have no gap, it should be accurately bridged over when a transmitter is used as receiver. The limit of speed of response depends upon the telegraphic instrument. Dr. Muirhead adapted a syphon-recorder to the purpose, because it is one of the quickest responders; he arranged it so that it could be used with intermittent currents, direct. Under these intermittent impulses the syphon trembles; and instead of the ordinary syphon signals, the slip is marked with dots and dashes. Constant mechanical tremor is usually employed for decoherence, but the author finds that decoherence can be brought about by electrical means, without any mechanical tremor, by connecting the coherer momentarily to a circuit less effective as a collector than that of the proper capacity-areas of the syntonised receiver. The battery and galvanometer detector-circuit may be used for this purpose; the coherer being momentarily connected to it, and while so connected letting it experience an impulse from a distance. Professor Lodge has designed a revolving commutator by means of which the coherer can be rapidly changed over from the resonating circuit to the instrument circuit, and finally to the "tapping-back" apparatus. A coherer is more sensitive when thus isolated and exposed to the full influence of the received oscillations; the subsequent detection of the effect by altered connections is very convenient for laboratory measurements. A diagram of a series of plotted measurements shows that the resistance of an undisturbed filings-tube is approximately a direct function of the intensity of the received stimulus, whether successive stimuli increase or decrease in strength. This electrical process of "tapping-back" is to be depended upon, but the process long continued fatigues the tubes until a mechanical shake is employed to restore it. Large-size apparatus made by Dr. Muirhead for actual distant syntonic work was exhibited, and means were shown for protecting and isolating the coherer when its receiving areas were being used as emitters; also a switch used for changing at one moment all the connections from "sending" to "receiving."

Professor Threlfall said he had come to the same conclusion as Professor Lodge as to the advisability of diminishing the number of contact points in the coherer. He had endeavoured to produce longer and more persistent waves, and thus to set afield greater effective energy. It was desirable to keep the waves as parallel as possible. He thought there was some probability that the wave-points could be altered and rendered more conformable by a process of diffraction.

Mr. Rutherford also had found it best to work with long waves. He fully appreciated the advantage of increasing the capacity of the oscillator by extending the surface of the metallic plates.

Mr. Campbell Swinton asked whether experiments had been made to verify Hertz results as to the influence of reflectors behind oscillators and receivers. He had found them disadvantageous. A single wire behind either apparatus seemed partially to annul the effect. He also asked whether Professor Lodge had observed the extraordinary sensitiveness of coherers to small changes of current in neighbouring circuits.

Professor Lodge, in reply, said he had observed the sensitiveness to slight sudden variations of current referred to by Mr. Campbell Swinton; for instance, when electric lamps were switched on or off. The effect of mirrors had been studied by Professor Fitzgerald. They required to be of large dimensions as compared to the oscillator and receiver, otherwise the true reflections were not obtained.

Dr. Silvanus Thompson afterwards exhibited a Tesla oscillator. This apparatus is intended to replace the two induction coils and spark-gap arrangements used by Mr. Tesla for high-frequency experiments. It consists of an induction coil with a separate self-inductance coil in the primary circuit. This self-inductance coil is also used as an electro-magnet for the separate interrupter of the primary circuit. A condenser is connected between one end of the primary coil and one terminal of the interrupter, so as to include both of them between its terminals. The primary is a single turn of copper strip, 6 in. wide. The secondary is one layer of thick wire; each turn separated from the next by an air space. The supply current, about half an ampere, may be taken from the electric light mains at almost any voltage from 50 to 200, direct or alternating.

Professor Lodge said it would work quite well at 10 volts. He pointed out also that if the straight discharge rods at the spark-gap were free to slide, the discharge drove them back into their sockets.

Professor Fitzgerald said it was stated at Toronto that the spark was broken at the interrupter when the condenser was charged, and that by the time the condenser was ready to discharge, the contact at the interrupter had been made again. It seemed to him that the condenser discharges and surgings must take place at a rate far higher than the period of the mechanical movement of the interrupter. The condenser charges and discharges were very rapid. It was not what is ordinarily called the "time constant" that was involved, for that only referred to constant voltage. Here the voltage was changing very rapidly indeed.

Professor Herschel asked if such an apparatus was suitable for work with Röntgen rays.

Dr. Thompson, in reply, congratulated Mr. Tesla upon the perfect working and compactness of his invention. The present form was not suited for Röntgen ray experiments, but Mr. Tesla had designed a special coil that was excellent for that purpose.

The President proposed votes of thanks, and the meeting was adjourned until February 11.

ELECTRICITY TO TAME WILD BEASTS.

Nicola Tesla Writes of the Interesting Possibilities of This New and Successful Device of Animal Trainers in Europe.

How the "Electric Subjugator" Shocks a Lion Into Submission When He Attacks the Trainer In His Cage.

TESLA ON ANIMAL TRAINING BY ELECTRICITY.

To the Editor of the Journal:

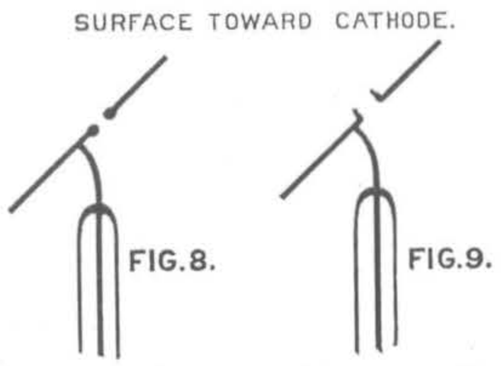
IT seems to me that there are interesting possibilities in the training of animals by electricity. Of course, it's rather out of my province, but the idea of the electrical subjugator appears feasible when one knows the power of electricity and the instinctive fear that brutes have of the unknown. And the electric method seems more humane than those I believe are in use—the whip, red hot irons and drugs, which are likely to do permanent injury, while the physical effects of an electric shock are soon gone, only the moral ones remaining.

The subjugator referred to will do the work, but I think an apparatus could be designed that would be less dangerous to the man. I do not desire to be understood as giving the matter deep thought, but I believe that if, instead of the armored backpad, the trainer used a wand with two prongs at one end, better results would follow. This wand would be connected with the supply cables and could be applied to any part of the animal's body at will. Its operation would be precisely the same as the subjugator here illustrated, the two prongs supplying the positive and negative poles of contact found in the flattened wires. With this wand an animal could be simply shocked, stunned or killed, as required.

To cure animals of jumping at men in cages, a screen of stout but flexible wire could be stretched between the trainer and his subject, the wires to be alternately positive and negative, and connected through the regulator with the dynamo. After a couple of springs which would hurl him half insensible back into his corner, the taste for unexpected jumps would leave the brute.

ROENTGEN-RAY NOTES.

BY WILLIAM ROLLINS.



XXI—THE APPEARANCE OF AN UNCOOLED ANODE IN A ROENTGEN REFLECTING FOCUS TUBE.

In my attempts to find out what happens in a Roentgen tube I have spent considerable time in studying the appearances of anodes spoiled in use. Through the courtesy of Kirmayer & Oelling I have been able to examine the tubes returned to them for new anodes. Where the force has been only sufficient to gently melt the anodes, the edges of the holes are rounded as shown in section in Fig. 8. If the force has been enough to quickly give the molecules a freer range, the holes made in the platinum have edges toward the cathode, and are rough and jagged where the metal stiffened into points and ridges, as shown in section in Fig. 9. The bombarding molecules from the cathode have not driven the platinum in front of them, as we might suppose when our minds are fixed upon the cathode. They have been opposed by another force operating in a contrary direction. As this force increases with the degree of excitement in the tube and operates perpendicularly with the surface of the anode even when, as in a focus tube of the reflecting type, this is at an angle with the cathode, I have no doubt it is the molecular rush of the forgotten anode.

XXII—DR. WILLIAMS'S TUBE.

Dr. F. H. Williams has recently shown me the tube illustrated in Fig. 10. It consists of an aluminum bulb, with a rubber stopper, through which passes a glass tube with the anode sealed in. Inside the glass tube is a rubber tube, through which water was admitted, the waste escaping between the tubes. This tube goes back to the time when only newspaper accounts of Roentgen's discovery had reached this country, showing that cooled anodes had been thought of before I invented my A–W–L tube. The inventions are in a way different, because at that early day the amount of force used was too small to injure the anode, the object being to prevent the warmth of the anode from injuring the rubber stopper, while in my tube the target on which the anode discharge is received is cooled, because, with the great force I frequently apply, it would otherwise promptly melt. Using these tubes, I have been able to approach the conditions long ago reached by Mr. Tesla and described in paragraph 139 of Thompson and Anthony's invaluable work on X-rays, where the action of the generator is alone sufficient to produce a vacuum in a tube, and where in practice the vacuum rises so quickly that none of the commercial methods of adjusting are efficient.

Now, after allowing due weight to the other reasons already mentioned in these notes for the vacuum rising, we are brought face to face with that other extraordinary truth of Mr. Tesla's that molecules of residual air go out through the glass walls of a vacuum tube. So it becomes interesting to offer all the experimental evidence we can to illustrate this truth, and in a future note I shall give what I have accumulated as appearing to bear on the subject. Meanwhile it is worth while to point out where work should be done to find the best means of keeping a vacuum steady. Potash is not efficient, because when it has parted with its water it is inoperative, and this is soon when a powerful generator is used. First, we should leave only inert gas in the tube. Then we need a substance which, under heat or electricity, will give large controllable volumes of a suitable gas. This gas should have a high molecular weight in order that the momentum of the molecules may cause them to strike the target with force. As this will be treated more fully in a future note dealing with the means of using the velocity of the cathode discharge, I turn now to mechanical methods of controlling the vacuum. On some of my tubes I have used a special form of stop-cock invented by Dr. F. H. Williams. It is tight when not in use, and when the tube is running we can admit microscopic amounts of air by turning a valve a few times. When it is connected with a small bulb of suitable gas and used with a tube containing only gas which does not combine with the terminals, we have eliminated some of the causes of the rise, and have only to consider the Tesla effect. In some of my direct-acting tubes, shown in previous figures, instead of using a sealed-in window, I have gone back to Lenard's aluminum window, which has not yet been made tight by any plan suggested, so in running the leak compensates for the rise. But this method is not under control, and, when not in use, the end must be kept plunged under mercury.

UNCOOLED ANODES IN ROENTGEN REFLECTING FOCUS TUBES.

XXIII—OXYGEN IN A VACUUM TUBE.

In searching for new lights by which to see that remarkable fact of Mr. Tesla's that molecules of the residual gases went out through the glass walls, I tried a number of experiments with different gases. Oxygen was chosen for one of these on account of its reasonably high molecular weight, and because I had reason to believe these molecules would be easier than some others to break under electric stress into electro-negative and positive groups, a matter of importance, because Roentgen light and smashed molecules go together. Whatever may be thought of this statement and of another, that it is broken molecules which go out through the glass, the experiments are of interest, for a Roentgen tube, in which the residual molecules are largely oxygen, is very bright and easy to exhaust, and also we have in stored-up oxygen the best means now known of regulating the vacuum. A simple way to prepare this stored-up oxygen is this: Mix four parts of chlorate of potash with one part of manganese dioxide. Heat them gently in a test tube until they form a coke-like mass. When cool, this is broken up into suitable pieces and placed in another tube, the end being sealed to exclude water vapor and gases. When required for use the tube is opened, a few grains of the mixture taken out and placed in a small bulb attached to a vacuum tube, which is then placed on the pump and exhausted to a high vacuum; heated to lower the vacuum, again pumped and heated, and this process continued until heating no longer lowers the vacuum. Then the little reservoir of stored oxygen is gently heated until the vacuum comes down. The pump is worked to raise the vacuum and the process repeated a few times. The tube is then sealed off. When in use the vacuum has risen, the reservoir of oxygen is gently heated while the tube is excited, until the vacuum is at the degree required for the special work on hand. Such a tube phosphoresces strongly after the current is turned off, and presents several interesting appearances which will be described if suitable half-tones can be made.

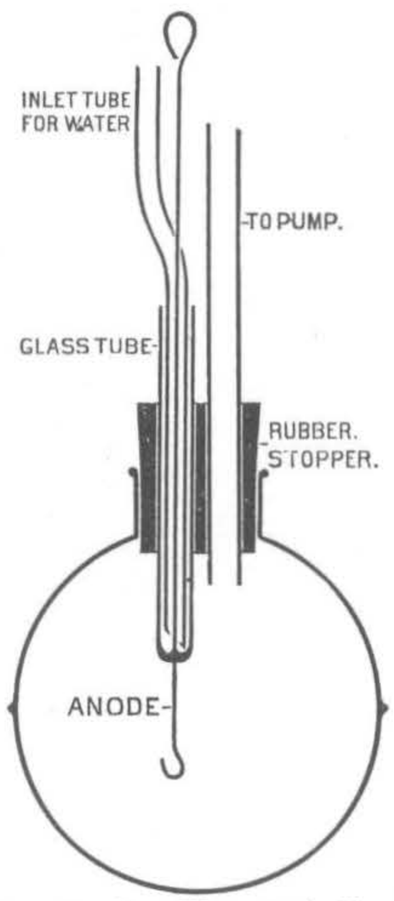


FIG. 10.—DR. WILLIAMS'S TUBE.

Tesla's Latest Advances in Vacuum Tube Lighting.

IN a letter to the *Electrical Review*, N.Y., Tesla describes the results of some recent experiments he has made in vacuum tube lamps, and in their application to photography and other purposes. Along with the letter are published copies of photographs taken with Tesla's new vacuum. One is a portrait taken by the light of a single vacuum lamp at a distance of 5 feet with an exposure of five seconds. Another is a page of letterpress taken by a single vacuum tube at a distance of 4 feet with an exposure of two seconds. The photographs are not equal to sunlight photographs, but resemble more those taken with a single magnesium flash light, the shadows being very harsh, but the amount of detail is considerable. It is difficult to say from Tesla's letter in what his improvements exactly consist. He appears to have reduced the size of the vacuum tube, and thereby, as he says, considerably reduced the dissipation of energy from its surface. The illuminating power of the lamp with which the photographs were taken he estimates at 1,000 candles. The great superiority in efficiency of his system over earlier attempts at vacuum tube lighting he considers is principally due to the use of his improved apparatus for "producing economically harmonical electrical vibrations of extreme rapidity," referring, no doubt, to his oscillator recently described in the ELECTRICAL REVIEW. Tesla promises soon to give further details of his system. The well known originality of nearly all Tesla's investigations leads us to look forward to the publication of the full description of his new system.

OUR NOTE-BOOK

BY EDGAR SALTUS

FROM THALES TO TESLA

Thales—Franklin, Franklin—Volta, Volta—Faraday, Faraday—Morse, Morse—Tesla. There is a formula not algebraic but convenient, which, imagination aiding, represents the diminishing leaps that electricity has taken in avoiding capture by man. The archaic and monstrous reptile is not wholly fanged as yet. But its elusiveness is clipped. In the processes to which it has been yoked the world is assisting at the domestication of an enigma. Presently it will be quite tame. Meanwhile from the garrulities of its purr the solution of multiple mysteries is obtainable. Wherever thought is, there, too, are sentries of science, a hand to the ear, listening. Among them is Moissan. Recently the monitions which he intercepted were so luminous that he saw diamonds, he saw more, he saw nature in her laboratory, and, following her method, with little else than iron, a crucible, electricity and brains, he produced solid sparks, little gems which are real diamonds. Memory aided, of course. He knew that Sir Humphry Davy had shown that the diamond is formed of but two elements—time and carbon. But though Sir Humphry could dissolve he could not construct. Carbon he could manage, yet not time. For time Moissan substituted electricity; or, more exactly, an electric furnace in which the heat equals that of the sun, the bowels of the earth, the throne of Satan—four thousand degrees Centigrade. Into it the iron went. The result was dissolved carbon in a crystalline form, and behold! the chemist had assisted at the birth of a diamond. Similarly from silica opals come. The receipt for a ruby reads, First get your aluminium. Given now an oven and a little cook-book and we won't have to go to Tiffany for our groceries any more. To such feminine uses will the reptile come.

TESLA'S ORIGINAL WORK.

[*From the London Electrical Review.*]

In a letter to the ELECTRICAL REVIEW, New York, Tesla describes the results of some recent experiments he has made in vacuum tube lamps, and in their application to photography and other purposes. Along with the letter are published copies of photographs taken with Tesla's new vacuum. One is a portrait taken by the light of a single vacuum lamp at a distance of five feet with an exposure of five seconds. Another is a page of letter-press taken by a single vacuum tube at a distance of four feet with an exposure of two seconds. The photographs are not equal to sunlight photographs, but resemble more those taken with a single magnesium flash-light, the shadows being very harsh, but the amount of detail is considerable. * * * The great superiority in efficiency of his system over earlier attempts at vacuum tube lighting he considers is principally due to the use of his improved apparatus for "producing economically harmonical electrical vibrations of extreme rapidity," referring, no doubt, to his oscillator recently described in the *Electrical Review*. Tesla promises soon to give further details of his system. The well known originality of nearly all Tesla's investigations leads us to look forward to the publication of the full description of his new system.

Century Magazine April 1898

THE NEW TELEGRAPHY.

RECENT EXPERIMENTS IN TELEGRAPHY WITH SPARKS.

BY A. SLABY.[1]

IN the early months of 1897, when the news appeared in the papers that it had been possible to carry out practically the sending of telegraphic messages without a wire for distances of a mile or more, there were many doubters on both sides of the ocean. People thought it nothing more than the sensational imaginings of some able writer for the press, who wished to present to readers hungry for novelties in electrical matters a particularly toothsome dish. On the contrary, those who have followed with attention and understanding the science of electricity, came to quite a different conclusion; for these knew that a German scientist, Heinrich Hertz, had proved ten years ago by convincing experiments that the electrical forces spread themselves through space like the rays of light—so much so, in fact, that there exists between these two phenomena (of electricity and of light) no difference of quality, but merely one of quantity.

To be sure, these electrical forces do not emanate from electrical phenomena of every kind, but only from such as we designate as quick-pulsating or oscillating streams. From this Nikola Tesla first made the most interesting practical deductions, and performed those wonderful experiments in which the electrical rays transform themselves directly into the desired rays of light, without taking the roundabout way over heat, and without the strength-devouring agency of metal wires. Nature, that unapproachable schoolmistress, furnished him a shining example; for she had already solved the great problem thousands of years before. In the body of the glow-worm, which delights us on warm summer evenings with the magic of its greenish glow, she employs her whole strength in the selective radiance of light. Nikola Tesla followed Nature's footsteps and came upon the banks of a new river, into which the springs of Nature pour her energies of light in broad streams. It fell to the lot of the young Italian Guglielmo Marconi to bring to realization the transfer of forces through space with the help of electrical rays, and in a form within reach of practical application.

First let us consider the means and apparatus wherewith he produced an efficient working radiation of electrical waves.

An electrical phenomenon observed long ago, the springing of sparks from one loaded conductor to another, furnishes the most powerful electrical radiation.

Hitherto we saw in such a discharge a simple passage of the electricity from one body to another, and hardly considered that the phenomenon, which is accompanied by brilliant crackling sparks, is more remarkable than any other electrical phenomenon. To-day we know that this discharge is an intermittent one, in such wise that unnumbered other discharges follow the first discharge of electricity, and in changing direction and with diminishing strength. The whole phenomenon passes with such enormous swiftness that the movements to and fro of the electrical forces are concealed from sight. On the contrary, the eye is capable of receiving as a completed fact only the impression of one single spark.

As an originator of sparks Nature shows to our view bounds that lie very far apart. It is a tremendous jump from the faint crackling that we hear on cold winter days when, in a heated room, we pass a rubber comb through our hair, to the flashing of gigantic lightning-bolts; and yet both consist of the same phenomena; from both the same invisible forces emanate. Marconi uses an artificial producer of sparks, the strength of which occupies a moderate middle place between the extremes that Nature shows. He employs the well-known induction apparatus, that important instrument for the production of Roentgen rays, and connects its binding-clamp with two spheres of brass,

[1] Privy Councilor Dr. Slaby is a professor in the Technical High School at Charlottenburg, near Berlin.

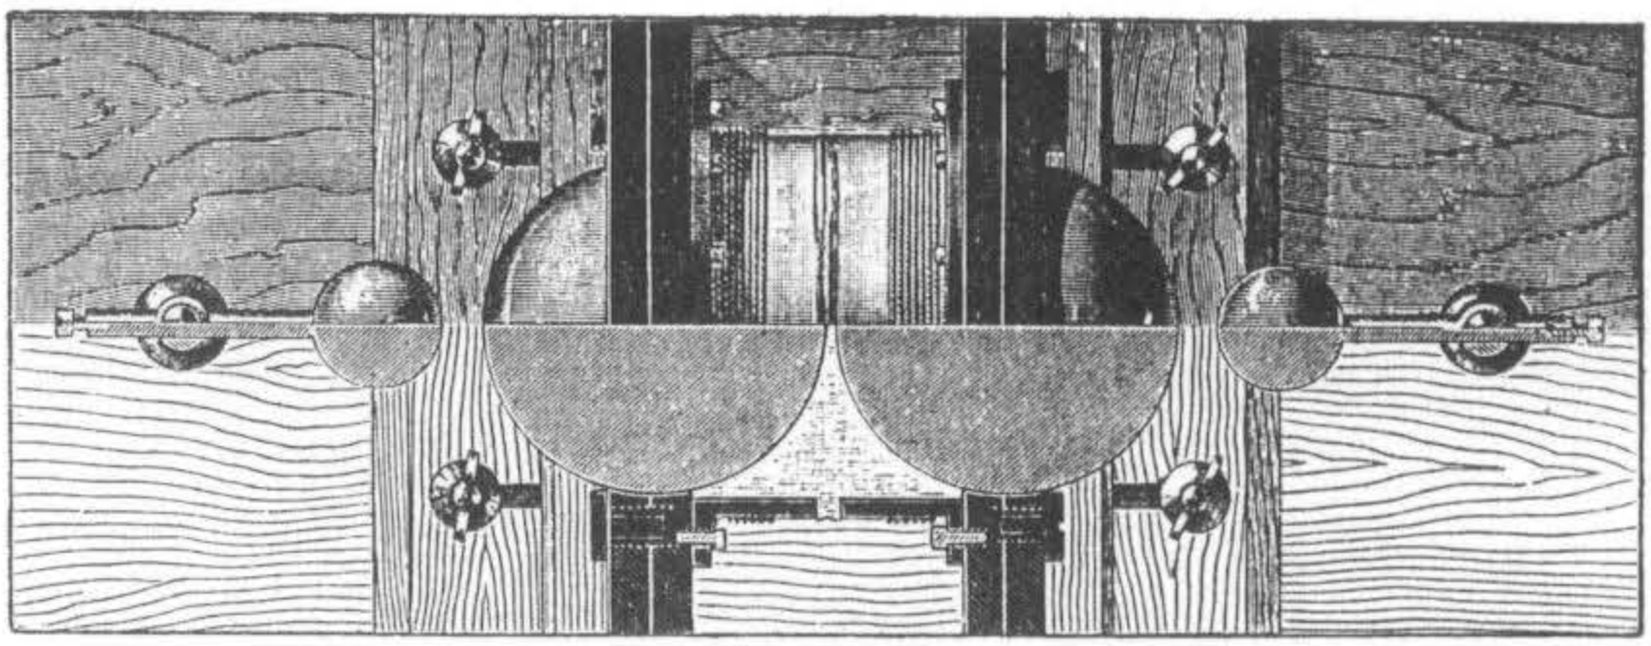

FIG. 1A. MARCONI'S SPARK-GENERATOR. FROM ABOVE.

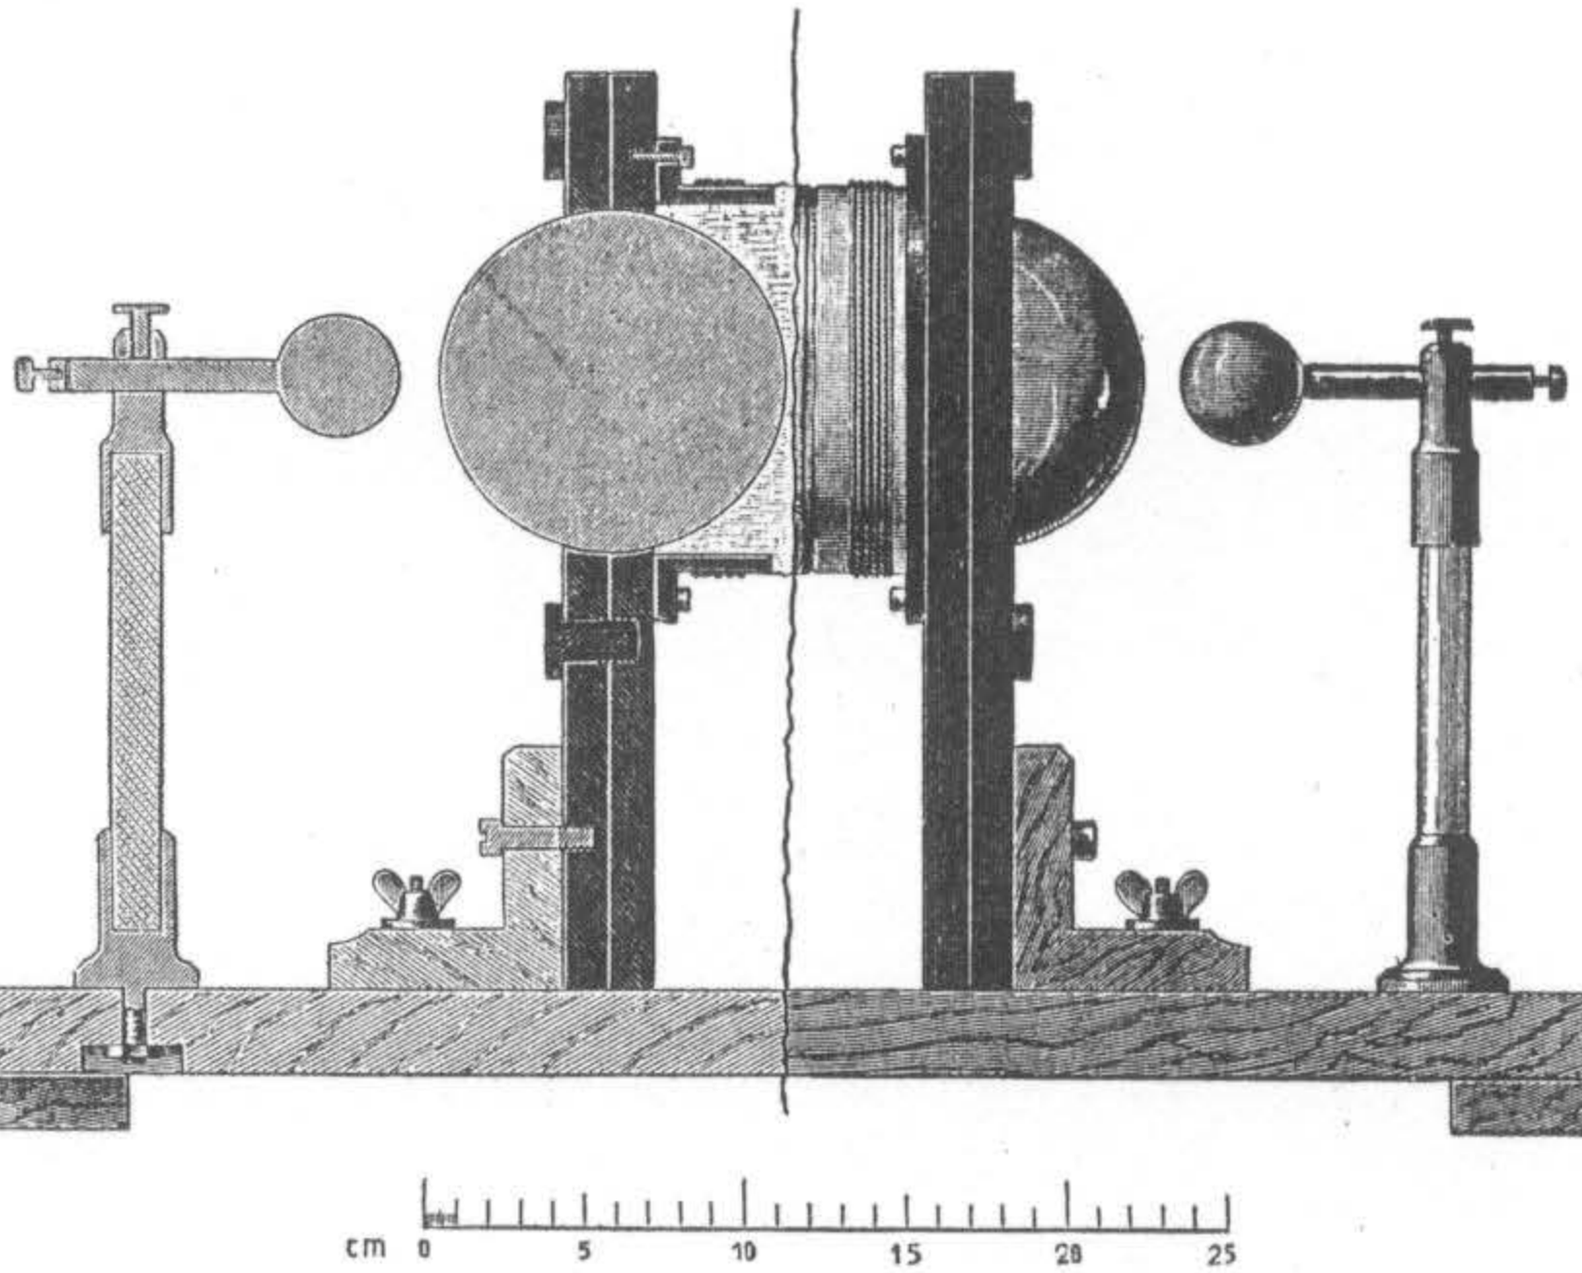

FIG. 1B. MARCONI'S SPARK-GENERATOR. CROSS SECTION, SIDE VIEW.

which are placed opposite each other at a distance of only a few millimeters (Fig. 1). When the inductorium is set in action we get an uninterrupted sequence of thick, white, shining sparks, the power of radiation of which is strengthened if the place of the sparks is filled with oil. In accordance with a process first used by Righi, he does not bind these brass spheres directly together with the binding-clamp of the induction apparatus, but charges them with the aid of smaller spheres which are placed at proper distance opposite the outer half of each of the larger spheres, which, in order to contain the oil, are surrounded with a shell of vellum.

From this apparatus for the production of sparks emanate the rays of electrical force. Heinrich Hertz was the first to make the arrangement whereby it is possible to establish their presence. For this purpose he employed the so-called resonators (Fig. 2), which are open circuits of wire the ends of which are provided with little polished balls of brass. By means of an isolated graduator, the air-space between the balls can be exactly fixed to very small fractions of a millimeter. When such a resonator is placed in the path of electric waves an electrical sympathetic ringing is roused therein, which shows itself in the passage of sparks at the point of non-contact or interruption in somewhat the same way that a tuning-fork is brought to sympathetic sounding by waves of sound. To be sure, the sparks are so minute that they can be seen only in a darkened room.

With the simple resource of this resonator Heinrich Hertz examined into the laws which the electric forces follow in their radiation.

The most remarkable among his experiments showed that the electric waves were reflected from a metal surface exactly in the same way that light is thrown back from a mirror. Moreover, by means of ingenious arrangements he discovered that the velocity with which the electric forces spread themselves through space is the same as the velocity of light—namely, three hundred thousand kilometers in a second.

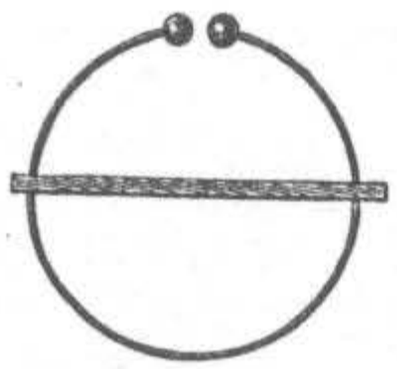

FIG. 2. HERTZ RESONATOR.

So far as it has in any case been possible, these and further experiments have brought us the certainty that light and electric rays are phenomena of the same kind, which differ from each other only in relations of size.

The retina of the eye is the sensitive instrument which permits us to become aware of the presence of rays of light; in the same way we may hereafter call the apparatus which shows us the electric rays an electrical eye. The resonator of Hertz is an eye which is still incomplete. It is weak and short-sighted. We can perceive with it only the most dazzling effects of the electric rays, and can, if I may so express myself, calculate only approximately the degree of their illuminating power.

The electrical eye which Marconi uses is essentially more sensitive; we may call it a clever improvement on the resonator of Hertz. The chief characteristic of the latter was the interruption of a metallic circuit by an air-space of uncommonly short width. The working of an electric ray impact showed itself in the appearance of visible sparks. But we can bring other means of assistance to bear in order to recognize the presence of infinitely small sparks which the human eye fails to see. The most sensitive means are always electrical; therefore we choose a continuous electrical current, the slightest traces of which can be detected by the galvanometer.

Let us imagine that the metal knobs of a resonator of Hertz have been so closely brought together that the air-space between them can be no longer detected even with the most delicate optical means; nevertheless, it is not necessary that a complete metallic contact has yet taken place. If we introduce into the wire circuit of the resonator a little galvanic battery (Fig. 3), say, in the nature of a desiccator, and a very sensitive galvanometer, then, as long as the electric stream is obstructed at the knobs, the needle of the galvanometer will remain at rest. But if the impact of an electrical discharge falls upon the circuit, electric effects tremble through it which are not barred by the air-space between the knobs, very much as a wave of water may spurt its way over an obstacle when it is turned into millions of little spray-drops. In this fashion is it that fine sparks spurt across; and though they are hidden from the keenest methods of optical reinforcement, yet for an instant they are there, and every spark of them fills the air-space with metallic steam. These guide the continuous current, and close the circuit. The result is a perceptible movement of the needle of the galvanometer. Either the needle swings back after the impact is finished,—then the isolating air-space has reëstablished itself as it was, and the electrical eye is ready to react to another impact,—or (and this is most commonly the case) fine scattered particles of metal, which have been consolidated again after evaporation, fill the air-space and build a metal bridge, whereupon the movement of the galvanometer's needle is permanent. But the slightest shock is sufficient to bring this bridge to a fall, and thus to break the metallic contact.

In the same way, as Branly first discovered, works a tube of glass when filled with iron or copper filings. Such a tube presents an insuperable resistance to the passage of an electrical stream, so that we can clamp it to the pole of a galvanic battery with metal fasteners without receiving a charge. But if this tube receives the impact of electric rays, then it conducts the main circuit, and the needle of the galvanometer moves. After the electrical radiation upon the tube is finished, a light shock given to the tube reëstablishes once more the complete resistance to the main circuit.

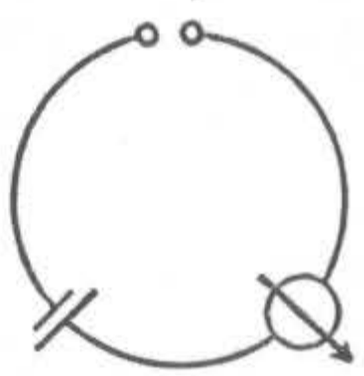

FIG. 3. RESONATOR WITH GALVANOMETER ATTACHED.

Fig. 4 shows an apparatus of this kind, in which the metal filings are replaced with iron nails loosely piled up one upon another. There are countless points of contact present having insulating surfaces. The radiation of electric waves excites among them an electric vibration, and countless invisible sparks at the points of interruption cause metallic contact.

Lodge of Liverpool appears to have been the first to use such tubes as electrical eyes for the study of the Hertz rays. In his ab-

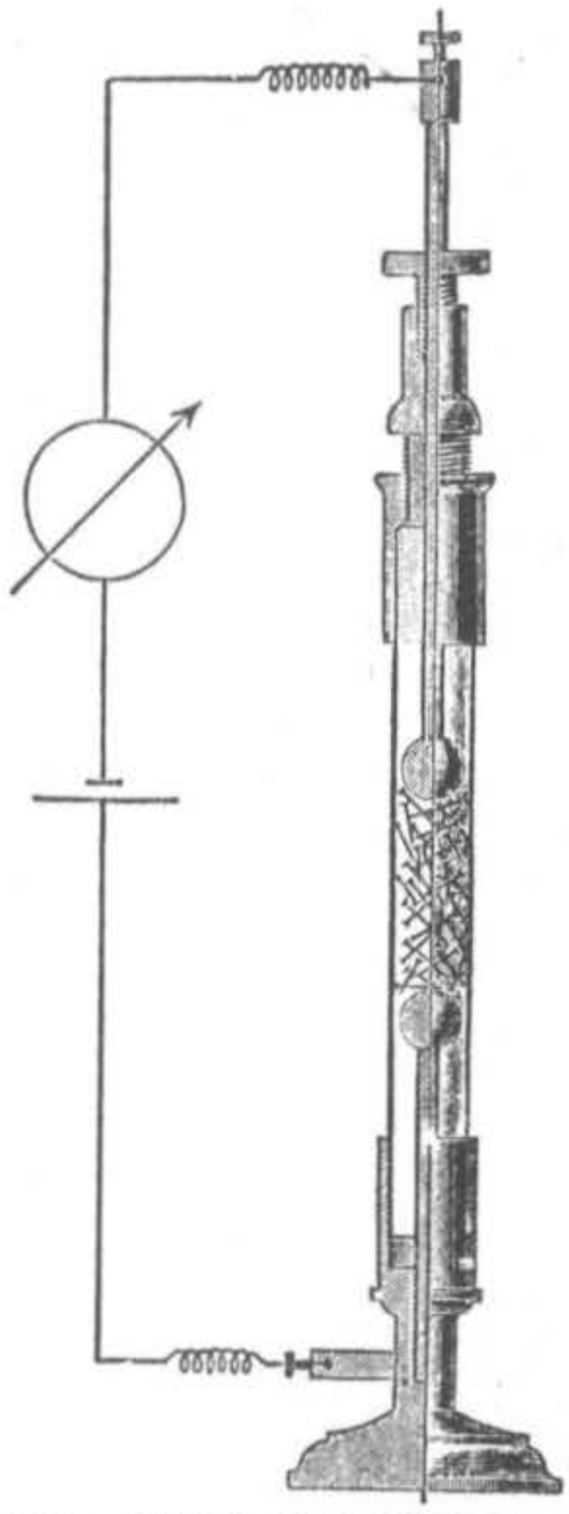

FIG. 4. THE LODGE COHERER AND BRANLY'S TUBE WITH METAL FILINGS TO REGISTER IMPACT OF AËRIAL ELECTRICITY.

sorbing book, «The Work of Hertz and Some of his Successors,» he describes various arrangements of this and of other kinds, which he had been using as early as 1889. From him came the term «coherer,» which he chose because a more intimate connection, as it were a cohesion, of the metal filings was produced by the electrical waves. One may also fairly consider Lodge the father of the idea of telegraphing with electric rays and such tubes; but he fixes as the farthest distance that can be reached one half an English mile (eight hundred meters), without ever having given any practical proof of the theory.

Marconi's electrical eye is pictured in Fig. 5. He uses a metallic powder, or, more correctly, a mixture of metallic powders, which consist of ninety-six per cent. nickel and four per cent. silver. This mixture is sealed up in a little glass tube between two knobs of silver, the meeting surfaces of which knobs are amalgamated by a trace of quicksilver. After it is filled, the tube is cleansed and soldered up; wires of platinum effect the passage of electricity, and are soldered on to the silver knobs; the tube is fastened with marine glue to a stick or pillar of glass, which serves as a support.

Fig. 6 shows the arrangement of Marconi's receiver. The main circuit, strongly drawn out, contains a desiccator (*A*), a sensitive relay (*B*), and the coherer (*C*). It is well known that a transferrer commonly used in telegraphy is called a relay. It reacts to very slender streams of electricity, and moves at the same time a tongue which conducts a second circuit with stronger batteries. When the coherer is cut off, the circuit is broken, and the tongue of the circuitless relay points to contact of rest. After the impact of the waves, cohesion in *C* permits the establishment of a current which turns the tongue of the relay on the working contact. Therewith the circuit of the battery (*a*) is closed, and the Morse indicator (*b*), which has been inserted therein, as well as the ticker (*c*), are set to work. At the first stroke of the ticker against the coherer the particles in the latter must fall asunder; thereby the first circuit becomes at rest, and the tongue of the relay lays itself at the point of rest and cuts off the battery (*a*). At a renewed subjection to the electric waves this action repeats itself. It is evident that by subjection of the coherer to intermittent radiation one can produce the Morse alphabet.

In January, 1897, when the news of Marconi's first successes ran through the newspapers, I myself was earnestly occupied with similar problems. I had not been able to telegraph more than one hundred meters through the air. It was at once clear to me that Marconi must have added something else—something new—to what was already known, whereby he had been able to attain to lengths measured by kilometers. Quickly making up my mind, I traveled to England, where the Bureau of Telegraphs was under-

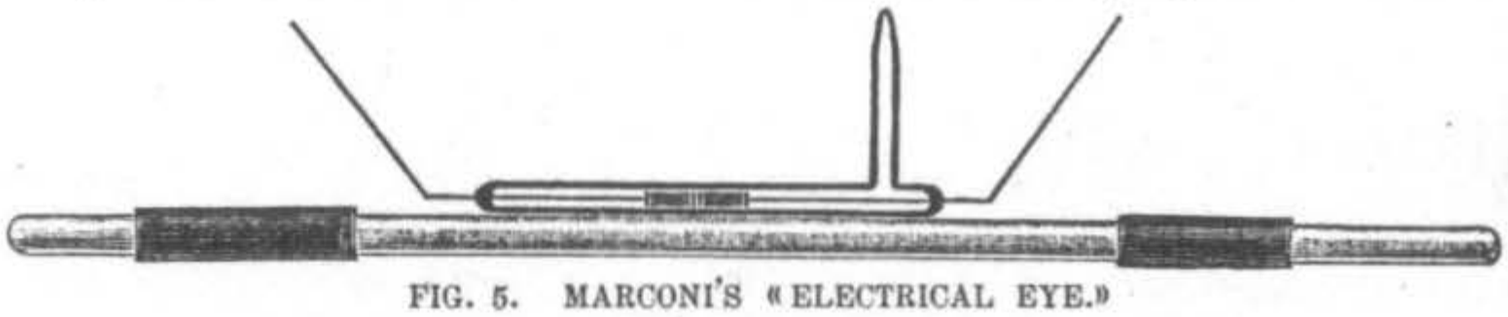

FIG. 5. MARCONI'S «ELECTRICAL EYE.»

taking experiments on a large scale. Mr. Preece, the celebrated engineer-in-chief of the General Post-Office, in the most courteous and hospitable way, permitted me to take part in these; and in truth what I there saw was something quite new. Marconi had made a discovery. He was working with means the entire meaning of which no one before him had recognized. Only in that way can we explain the secret of his success. In the English professional journals an attempt has been made to deny novelty to the method of Marconi. It was urged that the production of Hertz rays, their radiation through space, the construction of his electrical eye—all this was known before. True; all this had been known to me also, and yet I never was able to exceed one hundred meters.

In the first place, Marconi has worked out a clever arrangement for the apparatus which by the use of the simplest means produces a sure technical result. Then he has shown that such telegraphy (writing from afar) was to be made possible only through, on the one hand, earth connection between the apparatus and, on the other, the use of long extended upright wires. By this simple but extraordinarily effective method he raised the power of radiation in the electric forces a hundredfold. The upright extended wires work like the pierced tube of a watering-cart; the rays of electric force spurt, as it were, in every direction upright to the wire; they cause a great part of space to be drawn into sympathy.[1]

Now, since these wires are the essence of Marconi's discovery, the term «telegraphy without wires» is really erroneous; more correctly should it be called telegraphy by sparks, in opposition to the term used hitherto, «telegraphy by circuit» (*Stromtelegraphie*).

The experiments in England were carried out in the Bristol Channel. A mast thirty meters high was erected on the cliff near Lavernock Point—a cliff twenty meters high, one hour from the pleasant little bathing village of Penarth. Over the top of the mast was a cylindrical hood of zinc, two meters high and one meter in diameter. An insulated copper wire passed from the zinc cylinder to the foot of the mast to meet one pole of the receiver. The other pole was connected with the ocean by a long wire which ran down the face of the cliff. In the midst of Bristol Channel, five kilometers distant from Lavernock Point, lies the little island called Flatholm. There was the place for transmission. The apparatus to engender the sparks was in a little wooden cabin. Its knobs were connected, one with a zinc hood on a mast of the same height as that on Lavernock Point, the other with the sea.

After a few preliminary experiments, the sending of messages was perfectly successful. It will always be an unforgettable recollection how, on the morning of May 13, 1897, our party of five, cowering together in a big wooden case, because of the heavy wind, our ears and eyes bent with the most anxious care upon the receiving apparatus, suddenly, after the raising of the signal-flag agreed upon, perceived the first tickings, the first clear Morse letters on the tape! Silently and invisibly the message had been borne across the space from the rocky coast, ferried across by that mysterious medium, the ether.

After my departure the experiments were continued. It was possible to make clear telegraphic communications between Lavernock Point and Brean Down, straight across the entire breadth of Bristol Channel, fourteen and a half kilometers.

Having returned to my home, I went to work at once to repeat the experiments with my own instruments, with the use of Marconi's wires. Success was instant. I set up telegraphic communication between my laboratory and a factory about two kilometers away, where a water-tower was placed at my disposal for the placing of the wire of transmission. I resolved, however, to discontinue the connection, because there came a query from the office of the telephone company, whether in that district any local meteorological storm existed, since all the telephone-lines there were out of order.

Meantime the attention of the German Emperor had been drawn to the new form of telegraphy. It is known with what a lively interest and with what a depth of technical knowledge the Emperor follows the progress of applied science. Hardly a tract of this great field is foreign to him, and it is not un-

[1] The reader will find in THE CENTURY for April, 1895, in an article on Mr. Tesla's inventions, a quotation from his lecture, delivered at Philadelphia in February, 1893, and at St. Louis in March, 1893, in which he expressed confidence in the practicability of telegraphy without wires. In the same lecture will be found a description of the scheme, the connections, and the arrangement of transmitting- and receiving-instruments used later in Signor Marconi's experiments. (See «Inventions, Researches, and Writings of Nikola Tesla,» by Thomas Commerford Martin; New York, «The Electrical Engineer,» 1894, pp. 346–349.) A number of scientific men have already called attention to this fact. This does not detract from the distinct merit of Signor Marconi in having effected the transmission to a five- or sixfold distance by an application of devices which were thought capable only of a transmission of a mile or two.—THE EDITOR.

frequently the case that the reading of technical reports, foreign and German, is, as it were, a rest for him from the wearisome exertions of state affairs.

For carrying out extensive experiments, the waters of the Havel River near Potsdam were put at my disposal, as well as the surrounding royal parks—an actual laboratory of nature under a laughing sky, in surroundings of paradise! The imperial family delight to sail and row on the lakes formed by the Havel; therefore a detachment of sailors is stationed there during the summer, and I was permitted to employ the crews as helpers.

I placed the receiving apparatus in the sailors' barracks. The flagstaff there was considerably heightened, so that the highest point of the clear receiving wire was twenty-six meters above the level of the ground. For my first transmitting-station I chose a church lying on the other shore of the Havel, which was built by Frederick William IV, called the Saviour's Church at Sacrow, distant one and six tenth kilometers in an air-line. Fig. 7 shows the edifice. On one side of the basilica stands the clock-tower, which has a platform immediately below its roof. There a mast was placed, and from its highest point, twenty-three meters above the ground, a copper wire was suspended by means of a porcelain insulator. I had chosen the nave of the church as the place for my spark-generator, in order to be protected during rainy weather. The telegrams transmitted from Sacrow reached the sailors' barracks with unimpeachable clearness and exactness. To be sure, I was on one occasion in a state of lively dismay because of the indistinctness of the marks on the tape. It was the very day on which the Emperor desired to inspect the arrangements. It was only a short time before the doors closed that I was able to discover the origin of the interference and to suppress it. I had withdrawn the transmitting or spark-generating apparatus farther than was my wont within the entrance of the church, and thus it had got too near the stone flooring. By pulling the wires tighter the trouble was overcome. The sending of messages was very successful. The Emperor himself sent a telegram, and on his return to the sailors' station could convince himself of its safe arrival there.

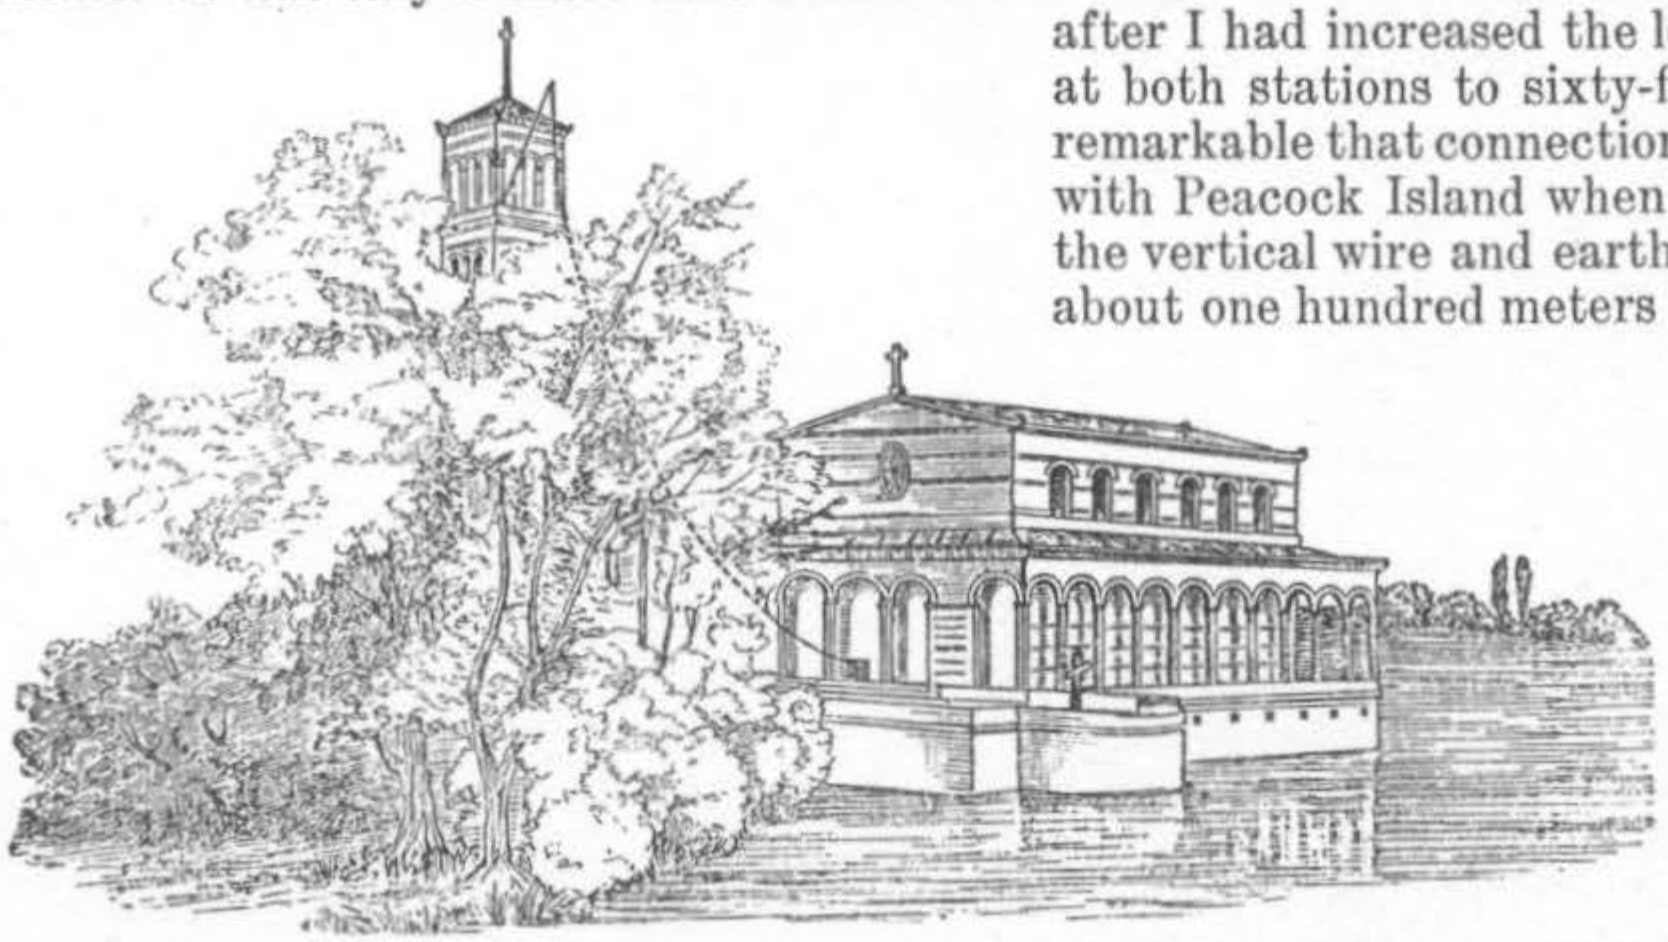

FIG. 7. FIRST TRANSMITTING-STATION, SACROW CHURCH, NEAR POTSDAM.

Further experiments at the Sacrow church gave an important result. When I carried the transmitter wire perpendicularly down the clock-tower to the entrance of the church and to the spark-generator placed there, the signs entirely failed to appear at the receiving-station. After a good deal of experimenting the obstacle was discovered. In the immediate neighborhood of the clock-tower are clumps of trees (see Fig. 7) which almost entirely concealed the vertical wire, so that from the sailors' station with the telescope one could only make out the upper section of the wire. The rays emanating from the wire were swallowed up by the group of trees as rays of light might be, or else led off toward the ground. The chief condition for success with telegraphy by sparks is that all obstacles which are found in front of the transmitter wire must be cleared away.

This fact was particularly felt when I wished to open telegraphic communication between the sailors' station and Peacock Island, three kilometers apart. The air-line between the two stations is crossed by a hilly, wooded tongue of land in the Glienicke Park, which is covered with houses. The electrical rays had to pass through these houses. It was successful, truly, but only after I had increased the length of the wire at both stations to sixty-five meters. It is remarkable that connection could also be had with Peacock Island when I substituted for the vertical wire and earth connection wires about one hundred meters in length, which I stretched parallel to each other, about two meters above the level of the ground.

The experiments in Potsdam had for their object the discovery of the basal conditions on which to predi-

cate success in spark telegraphy. In order to overcome greater distances, more auspicious places and methods had been considered.

In the meantime Marconi, while conducting experiments at Spezia which he carried out with the support of the Italian navy, had succeeded in telegraphing from a moving battle-ship, the *San Martino*, sixteen and three tenth kilometers to the arsenal of San Bartolommeo, and at a distance of eighteen kilometers in deciphering a few signals.

I resolved to attempt still greater distances.

The Emperor had ordered the balloon department of the army to assist in these experiments. The practice-ground of the military balloonists lies in Schöneberg, near Berlin, and a military railway runs thence directly south. At a distance of twenty-one kilometers in an air-line lies the village of Rangsdorf, on the railway itself. The sending apparatus was arranged there, and the necessary guard and balloon material were sent down.

After a few experiments, we succeeded on the 7th of October in establishing communication between the two posts. There was a cold, raw northwest wind, so that both the balloons, anchored at the two places, were driven about. At both stations thin copper wire was fastened to the baskets of the balloons, reaching two hundred and fifty meters to the apparatus. Connection with the earth was made by means of swords stuck in the ground.

The first telegram received under these conditions is reproduced by the autotype process in Fig. 8. The clearness of the Morse characters seems all the more noticeable because the electrical condition of the atmosphere on that day was as unfavorable as one could imagine. The electricity of the air was so strong that one could not touch the wires hanging down from the balloons without getting the severest electrical shocks. When one of the wires broke loose from the apparatus by reason of the strong wind, a lively jumping about took place among the soldiers standing near, for fear that they might be hit by the wires whipping to and fro. Nevertheless, the effect of those electrical interferences in the air are to be seen on the Morse tape only in a few points which did not mar the legibility of the Morse characters, consisting of short and long lines.

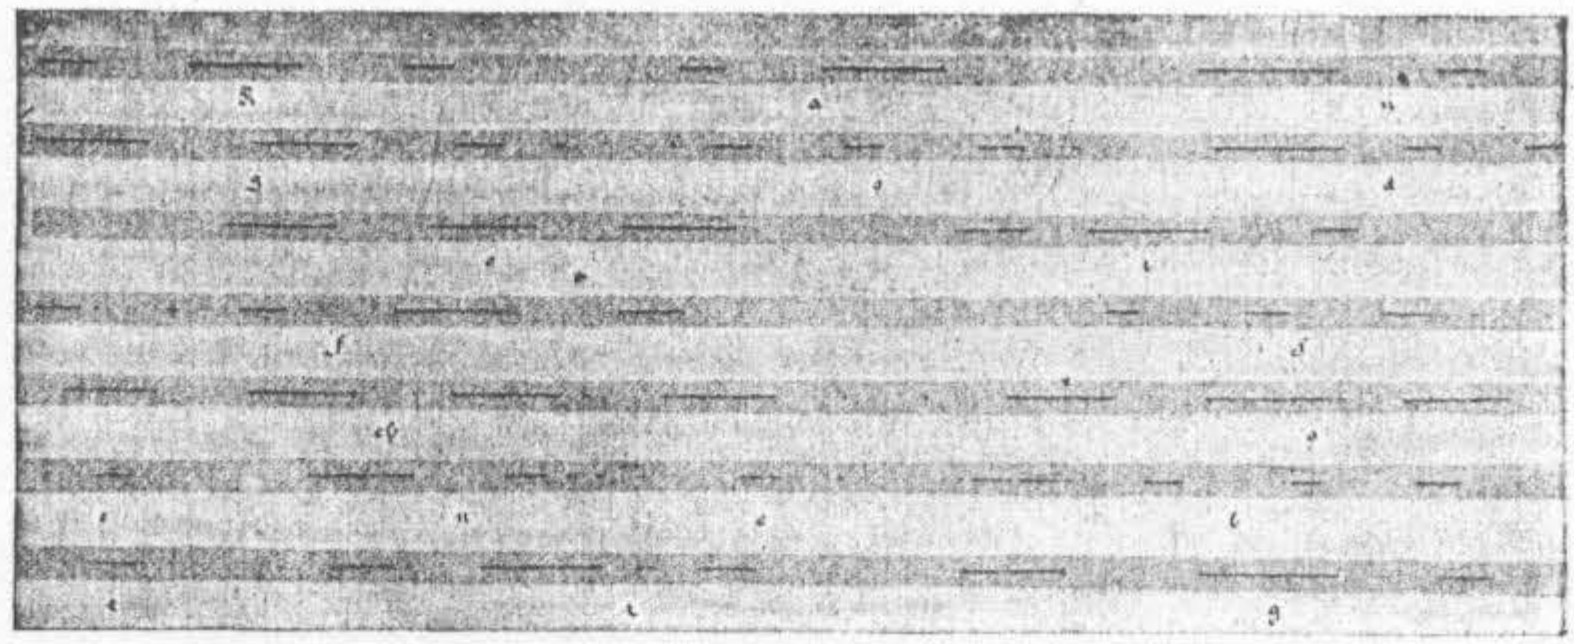

FIG. 8. FIRST TELEGRAM THROUGH THE AIR BETWEEN BALLOONS—«RANGSDORF, SCHOENEBERG.»

I have often been asked in what directions and in what field the use of spark telegraphy might be employed. Our knowledge of the phenomenon in question is, so far, a very modest thing; we are really in the very opening chapters. Who would care to say to-day how far, and whither, the path will lead us? I do not purpose to paint pictures of the future, but I believe I can state with emphasis that for certain purposes the new telegraphy is ripe to-day, and well worthy of consideration. The most important appear to me to lie in the military field. Besieged fortresses, and advancing armies which have the enemy between them, could make use of spark telegraphy to-day as a method of communication. The system works just as surely on a bright day as by night and in fog, though, to be sure, only in cases where balloons can be employed, since the distances reached when towers, masts, and high trees were used would hardly suffice in cases of this kind.

Quite as important is the usefulness of the discovery for the navy. Experiments of last summer have made perfectly certain the possibility of using captive balloons on the high sea. In place of balloons, without doubt, one might use the modern kites, brought to such a pitch of perfection in America, as those of Hargrave and others. I owe it to the kindness of an acquaintance in New York that I know something of these excellent kites, and a few experiments have already shown me that they are perfectly adapted to the carrying of thin wires.

There is a future for the use of spark telegraphy for lighthouses and light-ships. The receiving apparatus can easily be made in a handy form, not bulkier than a chronometer. On the approach to a lighthouse it

would not only give signs, but would tick out the name of the lighthouse; it appears even possible to provide the receiving apparatus with a regulator, to be adjusted at will according to whether a greater or smaller sensitiveness is desired, whereby the distance of the lighthouse can be read off.

An undeniable weakness of spark telegraphy is this: every telegram is imparted to the whole world; every receiver can take it up. Owing to this reason, for the present its application will have to be confined to particular cases. For practical purposes, if one desires to protect one's self from having despatches read by others, there remains always the use of signs arranged beforehand. In war, to be sure, telegraphy would become impossible as soon as a hostile spark-generator should cause a permanent disturbance of the characters. A very interesting battle might occur in the waves of ether.

Notwithstanding these undeniable shortcomings, let us not allow ourselves to be deprived of joy at the discovery of the new telegraphy. We are face to face with very peculiar phenomena. Nature has opened a new door for us. It is the mission of science at present to bring light into the opened room. After that we shall not have to wait long for the necessary technical progress.

TELEGRAPHY ACROSS SPACE.*

BY SILVANUS P. THOMPSON, F.R.S.

There is no such thing as wireless telegraphy. True, one can send signals for a distance of a yard or two without any wires, but in all the recent successful attempts to telegraph across space, whether by electric waves or by other means, wires are used. They do not, indeed, run from the sending station to the receiving station, but are used as base lines. For example, in the case of the longest distance yet reached in telegraphing by electric waves—13 miles over open country—the maximum distance attained in the recent experiments of Prof. Slaby, the length of the wires used as base lines at each end was nearly 1,000ft. As will be seen, in every case, wires or their equiva-

* Paper read before the Society of Arts, March 30, 1898.

lent are used to serve either as base lines or as base areas in the transmission.

Setting aside the mediæval myth of a sympathetic magnetic telegraph with two mere compass needles to point to letters ranged around a dial, there are three generic methods by which it has been found possible to signal across space without any directly communicating wire or cable. These may be conveniently classified as follows: (1) conduction methods; (2) induction methods; (3) wave methods.

I.—Conduction Methods.

These methods depend upon the use of water or earth as a means of conducting a fraction of the electric current from the base line at the sending end to the base line at the receiving end.

From the earliest days of telegraphy it has been a familiar fact that either earth or water might serve as a return circuit for an electric current, and, under certain circumstances, that signals could be sent even with an absolute gap in the metallic line, if there were provided by means of earth or water a sufficiently good path to enable current in adequate amount to be received beyond the gap in the line. This method has sometimes been called the leakage method, since it depends upon the circumstance that electric currents flowing in a conducting medium, such as water or moist earth, do not flow exclusively or even mainly along the path of least resistance, but spread out, some flowing along paths of greater resistance. If current enters a conducting stratum at any point by a single electrode, A, and leaves it at some other point by another suitable electrode, B, some of the current will certainly flow straight from A to B; yet the greater part will not so flow, but will stream around from A to B in long curving paths. If, then, two other electrodes, C and D, are inserted in one of these stream paths at a distance from A and B, some of the current—perhaps only a small percentage of it— may be picked up by a metallic line joining C to D. Hence it is possible, using A B as a sending base line, to signal to C D as a receiving base line at a distant place. The only limits to this method of telegraphy across space are (1) the strength of the original currents used in the sending base line, A B; (2) the sensitiveness of the apparatus used in the receiving base line, C D; (3) the ratio between the space distance from A B to C D and the lengths of the two base lines. This system of telegraphing across space has been proposed at various times. It has been used by Mr. Preece in several of those many experiments which he has made from time to time, and which will entitle him to be regarded as one of the foremost pioneers in this entire branch of telegraphic enterprise.

Morse himself—as recorded in Vail's early work on telegraphy—worked at this subject, and made experiments in 1842 on the Susquehanna river, about a mile wide. He engaged Prof. Gale to investigate the best conditions, and came to the conclusion that the base lines should be three times as long as the distance to be crossed. Mr. Dering, an English telegraph engineer, and Mr. Lindsay, of Dundee, have also worked in this direction.

After the introduction in 1877-78 of the Bell telephone it was found that the extraordinary sensitiveness of that instrument furnished a new means of picking up currents that would otherwise be too feeble to produce intelligible signals. The importance of this circumstance in extending the possibilities of distance telegraphy was not lost upon Mr. Preece. In 1882 he conducted a series of researches upon the establishment of telegraphic communication between the Isle of Wight and the Hampshire coast without any connecting cable across the Solent. An account of these experiments will be found in the report of the British Association for that year. Large metal plates to serve as electrodes were immersed in the sea at the ends of the two base lines. On the Hampshire coast the base line extended from Portsmouth through Southampton to Hurst Castle, a length of 20 miles. On the island the base line extended from Ryde through Newport to Sconce Point, and was about 16 miles long. From Portsmouth to Ryde the breadth of the sea is six miles, while Hurst Castle is only about a mile from Sconce Point. Hence in this case the length of the base lines considerably exceeded the average distance to be crossed. With this arrangement signals were passed in dot and dash which could be read on the Morse system with ease; but telephonic speech was not feasible. After many other experiments to be mentioned under the next heading, Mr. Preece established communication in the winter of 1893-4 across the Kilbrannen Sound between the Isle of Arran and Kintyre, a distance of over four miles. He also maintained telephonic speech across Loch Ness, a distance of 1¼ miles.

In the experiments from Arran to Kintyre, parallel wires about three miles long were used as base lines along the coast, while in some of the experiments two other base lines were used, being insulated wires laid along each coast at a height of about 500ft. above sea-level. A detailed account of these experiments will be found in the report of the British Association for 1894.

A year earlier Mr. Preece had made some striking experiments in the Bristol Channel between Lavernock Point on the South Wales coast and the islands of the Flat Holm and the Steep Holm, the distances of which are respectively 3·1 and 5·35 miles. His base line on the shore at Lavernock Point was a pair of copper wires weighing 400lb. per mile, suspended on poles for a length of 1,267 yards, their circuit being completed through earth. An alternating current was sent into this base line by an alternator worked by a 2-h.p. steam-engine, the voltage being 150 volts, the frequency 192 periods per second, and the current (maximum) 15 amperes. These alternations were broken up into dots and dashes by use of a Morse key. The signals were read on a pair of receiving telephones inserted in the distant base line, which in each case ran across the island and dipped into the sea. The length of these is not stated. Mr. Preece received messages easily over the three miles separating the mainland from the Flat Holm. But at the Steep Holm, 5·35 miles away, though the signals were feebly perceptible, telegraphic conversation was impracticable, as the sound could not be differentiated into dots and dashes. Mr. Preece came to the conclusion that with two base lines, each 10 miles long, he could with ease signal across a distance of 10 miles.

Prof. Trowbridge, of Harvard, has also investigated the possibility of transmitting signals through the earth by conduction, using a rapidly interrupted primary current and a telephonic receiving apparatus.

Many experiments have been made under accidental circumstances, all tending to prove the possibility of this mode of transmitting signals through the earth itself. The instruments in Greenwich Observatory are affected by the stray currents that escape into the earth from the badly-insulated return circuit of the City and South London Electric Railway, 4½ miles away. Another example is afforded by an accident which occurred some 10 years since at the Ferranti electric lighting station at Deptford, when one night one of the dynamos by some derangement became connected to earth. The whole of the railway telegraphs in the signal boxes of the railways in South London were temporarily put of order and rendered inoperative, while the currents flowing in the earth were perceived in the telegraph instruments so far northwards as Leicester, and so far south as in Paris. If this could occur as a mere accident, it is obvious that with properly-thought-out arrangements signals could easily be sent from one part of the globe to another by conduction through earth or water.

Most striking of all the cases of distance signalling by conductive methods is that presented by the transmission of signals over nearly three miles, which was carried out in 1894 by Dr. W. Rathenau, Mr. E. Rathenau, and Prof. Rubens. They selected as a suitable place for operations the open water of the Wannsee, which opens into the Havel, near Potsdam. Here at the south end, near the Friedrich-Wilhelmsbrücke, they immersed two metal electrodes, each having about 15 square metres of surface, at the two ends of a base line about 550ft. long. With 75 accumulators and a rotating interruptor giving about 150 currents per second, and a Morse key, they injected signals into the base line. At a distance of 4½ km., or nearly three miles across the water, near the shore at Neu Cladow, they set up the secondary base line, having electrodes of about four square metres each. These were hung in the water from two boats between which the connecting line—about 330ft. long—was stretched. In this line was inserted a telephone receiver of usual pattern. The current used was about three amperes, and there was not the slightest difficulty in hearing the dot-and-dash messages. Several situations for the receiving base line were tried, and it appeared that the interposition of a large sandbank between the two stations made very little difference.

II.—Induction Methods.

Induction methods are of two varieties. An electric charge upon a conductor may induce another electric charge upon another conductor at a distance by influence, or electrostatic induction. An electric current in a wire, during such time as it is increasing or diminishing, may induce another electric current in another wire in its neighbourhood by electromagnetic induction.

So far as I am aware, the only case in which electrostatic induction has been used in electric signalling is that of telegraphing (or telephoning) to trains in motion, as suggested about 13 years ago by Mr. Wiley Smith, of Kansas City. If a wire suspended over a train is electrified, either positively or negatively, charges are induced upon the metallic roofs of the cars, and if these are suitably connected to instruments on board the train, signals may be exchanged between train and wire without any metallic connection between the two. This suggestion was further developed, about the year 1886, by Mr. Phelps, and by Messrs. Gilliland and Edison. Descriptions of their methods will be found in the American electrical journals of that date. The system was successful both for telegraphing and telephoning, and was, indeed, adopted for a time by the Lehigh Valley Railroad Company. But it has been abandoned for a very simple reason. One of the consolations of railway travelling is that one is free from being disturbed by telegraph or telephone. No one on board an express wants to telegraph or be telegraphed to.

Electromagnetic induction has played so important a part in distance telegraphy that it must receive a more extended notice. Very early after the introduction of the commercial telephone, troubles arose from the exceeding sensitiveness of the instrument. Conversations in one line were overheard in another, while the ear was disturbed by an incessant buzz or rattle from the interference of stray currents from neighbouring telegraph lines. All these were at first attributed to induction—that is to say, to the electromagnetic influence of the currents in one line upon the neighbouring line. No doubt in some cases this is a cause, but unquestionably in many of the cases the disturbance was due not to induction at all, but either to leakage of currents across the surfaces of the insulating supports, over films of dirt or moisture, or else to leakage of currents from one line into the other through the earth-plates or earth connections. Unless circuits with metallic returns are used it is certain that the earth return will afford a means for stray currents to find their way into the telephone lines. Mr. Preece has narrated many cases in which telegraph or telephone messages that are being transmitted along some line have been heard, or rather overheard, in telephonic instruments in some totally disconnected and distant line. Many of these are due doubtless to stray currents through earth, but some are unquestionably due to true induction. A line or circuit absolutely insulated from any earth contact or earth return may yet act inductively. During the brief instant while the current in it is growing that current is setting up a magnetic field in the surrounding region, extending indefinitely but feebly into space. As the current dies away again this magnetic field also dies away. If in its growth or decrease this magnetic field encounters other wires it sets up E.M.F.'s in them, and thus originates disturbances. For the propagation of this effect from wire to wire no contact is needed. It is an effect that is dependent upon the properties of the intervening medium, and is proportional to its magnetic permeability. The ether of space itself—air, water, soil, and rock—are all of about equal permeability. Hence this kind of induction may be propagated from circuit to circuit whatever natural material intervenes. Mr. Preece has made repeated researches with a view of utilising this effect for the purpose of distance telegraphy. He has erected parallel base lines, sometimes in South Wales, sometimes near the mouth of the Dee, sometimes in Scotland. He has laid out, flat on the ground, great squares of insulated wire to test the inductive transmission from one area to another. On Newcastle town moor, and on the sands at Penarth, he has thus operated. It is not always easy in his experiments, particularly in those where earth connections were used, to be certain how much of the effect was due to true induction and how much to earth conduction. But in some of the cases there can be no doubt whatever. An excellent *résumé* of his work was given by him at the Chicago Congress in 1893. In this he describes how in one series of experiments he laid out on a level plain two quarter-mile squares of copper wire insulated with guttapercha, the distances between the two nearest sides of the two squares being also a quarter of a mile. In this case, using rapidly-interrupted or vibratory currents, and a Morse key to break them up into Morse signals, and applying in the other circuit a receiving telephone, conversation in the Morse code could be held readily between the two operators. This arrangement precluded all idea of earth conduction. In effect, Mr. Preece was working with a strange species of transformer, of which his two squares constituted respectively the "primary" and the "secondary," the "core" of the transformer being in this case partly of earth and partly of air. Mr. A. W. Heaviside has described an analogous case in which, wishing to establish telephonic communication to the bottom of a colliery in the North of England, he arranged a circuit in a triangular form along galleries about $2\frac{1}{4}$ miles in total length at a depth of 60 fathoms. On the surface of the colliery another circuit was laid out in triangular lines of equal size over and parallel to the underground line. Here, again, telephonic speech was perfectly clear by induction from line to line; or rather, in this case, from area to area. Each area enclosed something like 700,000 square yards, an ample base area when the distance to be penetrated was but 120 yards.

Earlier than the date of either of these experiments, the late Mr. Willoughby Smith had shown how, using two coiled circuits of wire at a distance of some yards apart, telephonic messages could be sent across air, or even through walls and floors.

The greatest distance to which Mr. Preece's experiments upon telegraph lines have been carried is 40 miles—namely, between the telegraph lines that run across the Scottish border by the east and west coasts respectively. Sounds produced in the Newcastle and Jedburgh line were distinctly heard on the parallel line at Gretna, though there was no line connecting the two places. Here, however, since both lines used earth returns, it is probable that most of the effect was due to conduction, not to true induction.

Instruments which operate by means of alternating currents of high frequency, like Mr. Langdon-Davies's phonophore, are peculiarly liable to set up disturbance in other circuits. A single phonophore circuit can be heard in lines 100 miles away. When this first came to my notice it impressed me greatly, and, coupled in my mind with the Ferranti incident mentioned above, caused me to offer to one of my financial friends in the City, some eight years ago, to undertake seriously to establish telegraphic communication with the Cape, provided £10,000 were forthcoming to establish the necessary basal circuits in the two countries, and the instruments for creating the currents. My offer was deemed too visionary for acceptance. The thing, however, is quite feasible. The one necessary thing is the adequate base lines or areas. All the rest is detail.

(*To be continued.*)

TELEGRAPHING ACROSS SPACE.*

BY SILVANUS P. THOMPSON.

II.—Induction Methods.

(Continued from page 468.)

One must not close this section without reverting to a most pregnant point of advance made about 1888 or 1889 by Dr. Oliver Lodge. When experimenting upon the oscillatory discharge, he conceived the happy idea of turning two circuits into resonance, or, as he termed it, "syntony" with one another, in such a way that when an oscillating electric spark occurred in one of the circuits, the inductive effect on the other immediately set up in it electric oscillations which manifested themselves by an overflow spark. I call this experiment pregnant because it affords a hint of another possibility—namely, that of signalling inductively from one area to another, and using around those areas, not merely circuits of wires, but syntonic circuits, which, therefore, are necessarily much more sensitive in their response one to the other. Some of Tesla's high-frequency experiments also have an obvious bearing on this point.

III.—Electric Wave Methods.

After Clerk Maxwell had predicted the existence of electromagnetic waves, and had shown that their speed of propagation is identical with that of light, it required, in reality, very little to demonstrate by experiment the existence of such waves. But that very little was not actually achieved until the year 1888, when the lamented Prof. Heinrich Hertz showed simple methods of producing, detecting, and measuring these waves. It had been known for many years, from the predictions of Kelvin and Von Helmholtz, and confirmed by the experiments of Fedderssen, that in many cases an electric discharge is of an oscillatory character. In the years 1887-8, Lodge, Fitzgerald, and others were investigating the nature of these oscillations, and the manner in which they are guided by conducting wires, when Hertz conceived the idea of investigating the disturbances which such oscillatory discharges set up in the surrounding space. He showed that, given a simple apparatus, which he called an "oscillator," consisting of two metal plates or conductors, connected by a conductor interrupted at one intermediate point by a "spark-gap," the oscillator on the appearance of each spark emitted a train of electric waves into the surrounding space. He further showed that if a mere circuit or ring of wire of suitable size, the continuity of which is interrupted at one point by a minute gap, is placed in the path of these travelling waves in a suitable position, the waves as they reach it set up electric surgings in this wire, and if sufficiently energetic cause it to show a small spark in the gap. This simple detecting device he termed a "resonator." Armed with these apparently primitive pieces of apparatus, he then devoted himself to the task of exploring the propagation of the waves. He found that, like waves of light, they could be reflected by metallic surfaces, could be refracted by prisms, concentrated by lenses, and even could be polarised. He measured their wave-length and velocity of propagation. He found that they could pass readily through walls of wood, stone, or brick, which are opaque to ordinary light-waves. Metals and other conductors of electricity, on the contrary, absorbed them, and were consequently opaque.

In these researches of Hertz we meet, for the first time,† with the recognition of a true travelling wave. With this immense discovery there was opened out an entirely new field of possibilities. Hitherto there had been inductive actions known which might reach out from wire to wire, only to fall back again when their excitant cause died away. But now the electric wave, once started on its path, did not collapse back into the wire when the spark ceased; on the contrary, it went travelling on. And just as the javelin, which can travel on after the impulse has ceased, can act at greater range than the sword, whose thrust is limited by the length of arm and blade, so the true electric wave, by the very fact that it is a true travelling wave, can carry signals to greater distances than the mere inductive influence that simply extends outwards from a wire or from a coil.

The work which Hertz had begun, was, after his death, carried on by a whole army of investigators. Of these, and of their achievements, the best account that has yet appeared is Prof. Lodge's little book on "The Work of Hertz and his Successors." To that book enquirers must be recommended for details. Suffice it here to say much has been done in perfecting both the oscillator and the detector. Notable amongst these matters have been the forms of oscillator designed by Lodge and by Righi; the latter having the spark gap immersed in oil or vaseline between two metal balls. Many forms of detector have been proposed. Very early Lodge produced one under the name of "coherer," consisting of a metallic point very lightly pressed against a metal plate, and connected in circuit with a galvanometer and a local cell. The light contact constitutes an imperfect joint, which is practically non-conductive until caused to cohere and conduct by the impact of an electric wave; or, perhaps more accurately, by the stimulus of the minute surging electric current which results from the impact of an electric wave. Subsequently, taking a hint from M. Branly, Lodge substituted as a detector a new kind of coherer, consisting of a small glass tube partly filled with loose metallic filings—iron or nickel by preference—joined in the circuit. Such a coherer acts as a species of relay, by means of which an electric wave, incapable in itself of affecting a galvanometer or other instrument, is enabled to do so indirectly by setting into operation a local current. After the coherer has thus operated, it usually remains in the conductive state until subjected to some mechanical jar or shock. Lodge proposed to apply for this purpose a mechanical tapper worked either by clockwork or by a trembling electric mechanism. On several occasions, and notably at Oxford in 1894, he showed how such coherers could be used in transmitting telegraphic signals to a distance. He showed that they would work through solid walls. Lodge's greatest distance at that time had not exceeded some 100 or 150 yards. Communication was thus made between the University Museum and the adjacent building of the Clarendon Laboratory. For more than 18 months the Rev. F. Jervis Smith, of Oxford, using a carbon powder coherer, has maintained communication between his house and the Millard Engineering Laboratory, over a mile away.

Even before this Mr. Nikola Tesla, in a lecture delivered at St. Louis in 1893, had made a further suggestion of great importance. He proposed to transmit electric energy by oscillations to any distance, without communicating wires, by erecting at each end of the stretch a vertical conductor joined at its lower part to the earth, and at its upper to a conducting body of large surface. This constitutes a vertical base line from which to disseminate the oscillating disturbances.

About two years ago a young Italian, Mr. Marconi, came to this country, and succeeded in inducing the British Telegraph Department to give him facilities for experimenting upon wave-method of transmission. First upon Salisbury Plain, and then across the Bristol Channel, he succeeded in transmitting Morse signals to greater distances than anyone had previously attained. He sent signals from Lavernock Point to Bream Down—about nine miles as the crow flies over the open channel. To accomplish this he used as base lines two vertical conductors earthed at their lower ends, and carrying at the top extended surfaces, He used a Righi transmitter. As receiver he employed the special form of Lodge-Branly coherer presently to be described. This was connected in the manner Lodge had recommended in a local circuit, and was tapped by a mechanical tapper operated by a vibrating electric mechanism. The local circuit operated a Post Office relay connected to a Morse instrument signalling the dots and dashes. The coherer was itself included in the vertical base line. So far all is old. The special coherer used in these experiments by Marconi has very fine metallic powder, chiefly of nickel and silver, in a small glass tube exhausted of air. He also applied shunting resistances to the relay contacts, and interposed a fine iron wire closely coiled, as an impedance in the local circuit on each side of the coherer.

In 1897, some further experiments were carried out by Prof. Slaby, of Charlottenburg, on an even larger scale. He abandoned everyone of the novelties introduced by Marconi, and fell back upon the methods previously known. He used a simple Lodge-Branly coherer, employed elevated conductors as base lines, discarded the useless little iron wire impedance coils in the local circuit, and substituted for the Post Office polarised relay one made out of a Weston galvanometer. His success shows that all that is essential can be thus attained. He chose as the scene of his operations the Havel, and set up elevated conductors upon the castle of the Pfaueninsel, and on the campanile of the church at Sacrow. Thus equipped, he transmitted signals, at first about three-quarters of a mile, then three miles across the water. He found trees and masts to interfere with the signals to some degree. He then proceeded, with the aid of the military authorities, to experiment over an open stretch of country—from Rangsdorf to Schöneberg. The elevated conductors were wires raised by means of hydrogen balloons to heights of nearly 1,000ft. Signals were obtained at a distance of 21 km., or over 13 miles. Neither in Marconi's nor in Slaby's successful operations were syntonic devices employed. The following table summarises the results of Marconi's and Slaby's work.

Commenting on these results, Slaby notes how over open sea a much greater distance appears to be attained from a base line of given length. Assuming Marconi's best proportion, he calcu-

* Paper read before the Society of Arts, March 30, 1898.

† Many years before, Prof. Joseph Henry had transmitted induced electric sparks from one circuit to another in different floors of a building. Doubtless, these were oscillatory; but it is impossible, at this time, to determine whether the arrangements were such as to produce true travelling waves, or whether the action was (like Lodge's later experiment of the two syntonic circuits) merely one of electromagnetic induction.

lates the vertical length of base line needed for communicating across the English channel at Dover to be 265ft., while from London to Paris, over land and sea, would require 4,700ft. He even estimates base lines of 6,600ft. as sufficient, were it not for the curvature of the globe, to serve for communication across the Atlantic.

	Distance. Miles.	Base line. Feet.	Ratio.
Marconi—			
Flat Holm (sea)	3¼	150	100
Bream Down (sea)	9	200(?)	250(?)
Spezia (land and sea)	4¼	100	200
Spezia (open sea)	11	100	500
Slaby—			
Sacrow (water and trees)	¾	80	70
Pfaueninsel (water and buildings)	3	200	50
Rangsdorf (land)	13½	950	70

The most recent improvements made towards perfecting this method of transmission are those of Dr. Oliver Lodge, whose labours, continnued during the past few months, are still in progress. He has first reorganised the transmitter apparatus so as to make it a more persistent radiator. It emits longer trains of waves. This has been accomplished by introducing in the path of the oscillations, between the spark-gap and the wings, a few turns of stout wire to act as an impedance coil. By this means the oscillations can be accurately tuned. The receiving apparatus is also tuned ; in fact, each apparatus is made to operate both as emitter and as receiver, in turn, as required. Lodge has also modified the arrangements of the coherer circuits, to render them more certain of operation, no local current being allowed to pass through the coherer until after it had been affected by the waves. He has, in fact, thoroughly redesigned the sending and receiving instruments upon a rational basis, so that they shall be both less sensitive to stray impulses, and more sensitive to properly attuned waves. The results obtained with these have not yet been made public ; but, employing a siphon recorder as the receiving instrument, remarkable precision of signalling has been attained. Further developments in this direction will doubtless be awaited with much interest. Meantime, in other countries—the United States, Russia, and France—other experimenters are at work. Any account given at the present time will, therefore, be necessarily incomplete.

In passing finally from a review of that which has already been attained to that which may reasonably be contemplated as within reach of attainment in the near future, I have no wish to assume the *rôle* of the prophet. Still less would I desire to emulate the example of the imaginative *litterateur* who, whether his name be Jules Verne or H. G. Wells, stimulates the public curiosity by amazing speculations, and in doing so renders the dis-service that the public so stimulated is made less capable than before of distinguishing between that which is and that which is not within the bounds of reasonable possibility.

It has been shown that there are three general methods of transmitting electric signals across space. All of them require base lines or base areas. The first—conduction—requires moist earth or water as a medium, and is for distances under three miles the most effective of the three. The second—induction—is not dependent upon earth or water, but will equally well cross air or dry rock. The third—electric wave propagation—requires no medium beyond that of the ether of space, and is, indeed, interfered with by interposed things such as masts or trees. Given proper base lines or base areas, given adequate methods of throwing electric energy into the transmitting system, and sufficiently sensitive instruments to pick up and translate the signals, it is possible, in my opinion, so to develop each of the three methods, that by any one of them it will be possible to establish electric communication between England and America across the intervening space. It is certainly possible, either by conduction or by induction ; whether by waves I am somewhat less certain. Conduction might very seriously interfere with other electric agencies, since the waste currents in the neighbourhood of the primary base line would be very great. It is certainly possible either by conduction or induction to establish direct communication across space with either the Cape, or India, or Australia (under the same assumptions as before), and at a far less cost than that of a connecting submarine cable. I doubt very greatly whether the wave method can be made applicable at all to these so-distant parts of the globe. But whether by conduction, by induction, or by waves, I am firmly convinced that the immediate road to commercial success lies in two things. Firstly, we must frankly recognise that there is no such thing as telegraphing without wires—that the base line, or the base area surrounded by wires, is a fundamental necessity. Secondly, we must look to establishing real syntony between the sending and the receiving parts of the apparatus to render it, as far as possible, sensitive and independent, without which conditions such systems will become too costly and too unmanageable for commercial ends.

[The paper was illustrated by numerous slides illustrating the methods and instruments used by Hertz, Lodge, Righi, Marconi, and Slaby in their investigations, and the newest syntonic apparatus of Lodge. Experiments were also shown illustrating the transmission of electric waves and their reception and detection. A small Lodge apparatus, constructed by Mr. Miller, was also exhibited in operation.]

Discussion.

The Chairman said no doubt all present had come with great expectations, anticipating much pleasure in hearing of the latest developments of one of the most interesting and valuable applications of modern science to useful purposes—electric telegraphy. But whatever their expectations they must have been more than realised by the exceedingly lucid exposition by Prof. Thompson of a most intricate and difficult subject ; so lucid, in fact, had it been that probably few realised how intricate it was. He felt with Prof. Thompson that perhaps in the immediate future the application of wireless telegraphy to practical purposes was not quite so wide as some might have anticipated and hoped ; but at the same time there were purposes to which they might reasonably hope it might be applied, such, for example, as communication between the shore and lightships, and possibly between ship and ship. It was satisfactory to learn that means were being sought for, and had been to some extent found, of differentiating one telegraphic signal sent through space from another by tuning. That was to him a particularly interesting point, and the explanations which had been given of the methods adopted by Prof. Oliver Lodge for obtaining the transmission of a particular message, and the receipt of that message by the particular person intended to receive it were specially valuable. Obviously it would be very inconvenient if messages sent through space were indifferently receivable by everyone who chose to play the part of an eavesdropper. That condition of things would somewhat resemble that described in one of Hans Christian Andersen's stories, where the fumes coming from a pipkin revealed to everyone who chose to smell them what each particular person was having for dinner. It was not very desirable that that kind of curiosity should be gratified in connection with telegraphy, and it seemed to him that the uses of telegraphy through space would be very much limited if this sort of thing could not be prevented. Prof. Lodge's line of experiment, however, seemed to tend in that direction, and to show the means of confining a message to the person intended to receive it. He was sure Prof. Thompson would be pleased to answer any questions on any point that had not been made clear if there were any such, any questions which could arise having been already answered in anticipation. If no one had any such query to put he would conclude by proposing a hearty vote of thanks to Prof. Thompson for his paper.

The vote of thanks was carried unanimously.

ELECTRIC SPARKS TO BLOW UP WAR SHIPS

Tesla Figuring on Exploding the Enemy's Magazines by an Air Current.

War without explosives may come eventually if the hopes of Nikola Tesla are realized. Experiments now being made by the famous inventor may prove that an electric spark can be sent miles and miles through the air to lodge in the powder magazine of an enemy's ship and cause the instant destruction of the vessel.

It is not a new invention Mr. Tesla is working on, rather a perfection of one already found practicable—his oscillator, that marvellous electrical machine with which he was able to transmit messages without wires or artificial conductors of any kind. This instrument, with the aid of powerful machinery, may be able to start a vibratory wave that accumulates force as it progresses and, finally striking the object against which the wave is directed, does so with such a percussion as to set off any explosives it comes in contact with. None of the ammunition in the magazine of an enemy's ship would be safe from this vibratory wave. All that would be necessary to insure the success of Mr. Tesla's operations, should his scheme prove practicable, would be to know the location of the vessel to be destroyed, and the oscillator is to have an appliance for locating it. If this engine of death should be perfected before the end of the present hostilities it would be safer for Spanish war ships to leave their powder at home, for Mr. Tesla intends to offer the use of his invention to the United States.

Mr. Tesla at present refuses to give any details. He merely admits that he is working on the plan.

"I cannot say when my plans will be perfected," said he yesterday, "or whether they will be of any use in the present war. I wish you would merely say that I am trying to be useful to the United States."

Oscillatory Currents and Some of Their Phenomena—I.

BY PROF. E. F. NORTHRUP.

Intense interest has of late been aroused in the many striking phenomena connected with oscillatory currents. This interest was first awakened among professional electricians and physicists by the extraordinary experiments of Hertz, later the general public became excited over the fairy-like effects obtained by Tesla, with his currents of high potential and high frequency, and now comes the production of the X-rays, which have forced a large body of scientists, the doctors and surgeons, to give their attention to electrical matters. Marconi's wireless telegraphy, an outgrowth of the experiments of Hertz and Lodge with oscillatory currents, is likewise exciting general attention. The interest felt in these matters is extended, but people's notions are in general vague as to the methods used for obtaining the effects, or the principles upon which they depend.

It is, however, surprising to note how many of the phenomena of oscillatory currents may be explained and connected by a right application of a very few simple physical principles with which everyone is instinctively acquainted. Furthermore many of the most interesting results may be obtained by any one who has a little ingenuity, clear physical conceptions, a few dollars and a room in which to experiment. It is feasible for every doctor using X-ray apparatus, and station-tender who has the disposal of alternating or direct currents, to rig up the necessary simple apparatus to repeat experiments along this line and to materially contribute to the general fund of knowledge upon the subject.

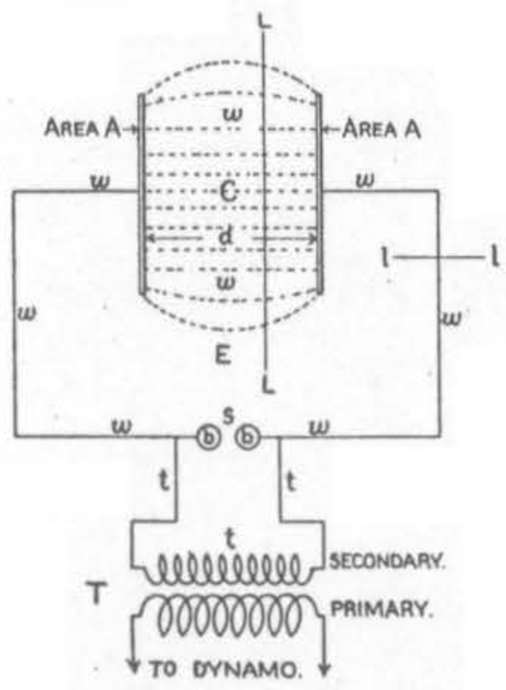

FIG. 1.

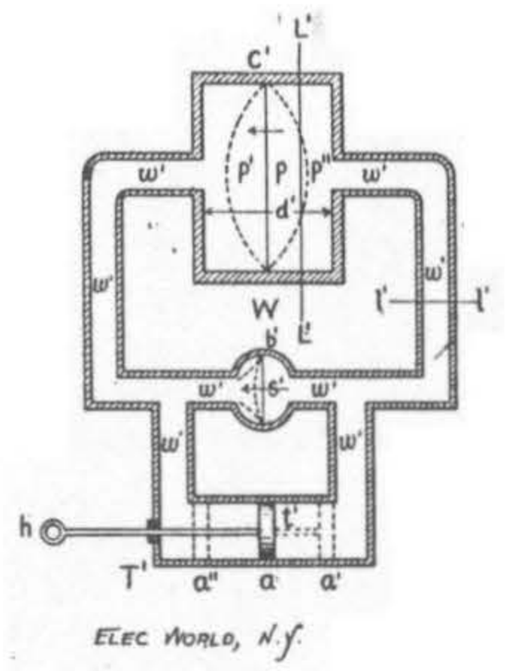

FIG. 2.

The writer will try and describe for the above class of readers of THE ELECTRICAL WORLD, in a simple non-mathematical manner and as far as possible non-technical form, the general methods and the construction of the necessary apparatus for obtaining oscillatory currents and their effects. He shall feel well repaid for his undertaking if doctors and others are induced to try for themselves some of the experiments to be described, and if they derive from their efforts a share of the delight which he felt when experimenting along the same line.

A clear physical conception of what constitutes an oscillatory current should be obtained before the attempt is made to describe what may be done with such currents. This may justify the somewhat lengthy description which follows:

A common arrangement for obtaining an oscillatory current is diagrammatically illustrated in Fig. 1. Here C is a condenser, which may be considered as consisting of two square brass plates, having each an area A parallel and separated from each other by a distance d. T is a transformer, from the secondary of which a high-potential current, of 20,000 volts, say, may be obtained. b b are two metal balls, separated from each other about one-quarter inch. When a low-voltage slowly alternating current is sent through the primary of the transformer, the high voltage induced in the secondary of the transformer causes a discharge to pass across the air gap s, and an oscillatory current, that is, a current which, so to speak, swings back and forth in opposite directions like a pendulum, is found to exist in the circuit w (including the insulating space between the plates of the condenser). In the circuit t the current is slowly alternating, while in the circuit w the current is rapidly oscillating.

Several important characteristics of this oscillatory current may be understood by any one not an electrician by considering the water analogue which is illustrated in Fig. 2. Here the arrangement to be described is shown in section. w' w', etc., is a system of iron pipes. C' is an iron box, its dimension perpendicular to the plane of the paper being, say, the same as its width, d'. Dividing this box into two compartments is an elastic rubber partition, P. This partition under pressure may be strained so as to take the position P' or P''. Across the enlarged portion of the pipe, b', is a partition, s'. This partition is likewise supposed to consist of rubber which will yield a trifle under moderate pressure and suddenly break when the pressure becomes great. The piston t' may be moved by the handle h back and forth in the cylinder T'. At the start let the piston have the position a, let s' be intact and P in its normal position. Conceive the whole system, pipe, cylinder and box, completely filled with water, which is a practically incompressible fluid. Now grasp the handle and push the piston toward the right. The water pressure upon the left hand side of the diaphragms P and s' will be decreased and the pressure upon the right hand side will be increased. As the piston approaches nearer to the position a', shown in dotted lines, the elastic diaphragms P and s' will be strained more and more to the left. When the piston has reached a' suppose P to be strained into the position P' and suppose the strain upon s' to have become so great that it very suddenly breaks. The instant s' breaks the pressure is released upon the right hand side of P', and hence the water is forced to move out of the right hand side of the box, through the circuit of pipe w', around into the left hand side of the box. Note that the velocity with which the water flows in the pipe circuit continues to increase until the force urging the water on ceases to act. This force is the elastic reaction of the partition P. The velocity will evidently be greatest when the diaphragm is in its normal position P. Since, however, the water is now in rapid motion it cannot suddenly come to rest, hence it continues to move in the same direction until it has forced the elastic diaphragm into the position P''. The direction of motion of the water is then reversed. It surges back again in the opposite direction; the original motion is then repeated and so on. These back and forth oscillations of the mass of water, however, grow less and less extended, on account of the decay of the motion due to the friction of the water against the sides of the pipe, until after a greater or less time the water comes to rest. Now imagine that a new diaphragm s' is suddenly created and that the piston continues to be moved very slowly back and forth. In whatever direction this piston is moved a pressure must finally be produced on s' which will burst it, and the above series of oscillations of the water be repeated. If the piston continues to move back and forth with a regular motion and the diaphragm s' is magically restored whenever the surging water comes to rest, there will be a continued series of oscillations of a mass of water, which illustrate and obey many of the laws of the oscillations of electricity which occur in the electric circuit illustrated in Fig. 1.

The principal points of similarity between the electric and the water circuits are as follows: The rougher is the interior surface of the water pipe w' the greater will be the friction of the water against this surface and the more rapidly will the oscillations of the water die out. This roughness of the pipe corresponds to the quality of the wire forming the electric circuit, one of the factors which determines its ohmic resistance. The electric oscillations would die out quicker in a circuit made of iron wire than in one made of copper wire. If the ohmic resistance of the electric circuit is greater than a certain amount the oscillations will not exist at all.

The time which it takes for the column of water to make one complete oscillation, that is, for the diaphragm P to move from its position P' to P'' and back again to P', is seen plainly to be dependent upon two circumstances, the mass of water which moves back and forth and the elasticity, as well as the area of the partition P. If the pipes in which the water oscillates are long, the oscillations are necessarily slower than if they are short. The time for a complete oscillation to take place will also be greater when the diaphragm P is very yielding than when it is les so. A stiff diaphragm of small area will urge the water back and forth more quickly than one of large area and very elastic.

In the electric circuit there is something which corresponds to the mass of the water in the water circuit in determining the time which is required for a complete oscillation of the electricity to take place. This something is the medium surrounding the circuit and bears no resemblance to the water except in having inertia. When the electricity is said to flow in the wire more or less of this medium is in motion. The mass of this medium which is in motion when a current of electricity flows depends upon the length of the wire and

the way in which it is coiled up, just as the mass of the water depends upon the length and diameter of the water pipe. The velocity of the motion of the medium is proportional to the strength of the electric current which is said to flow in the wire. This motion of the medium which surrounds the circuit is made manifest in the so-called lines of magnetic force. When a unit quantity of current sets in motion a certain mass of the medium surrounding the electric circuit, the circuit is said to have a certain inductance or coefficient of self induction. This inductance of the circuit then is represented in the water analogue by the mass of the water, and as the period of oscillation of the water is proportional to its mass, so the period of oscillation of the electricity is proportional to the self inductance of the electric circuit. The longer the wire and the more it is coiled up the greater this will be.

In the electric circuit just before the E. M. F. or force which urges electricity into motion becomes great enough to break down the thin air gap between the balls, this being represented by the partition s' in the water analogue, there is a strained condition of the medium between the two condenser plates. This is produced by the E. M. F. acting across the space between these plates just as the water-pressure force acts on the diaphragm P to strain it.

Now a particular thickness of medium or dielectric, as it is called, will be strained out of its normal condition by a certain E. M. F. by an amount which depends upon its nature, the same as a certain thickness of rubber diaphragm will be strained from its normal position under a given water pressure by an amount depending upon its flexibility. The amount of strain produced in both cases will be less the greater is the thickness of the substance strained. Evidently then the nearer the condenser plates are together the greater will

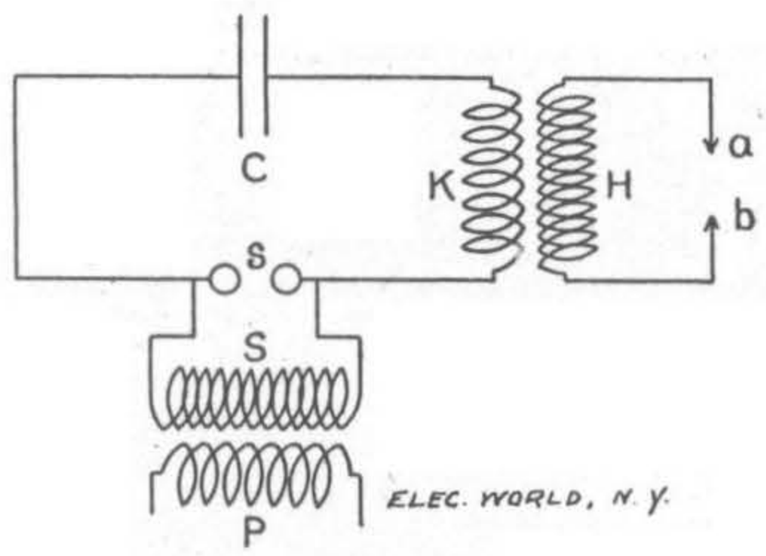

FIG. 3.

the dielectric between the plates be strained or displaced and the greater will be the quantity of electricity which will have been moved across any imaginary plane, as L L. Likewise a greater quantity of water will move across any imaginary plane L' L' under a given pressure when the rubber partition is made more yielding. Note also the important fact that under a given pressure of the piston as large a quantity of water is forced across any imaginary plane l' l' as across any other imaginary plane, as L' L'. In the same way as large a quantity of electricity crosses one section of the circuit as any other. In short, as much electricity moves across the portion of the circuit which is made up of a so-called insulator as moves across any section of the conducting portion.

We may tabulate as follows the conditions which govern alike the oscillations in the water circuit and the electric circuit:

WATER CIRCUIT.	ELECTRIC CIRCUIT.
Roughness of interior of pipe.	Resistance of wire due to quality.
These determine the rate at which the oscillations die out.	
WATER CIRCUIT.	ELECTRIC CIRCUIT.
Mass of water in circuit.	Mass of medium in motion when current flows or self inductance of the circuit.
Flexibility of diaphragm P.	Capacity of electric condenser.
These determine the time during which a complete oscillation occurs.	
WATER CIRCUIT.	ELECTRIC CIRCUIT.
Pressure which piston can produce.	E. M. F. of transformer.
Length of air gap S'.	Strength of partition S

From the above comparisons it is seen that greatness of area of the condenser plates and their nearness together, or in electrical language, greatness of capacity, corresponds to greatness of elasticity and area of the rubber diaphragm, and hence the greater is the capacity of the electric condenser the slower will be the oscillations in the electric circuit. The sudden restorations supposed for the diaphragm s' are actually accomplished in the electric circuit by the inrush of cold non-conducting air as often as the oscillations in the circuit w have died out.

Let a circuit now be arranged as in Fig. 3. This circuit is supposed to be like that of Fig. 1 in all respects, except that at K the wire is wound into a coil or solenoid of eight or ten turns. Another coil of fine wire, H, is supposed to be wound around the coil K. When an oscillatory current now passes through the coil K a current is induced in the coil H. No known mechanical analogue can well illustrate of explain why a varying current of electricity in one circuit will induce or cause a current to flow in a neighboring circuit. Such, however, is the fact, the discovery of which added lustre to the already immortal name of Faraday. What concerns us here is that the force with which the electricity in the coil H is urged forward is, in the case illustrated above, very great. The high E. M. F. which is induced in the coil H is due to the very rapid rate at which its turns are cut by the magnetic lines which are produced by the oscillating current flowing in the coil K. When the circuit in the coil K has its maximum value there is a maximum number of lines of induction in the space about the two coils. When the condenser C is fully charged, and there is no current in the coil K then there are no lines of induction in the field. Now, if the two coils are wound so as to be close together and well insulated from each other, the lines of induction, which come into and go out of the field as the current in K rapidly changes its value and direction must all cut the turns of the coil H. These turns will be cut twice every time the current in the inducing circuit makes a swing in one direction; once as the current rises from zero to its maximum value and once as it again sinks to zero. Since the oscillations of the current take place with enormous rapidity, the turns of H are cut by the magnetic lines of induction with a like rapidity. It is an experimentally determined fact that the E. M. F. set up in a circuit which is being cut by lines of induction is proportional to the number of such lines per second which cut it, or as usually expressed, to the rate of change of induction through the circuit; hence in the circuit which includes the coil H the E. M. F. induced is very great. For example, the E. M. F. induced in H will be sufficient to produce an 8 or even a 10-inch discharge through air between the terminals a and b, when the circuits have approximately the following proportions: From the secondary S, of the transformer T, a sufficient E. M. F. must be obtained to discharge across the discharge gap s when a quarter of an inch long. The condenser C must have a capacity of about one two-hundredth of a microfarad, or a capacity such as would be obtained by stacking up about forty sheets of double thick window glass 10 by 10 inches and thirty-nine sheets of tin or copper. The coil K may have about ten turns of heavy wire and the coil H about 500 turns of fine wire. The current in H, of course, changes its direction with the same frequency as the current in K; that is, some millions of time in a second. The discharge from the coil H is what has been popularly called the Tesla current of high potential and high frequency. It may be remarked here, however, that phenomena of this class have been studied and developed in quite as able a manner by Prof. Elihu Thomson.

Before attempting to explain the effects, uses and practical methods of producing oscillatory currents it may be well to show diagrammatically the various arrangements of circuits which will give rise to such currents.

In Fig. 4 D is a direct current dynamo. The higher the voltage of this dynamo the better, for the effects to be described are increased in proportion to the square of the voltage; 500 volt machines used to operate electric street lines will give powerful effects. C is a condenser made of paper and tinfoil soaked in wax and having a very great capacity. P is a coil of a dozen or more turns, and S is a coil of several thousand turns. K is a device for alternating, allowing the condenser C to be charged by the dynamo, and for closing the circuit through the coil P, so the charged condenser can discharge through the coil. It operates as follows: a a and b b are strips of metal fastened on a cylinder of wood or hard rubber and cross-connected as shown. n' n' n n are four brushes which bear upon the cylinder, and have the relative positions shown in the

diagram. It will be easily seen that if the cylinder is made to rapidly rotate in the direction of the arrow that when the brushes *n n* bear on two conducting pieces the condenser is in circuit with the dynamo and is being charged, and that the coil *P* is out of circuit, and that when the two brushes *n' n'* bear upon conducting pieces the condenser is in circuit with the coil *P*, and that it will then discharge through the coil, the dynamo then being out of circuit with the condenser. When, however, the condenser discharges an oscillation of electricity will take place through the coil *P* in the same way and for the same reason that it did in Fig. 1.

The oscillatory current in *P* will induce an oscillatory current of the same frequency in the coil *S*. If the coil *S* has many turns the current induced in it will be urged forward with a very high E. M. F., so that a long discharge may be obtained between the terminals *p p'*. Since, however, the condenser *C*, for reasons to be explained, must be made very large, the oscillations in the coil *P* will be very much slower than in the case of the circuit of Fig. 1, which is supposed to contain a condenser of small capacity, but charged to such a high degree or potential that it can discharge across an air gap.

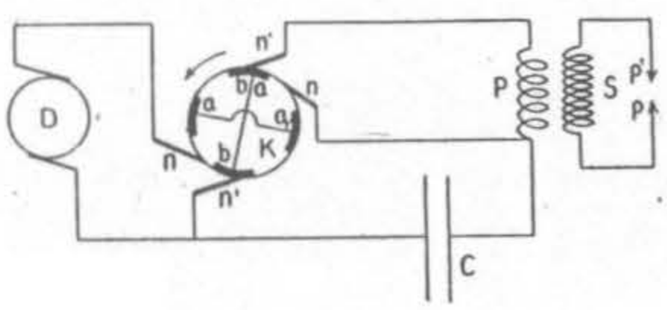

Fig. 4.

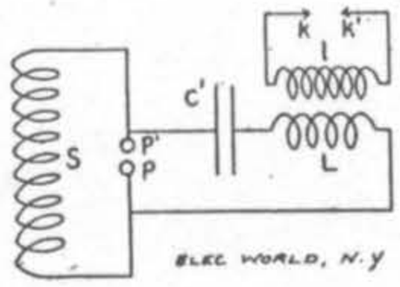

Fig. 5

Since the current swings slowly back and forth through the coil *P*, the rate at which the coil *S* is cut by lines of induction is not very great, and to obtain a high E. M. F. in the coil *S* this coil must have a great many turns of wire. This follows from the well-known principle that the E. M. F. set up in each turn by the inductive action is added to that set up in the other turns. The oscillatory current in the coil *S*, while having a very high potential, or in other words the power to discharge through a considerable length of air, oscillates with comparative slowness. To obtain an extremely rapid oscillation we may modify the circuit as illustrated in Fig. 5.

The terminals of the secondary coil *S* end in two balls, separated from each other about a quarter of an inch. A condenser of small capacity in series with a coil of a half dozen turns is joined to the opposite sides of the discharge gap *p p'*. If *S* then has potential enough to discharge across this gap an oscillatory current of very great frequency will flow in the coil *L*, which, by means of the coil *l*, can be raised or lowered in potential.

The condenser *C*, Fig. 4, must have a very large capacity, for the following reason: The quantity of electricity which any charged condenser contains is proportional to the potential to which it has been charged or to the force, so to speak, with which electricity was forced into it. Referring to Fig. 2 it is evident that the excess of water in the box on one side of the partition *P* over that on the other side will be proportional to the force exerted upon the handle *h* of the piston *t'*. Now this excess of water on one side of the partition *P* corresponds to the quantity of electricity in the condenser *C* of Fig. 1, and the force exerted upon the handle *h* to the potential or E. M. F. of the secondary of the transformer *T* which charges the condenser *C*. Such being the case, if the condenser *C* in Fig. 4 had a small capacity and was only charged by the low E. M. F. of the dynamo *D*, it would contain very little electricity. which, when discharged through the coils *P*, makes a rapid oscillation but produce a current having very little intensity. In short, the condenser *C* would have very little energy stored up in it, and however the relations of the two coils *P* and *S* are adjusted, only a small display of energy could be obtained from the terminals *p p'*. If we attempted to make the discharge between *p p'* long it would be found to be very thin, and if a condenser, *C'*, were connected across its terminals the discharge would be very much shortened, if not eliminated altogether. It can be shown that the energy contained in any condenser is proportional to its capacity and to the square of the potential to which it is charged, so that when working with low potentials very large condensers must be used to obtain effects which exhibit much energy.

Oscillatory Curves and Some of Their Phenomena—II.

BY PROF. E. F. NORTHRUP.

In the circuits shown above the condensers have been considered as consisting of two or more sheets of metal separated a short distance from each other by insulating material. Any such condenser, even when the separate sheets have a small area, will have a capacity large enough to make the oscillations much slower than is desirable for many forms of experiments which may be performed with oscillatory currents. When therefore it is desired to obtain the most rapid oscillations, such as are used for the production of electric waves (about which more will be said later), it will be found convenient to arrange the circuit as indicated in Fig. 6.

Here *S S* are two sheets or spheres of metal; *s* is the discharge gap and *l l* is the wire along which the very rapidly oscillatory currents flow. The two metal sheets, together with the surrounding air, form a condenser in all respects like the condenser in *E*, Fig. 1, except that it has a very much smaller capacity on account of the great distance that the plates are separated from each other and

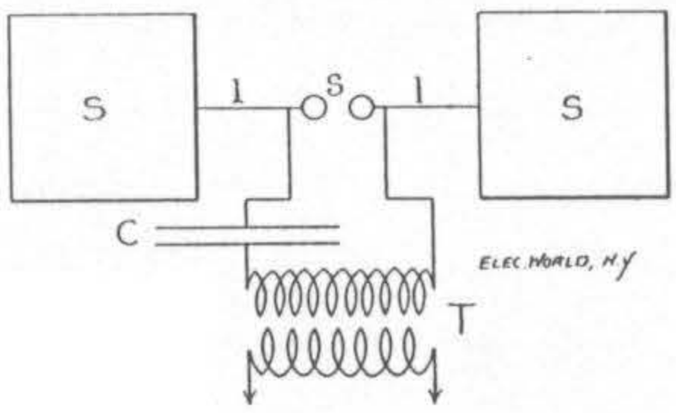

FIG. 6.

from other conducting matter. Another condenser, *C*, is indicated as placed in series with the secondary of the transformer *T*. The importance of this condenser rests on a practical point in the operation of the contrivance, as shown. The author has found that the secondary of a transformer generally gives such a large current that when the air gap *s* breaks down an arc of very low resistance is permanently established across this gap if the condenser *C* is left out, and that no true oscillations take place in the wire *l l*. By inserting a small condenser, as *C*, in the circuit of the secondary of the transformer the current becomes cut down to a low value, while the distance that the spark can jump in the spark gap *s* is not diminished. In this case the arc does not form permanently across *s* and

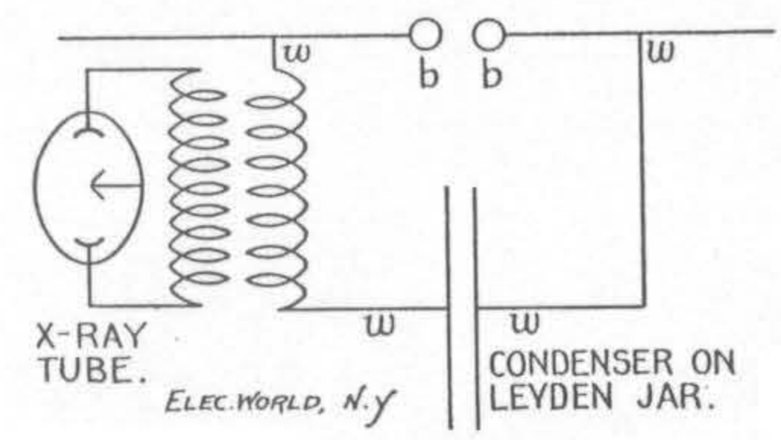

FIG. 8.

good oscillations are obtained. A blower or polished balls or other devices often used to break the arc will then often not be required.

The customary way of exciting oscillations in a circuit like the above is to employ in place of a transformer an induction coil, as shown in Fig. 7. This is the arrangement first used by Hertz in his experiments on electrical waves. An induction coil will not, however, give as good or as powerful effects as a transformer. The chief reason for this is that the induction coil only supplies energy to the circuit in which the oscillations take place, at comparatively long intervals, the discharge from an induction coil not being continuous, as it practically is from a high-potential transformer.

Oscillatory currents may be obtained also from a Holtz or influence machine. Arranging the circuits as in Fig. 8, where *b b* are the terminals of the influence machine, very rapid oscillatory currents of small energy may be obtained in the circuit *W W W W*, but of sufficient power in the case of a large machine to excite vacuum tubes and X-rays. In the case shown the induced current will pass through the vacuum or X-ray tube when the spark passes between *b b*.

I shall now show some devices which ought to give oscillatory currents of great power, although I have never had an opportunity to actually test the matter. I offer the devices as of sufficient interest to be worth testing by experiment.

In Fig. 9 *D* is a direct-current dynamo of any voltage, *I* is a coil of a great many turns of heavy wire wound on an iron core, *c c*. *C* is a condenser, *s* a spark gap between balls about an eighth of an inch apart. *P* is a coil of a few turns of large wire and *f* a coil of fine wire. *K* is a device by means of which two carbons may be made to touch each other and then be drawn quickly apart until the arc which forms on separating them is broken. Now it is well known that when a direct current is passing through a coil wound on an iron core and of a great many turns, that on suddenly breaking the circuit the current which is flowing in the coil tends to keep on flowing in the same direction with such persistency that a spark of considerable length will occur at the point where the circuit is broken. Hence if the carbon points at *K* are brought into contact and a large current flows through *I*, on quickly separating them an arc of low resistance will first form between the points and, when the separation becomes

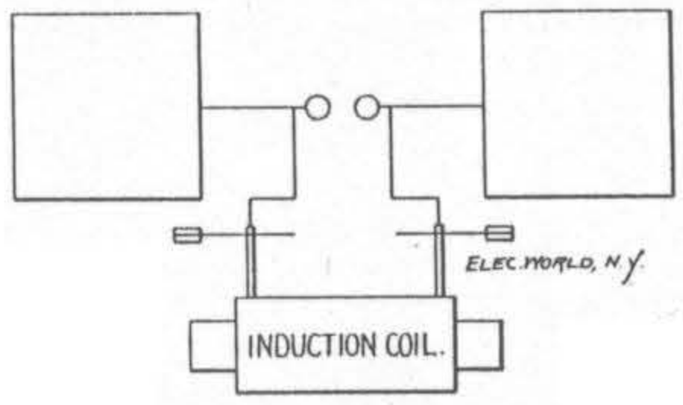

FIG. 7.

great enough, will quite suddenly break. The current in *I* will, however, tend to keep on flowing and as it has no other path to take will flow into the condenser *C*, charging this to a high potential, and, if matters are rightly arranged, this potential may be made great enough to cause a discharge to take place across the air gap *s*. If this occurs the condenser wil discharge through the coil *P* with an oscillatory current which will induce a current in the coil *f*. Thus a long discharge between the terminals *a a* may be obtained. It would be desirable to have the break in the circuit which is supposed to occur at *K* made at a number of different points at once. Devices for accomplishing this anyone can readly design.

In Fig. 10 *A* is an alternating current dynamo, *T* a commercial

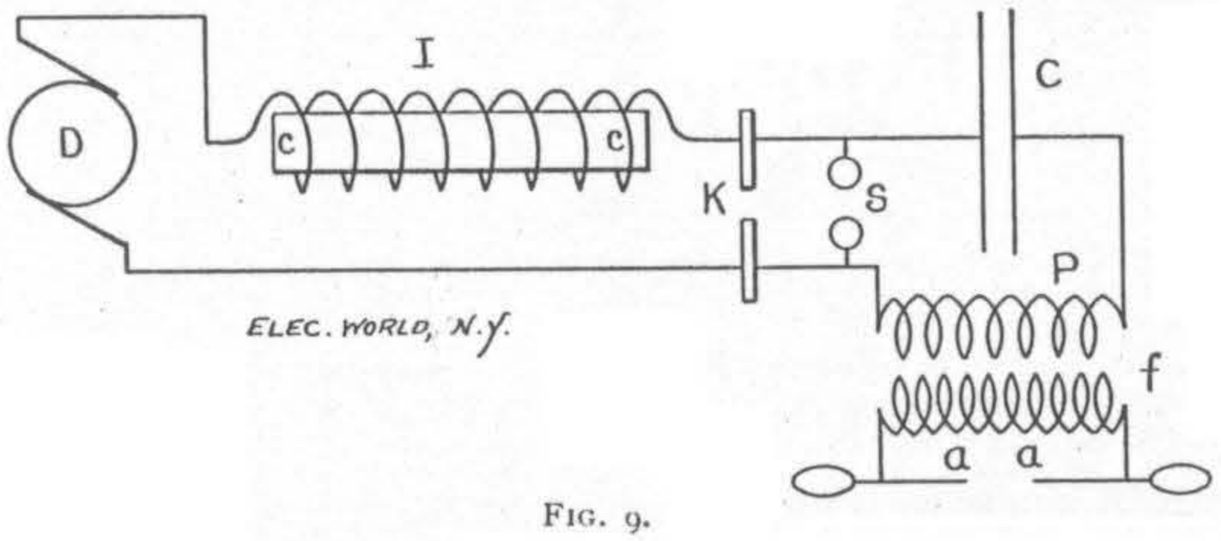

FIG. 9.

transformer which will give across the terminals of its secondary a potential of 100 volts. *L* is a very large coil of wire wound on an iron core, or what would serve the purpose as well, the secondaries of several transformers connected in series. *C* is a condenser of moderate capacity, *P* a coil of a few turns of heavy wire, *f* a coil of fine wire and *s* a spark gap. Suppose that a momentary current flows through the primary of the transformer *T*, then a momentary E. M. F. will act in the secondary of the transformer, tending to start a current flowing through the circuit, including *L*, *C* and *P*. The condenser *C* will be charged to a low potential and will then immediately discharge, causing a weak oscillatory current to circulate in the condenser circuit, Assume now that each time this oscillatory current starts to flow in one direction or the other a new current is sent through the primary of the transformer in such a direction that the E. M. F. induced in the secondary of the transformer helps the current which is already flowing in the secondary along in the same direction. This current will then evidently be increased. If we start a rocking chair rocking and each time it starts to go back in one direction give it a slight push it will be made

by very slight impulses to rock back and forth a great way. If the impulses given to the chair are not rightly timed it will almost be brought to rest. Just so in the above electric circuit. If the oscillatory current has a natural rate of swing back and forth in the circuit and the alternating current through the primary of the transformer changes its direction at the same rate as the oscillatory current naturally swings, the surgings of this latter current will become very great and the condenser *C* will become charged to a very high potential and with a large quantity of electricity. The potential to which the condenser may be charged, by rightly varying the natural period of its circuit until it is the same as the period of the alternating current through the primary of the transformer, may be made fifty times as great as the potential which could be obtained from the secondary of the transformer alone. Or, in other words, the potential

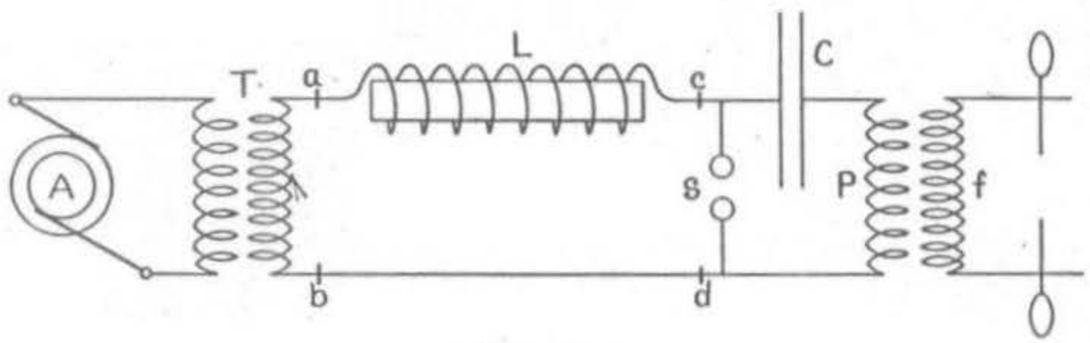

FIG. 10

between the points *c* and *d* may be made fifty times as great as the potential between the points *a* and *b*. If the potential between *a* and *b* is 100 volts the potential between *c* and *d* would be great enough to cause a discharge to take place across the air gap *s*, and this would cause a much more rapid series of oscillations to take place through the coil *P*. These could be used to induce a very high potential in the coil *f*. The circuit may be adjusted to resonance, as it is called, with the alternating E. M. F. in the transformer, by varying the number of turns in the coil *L* or the amount of iron in this coil, the capacity of the condenser, or, where it can be managed, by varying the speed of the alternator *A*.

Oscillatory Currents and Some of Their Phenomena—III.

BY PROF. E. F. NORTHRUP.

PRACTICAL HINTS FOR CONSTRUCTING OSCILLATOR.

The chief and almost the sole difficulty encountered in the construction of efficient oscillatory current apparatus of reasonable size is in obtaining sufficient and permanent insulation. The liking of a high-potential high-frequency current for any path of discharge beside that between the terminals will often drive the experimenter to despair. A few general facts therefore in regard to the subject of insulators and insulation will not be out of place.

As Professor Fessenden has pointed out in a recent paper read before the American Institute of Electrical Engineers and printed in THE ELECTRICAL WORLD April 2, 1898, we may speak of an insulating substance as that which will more or less effectually prevent a slow leakage of the electric current or as a substance which, permitting more or less leakage, will prevent a disruptive or sudden discharge. These two aspects of an insulator may be very prettily illustrated as follows: Provide a glass tube about an inch in diameter with a tight fitting cork for each end. Insert a pointed wire through each cork, so that the two wires will come within the tube and be capable of meeting at its centre. Fill the tube with ordinary water and pull the two ends of the wire a short distance apart. If a high-frequency high-potential current source be attached to the ends of the wires outside the tube, it will be found that the water has considerable insulating power against a disruptive discharge. When the ends of the wires are sufficiently near, however, the discharge will pass through the water, giving a beautiful light. It will be observed, also, that bubbles come off everywhere from the sides of the wire. These show that considerable current is flowing through the water in the ordinary way, while the water is behaving as a highly insulating substance to the disruptive discharge. After the water becomes thoroughly fouled no disruptive discharge can be obtained, the current all passing through the water by electrolysis. The kind of insulation required for oscillatory currents is that which will prevent the disruptive discharge. For reasons to be shown an insulator may have enormous strength for an E. M. F. which acts for only an instant and yet be very weak for the same E. M. F. applied for a considerable time.

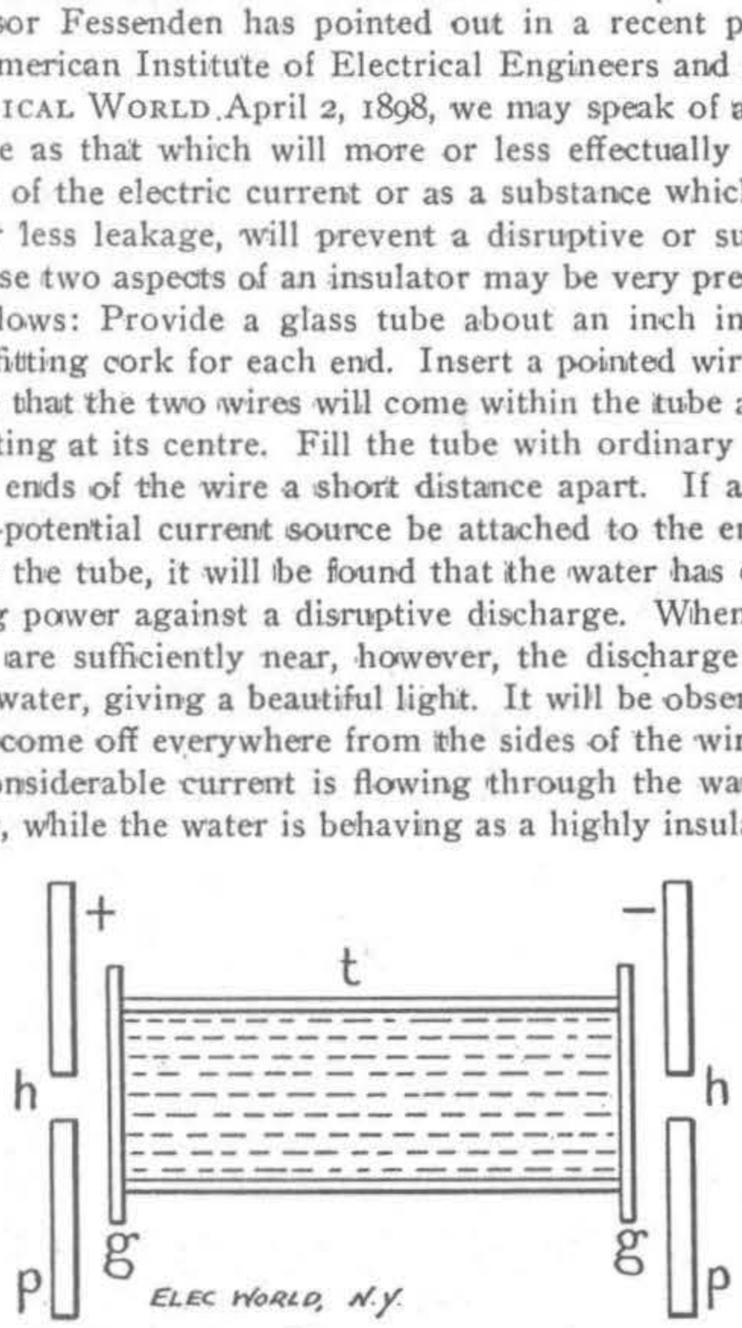

FIG. 11.

An experiment first performed by Faraday will teach us much about insulators. The experiment is illustrated in Fig. 11. *p p* are two circular brass plates with small holes *h h* in their centre. *t* is a tube with glass ends *g g*. Such a tube Faraday filled with carbon bisulphide and a great many short pieces of silk thread. By applying the eye to one of the holes *h h* he could not see through the tube because the short pieces of silk were turned in all directions. When, however, *p p* were given opposite charges of electricity the threads all arranged themselves in line and he obtained clear vision through the tube lengthwise. This shows that the silk is a better conductor of the lines of electric stress than the liquid in the tube. Now assume the silk to be also a poorer insulator than the liquid, and that the difference of potential of the two plates is so great that a discharge is just on the point of taking place between the plates through the liquid alone. At the first instant that the plates are charged the particles, supposedly of weak insulating power, will not be lined up, but after a greater or less time they will become so, when the path for the current to pass through being weakened by this alignment of the particles the discharge will occur. Thus we have one case in which an instantaneously applied E. M. F. would not break down an insulator, while one longer applied of the same value would. The same will hold true in a like measure if the two plates are being alternately charged with electricity of opposite signs. Now there are few oils or other insulating liquids which are perfectly pure and free from foreign particles, and the very effect here described often takes place, especially with high-potential currents of a moderate frequency. I have found oil, which had an instantaneous insulating value for the current from a high-potential transformer several times stronger than air, prove actually weaker than air for a long applied electric pressure. By making the insulator a solid we ought to prevent this polarization of the particles, but, with high-frequency currents, we fall in two other difficulties which are harder still to eliminate.

Almost all solids become conducting when hot, glass, for example, being an excellent conductor when melted.

Now it is a well-known fact that a high-potential high-frequency current will eat its way through the best of solid insulators a distance that it could not begin to penetrate at once, and that, too, when no air is present, the terminals being perfectly imbedded in the solid insulator. My own conception (formed probably by reading Professor Fessenden's article on insulators) of one cause of this will be made plain by referring to Fig. 12. Let *P* and *P'* be two metal plates of indefinite area. Suppose black fibre to be an insulating material between these plates and suppose this to be impure, having particles of some better insulating substance, but of higher specific inductive capacity than the fibre imbedded in it. Let *p*, *m* and *n* be three such particles. If *P* is charged positive and *P'* negative the lines of electric stress, finding an easier passage through these particles, will be bent out of their course somewhat, as shown in the diagram. Since a charge of electricity is nothing but the locus of the ends of such lines of stress, *p*, *m* and *n* will have by induction small apparent charges of electricity upon their ends, as indicated in the diagram. Suppose *m* and *n* are near enough together so that a discharge may pass between their approximated ends. Now if *P* and *P'* are charged to a steady potential, such a discharge between the particles taking

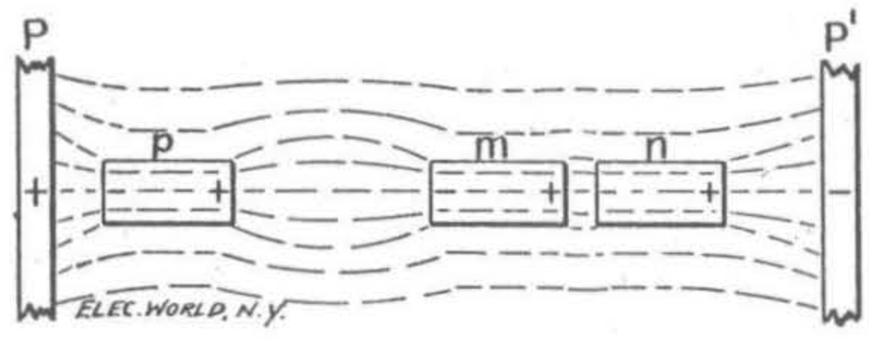

FIG. 12.

place but once might produce no visible effect, but if the two plates are rapidly charged alternately positive and negative by means of an oscillatory E. M. F. the discharges between the particles would be rapidly repeated, and since heat is always the accompaniment of discharge the insulating medium about the particles would become heated and thereby greatly weakened, so that the local discharges in its substance would become more and more numerous, and finally the discharge would find its way directly from plate to plate. Very few solids are so homogeneous that the above effect will be entirely absent. Substances which readily conduct lines of electric stress or, as the term is, have a high inductive capacity are usually very poor insulators for oscillatory currents. High specific inductive capacity may be a quality inherent to the substance itself or merely a result of impurities scattered through the substance. Referring to Fig. 12 we may suppose that the insulating medium between the plates is solid sulphur, which has a small specific inductive capacity, that is, it conducts lines of electric stress only a little better than air does. Suppose now the particles, such as *p*, *m* and *n*, to be of metal and extremely numerous. The lines of electric stress would find an easy passage through these particles and the actual path which they would have to travel through sulphur would be small, hence the sulphur would appear to have a great specific inductive capacity. In this case, however, the apparent specific inductive capacity is obtained at the expense of dielectric strength. It would therefore be folly to use such a contaminated substance as an insulator between the metal plates of a condenser. The apparently high specific inductive capacity of the substance would make the capacity of the condenser great for its size, but only at the expense of insulation. The apparent specific inductive capacity of many substances may be greatly lessened by drying out the moisture which is occluded in the pores.

Aother potent cause of dielectrics or insulators breaking down

under a continued strain of rapidly alternating potentials is what Tesla terms molecular bombardment. To observe this effect fill a box containing a high-frequency high-potential coil with a very viscous insulator, as a mixture of resin and machine oil. Place in the bottom of this box a piece of asbestos or any substance which contains a quantity of air in its pores. On account of the thickness of the insulating compound this air would ordinarily remain permanently entrapped. When, however, the coil is in action the air bubbles are agitated with great violence. They heat the insulator surrounding them and soon work their way to the top of the box through a substance so thick that a stick could hardly be pushed into it. It is useless to try to insulate high-frequency currents with homogeneous solids unless every trace of air can be avoided, for this molecular bombardment, which heats and destroys the insulating property of the solid, will eventually destroy success. Tesla remarks that a solid insulator containing a particle of air will in time be as surely eaten through by the high-frequency discharge as a stone let go will fall to the ground.

I have observed another property of insulators for high-potential high-frequency discharges which is quite remarkable, and which I shall not here attempt to explain, but merely to state the fact as I have observed it, hoping only that some experimenter will investigate the matter thoroughly. A high-frequency coil was constructed with a separation between the primary and the secondary which was calculated as being quite sufficient to prevent breakdown when machine oil was used as the insulator. It was thought that the insulating power of the oil would not be lessened by dissolving pure resin in it. This was accordingly done, the proportions being such that when the mixture became cold it would scarcely flow, but yet was not a solid. This mixture when very hot was poured over the coil, which was immediately set in operation for two hours without a sign of a breakdown. Every particle of air had been expelled, and yet when the coil was tried the following day under exactly similar conditions, except that the insulator had become cold, it broke down in many places between the primary and the secondary coils. This observation leads me to believe that under certain conditions a substance becomes a better insulator as it is made more fluid, though the fluidity is gained by raising the temperature. I may add that tests show that the more fluid oils are much better insulators for high-frequency high-potential currents than the thick oils, kerosene being especially superior.

It is a remarkable fact that while engine and other kinds of oil may be taken as from eighteen to twenty-four times as strong as air for the high-potential high-frequency currents, it can only be taken as about equal to air for the discharge from a high-potential transformer capable of giving an inch discharge through air. (See The Electrical World, April 2, 1897.) Solid dielectrics, such as a mixture of beeswax one part and resin three parts, or resin softened a little by a small portion of engine oil, hold up the high-potential slowly alternating E. M. F. of a high-potential transformer much better than oil, while the reverse holds true with high-frequency E. M. Fs.

Micanite is the best all around solid dielectric to employ where it can be used with slowly alternating E. M. Fs. that I have found. A sheet 1-1000-inch thick will hold up about 1000 volts if it does not become heated. The best solid dielectric for slowly alternating E. M. Fs., which can be melted and poured over the parts of the apparatus, is resin with a very small portion of a good quality of engine oil melted with it and thoroughly stirred in. Paraffin that has been heated a long time is also very good. For the high-frequency currents I would recommend after much experimenting a good quality of clear, well-strained engine oil, and that it should be heated quite hot before being poured over the apparatus. Oil is the only insulator for these currents which can be counted as safe for all time. As a rule it is advisable to avoid the use of substances which have a high specific inductive capacity. A 5-inch high-frequency discharge will quickly eat a hole through an eighth of an inch of glass.

I will now give a somewhat detailed account of how to construct the separate parts of a high-frequency apparatus which will run on a 104 or a 52-volt alternating-current city circuit, and be capable of giving a copious high-frequency discharge 8 inches long. The apparatus will be especially designed with a view to exciting X-ray tubes.

It is often customary to use an ordinary induction coil for the high-potential transformer. If such is used the condenser is cut out of circuit and the primary of the coil connected through an inductive resistance to the alternating current mains of the lighting circuit. An induction coil, since it has an open magnetic circuit, is an extremely inefficient form of transformer to employ. There is moreover a very important reason why it is desirable to employ a transformer of high efficiency. When resistance is thrown in circuit with the primary of the induction coil the effect on the discharge across the gap in the circuit of the condenser is merely to shorten it. The high frequency discharge is likewise shortened, but is of the same thickness or quantity. If, however, the transformer is of an efficient type, adding inductive resistance to the primary has the curious effect of causing the discharges in the condenser circuit across the gap to take place less frequently and the high frequency discharge, while remaining of the same length, is much thinner, and, by a proper adjustment of the inductive resistance and of the length of the spark gap in the condenser circuit, the high frequency discharge may be made to assume the appearance of a discharge from a Holtz machine or to become so fine and threadlike as to be scarcely visible. This ability to adjust the thickness of the high frequency discharge without changing its length has great value in working with X-ray tubes.

In Fig. 13 is shown a design of an efficient form of a high-potential transformer, which experience has shown to be admirably adapted to the work for which it is intended. Consideration has been given to cheapness and ease of construction. The secondary requires but 3 pounds of double silk covered No. 32 wire. It is intended to be used on an alternating circuit of about 125 alternations

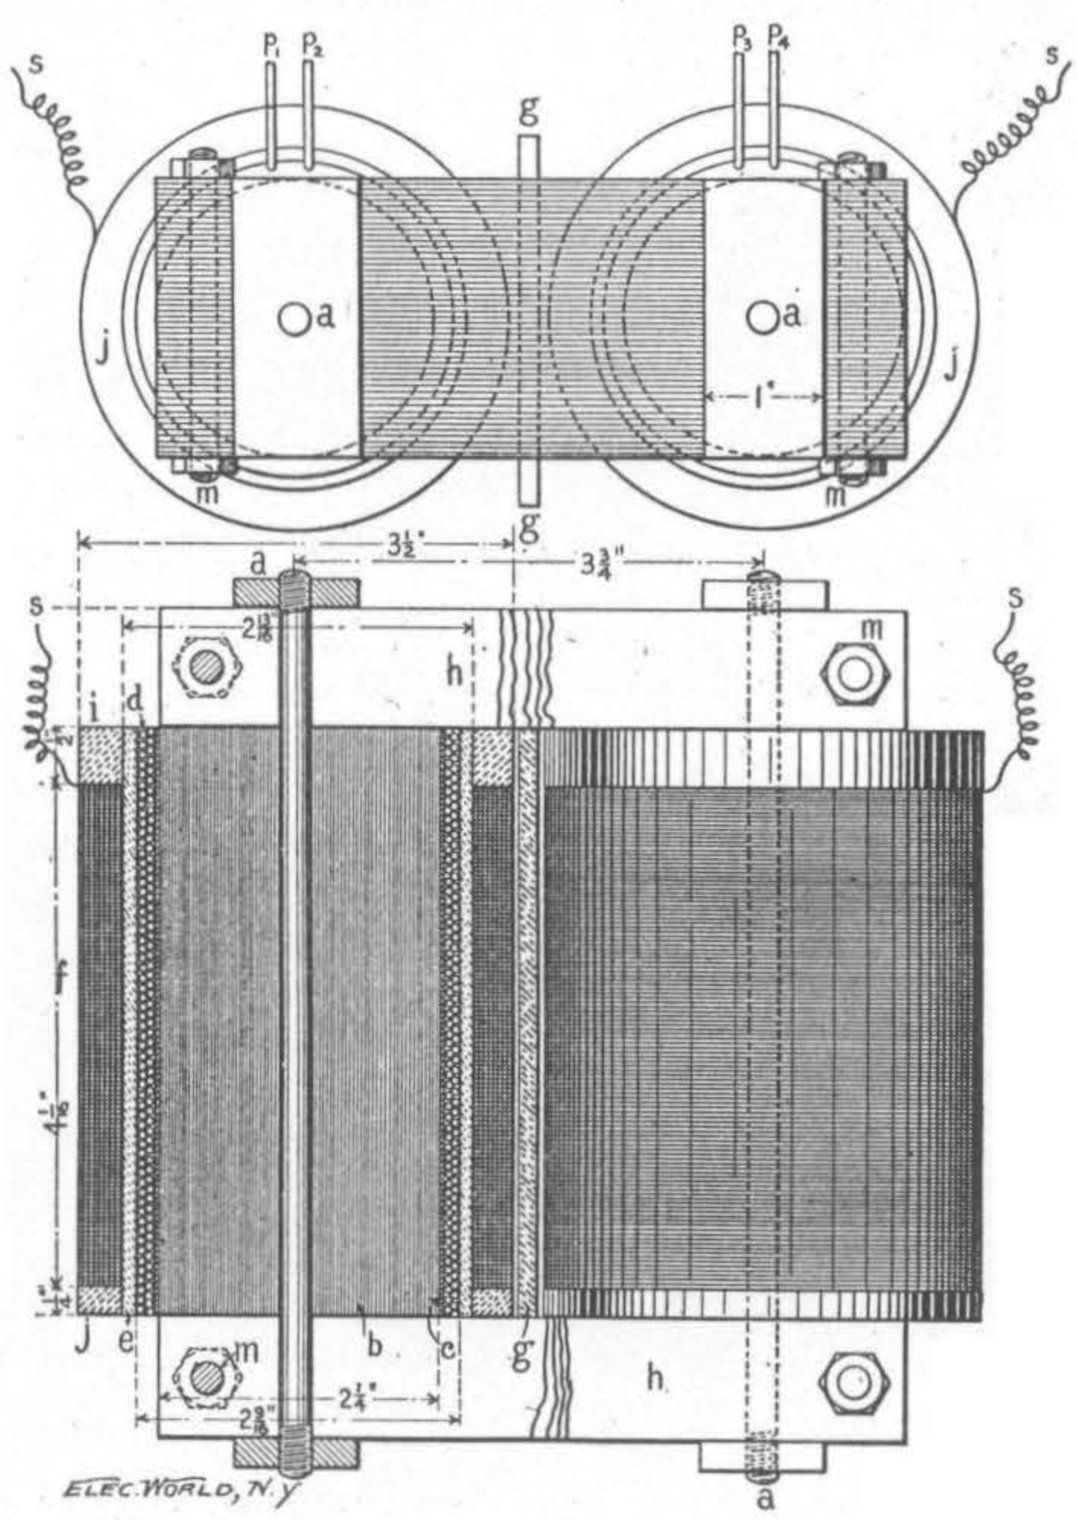

Fig. 13.

A = plan, *B* = section of elevation.

a a = bolts, *b b* = iron cores of No. 16 soft annealed wire.

c c = paper insulation $\frac{1}{32}$ of an inch thick.

d d = space for primary winding. This consists of 115 turns on each half of transformer, of No. 15 magnet wire wound in two layers.

e e = micanite tubes ⅛ of an inch thick to insulate secondary windings from primary.

f f = space for secondary windings which are wound in 26 sections for each side, 52 sections in all. Sections $\frac{3}{32}$ of an inch thick, $\frac{1}{16}$ of an inch of fiber insulation between each section. Depth of secondary winding may be increased if greater E. M. F. is required. Use double silk-covered No. 32 wire.

g = glass plate to prevent a discharge between the two halves of the transformer.

h h = iron yokes to complete magnetic circuit. These yokes should be built up of iron strips one inch wide and not over $\frac{1}{16}$ of an inch thick and bolted together with bolts *m m*.

i i = red fibre or micanite rings.

j j = red fibre or micanite rings.

p_1 p_2 p_3 p_4 = ends of primary windings, which may be connected in series or multiple.

s s = ends of secondary winding.

per second. By connecting the primary coils in series or in parallel it may be used on 104 or on 52 volts. An inductive resistance should be constructed to be connected in circuit with the primary of the transformer. If the condenser with which the transformer is used has the capacity of the one to be described the inductive resistance should consist of a closed magnetic circuit having two square inches of cross section of iron and 200 turns of No. 12 wire so arranged that more or less of the turns may be thrown in or out of circuit according to the voltage of the supply circuit and to the thickness of the high-frequency discharge which is required. The construction of the transformer will be plain from the description printed below the diagram. Since for insulating these high potential low frequency potentials micanite gives the best results of any thing which I have tried, it is worthy of remark that the firms which

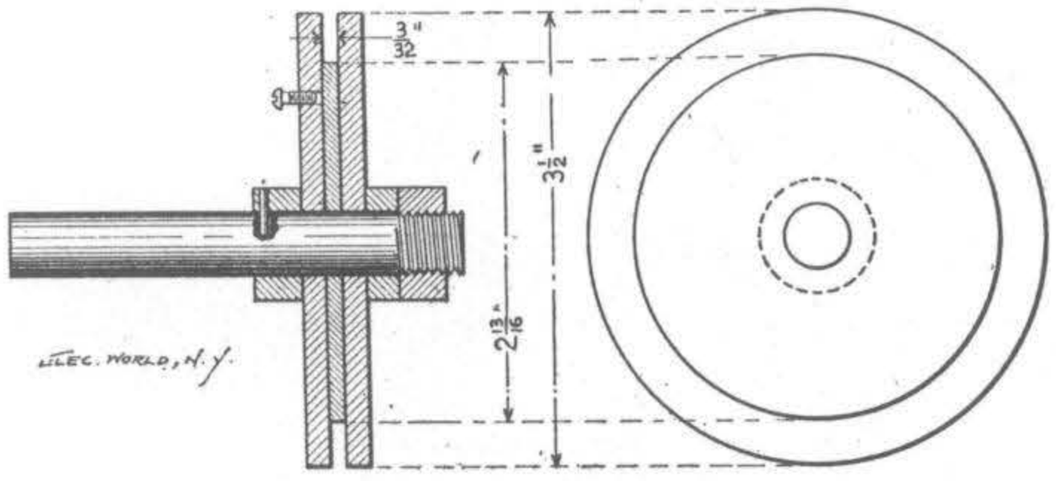

FIG. 14.

manufacture it will furnish it in most any conceivable form. It may also be remarked that black fibre should never be used, as it is useless as a high insulator. The red is much better, but is far inferior to micanite.

It is absolutely essential that the secondary of the transformer be wound in a large number of sections, and that these be thoroughly insulated from each other. The sections may be conveniently wound on a form like that shown in Fig. 14. The wire as it is being wound upon the form should run through a hot wax compound so that the coils will hold together when taken out of the form. Beeswax one part and resin four parts makes a very suitable wax. If the form is well oiled before the wire is wound upon it the coils will readily come off the form. The sections may be insulated from each other by rings of red fibre, one-sixteenth of an inch thick. The spark length of the transformer is about double when the condenser is placed in parallel with the gap. Three-eighths of an inch with the condenser connected in is sufficient for all practical purposes. If, however, a greater E. M. F. is required the sections may be wound a little deeper than those indicated in Fig. 13.

It is generally supposed that to obtain first-class oscillations and hence a smooth secondary discharge that the discharge across the gap in the condenser circuit must be blown out by a strong air blast or in some way mechanically interrupted. If, however, the capacity of the condenser is correctly proportioned to the transformer and a double discharge gap is employed the discharge will be automatically interrupted, and the oscillations will be as perfect without as with artificial interrupters.

A good condenser to go with the above transformer may be made as follows: Select about thirty sheets of a good quality of double thick window glass and examine these for flaws, casting out all defective sheets. For an eighth-inch discharge apparatus a suitable size for these sheets is 15 x 8½ inches x ⅛-inch thick. Very thin sheet copper or brass makes the best conducting material to use between these plates. The margin of glass between the edge of the copper and the edge of the glass along the sides of the plates should be one-half inch and the margin at the end of the plates should be 1 inch. At the other end the metal sheet may project one-half inch beyond the glass. Prepare a mixture of resin and oil by melting the resin and stirring into it a small quantity of engine oil. The proportions should be such that when the mixture is quite cold it will be hard, but not brittle like pure resin. Now dip one at a time all the metal sheets in the hot mixture so as to give them an even coating of the compound, and stack up the condenser. Hold the condenser plates in place with a light framework of wood. Place the condenser in an iron pan a little larger than the plates and about 5 inches deep. Fill the pan with the melted resin and oil and keep the whole hotter than boiling water for an hour or so, and press upon the condenser plates from time to time so as to expel as far as possible all air from between the glass plates.

When the air has been removed take the pan off the fire and allow the contents to become quite cold. Then by heating the pan on the outside with a gas flame the condenser will slide out as a solid cake. With a chisel the superfluous wax and the wooden frame are easily removed. The ends of the metal sheets which project beyond the ends of the glass plates may now be bent over flat and soldered together. Such a condenser will withstand potential difference which will give an inch discharge through air, and will show no brush discharge or glow in the dark. A still better condenser may be made of micanite sheets, each about one-thirty-second of an inch thick. The condenser made of this material should be stacked up and then placed in an oven till the micanite is softened and then be placed in a letter press and compressed while cooling. The only drawback to micanite is its expense. If it is intended to have the condenser in the same box with the high-frequency coil, which necessarily contains oil, no other insulation than the glass and oil is needed. Dry condensers like the above are, however, very convenient where the parts of the apparatus are in separate boxes, the box containing the high-frequency coil alone requiring oil.

The high-frequency transformer may be made in a great variety of ways. From theoretical considerations and after much experimenting I have arrived at the form shown in Fig. 15 as at the same time the most efficient and the easiest to construct. It can be shown that the potential obtainable at the terminals of the secondary or the length of discharge is practically independent of the number of turns in the primary coil, provided it has one turn and the total resistance (ohmic) of the primary coil is kept constant. The length

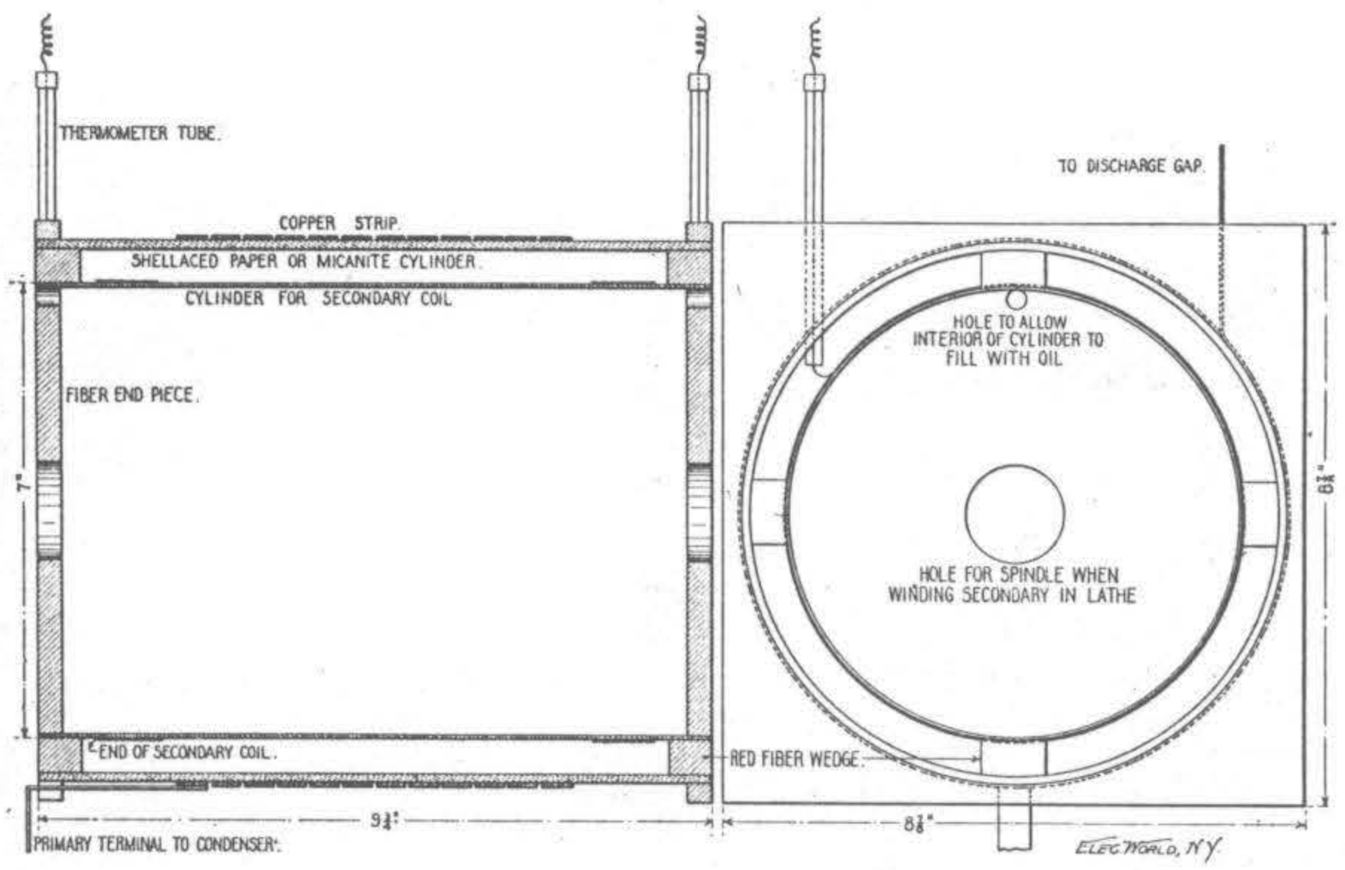

FIG. 15.

of discharge is proportional among other things to the number of turns per unit of length of the secondary coil, the length of this coil, and to its diameter. Experience shows that the secondary coil cannot be wound upon a solid cylinder of wood without greatly cutting down the spark length. In Fig. 15 the secondary coil is shown wound upon a cylinder made of thoroughly shellacked paper, or better still, upon a cylinder of micanite. No. 34 or 32 double silk covered, or even single silk covered copper wire is used for the secondary and is wound upon the cylinder sixty-four turns to the inch by means of a screw cutting lathe. After the wire is wound smoothly upon the cylinder it is covered with a thick coating of shellac poured over it. It is also well, while winding the wire on the cylinder, to have it run through shellac. Care must be exercised not to have any of the turns overlap each other. The primary is wound upon a larger cylinder, as shown in the diagram. The most advantageous material to employ is insulated copper strip such as is used in winding some kinds of dynamos. Strip about three-eighths of an inch wide and three sixty-fourths of an inch thick, triple cotton covered, is what I have used to advantage.

Since, however, most of the resistance of the circuit is encountered at the discharge gap most any kind of coper wire will answer for the primary. The turns should come nearly together and the completed coil should have about two-thirds the length of the secondary coil. The inside cylinder upon which the secondary is wound has a disc of hard wood or red fibre fitted into each end, and the ends of the outside cylinder fit into circular holes cut in square pieces of fibre, as shown in the diagram. The cylinder for the secondary is held centrally in the outside cylinder by fibre wedges so that it can be removed if required. The secondary terminals are brought up through thermometer tubing, as shown in the figure. It is almost needless to remark that no nails or metal should be used in the construction of this part of the apparatus. When the high-frequency transformer is placed in a box and covered with a good quality of engine oil a continuous 9-inch discharge may pass between the terminals without any danger of breakdown. If, however, any solid wax compound is used as an insulator, though it may hold up for a time, sooner or later the discharge will eat its way through the insulation and cause a breakdown. Unless the apparatus is made on an excessively large scale for the length of discharge to be obtained it is my belief that oil is the only insulator that can be *permanently* depended upon. Paraffin does not dissolve in engine oil and a box can be made oil tight by pouring into it boiling hot paraffin until the pores and cracks of the wood are well filled. If one is constructing a high-frequency apparatus for experimental purposes it is well to put the different parts of the apparatus in separate boxes. Only the box containing the high-frequency transformer need be filled with oil. If, however, it is desired to have all the parts of the apparatus in one box complete the best

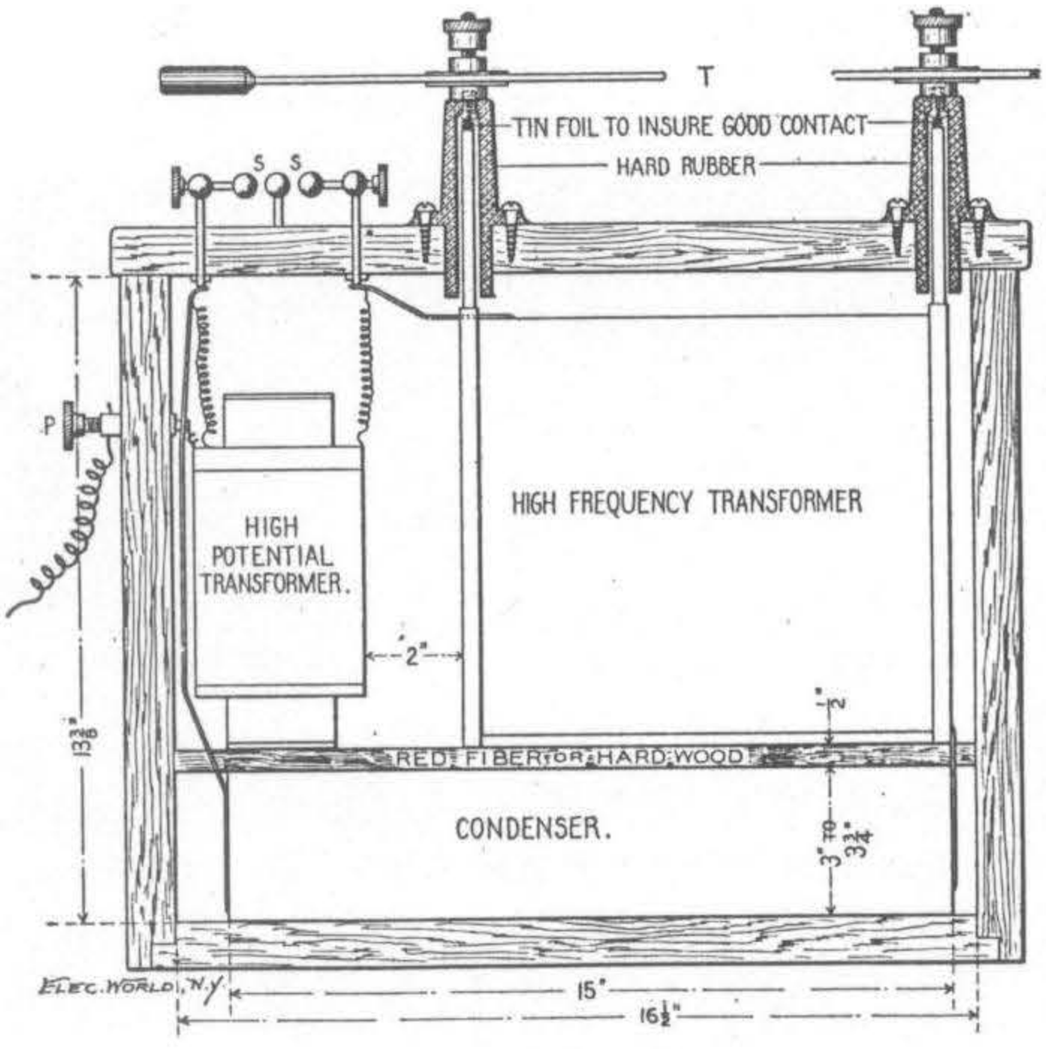

Fig. 16.

relative positions for the different parts of the apparatus and the necessary size of box to use so as to get the required insulation is shown in Fig. 16. The discharge across the gap *s s* is very noisy and it is an advantage to enclose this gap in a small box. This will greatly deaden the noise. The box must not be too small or it will get very hot from the heat generated at the discharge gap.

The large box may be filled to a level with the top of the condenser with melted resin and then filled the rest of the way with engine oil. The cover can be fitted on the top of the box, so as to be oil tight by laying a strip of asbestos soaked in paraffin on the top edge of the box and screwing the cover down tight while the asbestos strip is still hot. A vent hole must be left in the top of the box. When the terminal farthest from the transformer is connected to earth there is a great tendency for a discharge to take place to the iron of the transformer and to the binding post *p*. It is this which necessitates the separation of 2 inches between the high potential and the high-frequency transformer.

Oscillatory Currents and Some of Their Phenomena—IV.

BY PROF. E. F. NORTHRUP.

The high frequency apparatus, described above, is unquestionably the most powerful type of apparatus for the production of the X-rays. It has advantages over all other types of apparatus, such as induction coils and friction or Holtz machines, in giving a discharge of great quantity, which is practically continuous. Furthermore, the thickness of the discharge admits of being regulated through a wide range, the length of the discharge remaining unaltered.

With high-frequency currents produced, as described above, to excite the X-rays, the limit as to the quantity of rays which can be obtained is determined solely by the construction of the tube. A tube of any particular construction when exhausted for the production of X-rays is capable of dissipating only a certain maximum amount of energy. If more energy in the form of a discharge of greater quantity is sent through the tube the platinum upon which the cathode rays strike, as well as the walls of the tube, becomes dangerously hot. Obviously, if the high-frequency apparatus has sufficient power to furnish the largest and strongest tube upon the market with the maximum amount of energy which it is capable of taking, and this power can be controlled so that it may be diminished to an amount which smaller tubes require, then the apparatus is suited to every range and variety of X-ray work.

The apparatus described above will do all this.

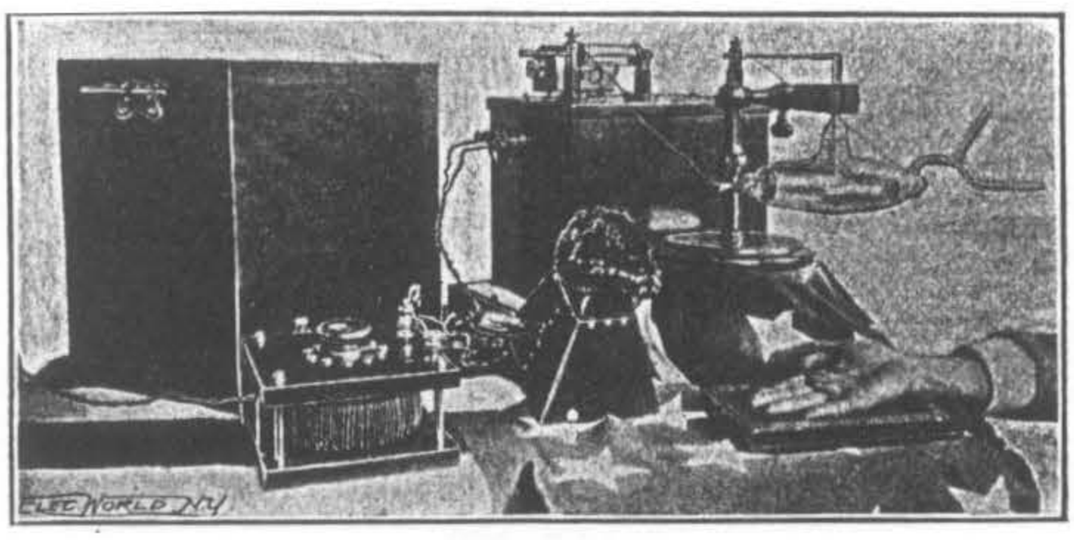

FIG. 17.

The X-rays are now known to be non-homogeneous; that is, as the exhaustion of the tube proceeds new rays are given off which have greater penetrative power than the rays which first make their appearance when the vacuum is lower. For obtaining the most penetrative rays, with which to view the ribs, the hip joint, etc., the vacuum should be very high. If, however, the exhaustion is carried too far the discharge will prefer the path around the glass outside the tube to the path through the tube. If then the distance between the terminals of the tube is, say, 9 inches, there is no object in having a machine to excite the tube which will give a discharge greater than 9 inches. In point of fact the discharge length need not be more than two-thirds of the distance between the terminals of the tube, because the discharge will run a greater distance over the surface of glass than it will through air. A Thompson double focus tube which has the distance between its terminals about 9 inches will be excited by an apparatus giving a 6-inch discharge of large quantity to its utmost limit.

The 8-inch discharge apparatus, described above, if intended only for X-ray work is, therefore, larger than will be required, although on account of the perfect manner in which the discharge may be regulated it will serve well for this work. If the apparatus is intended solely for X-ray work and it is desirable to have it portable, it may be considerably reduced in size over the one described above. Fig. 17 shows an apparatus made by the author which is intended only for producing X-rays and constructed so as to be portable. The picture shows the apparatus with its various auxiliary parts set up ready for taking an X-ray photograph. The box shown on the left of the picture is the case which is used for protection to the apparatus and for transporting it about. The entire outfit, including the variable inductive resistance and case, weighs 147 pounds. The apparatus is constructed essentially like the one described. The discharge gap of the condenser circuit is enclosed in a small box made of blackened brass on the sides and slate ends. Windows in this box allow the double discharge gap to be seen. The tube which appears on the front of the top of the box is to make the discharge through a series gap, which it is sometimes desirable to have in circuit with the tube, noiseless. The inside dimensions of the box are 12 x 8 x 12 inches deep. The transformer is made like the one described above. The condenser is made of thirty plates of glass, 7½ x 11 inches, and twenty-nine thin sheets of copper. The high-frequency transformer is made 6¾ inches long over all. The inside cylinder, on which the secondary of No. 34 wire is wound, sixty-four turns to the inch, is 5¾ inches in diameter. The outside cylinder, on which the primary of ten turns of copper strip is wound, is 6⅝ inches in diameter. The condenser would have been better if made of fourteen sheets of micanite one-thirty second of an inch thick. On 104 volts when the apparatus is giving its thickest discharge it takes less than five amperes. As the discharge is made thinner and more threadlike by adding inductive resistance in the primary circuit the amount of current required is much less. When the discharge has its maximum thickness it will heat the platinum radiant of a Thompson double focus tube white hot in five seconds.

By putting considerable resistance in the circuit of the primary of the high-potential transformer and increasing the length of the discharge gap enclosed in the small box till the discharge will just be able to pass, the high-frequency discharge may be made to simulate

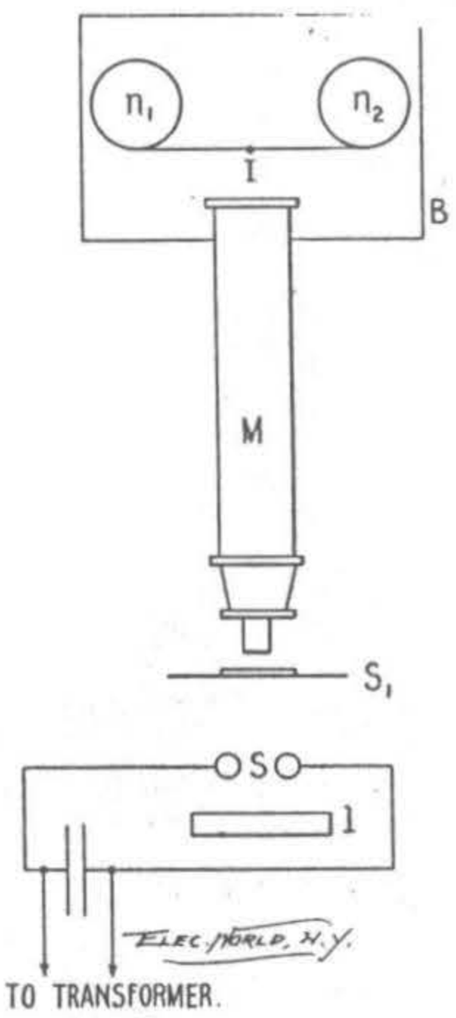

FIG. 21.

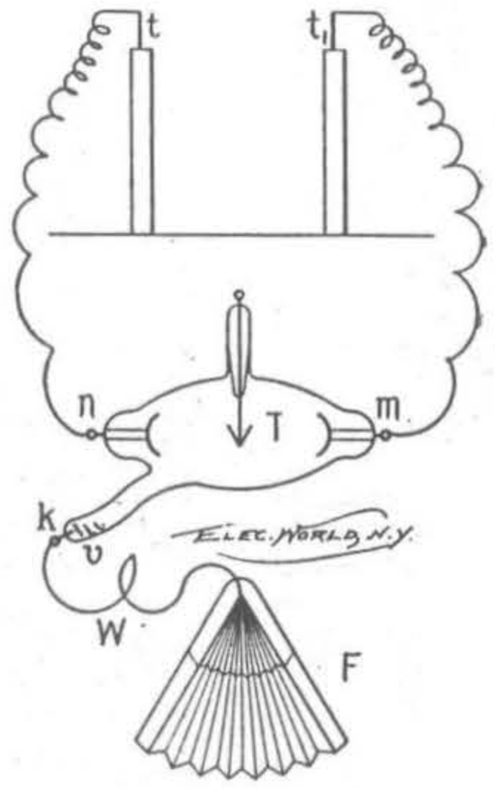

FIG. 18.

so perfectly the discharge from a friction machine that the eye can detect no difference. Now if the transformer had been made like an induction coil and the condenser had been of very much smaller capacity the discharge across the gap in the condenser circuit would have been of the nature of an arc and the high-frequency discharge could not have been obtained without suddenly interrupting this arc by an air blast or in some other mechanical way. I dwell upon this point, since it seems to be the universal notion that the most perfect form of high-frequency discharge can only be obtained by an artificial interruption of the discharge across the gap in the condenser circuit.

Though a discharge through air of 5 inches means a potential difference of about 250,000 volts the physiological effects of the high-frequency discharge are very mild. With an apparatus like the above, having a large condenser, the shock felt by taking hold of both terminals is quite severe, but not at all dangerous to even the life of a cat, as was determined by experiment. If one presents his hand to one terminal, the discharge will go between one-fourth and one-third of the total discharge length between the terminals to reach it, but with the exception of a very slight burn, is not felt. If a piece of metal is held in the hand and presented to the terminal no sensation whatever is noticed. A very severe but probably not fatal shock would be experienced if the current in the primary of the high-frequency transformer were to be passed through the body. It is therefore advisable never to attempt to adjust the discharge gap in this circuit while the machine is in operation.

The limits of this article will not permit of a description of the many striking experiments which can be performed with the high-frequency and high-potential currents. Only a few simple and

easily obtained effects may be mentioned, leaving the reader to pursue this fascinating subject by reading the lectures of Tesla and by his own experimenting.

The chief peculiarity of the high-frequency discharge is its ability to pass to an insulated object from one terminal.

Set the coil working and hold a small piece of metal suspended on a thread within an inch or two of one of the terminals. A fine thread-like discharge will pass to the metal, though this be no larger than a small nail. If the piece of metal is increased in size the thickness of the discharge which passes to it is much increased. Decreasing the distance between the terminals of the coil decreases the discharge to the piece of metal and the distance which it will pass. Thus the discharge to the insulated piece of metal depends for its strength upon the size of the metal piece and upon the air resistance which the discharge between the terminals of the coil has to pass through. This action of the high-frequency discharge finds an important application in regulating the vacuum of X-ray tubes. In Fig. 18 *t t* are the terminals of the high-frequency apparatus, to which the tube *T* is connected. The tube has a projection *v*, in the end of which is some caustic potash and a terminal *k*. *F* is an ordinary paper fan covered with tinfoil to make its surface conducting. *F* is attached by a small wire to *k*. If the vacuum of the tube is very low the potential of the points *n* and *k* is nearly that of the earth, and very little current will flow through the wire *W*. If, however, the vacuum of the tube becomes very high the potential of the points *n* and *k* reaches very high positive and negative values, the changes from positive to negative values occurring with great rapidity. In consequence of this the fan *F* is charged positive and negative alternately with a like rapidity, and a feeble current flows in the wire *W* and through the potash in the neck *v*. This current heats the potash and causes it to give off some of the moisture which is absorbed in it and the vacuum is thereby lowered. The amount of current in the wire *W* can be controlled by closing up the fan, thereby diminishing its surface. Thus by regulating the surface of the fan the vacuum of the tube may be maintained at a point best suited for the production of X-rays. An arrangement of this character will only operate with a high-frequency apparatus.

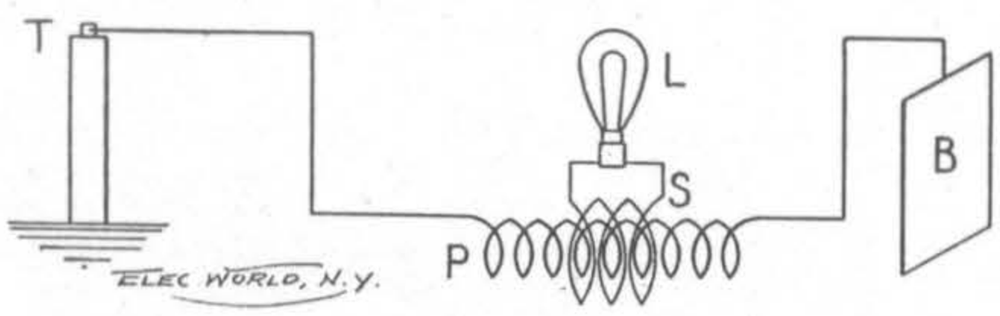

FIG. 19.

Connect a fine wire to each terminal of the high-frequency apparatus. Lead these wires to an insulating support about 10 feet away and adjust the wires so that they are parallel to one another and about 6 inches apart. The current being turned on a beautiful purple sheet of light will fill the space between the wires. In this and other light experiments the room should be darkened to observe the effects at their best. With a powerful apparatus a square metre or more of space may be covered with this purple sheet of electric flame. The effect may be varied by causing a cylinder of light to form between two circular discs of metal connected to the coil with short leads and made to face each other at a distance of a foot or 18 inches apart.

Take a plate of thick glass and paste on opposite sides of it two circular pieces of tinfoil about as large around as a dollar and connect one to one terminal of the machine and the other to the other terminal. The discharge will spread out in streamers some distance over the surface of the glass surrounding the tinfoil discs with a brilliant sheet of light. The high-frequency discharge will not puncture an ordinary window pane at once, but if the two terminals are placed on opposite sides of the pane the discharge spreading out over the surface of the glass will after a short time heat it, when, the glass becoming conducting, the discharge will pass through. The glass shows no hole, but only a spot where it has been melted and again solidified. A 10-inch discharge will in this way eat its way through a cake of paraffin 2 inches thick. If the discharge is passed through a capillary tube the tube becomes brilliantly lighted. If any kind of a vacuum tube is presented to only one terminal of the coil it is quite brightly illuminated. The illumination is much increased by hanging a piece of tinfoil on the free end of the tube. By touching any point of the tube with the finger the illumination of that spot is increased. An incandescent lamp may have its filament brought to incandescence by using only one terminal of the coil in the manner illustrated in Fig. 19. *T* is the terminal of the coil, to which a plate *B* is attached. *P* is a coil of fine wire and around this is wound a coil of a few turns of coarse wire, the ends of which are connected to the lamp *L*. This experiment may be modified in a variety of ways. But the reader who cares to pursue this side of the subject must be referred to Tesla's lectures.

Perhaps of all the striking phenomena of oscillatory currents the most remarkable are the phonomena of impedance which these currents exhibit. To show these arrange matters as shown in Fig. 20. Here *T* is a high-potential transformer, like the one described above. *C* is a condenser, preferably of small capacity. *s* is a double discharge gap, *w* is a heavy copper wire, *l l* are incandescent lamps of high resistance and l_1 l_1 are lamps of lower resistance. When the transformer is working discharges will take place across the air gap *s*, and the high-resistance lamps *l l* will burn more brightly than the lamps of lower resistance, l_1 l_1. These lamps burn in spite of the fact that they are short circuited by the heavy wire *w*. If the lamps are dispensed with and the points p_1 p_1 of the circuit are approached to within a small fraction of an inch of each other while the rest of the circuit to the right of these points forms a loop of some size a discharge will pass between the approximated points of the circuit, which indicates a potential difference between these points of several hundred volts. The wire *w*, which would offer scarcely any resistance to the passage of a direct current, impedes these oscillatory currents as if it were of dry wood.

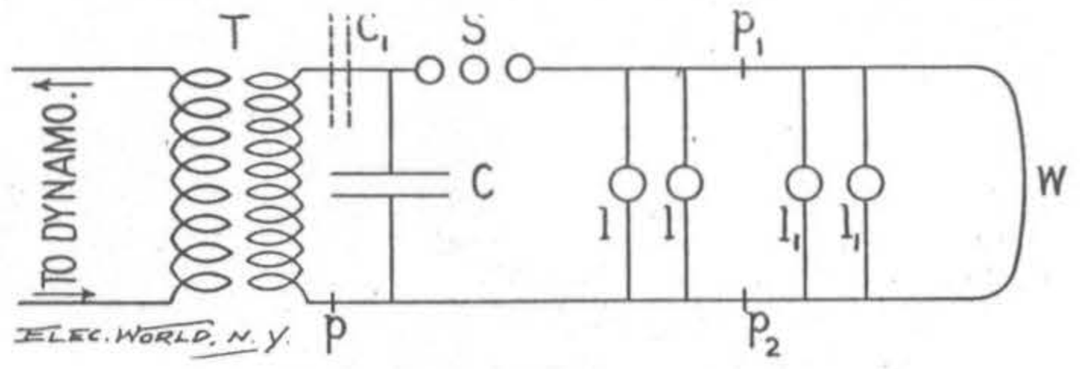

FIG. 20.

These impedance phenomena increase with the frequency of the oscillations, which must be made very great by making the condenser *C* of small capacity and the circuit of wire short. A Leyden jar will answer very well for the condenser and an induction coil may be used for the transformer. In this case, however, a continuous arc is apt to occur at the discharge gap, and as the resistance of an arc is small the condenser will not be highly charged and the oscillations will be poor. This difficulty may be overcome either by blowing out the arc with a moderate blast of air or sometimes by inserting another condenser, C_1 (shown in dotted line), in the circuit. This condenser should have a little greater capacity than the condenser *C*. In this way *C* can become charged to its full capacity while C_1 holds back the current from the transformer so that a flaming arc cannot occur across the discharge gap. In this and other experiments on the oscillatory discharge it is desirable to arrange matters so that the condenser in the circuit carrying the oscillatory discharge is supplied with electricity from the transformer more slowly than it empties itself of its charge when the air of the discharge gap breaks down. In this case the low-resistance arc at the gap is automatically broken. It is hard, however, to say just what conditions are required to produce the best oscillations in any particular case without blowing out the arc. This would be a very useful matter to experiment upon till the principles are determined clearly which govern the automatic interruption of the arc. It may be that adding a suitable ohmic or inductive resistance at the point *P*, Fig. 20, would serve the same purpose as the condenser C_1.

No mention has been made of the use of iron in the coils to increase the inductive action between a primary and a secondary circuit. A simple experiment will show why iron cannot with advantage be used. Take a glass tube and wind on it a few turns of wire and send through this wire, which will correspond to the primary of the high-frequency transformer, an oscillatory current. If now a fine iron wire is inserted in the tube it will in a few seconds become too hot to handle. A large number of wires put in the tube will also become very hot, but not so quickly as one. This

heating of the wires is probably due not only to hysteresis or molecular friction, which resists the rapid reversals of the magnetization, but also to currents which are induced in the metal. Heating of the iron represents a great loss of energy and as the inductive effects can be obtained without it nothing is to be gained by its use.

If the circuits are arranged like that shown in Fig. 1, the condenser being made of about fifteen glass plates a foot square, and the wire w is not over 6 inches long, when the oscillatory discharge is passing the short wire w_1, even if it is as large as No. 14, will become sufficiently hot to burn its insulation, while the No. 32 wire of the transformer supplying the energy to the transformer remains perfectly cool. This indicates that a very large current flows in the condenser circuit when oscillations are taking place. The discharge through the gap is entirely different in character from what it is when no condenser shunts the gap. In the latter case it is a species of flame, having a yellow hue and nearly noiseless. In the former case the discharge becomes very noisy, extremely brilliant and very blue. By waving a stick in the light of the discharge the light is seen to be discontinuous, as the moving stick gives rise to a large number of multiple images. As the balls of the gap are more and more separated the intervals between the separate discharges become greater. This light undoubtedly has powerful actinic properties, and the idea suggests itself that kinetoscopic views might be taken with its aid, especially of moving microscopic objects. An arrangement something like that shown in Fig. 21 might be adopted.

Here S is the discharge gap, giving rise to the brilliant rapidly interrupted light, l is a condensing lens, S_1 is the slide of the microscope containing the moving microscopic object, M the microscope; N_1 N_2 are two rolls, on which a sensitive film runs, B a box to exclude light. The microscope can be easily arranged to throw the magnified image on the film at I. If the film be now rolled from one roll to the other while the rapidly intermittent discharge is passing at S, kinetoscope views ought to be obtained on the film without great difficulty. At any rate the brilliant and intermittent character of the light ought to find useful application in some way similar to the above.

TESLA'S GREAT INVENTION TO BLOW UP HOSTILE WARSHIPS BY ELECTRIC WAVES.

"I am perfecting an electrical engine of war which I am ready to offer to the Government. It is to exert such a terrible force as to disable war ships and powerfully affect vast armies on land at great distances."--TESLA.

HOW TESLA'S OSCILLATOR WILL HURL DEATH AND DESTRUCTION INTO AN ENEMY'S SHIP BY MEANS OF ELECTRICAL VIBRATION.

The Terribly Destructive Electrical Engine of War.

BY NICOLA TESLA.

I AM perfecting an electrical engine of war which I am about to offer to the Government. It is to exert such a terrible force as to disable war ships and powerfully affect vast armies on land at great distances.

If this device acts as effectively on a large scale as it does in my laboratory, the results will be incalculable. When put into operation it will tend to bring war to a speedy end by reason of its unlimited power of extermination

It is the application of the principle of oscillating waves. By this means electrical currents of high potentials can be sent out in all directions and aimed against the vulnerable part of a hostile army or war ship.

Five years ago I discovered that electrical vibrations produced by a novel kind of apparatus, which I have since considerably improved, may be propagated through the earth and through the air, and from experimental data I have calculated that such vibrations can be propelled a distance equal to the diameter of the earth. To effect this an expenditure of energy of about five hundred horse-power is needed, although this estimate may not be quite true, as there are a number of uncertain quantities in the calculation.

I intended to use the principle primarily for the transmission of signals over great distances, but soon I saw that something of greater importance could be accomplished by its use.

The only way to insure the action was to construct apparatus on novel principles which would make possible the production of waves of many hundred times greater intensity.

I foresaw long ago that, despite the strenuous efforts of the President to maintain peace, war would break out and I have concentrated my energies upon perfecting these devices and rendering them immediately available.

This, in fact, is the only reason why I have not, up to this time, offered my services as a volunteer, which I would certainly have done under other circumstances. In this respect, I may say, I have already formed definite plans.

Although the United States have taken energetic measures, and are determined to bring the difficulty to a speedy termination, I fear that the war will be prolonged, and it will become all the more important to apply improved electrical measures and contrivances.

Electricity to Become Our Greatest Weapon.

BY W. J. CLARKE,
General Manager of the United States Electric Agency.

To fire a cannon and blow up a war ship by electricity without any connections may seem miraculous. Yet this is exactly what will be done on a small scale at the Electrical Agency. This spectacle is designed to show the newest and most wonderful development of electricity at the present it seems like this remarkable American achievement may be converted into the great military use by directing it against a hostile fleet or army.

In this way not only may approaching war ships be sunk far out at sea by the medium of torpedoes, but troops on land can repel invasion by firing the batteries of their own and then landing miles away from their exposed guns. All the appliances for this latter purpose have been developed.

At the present stage of development of this art it is necessary to have all the equipment on or close to the cannon or war ship to be acted upon by the electrical waves produced by pressing the key at the distant station, but the results of recent experiments indicate that we should be able to explode the powder in the magazine of our enemy's war ship without any corresponding electrical waves from such ship.

I also believe it possible to totally disarrange the electrical signal system in the ship by the same means and without allowing them to affect our signal system.

It will also be possible for the whole fleet to be at the absolute control with the mere pressing of a key by the Admiral being sufficient to stop or start the engines of every motorized china, to turn their lights on or off and to make them perform many other simultaneous actions

No. 141 East Twenty-fth street, New York, April 20, 1898.

As Described for the Journal by Prof. Garrett P. Serviss.

BY GARRETT P. SERVISS.

The Famous Scientist and Lecturer Describes Tesla's Wonderful Oscillator.

The great naval war between the United States and Spain, which bids fair to make the close of the nineteenth century forever memorable, may, if Mr. Nicola Tesla is able to fulfil his promises, also mark the greatest advance in the art and science of destruction that war has ever known.

For several years now the public has been familiar with the fact that Mr. Tesla, who in many respects is recognized as the foremost master of electrical science now living, has been able to produce by means of an instrument called the electrical oscillator a vibratory force capable of causing brilliant lights to burst forth in the centre of a room without material connection with any electrical instrument, and electro-magnetic phenomena to manifest themselves at great distance from the oscillator and without connection with it by wire or otherwise.

More recently great attention has been aroused by the experiments of Mr. Tesla of Senor Marconi, an Italian; of Mr. W. J. Clarke of this city, and others, in the transmission of telegraphic dispatches without wires. Dispatches of this kind have been sent from a distance of not less than twelve miles.

Electric Vibrations to Shatter Spanish Ships.

Mr. Tesla himself has repeatedly declared that it would be possible to send a current into the earth an electric vibration which would reach the planet Mars, in that if there were people and instruments there to receive it telegraphic communication might be opened up between the earth and that distant world.

The practical principle underlying all of these surprising experiments is one which is now invoked by Mr. Tesla in the invention of an instrument of arms quite as potent and wonderful as some of the devices which have recently been suggested in stories of mimic warfare. But up to the outbreak of the present hostilities with Spain no one had apparently thought of turning this tremendous and mysterious power to other than peaceful uses.

There seems good reason to hope that early in the coming century it might become possible to do away entirely with cumbersome telegraph wires, and that houses and city streets and squares might be filled with artificial daylight without the aid of the elaborate apparatus at present employed.

In fact, almost everybody familiar with the experiments going on in the laboratories of Mr. Tesla and the other great inventors has been looking forward to the dawn of a new era in electrical science, an era which would mark as great an advance in the condition of the world as anything that has ever occurred in its history.

But it now appears these new potencies are to be turned to an unexpected and even terrible employment. In the electrical exhibition to be given in this city the coming week the public will have an opportunity to see the application of the invisible electrical oscillations to the firing of cannon and the blowing up of models of ships. This is wireless telegraphy in a new form.

What the Electrical Oscillator Will Do.

The invisible waves of electricity, radiating from their source, carry not information, but destruction. It will only be necessary, according to the belief of the inventors, to increase the power and range of the oscillations in order that what is done with toy vessels in the exhibition hall may be accomplished with actual ships of war invading the harbor of New York or met in the open sea.

Mr. Goldwin Smith may find that he spoke far more truth than he was aware of the other day when he declared that Spain would be enormously overmatched in this war because the Spaniards had no mechanical genius. In the mechanical application of science it is not self-flattery to say that America stands foremost. Let Mr. Tesla turn his electrical oscillator into an engine of war and America will be more than foremost—there will be no second.

On account of the intense interest which Mr. Tesla's declaration is certain to awaken, it is important to point out how far the application of the electrical oscillator for use as an instrument of war has practically progressed and what remains yet to be done.

From a central station on the shore, or from a ship of war, it is possible to send forth without the aid of wires electrical oscillations in widening circles, like waves in water, to an effective distance of several miles. Anywhere within the radius of such waves an electric spark can be produced by means of a proper instrument or receiver. But an enemy's war ship cannot be expected to contain such a receiver, and particularly not in such a position that a spark from it could reach the ship's powder.

The problem remaining to be solved is how to produce electric sparks within the radius of influence of the oscillatory waves without the existence of a transforming instrument at the receiving end. Both Mr. Tesla and Mr. Clarke, who have worked independently upon this matter, assert their belief that it will be possible to produce such sparks. Not only so, but these gentlemen speak of the problem in a manner which gives reason to hope that the solution will not be long deferred.

Aiming Lightning Bolts at the Enemy.

It may even be possible to focus the oscillations on a particular ship. In that case all danger of exploding our own mines and magazines in the neighborhood would be eliminated.

Supposing this final problem solved, then the situation of affairs will be as follows: An enemy's fleet is seen approaching the harbor. One or more electric oscillators placed in a commanding position on headlands or on anchored ships of war are prepared for their deadly work.

The enemy approaches with ships flying, cleared for action, conscious of overpowering numbers in his favor, confident of success. Perhaps by means of some of the appliances now existing for that purpose he may have cleared the channels of mines, and believes he can enter the harbor in safety.

On come the battle ships, volumes of black smoke rolling backward in the breeze, their guns glittering, a fearful spectacle. They are prepared for hostile shots and expect them, but none comes. The great batteries of Sandy Hook are silent. There is no thunder from the gigantic mortars in the sandpits.

HOW THE OSCILLATOR AND THE ELECTRICAL EXPLODING [illegible]

"The Yankee pigs are afraid to shoot," says the Admiral of the Spanish Squadron, "the mere sight of a Spaniard has terrified them. In two hours, gentlemen of Spain, the great city of the New World will be ours.

But at this moment, unknown and invisible to the Spanish commander and his men, Mr. Tesla has touched an electric button. Likewise invisible, but with the speed of light, the electric oscillations expand over the bay. Unnoticed they penetrate the steel sides of one of the Spanish ships and little blue sparks play through its magazines

Bang! Boom! Bang!

The great steal hull leaps, bursts and is scattered far and wide on the foam beaten waters.

The Spanish commander does not understand what has happened. He believes the magazines of the ship have blown up of their own accord. Perhaps he recalls the insultin words of the Spanish "report" on the blowing up of the Maine, and wonders whether there has not been some "carelessness" on a Spanish warship.

Will Sink Spaniards.

And now suddenly the great batteries at the Hook begin to open. The smoke rolls over Atlantic Highlands; the piercing flashes of the guns are visible even in the broad daylight and the thundering reverberations shake the city miles away. Fort Wadworth and Fort Hamilton are next ablaze.

"The Spanish ships are still advancing," says the bulletins.

"The forts seem unable to sink them."

"They are nearing the Narrows."

"The oscillators! What are the oscillators doing?" cried the maddened crowd. "Will they never sink them? Will they never blow them up?"

But these things the Spaniards are prepared for. Their armoried sides are battered and smashed, but still their vitals are not touched and their great guns reply fiercely to the fire of the forts.

Three million hearts listen to the bellish uproar. "All work is abandoned. Houses and offices are deserted; the thronging multitudes in the streets are crazed with excitment. Ticking telegraph instruments transmit every instant the latest news of the fight and the men at the bulletin boards seem electrified, and write and rub out and write again amid the cheers and the shouts of the inlookers.

"Mr. Tesla has touched an electric button. . . . electric oscillations expand over the bay Bang! boom! bang! . . . . The great steel hall leaps, bursts, and is scattered far and wide on the foam beaten waters."

NIKOLA TESLA.

Nikola Tesla's

REVOLUTION IN

War Telegraphy.

He Believes He Will Be Able to Successfully Operate Without Wires from a Ship 100 Miles Away.

(Copyright, 1898, by Charles Culver Johnson.)

New York, April 30.—Nikola Tesla has made an instrument for telegraphing without wires by which a vessel a hundred miles from our coast will be able to send messages to the shore. Mr. Tesla tells me that he is ready to offer this invention to the Government for use in war. Its advantages are easy to understand. There has been much talk of telephoning to moving ships and some discussion of the feasibility of sending out a cable repair ship to pick up one of the great ocean cables and send us messages telling of the approach of an enemy.

The telephoning would be over a short range and the cable ship would be confined to observation along the line of cable communication. The wireless telegraph would enable any ship within 100 miles of a coast station to send messages to the shore. The ships of a fleet lying off Havana could receive their instructions from the Navy Department by way of Key West and telegraph to Secretary Long and the President just what was happening in Cuba.

Mr. Tesla is not prepared to make public the details of his invention. He always gives his conclusions to the world through articles in a scientific periodical, which he writes with the utmost care. But he said to me yesterday: "You may say that I have succeeded in making a machine a thousand times more powerful than any ever made before. With it I expect to send messages without wires over long distances—probably 100 miles."

I asked Mr. Tesla if his invention was so near perfection that it might be of use in the war with Spain.

"I think so," he said. "If it can be used, I have no desire for compensation. It is not for sale. But I will freely offer it to the Government. One reason I cannot tell you just what my machine is, is that if it can be used on our ships it will give us an advantage; and I shall be proud to have been of so much use to my country."

"Then you consider yourself a good American, Mr. Tesla?"

The inventor threw up his hands and looked incredulous at the suggestion of doubt.

"I a good American?" he said. "I was a good American before I ever saw this country. I had studied its government; I had met some of its people. I admired America. I was at heart an American before I thought of coming here to live.

"What opportunities this country offers a man! Its people are a thousand years, yes, a thousand years, ahead of the people of any other nation of the world. They are big, broad-minded, generous. I could not have accomplished in any other country what I have done here. I was in France for a time. I tried to work out some of my ideas there. But I could get no encouragement. I could find no one to back me. When I came here, I met men immediately who were ready to help me to develop my ideas. The American people are quick to hold out a helping hand and to give recognition. Yes, I am as good an American as there is. I have nothing to sell to the Government of the United States. If it needs my services in any way it is welcome to them.

"Of this invention I can tell you that it is the result of more than five years of hard work. The experiments, which have been carried on in Europe and which have attracted so much comment, follow the lines that I laid down some years ago. For a long time the experiments abroad did not follow these lines, and they were not successful. Signals could be sent, but only short distances. When they returned to my system they found that they could send messages to a much greater distance.

"Five years ago in the course of a lecture, speaking of the transmission of intelligible signals or perhaps even power to any distance without the use of wires, I said: 'I am becoming daily more convinced of the practicability of the scheme; and though I know full well that the great majority of scientific men will not believe that such results can be practically and immediately realized, yet I think that all consider the development in recent years by a number of workers to have been such as to encourage thought and experiment in this direction. My conviction has grown so strong that I no longer look upon this plan of energy or intelligence transmission as a mere theoretical possibility, but as a serious problem in electrical engineering, which must be carried out some day.

"The idea of transmitting intelligence without wires is the natural outcome of the most recent results of electrical investigations. Some enthusiasts have expressed their belief that telephony to any distance by induction through the air is possible. I cannot stretch my imagination so far, but I do firmly believe that it is practicable to disturb by means of powerful machines the electrostatic condition of the earth and thus transmit intelligible signals and perhaps power.

"In fact, what is there against the carrying out of such a scheme? We now know that electric vibration may be transmitted through a single conductor. Why then not try to avail ourselves of the earth for this purpose? We need not be frightened by the look of distance. To the weary wanderer counting the mile posts the earth may seem very large, but to that happiest of all men, the astronomer, who gazes at the heavens and by their standard judges the magnitude of our globe, it appears very small. And so I think it must seem to the electrician, for when he considers the speed with which an electric disturbance is propagated through the earth, all his ideas of distance must completely vanish.'

"I have been working on that problem ever since. For a long time I experimented with delicately adjusted instruments, but I found them unreliable. I would send signals for a few blocks and then a strong current of electricity somewhere in the neighborhood or some atmospheric condition would interrupt them.

"After a time I saw that this would not do. I must have something reliable, then I set about making a machine which would give me more powerful vibrations. I have succeeded beyond my expectations. I have made a machine which is a thousand times as powerful as any now known. With it I could stop every electric current—every telegraph or telephone in this neighborhood." With a sweep of his arm the inventor suggested that populous district which surrounds the building in Houston Street, where his laboratory is.

"But could not some one else destroy the effectiveness of your signals with a counter-current?" I asked.

Mr. Tesla hesitated and answered rather slowly: "Yes, yes, he could. But he'd have to be a devil of a fellow." Which ingenious statement I interpreted as meaning that the "other fellow" would have as strong a machine as that of Mr. Tesla.

Mr. Tesla told me that the new machine filled very little space. "It is not so large as that table," he said, indicating a very small one which stood against the wall, covered with scientific magazines.

"It could be put aboard a ship without inconvenience, then?"

"Certainly."

"And how about the current to operate it?"

It could be had from a small dynamo such as they have aboard all the ships the navy."

Mr. Tesla says that his original theory concerning the transmission of signals, and possibly of power, without wires had been confirmed by his experiments. On this subject he said some years ago:—

"A point of great importance would be first to know what is the capacity of the earth, and what change does it contain if electrified? Though we have no positive evidence of a charged body existing in space without other oppositely electrified bodies being near, there is a fair possibility that the earth is such a body, for by whatever process it was separated from other bodies—and this is the accepted view of its origin—it must have retained a charge, as occurs in all processes of mechanical separation. If it be a charged body insulated in space its capacity should be extremely small, less than one-thousandth of a farad. But the upper strata of the air are conducting, and so, perhaps, is the medium in free space beyond the atmosphere, and these may retain an opposite charge.

"Then the capacity might be incomparably greater. In any case it is of the greatest importance to get an idea of what quantity of electricity the earth contains. It is difficult to say whether we shall ever acquire this necessary knowledge, but there is hope that we may, and that is by means of electrical resonance. If ever we can ascertain at what period the earth's charge when disturbed oscillates with respect to an oppositely electrified system or known circuit, we shall know a fact possibly of the greatest importance to the welfare of the human race. I propose to seek for the period by means of an electrical oscillator, or a source of alternating electric currents.

"One of the terminals of the source would be connected to earth, as, for instance, to the city water mains, the other to an insulated body of large surface. It is possible that the water conducting air strata, or free space, contain an opposite charge and that, together with the earth, they form a condenser of very large capacity. In such case the period of vibration may be very low and an alternating dynamo machine might serve for the purpose of the experiment. I would then transform the current to a potential as high as it would be found possible, and connect the ends of the high tension secondary to the ground and to the insulated body. By varying the frequency of the currents and carefully observing the potential of the insulated body and watching for the disturbance at various neighboring points of the earth's surface, resonance might be detected.

"Should, as the majority of scientific men in all probability believe, the period be extremely small, then a dynamo machine would not do and a proper electrical oscillator would have to be produced, and perhaps it might not be possible to obtain such rapid vibrations. But whether this be possible or not, and whether the earth contains a charge or not, and whatever may be its period of vibration, it certainly is possible—for of this we have daily evidence—to produce some electrical disturbance sufficiently powerful to be perceptible by suitable instruments at any point of the earth's surface."

At the time he made this statement, Mr. Tesla proposed the following plan for signalling without wires:

Assume that a source of alternating currents be connected with one of its terminals to earth (conveniently to the water mains) and with the other to a body of large surface, P. When the electric oscillation is set up there will be a movement of electricity in and out of P, and alternating currents will pass through the earth, converging to or diverging from the point C, where the ground connection is made. In this manner neighboring points on the earth's surface within a certain radius will be disturbed. But the disturbance will diminish with the distance, and the distance at which the effect will still be perceptible will depend on the quantity of electricity set in motion.

Since the body P is insulated in order to displace a considerable quantity, the potential of the source must be excessive, since there would be limitations as to the surface of P. The conditions might be adjusted so that the generator or source S will set up, the same electrical movement as though its circuit were closed. Thus it is certainly practicable to impress an electric vibration at least of a certain low period upon the earth by means of proper machinery. At what distance such a vibration might be made perceptible can only be conjectured.

At another place Mr. Tesla said that if it was at all possible to transmit signals through the earth or its environing medium, "distance does not mean anything." In fact, he not only suggested the wireless telegraph first, but he first suggested the means by which all after results have been achieved, and the fact that they could be made to cover great distances. The most that is claimed for Marconi by scientists is that he has succeeded in telegraphing without wires for a greater distance than any one before him. But if Mr. Tesla's new machine accomplishes what he confidently predicts, Marconi's laurels will be plucked very quickly from his brow.

What makes the new machine more important is its superiority to the influence of others. A recent writer on Marconi's system said that "in war telegraphy would become impossible as soon as a hostile spark generator should cause a permanent disturbance of the characters." If Mr. Tesla is not mistaken only "a devil of a fellow" will be able to disturb his signals; and if the Tesla system can be kept a secret there is no likelihood that any disturbing element will enter into the transmission of signals by our army and navy during the trouble with Spain.

CHARLES CULVER JOHNSON.

TESLA PERFECTING A WAR ENGINE.

Electrical Device to Destroy the Enemy's Fleets and Armies.

IS CONFIDENT OF SUCCESS.

He Will Offer the Destroying Agency to the Government—Another Scientist Comments Favorably on the Inventor's Scheme.

BY NICOLA TESLA.

REPUBLIC SPECIAL.

New York, April 30.—I am perfecting an electrical engine of war which I am about to offer to the Government. It is to exert such a terrible force as to disable warships, and powerfully affect vast armies on land at great distances.

If this device acts as effectively on a large scale as it does in my laboratory, the results will be incalculable. When put into operation, it will tend to bring war to a speedy end by reason of its unlimited power of extermination.

It is the application of the principle of oscillating waves. By this means electrical currents of high potentials can be sent out in all directions, and aimed against the vulnerable part of a hostile army or warship.

Five years ago I discovered that electrical vibrations produced by a novel kind of apparatus, which I have since considerably improved, may be propagated through the earth and through the air, and from experimental data I have calculated that such vibrations can be propelled a distance equal to the diameter of the earth. To effect this an expenditure of energy of about 500-horse power is needed, although this estimate may not be quite true, as there are a number of uncertain quantities in the calculation.

I intended to use the principle primarily for the transmission of signals over great distances, but soon I saw that something of greater importance could be accomplished by its use.

The only way to insure the action was to construct apparatus on novel principles, which would make possible the production of waves of many hundred times greater intensity.

I foresaw long ago that despite the strenuous efforts of the President to maintain peace, war would break out, and I have concentrated my energies upon perfecting these devices and rendering them immediately available.

This, in fact, is the only reason why I have not, up to this time, offered my services as a volunteer, which I certainly would have done under other circumstances. In this respect, I may say, I have already formed definite plans.

Although the United States have taken energetic measures and are determined to bring the difficulty to a speedy termination, I fear that the war will be prolonged, and it will become all the more important to apply improved electrical measures and contrivances.

BY PROF. SERVIS, SCIENTIST.

The great naval war between the United States and Spain, which bids fair to make the close of the Nineteenth Century forever memorable, may, if Mr. Nicola Tesla is able to fulfill his promise as stated above, also mark the greatest advance in the art and science of destruction that war has ever known. For several years now the public has been familiar with the fact that Mr. Tesla has been able to produce by means of an instrument called the electrical oscillator a vibratory force capable of causing brilliant lights to burst forth in the center of a room without material connection with any electrical instrument, and electro-magnetic phenomena to manifest themselves at a great distance from the oscillator and without connection with it by wire or otherwise.

More recently great attention has been aroused by the experiments of Mr. Tesla; of Senor Marconi, an Italian; of Mr. W. J. Clarke of this city, and others, in the transmission of telegraphic dispatches without wires. Dispatches of this kind have been sent from a distance of not less than 12 miles. The practical principle underlying all of these surprising experiments is that which is now invoked by Mr. Tesla in the invention of an instrument of war quite as potent and wonderful as some of the devices which have recently been suggested in stories of mimic warfare. But up to the outbreak of the present hostilities with Spain no one had apparently thought of turning this tremendous and mysterious power to other than peaceful uses.

There seems good reason to hope that early in the coming century it might become possible to do away entirely with cumbersome telegraph wires and that houses and city streets and squares might be filled with artificial daylight without the aid of the elaborate apparatus at present employed.

Almost everybody familiar with the experiments going on in the laboratories of Mr. Tesla and the other great inventors has been looking forward to the day of a new era in electrical science, an era which would mark as great an advance in the condition of the world as anything that has ever occurred in its history.

But it now appears these new potencies are to be turned to an unexpected and even terrible employment. In the electrical exhibition to be given in this city the coming week the public will have an opportunity to see the application of the invisible electrical oscillations to the firing of cannon and the blowing up of models of ships. This is wireless telegraphy in a new form.

The invisible waves of electricity, radiating from their source, carry not information, but destruction. It will only be necessary, according to the belief of the inventors, to increase the power and range of the oscillations in order that what is done with toy vessels in the exhibition hall may be accomplished with actual ships of war invading the harbor of New York or met in the open sea.

On account of the intense interest which Mr. Tesla's declaration is certain to awaken, it is important to point out how far the application of the electrical oscillator for use as an instrument of war has practically progressed, and what remains yet to be done. From a central station on the shore, or from a ship of war, it is possible to send forth, without the aid of wires, electrical oscillations in widening circles, like waves in water, to an effective distance of several miles. Anywhere within the radius of such waves, an electric spark can be produced by means of a proper instrument or receiver. But an enemy's warship cannot be expected to contain such a receiver, and particularly not in such a position that a spark from it could reach the ship's powder.

The problem remaining to be solved is how to produce electric sparks within the radius of influence of the oscillatory waves without the existence of a transforming instrument at the receiving end. Both Mr. Tesla and Mr. Clark, who have worked independently upon this matter, assert their belief that it will be possible to produce such sparks. Not only so, but these gentlemen speak of the problem in a manner which gives reason to hope that the solution will not be long deferred.

It may even be possible to focus the oscillations on a particular ship. In that case all danger of exploding our own mines and magazines in the neighborhood would be eliminated.

Supposing this final problem solved, then the situation of affairs will be as follows: An enemy's fleet is seen approaching the harbor. One or more electric oscillators, placed in a commanding position on headlands or on anchored ships of war, are prepared for their deadly work.

The enemy approaches with flags flying, cleared for action, conscious of overpowering numbers in his favor, confident of success. Perhaps by means of some of the appliances now existing for that purpose he may have cleared the channel of mines and believes he can enter the harbor in safety.

On come the battleships, volumes of black smoke rolling backward in the breeze, their guns glittering—a fearful spectacle. They are prepared for hostile shots, and expect them, but none comes. The great batteries of Sandy Hook are silent. There is no thunder from the gigantic mortars in the sandpits.

"The Yankee pigs are afraid to shoot," says the Admiral of the Spanish Squadron; "the mere sight of a Spaniard has terrified them. In two hours, gentlemen of Spain, the greatness of the New World will be ours."

But at this moment, unknown and invisible to the Spanish commander and his men, Mr. Tesla has touched an electric button. Likewise invisible, but with the speed of light, electric oscillations expand over the bay. Unnoticed they penetrate the steel sides of one of the Spanish ships, and little blue sparks play through its magazines.

Bang! Boom! Bang! The great steel hull leaps, bursts and is scattered far and wide on the foam-beaten waters.

The Spanish commander does not understand what has happened. He believes the magazines of the ship have blown up of their own accord. Perhaps he recalls the insulting words of the Spanish "report" on the blowing up of the Maine, and wonders whether there has not been some "carelessness" on a Spanish warship.

And now suddenly the great batteries at the Hook begin to open. The smoke rolls over Atlantic Highlands; the piercing flashes of the guns are visible even in the broad daylight, and the thundering reverberations shake the city miles away. Fort Wadsworth and Fort Hamilton are next ablaze.

But these things the Spaniards are prepared for. Their armored sides are battered and smashed, but still their vitals are not touched and their great guns reply fiercely to the fire of the forts.

Three million people listen to the hellish uproar with hearts beating at their throats. All work is abandoned. Houses and offices are deserted; the thronging multitudes in the streets are crazed with excitement. Ticking telegraph instruments transmit every instant the latest news of the fight and the men at the bulletin boards seem electrified, and write and rub out and write again amid the cheers and shouts of the onlookers.

"The Spanish ships are still advancing," say the bulletins.

"The forts seem unable to sink them."

"They are nearing the Narrows."

"The oscillators! What are the oscillators doing?" cried the maddened crowd. "Will they never sink them? Will they never blow them up?"

Already stray shots are coming across the sandhills and falling in the outskirts of Brooklyn. The confidence with which the assailed city had waited the attack in the morning, when the news of the approach of the enemy's fleet was heard, is rapidly turning to despair.

But the oscillators are all right. There has been a temporary disarrangement, but the trouble is rapidly remedied, and presently cut through the thickening battle smoke steal those invisible undulations, thrilling through the air, touching the red and yellow emblems of Spain, insolently flaunting from the mastheads of the ships, but not disturbing them. They have a deadlier mission. Through the hulls they penetrate, and once more little blue flames flicker among the magazines. And now not but one, but half a dozen Spanish warships suddenly leap, as the Maine leaped, and, like her, go to the bottom. But they have gone down in a fair fight.

The battle is over,

The Spanish armada has been blown into space.

Such is the picture of what we should expect to behold provided the inventors who have this problem in hand are able to achieve all that they now confidently expect to do.

Transmission

POLYPHASE INDUCTION MOTORS.

ALTERNATING current motors, although developed and perfected much later than direct current motors, were soon recognized to possess such great practical advantages that they have by rapid strides largely supplanted the latter in many important applications. They have, in fact, done more; being advantageously used in places where electric power could not be previously employed by reason of some of the inherent characteristics of direct current apparatus.

Alternating current apparatus, owing to the field which it originally occupied, was for a long time looked upon by many as applicable only to the transmission of power over long distances. The extreme simplicity and flexibility of the alternating system, however, added to the attractions of the polyphase motor, have led to the use of polyphase apparatus for the distribution of power in factories, mills, mines, and other industrial establishments where the distances are comparatively short. A large factor in the present popularity of alternating current power is due to the high state of perfection to which the improved polyphase motors have been brought; yet despite their practically exclusive use on all power transmissions, a knowledge of their mode of construction and principles of operation are not commonly understood. To give needed information on these points may best be done by describing distinctive forms of apparatus, for which the type "C" motor of the Tesla polyphase system, as brought out by the Westinghouse Electric and Manufacturing Company, is first selected for illustration and description. Tesla polyphase induction motors have two main elements; viz.: the primary, which is directly magnetized by the currents supplied from the line circuits; and the secondary, in which low potential currents are induced by the action of the primary. The windings of the primary are so arranged that when supplied with alternating currents differing in phase; *i. e.*, polyphase currents, a rotating magnet field is produced. This field acts upon the secondary winding and induces currents therein. Rotation is produced by the action between the secondary currents and the rotating field of the primary. The principle upon which motors of this class operate was discovered by Mr. Nikola Tesla, whence their name.

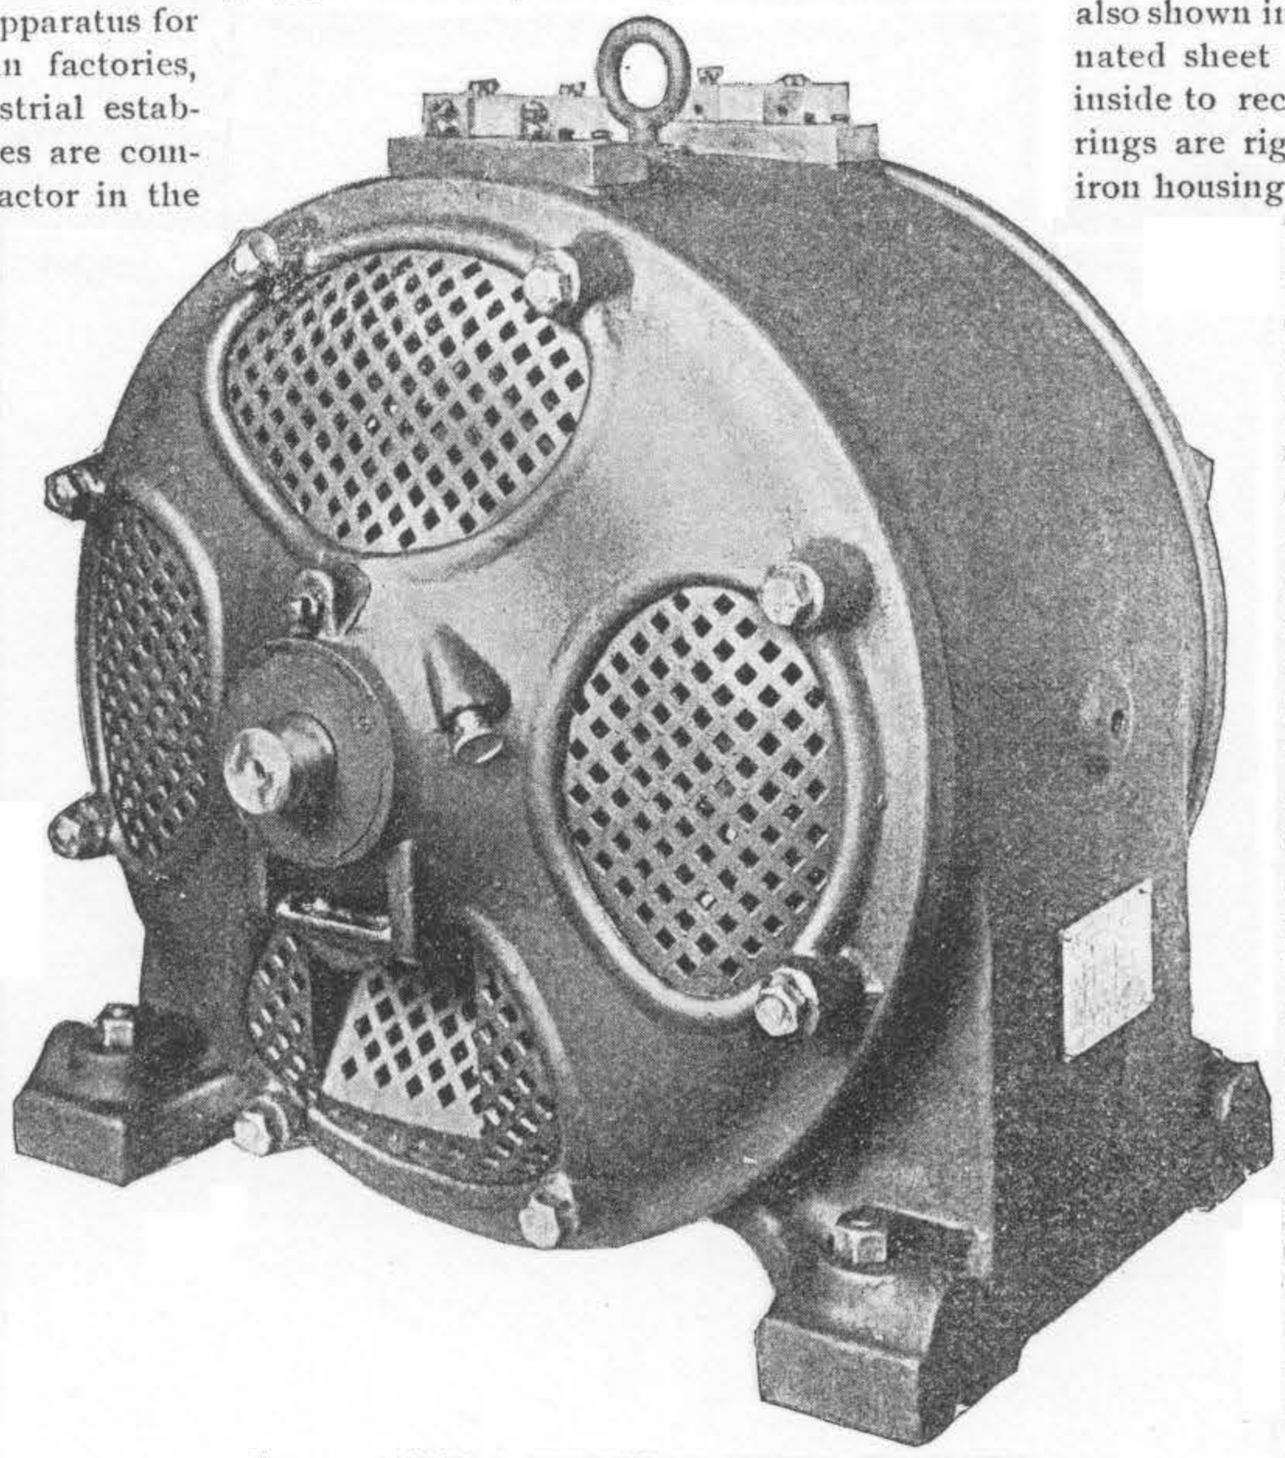

FIG. 1.—A TESLA INDUCTION MOTOR COMPLETE.

The revolving element of an induction motor may be either the primary or the secondary. In the motors described herein, the primary is stationary and the secondary revolves; hence, for purposes of comparison, the primary may be regarded as corresponding to the field magnets, and the secondary as corresponding to the armature of a direct current motor.

The form of the motor is shown in the accompanying illustrations, among which is that of a complete machine as shown in figure 1. It will be noted from the illustrations, that from a mechanical standpoint the induction motor is reduced to the simplest possible elements; *i. e.*, a stationary part, permanently connected to the main circuits, and a rotating part having no electrical connection with any other portion, and absolutely no electrical contacts or adjustments; in fact, no sliding or working friction except that of the shaft in the journals. It will therefore be observed that as a piece of moving machinery this type of motor is designed and built to operate for long periods of time with but a very small amount of cleaning and an occasional renewal of oil.

The hollow cylindrical frame of cast iron shown in figure 2, in which the primary is mounted, forms a base for the machine and also supports the two brackets carrying the self-oiling bearings. Ordinarily, perforated iron plates fitted into these brackets protect the rotating element and permit excellent ventilation, but they may be replaced by solid plates when it is desired to make the motor absolutely dust-proof. It will be noted that the housing compietely encloses the primary and secondary elements, and protects them from any external damage. The primary element, also shown in figure 2, is built up of laminated sheet iron rings, slotted on the inside to receive the conductors. These rings are rigidly supported by the cast iron housing which encloses the primary.

The conductors are machine wound coils, which are thoroughly insulated before being placed on the core. The secondary, which is shown in figure 3, is built up of laminated steel discs, made of a high grade of metal, mounted upon an open spider, and carrying in slots around the periphery the rectangular copper bars of the winding. The construction is such that the conductors cannot be thrown out by centrifugal force, the whole secondary being extremely simple, rigid and durable. Its conductors are all purposely short circuited, therefore it is evident that no accidental short circuit can possibly occur that will cause injury to the windings, and the danger of interruption to service from this cause, always a menace in direct current apparatus, is absolutely eliminated. The construction is also practically indestructible from heating, raising of coils, or mechanical injury in handling. This is undoubtedly the simplest and most durable form of secondary ever devised. Moreover, the end brackets may be bolted to the frame in any one of four different positions, so that the oil chambers in the brackets will be in the proper position whether the frame is bolted to the floor, the wall, the ceiling, or at a forty-five degree angle.

The type "C" motor is made with a variable speed for cranes, elevators, hoists, and similar classes of work, the variable speed motor being especially designed to give a proper speed curve, and is supplied with suitable regulating devices when necessary.

The power factor of an induction motor is found by dividing the real horse-power applied to the motor, by the apparent applied horse-power.

The energy supplied to a direct current motor is found by multiplying the current by the voltage; but in the case of an alternating induction motor, this product, designated the "apparent' energy, is greater than the real energy on account of the fact that

the current in such large motors "lags" behind the electromotive force, and hence the useful effect is less than would be the case if the current and electromotive force were coincident in phase. The current, however, exerts its full heating effect upon the conductors, and the excess current causes a corresponding drop of potential in the circuit. It is therefore desirable to reduce the lag as much as possible; *i. e.*, to bring the real and apparent energies

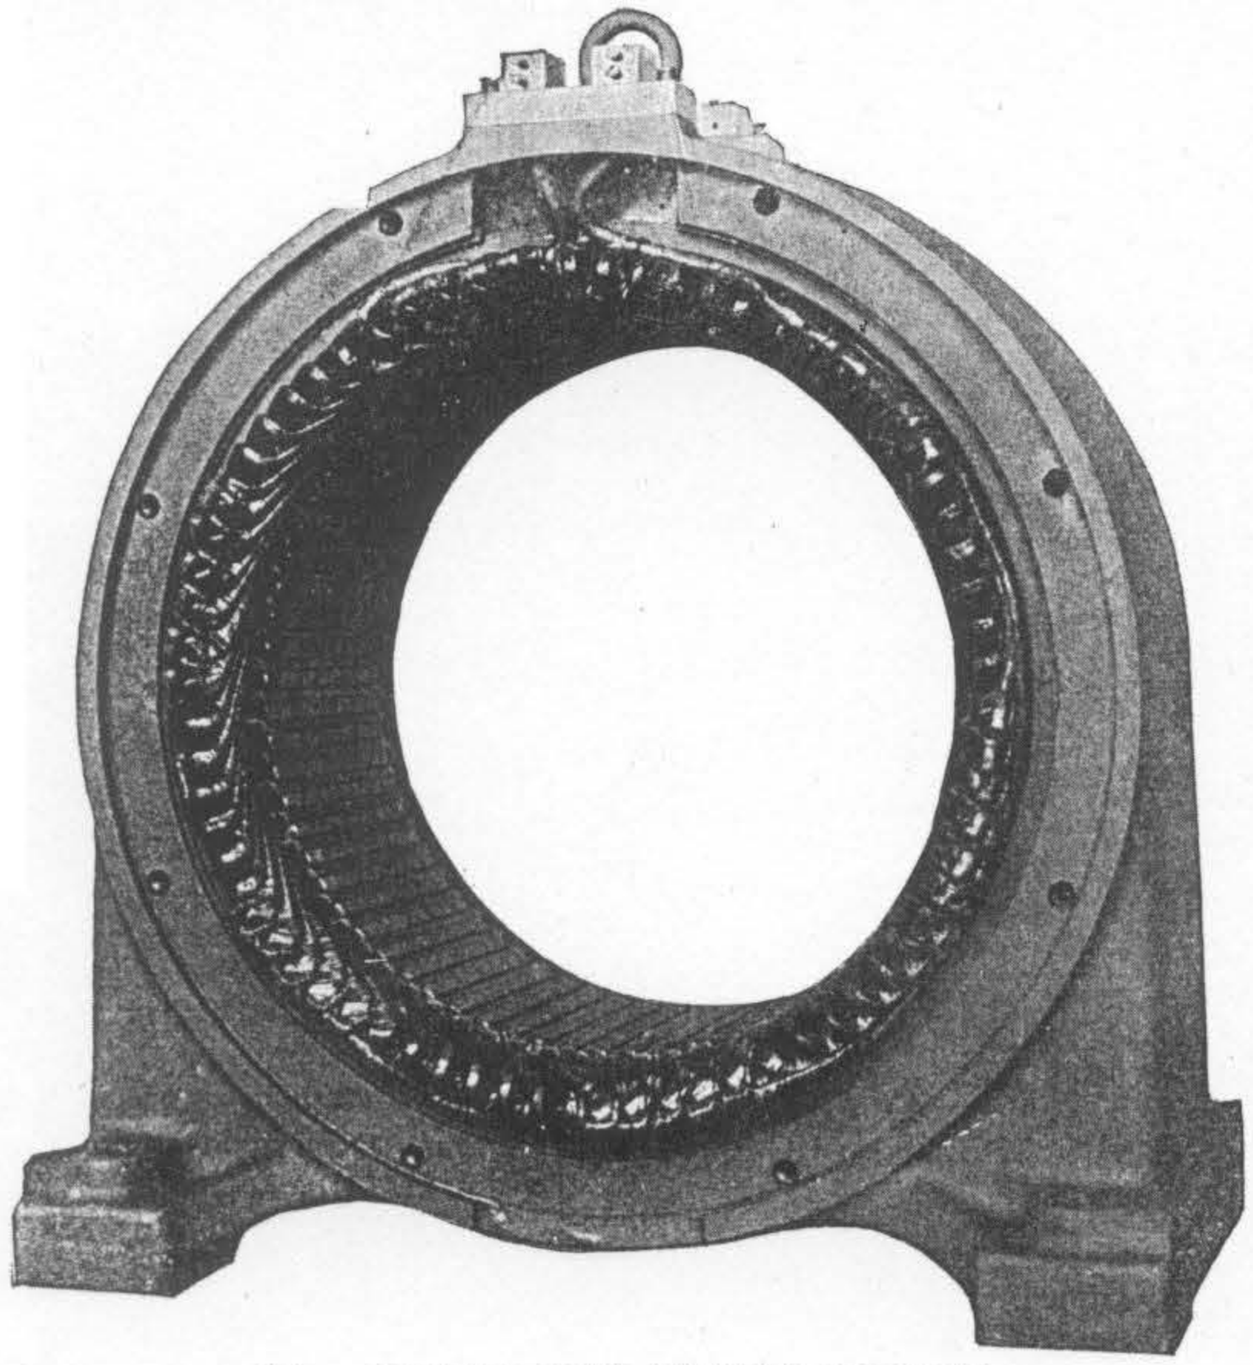

FIG. 2.—PRIMARY, WITH WINDING COMPLETE.

to coincide as near as we can. If it were possible to entirely eliminate the lag, the real and apparent horse-power would be equal, and the power factor would be 100. Special attention has been given to this matter in the designing of these machines, with the result that their power factors are very high.

The designs and principles governing the construction of the type "C" motor are fortunately favorable to a particularly attractive feature; *i. e.*, the maintaining of a high and almost constant efficiency from full load to one-half load. Under the conditions which prevail in a very large proportion of electric motor service, the motors are operated much of the time at considerably less than their full rated capacities. With the type "C" motor, therefore, by maintaining a constant efficiency, there can be secured to the user an all day or average efficiency very much above that heretofore possible, with either direct or alternating current motors. The variation of speed between no load and full load is small, being less than that found in direct current motor practice.

A polyphase induction motor may be started by connecting it directly to the circuit with an ordinary switch, and small motors are so started in practice. The larger motors, however, are started on a reduced voltage, the full electromotive force of the circuit not being applied until the motors have reached a considerable speed.

In the Westinghouse system, the low electromotive force is ordinarily obtained by the auto-starter, shown on page 37, and which consists of a double throw switch mounted on a cast-iron box in which are two auto-converters. When the switch is closed in the position shown in the cut, the auto-converters are connected across the circuits and deliver a low electromotive force to the motor, but when the switch is thrown in the opposite direction the auto-converters are cut out and the motor is connected directly to the circuit. Three or four wires are connected directly to the auto-starter, and the same number of wires connect the auto-starter to the motor. The auto-converters are arranged with loops so that one of several voltages may be applied for starting, thus adjusting the torque for the work the motor has to do. Thus a motor operating a machine having great inertia may be made to give a correspondingly strong starting torque, or one driving a light device may be adjusted for extremely light starting torque with a corresponding reduction of current.

On two-phase circuits in which there are four wires, different electromotive forces exist between the different pairs of wires, and in some cases this affords a simple way of obtaining a low electromotive force for starting. A simple double throw switch is required, by which the low electromotive force for starting is obtained by one connection, and the full electromotive force for running by throwing the switch to the opposite position.

When it is necessary to install motors in a grain elevator, a woolen mill, a mine, or in any place exposed to inflammable gases or floating particles, or not easily accessible, the starting devices may be located at a convenient point more or less remote from the motor, thus eliminating all danger from fire due to possible sparks.

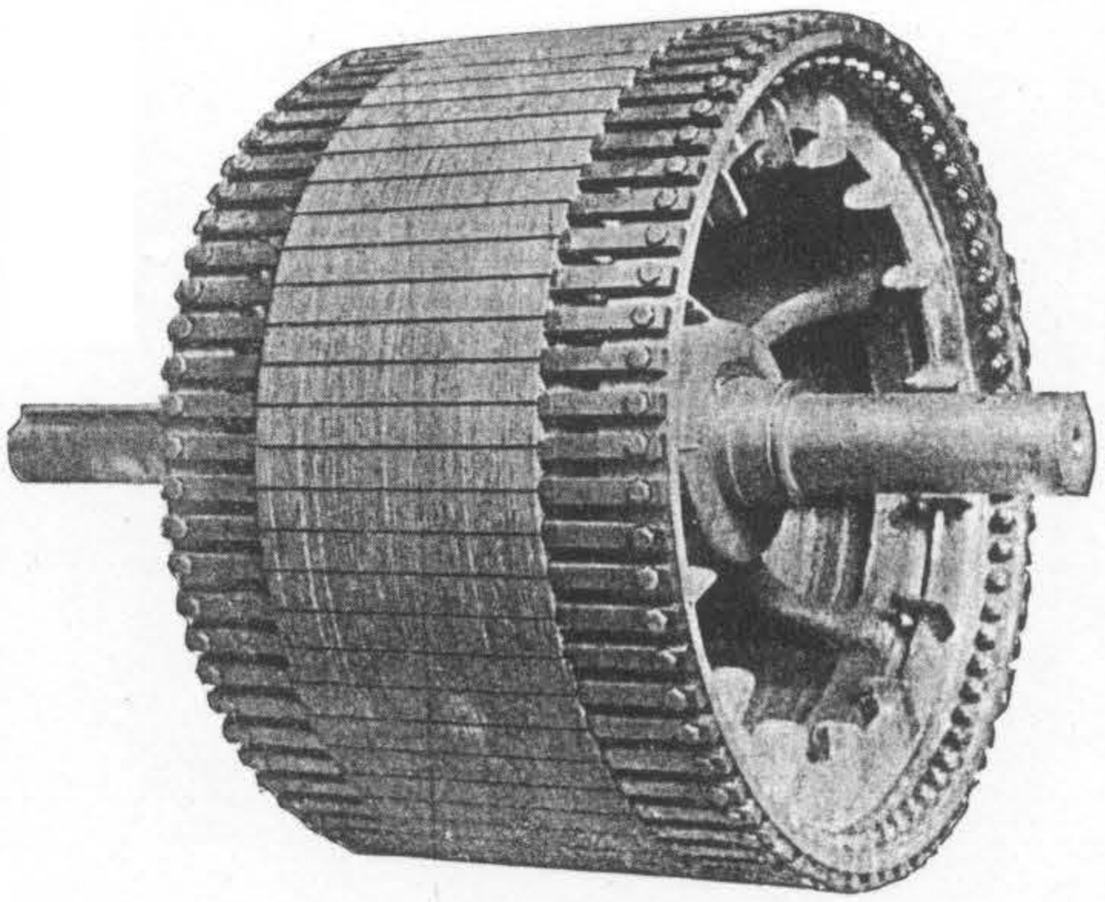

FIG. 3.—SECONDARY COMPLETE, SHOWING COPPER BARS CONNECTED TO END RINGS.

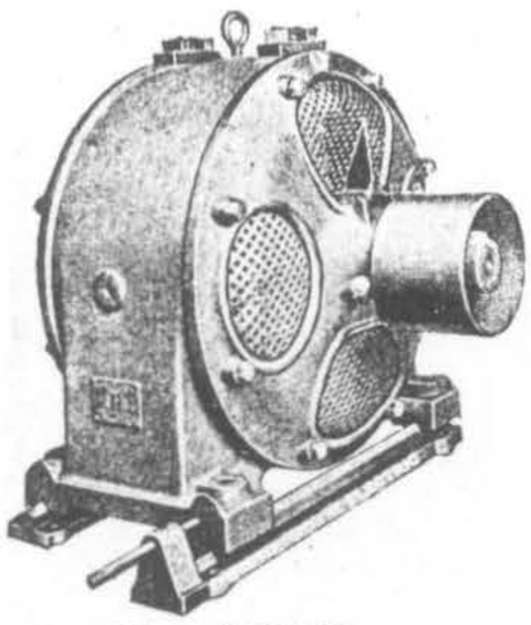

Tesla and Old Age.—According to the *Public Health Journal* of New York, Nikola Tesla has made a somewhat amusing contribution to medicine. He has found a way of warding off the ravages of time from the surface of the body. This is of especial interest to the ladies. He tells us that between 4,000 and 7,000 microbes fall on every square foot of the human body and settle there in 24 hours. If we could see the surface of the body with a microscope, we would see it swarming with millions of germs. This would not only, he says, be a hideous sight (he evidently pictures them in his mind's eye with heads and long claws), but they would be seen to be eating the skin and destroying its freshness at a rapid rate. The reason that old people are yellow and wrinkled is because the microbes have for years fed upon their skins. Tesla recommends, in the first place, thorough washing of the skin once a day with alcohol, and has invented a battery which shoots the microbes off into space with great violence, sometimes to the distance of 4ft. or 5ft. If this discovery of Tesla's leads people to wash who would otherwise not do so, it would be a boon indeed. We are afraid it will appeal more to those over-sensitive people who are already tottering under the weight of many more or less senseless fads.

EXPERIMENTS ON INDUCTION COIL CONDENSERS.

BY ALFRED G. DELL.

The following experiments were made to determine the relation between an induction coil and its condenser.

The apparatus used consists of an induction coil and a separate interrupter with a condenser in its base, so arranged with a separate contact that the breaks were made entirely independent of the battery strength passing into the induction coil, a separate cell of battery being used to run the interrupter. The separate interrupter has switches arranged to throw in or out of use the condenser connected to it. The induction coil has an interrupter and condenser of its own, but in making these experiments its interrupter was locked so it could not move, and, of consequence, its condenser was out of use.

I tried the arrangement as described above, and found I obtained from the secondary of the coil fair and vigorous sparks when the interrupter was in use, and the sparks at break of the primary were very small. On throwing out of use the condenser, I found exactly the opposite; the sparks from the secondary were very minute, and the sparks at the break of the primary were large and bright. I attached in the circuit of the secondary a Leyden jar in shunt with the spark gap, and then, after removing the jar, I attached a Tesla coil. In both cases the condenser was without any effect; the electrical energy received being the same whether the condenser was in or out of use.

I also attached a double cathode Crookes tube to the Tesla coil, and failed to distinguish from the light received in a fluoroscope whether the condenser was in or out of use.

I attached several very sensitive Geissler tubes, one at a time, and examined the anodes and cathodes, striæ, and intensity of the light obtained. I failed to discover any difference in any respect, whether the condenser was in or out of use. It is evident that if there are any discharges at make of interrupter, they are not affected by the condenser being in use; neither has the condenser any influence on the striæ, nor the intensity of light obtained.

I now come to experiments where I found a difference in the phenomena. I attached to the secondary of the coil a Geissler tube made of six feet of glass tubing one-quarter of an inch in diameter, wound into a spiral of five and one-half inches of diameter; there being no bulbs around the electrodes; of consequence the discharges were confined to rather small spaces. The tube is inclined to be refractory to quite small discharges. I having found sparks too small to light it up fully.

With this tube I discovered a slight difference in the light attained, but not in the striæ or the anode and cathode. I, as a last test, attached two Crookes tubes. The first used would not receive the discharges when the condenser was out of use, nothing appearing but a faint glow, which I attributed principally to the discharges from the electro-static field surrounding the connections of the tube.

The other tube contains a lower vacuum, it being more suitable for a

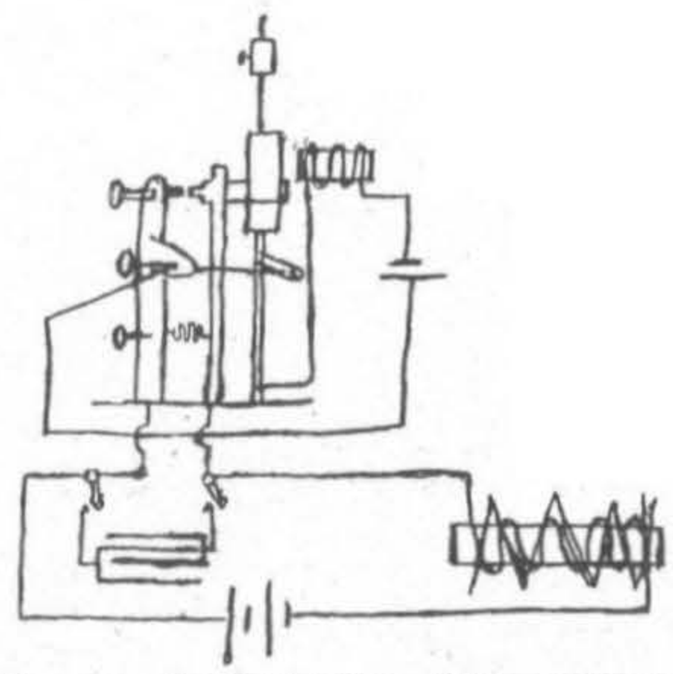

DIAGRAM ILLUSTRATING "EXPERIMENTS ON INDUCTION COIL CONDENSERS."

static machine, but with a spark-gap in series with the tube and coil, it gives X rays of considerable strength when the spark-gap is at its full length to hold the sparks, the X rays varying in strength with the length of spark-gap. This tube lighted up brightly with condenser out of use, but on opening a spark-gap in series I had, in a manner, no spark and the light disappeared. My deductions from the above experiments are that the condenser destroys the spark at break of the primary, which is necessary to preserve the platinum points and makes the spark in the secondary. If the arrangement used does not require a spark larger than the one obtained without condensers to break across an air space, the condenser is entirely without effect in the results obtained. Where an air-space has to be crossed the spark must be of sufficient length to pass it or there will be no discharge. I have noticed, sometimes, that in experimenting with Crookes tubes and a fluoroscope there would be a sudden dark space, a discharge having failed to pass, and I also noticed at such failures the spark at the break of primary was very bright.

From the above experiments, I think the cause of the dark spaces is fully explained. The extra discharges at break do not pass into the condenser; the dark discharges are the same as if there was no condenser in use. With Geissler tubes, that are sensitive, there are no dark spaces seen.

I will now give an experiment somewhat different from the above, hoping I will be pardoned for the digression. I have often noticed that when an interrupter, attached to the core of an induction coil, was in operation, and a spark-gap was in circuit with the secondary of the coil, that if the spark-gap was closed, or very nearly so, there was an interference of some nature with the running of the interrupter. I energized a coil from an exceedingly weak cell of battery, and found that the interrupter would run as long as the spark-gap was well open, but as soon as closed the interrupter would stop.

I do not propose to theorize concerning it; I only give it as a peculiar experiment. I depend upon experiments almost entirely for my information, believing they are the only reliable criteria.

If my experiments are of any benefit, my object in publishing them has been obtained.

TESLA AND OLD AGE.

NIKOLA TESLA has made a somewhat amusing contribution to medicine. He has found a way of warding off the ravages of time from the surface of the body. This is of especial interest to the ladies. He tells us that between 4,000 and 7,000 microbes fall on every square foot of the human body and settle there in 24 hours. If we could see the surface of the body with a microscope we would see it swarming with millions of germs. This would not only, he says, be a hideous sight (he evidently pictures them in his mind's eye with heads and long claws), but they would be seen to be eating the skin and destroying its freshness at a rapid rate. The reason that old people are yellow and wrinkled is because the microbes have for years fed upon their skins. Tesla recommends, in the first place, thorough washing of the skin once a day with alcohol, and has invented a battery which shoots the microbes off into space with great violence, sometimes to the distance of four or five feet. If this discovery of Tesla's leads people to wash who would otherwise not do so, it would be a boon indeed. We are afraid it will appeal more to those over-sensitive people who are already tottering under the weight of many other more or less senseless fads.

Concentration of Power by Electric Transmission at Taunton, Mass., Tack Works.

ONE of the most forcible of the advantages of electrical transmission of power is that this method often makes it possible to combine two or more steam plants into one, greatly diminishing the cost of labor and supplies. Such an advantage appeals especially to the mill owner, who may operate shafting in several buildings and departments by separate sources of power. A conspicuous example of a wasteful arrangement is in the works of one of the largest locomotive shops of the country, where part of the plant is operated by water power, part by steam power, and part by compressed air, the latter necessitating an extra engine and compressor.

Electric transmission, and notably the polyphase system, as developed by the Westinghouse Company, has made it possible to centralize the power in such shops. When Lieut. L. O. Garrett took charge of the affairs of the Atlas Tack Co., of Taunton, Mass., as manager, he instituted a thorough investigation as to the power required for the various classes of tack making machinery under normal conditions. The mills of this company at Taunton are three in number, located from 800 to 1,200 feet apart, and were until recently operated by three separate steam plants, with the accompanying wastefulness incident to small units. It was found that owing to variations in the amount of power required from day to day for the different classes of work, the duty of the three steam plants could be easily performed by a single steam plant of two-thirds their united capacity.

So large a saving in coal and labor as was expected from this arrangement induced Lieut. Garrett to engage the services of Mr. T. W. Sprague, of Boston, Mass., to investigate jointly with him the various systems of transmission. The parties interested inspected personally a number of the principal polyphase plants among the New England mills, and finally selected the Westinghouse three-phase system, 3,600 alternations, as best adapted to the work of the Atlas Tack Co. This system, in connection

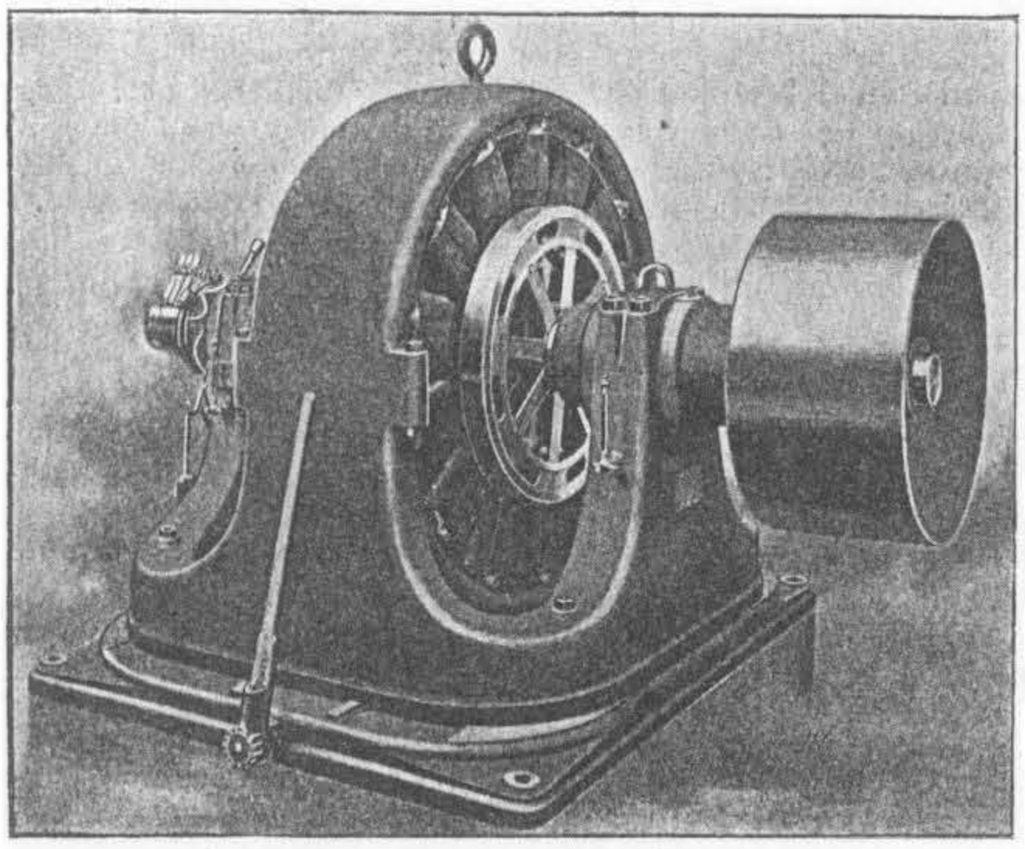

FIG. 1—150 K. W. WESTINGHOUSE GENERATOR.

with the Tesla "Type C" motors, made by the Westinghouse Electric and Manufacturing Co., has attained marked success in every instance in which a plant has adopted it, and the alternate current motor, though developed later than the direct current motor, has been favorably received in all such installations.

The Atlas Tack Co. are to use a 150-kilowatt Westinghouse generator, shown in Fig. 1, which will operate 9 Tesla induction motors of the above type, shown in Fig. 2, ranging from 3 to 50 horse power, in the various mills. The gas lighting system of the mills will be replaced by about 1,000 incandescent lights.

The company instituting these changes is one of the most progressive of manufacturing concerns, employing over 500 men,

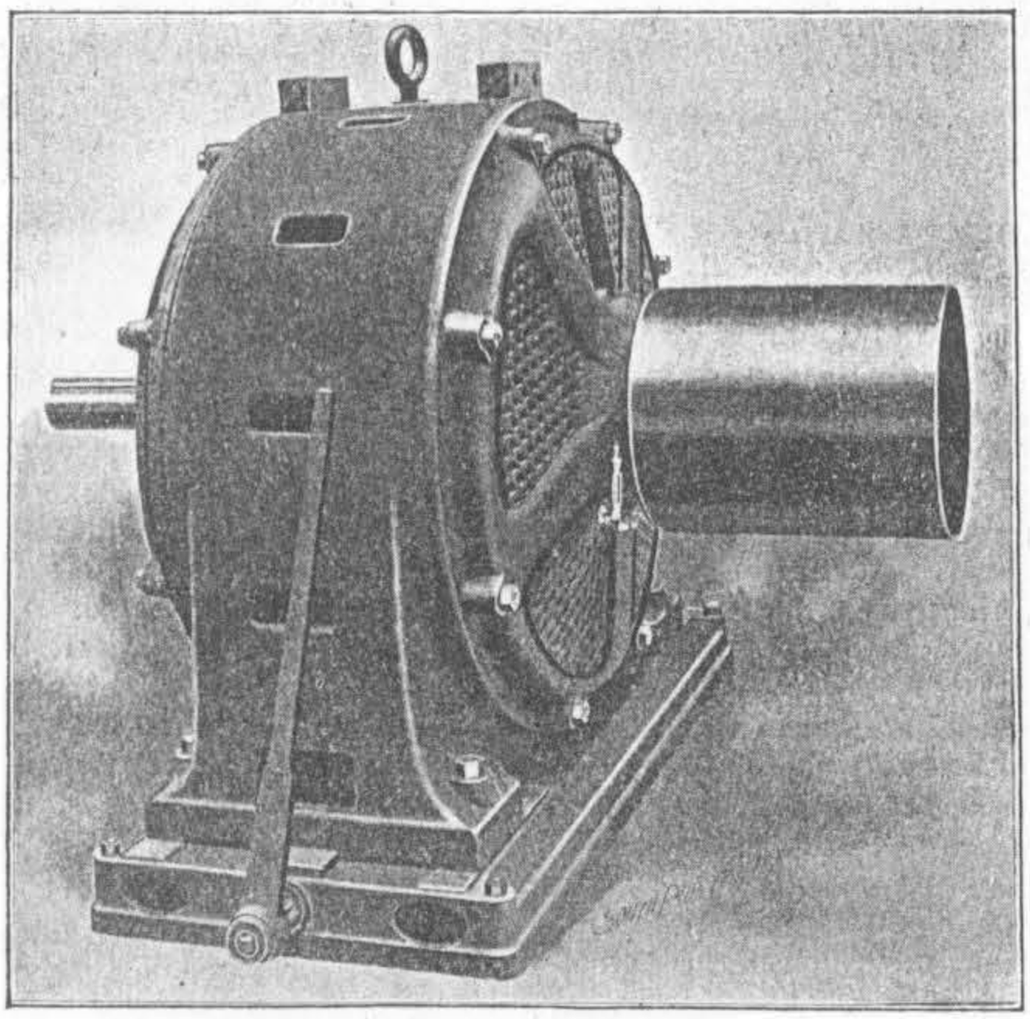

FIG. 2.—TESLA INDUCTION MOTOR.

and making some 10,000 brands of tacks, rivets, etc. Considerably over 50 per cent. of all the tacks and rivets made in the United States are produced at their shops, and their electrical equipment will be watched with interest, and no doubt imitated by many other concerns of the kind.

The adaptability of the "Type C" motor, as made by the Westinghouse company, to so many varied fields of usefulness, has surprised many, who have possibly been prejudiced against the alternating current motor; but the cause of their surprise constitutes one of the strongest proofs of the reliability of this new Westinghouse product.

THE DEVELOPMENT OF HIGH FREQUENCY CURRENTS FOR PRACTICAL APPLICATIONS.

There will be found in another part of this paper a description of an extensive line of interrupters or circuit make and break devices lately patented by Mr. Nikola Tesla for use in the production of high-frequency currents. Oscillatory currents with a frequency of several hundred thousand alternations per second are fortunately easily generated by the simple discharge of a condenser through an inductive path, the main difficulty in producing them being the means of again starting the oscillations whenever they die out, as, of course, they do in a very small fraction of a second. The electrical method by means of a discharge is, of course, extremely wasteful, and mechanical devices for this purpose have heretofore been very troublesome, particularly in the contacts.

Mr. Tesla has been working at this problem for some years, recognizing that its solution was essential to the success of the commercial application of such currents. The results of this work appear in these recently issued patents. In general he uses a jet contact for the make and break device or circuit interrupter similar to the jets used in laboratory work for brief contacts in the determination of the wave form of alternators, etc. Mercury is preferred, owing to the high specific resistance of its vapor, and the low resistance of the liquid and a form in which jet meets jet possesses advantages, as in this case there is no sparking to or from a solid metal. Further, the contacts are made in an inclosed chamber filled with some inert gas, if necessary under considerable pressure. If atmospheric pressure is used, the apparatus is simply hermetically sealed, the small amount of oxygen contained within being soon absorbed by oxidation, leaving an inert insulating medium of nitrogen. If pressure is desired—and high pressure cuts down the arcing of such devices even more than does a high vacuo—anhydrous liquid ammonia may be used, the minute sparks gradually dissociating the ammonia into its elements, hydrogen and nitrogen, the former diffusing through the containing walls, leaving inert nitrogen under pressure.

The designer states that these machines run satisfactorily, without apparent change in the liquid, and requiring a surprisingly small amount of attention, small instruments transforming several horse-power continuously for long periods with no attention whatever. More than this, he also states that the efficiency of conversion between the direct current supplied and the high frequency current obtained, the latter being measured by calorimetric methods, is as high as 95 per cent. This being the case, the use of such currents for lighting purposes may be expected as soon as the luminous efficiency of exhausted bulbs or tubes under the action of such currents approaches or exceeds that of the incandescent filament, the fulfillment of which condition Mr. Tesla confidently promises. Such currents may also find a wide application in other fields, one of which is the electro-chemical, for the production of such compounds as ozone, in which high-frequency currents are said to give a much greater output per unit of energy than those of frequencies now used. Other chemical conversions are also readily accomplished by the same means, a promising one being the oxidation of atmospheric nitrogen, giving, if commercially practicable, promise of an enormous use of electrical energy in the production of nitrates and other nitrogenous substances, for which there is a great demand in the arts.

Mr. Tesla's Circuit Interrupters.

For the production of intermittent currents for use in obtaining oscillatory currents of very high frequency by means of charging a circuit possessing capacity and self-induction, Mr. Nikola Tesla has designed a large number of interrupters or make and break devices embodying many ingenious features. These interrupters, or, as Mr. Tesla calls them, circuit controllers, were patented in a group of patents issued August 16, 1898.

In order to make clear the purpose of these devices it may be well to give an untechnical explanation of the means of producing high frequency or oscillatory currents. Whenever a charged condenser is short circuited through a circuit containing self-induction the sudden rush of current, by an action analogous with mechanical inertia, over-discharges the condenser, charging it up in the reverse direction; this again discharges the other way, again reversing the charge in the condenser, and so on, the oscillations gradually dying out at a rate dependent on the resistance of the circuit. With ordinary Leyden jars and the small self-induction obtained by a few turns in air, these oscillations have a frequency of several hundred thousand alternations per second, this frequency running up as the capacity of the condenser or the amount of the self-induction is diminished, being, in fact, inversely proportional to the square root of the product of the capacity and the self-induction. To start such an action the condenser must first be charged and then closed on its discharge circuit. The simplest way of accomplishing this, and the means most commonly used, is to insert a spark gap in the circuit and in shunt with this spark gap connect the secondary of a high-voltage transformer supplied with ordinary alternating current, or the secondary of an induction coil. The action, then, is as follows: As the voltage rises in the transformer the condenser is gradually charged until the pressure gets so high that it jumps across the spark gap. The spark or arc here formed is of such a low resistance that the condenser and its discharge circuit are practically short circuited through it, and the oscillations continue for a short while, until the arc dies out, the action being repeated at the next reversal of the alternating current supplied.

Such a method is extremely wasteful of power, for two reasons. First, because the secondary of the transformer is short circuited just at the peak of the wave; and, second, because the arc or spark offers some resistance to the high-frequency oscillations, which, therefore, die out more quickly than they would if they were not opposed in this way. A far better plan, therefore, is the use of a mechanical interrupter, such as those described below, the action of which can best be understood by a reference to Fig. 3. Here *A A* are the terminals of the source of supply, which may be either direct or alternating current at commercial pressures, 100, 200, 500 or 1000 volts. *A'* is a highly inductive coil which should be wound on iron. *A''* is the condenser, *B* a small self-induction, and *C* the interrupter. The action is as follows: When the circuit is open at *C*, the pressure applied from the source of supply acts through *A'* and *B* to charge the condenser, *A''*. Suddenly *A''* and *B* are short circuited through the interrupter, *C*, and the condenser discharges with oscillations, occurring perhaps several hundred thousand times per second. These gradually die out, becoming negligible after perhaps 200 or 300 oscillations, when the circuit is suddenly opened again at *C*. It should be noted that *C*, besides short circuiting the condenser through its slight self-induction, *B*, has also short circuited the source of supply connected to the terminals, *A A*, through the inductive coil, *A'*. This short circuit is so brief, however, that the incoming current has not had time to rise to an undesirable strength, but has been held back by the self-induction of *A'*. It has also while rising been storing up, so to speak, a certain amount of energy in the magnetic circuit of *A'*. Now, when the circuit at *C* is again opened, this current, passing through *A'*, tends to persist, owing to the self-induction therein, and charges the condenser *A''* up to a voltage considerably higher than that of the source of supply, the energy absorbed in the magnetic circuit of *A'* passing out thus into the condenser *A''*, charging it to a high voltage, the interrupter, *C*, afterward short circuiting this and allowing the current to oscillate again through the discharge circuit, *B*.

Thus the interrupter, *C*, inductive coil, *A'*, and the source of supply act to open the condenser circuit for a brief instant and charge the condenser by a sort of electrical blow, immediately short circuiting it again and allowing it to discharge in oscillations. If the condenser discharge circuit is tuned to a frequency of, say, 300,000 per second, and its resistance is such that 300 oscillations take place before they die down to a negligible value, the interrupter, *C*, should make and break the circuit about 1000 times a second. There will then exist in the condenser discharge circuit, *B*, a cycle somewhat as follows: A sudden surging charge followed by an oscillatory discharge, starting with high waves, which gradually die down until interrupted by the next surging charge, etc. Owing to the enormous frequency of these oscillatory discharges, they can be transformed by ordinary double-winding, stationary alternating transformers, with a very small amount of material for their capacity, since the capacity of any transformer is proportional to the rate of change of lines of force, and is hence proportional to the frequency of the alternating currents therein. So high is this frequency that an air magnetic circuit is all that is necessary, iron, in fact, being a disadvantage, owing to the energy lost within it in eddy currents and hysteresis, with such a high frequency. In the figure, *B* represents the primary of such a high-frequency air transformer, *B'* being the secondary, with a winding of more turns to obtain higher tension, the output of which is delivered to any translating devices, as *B''*.

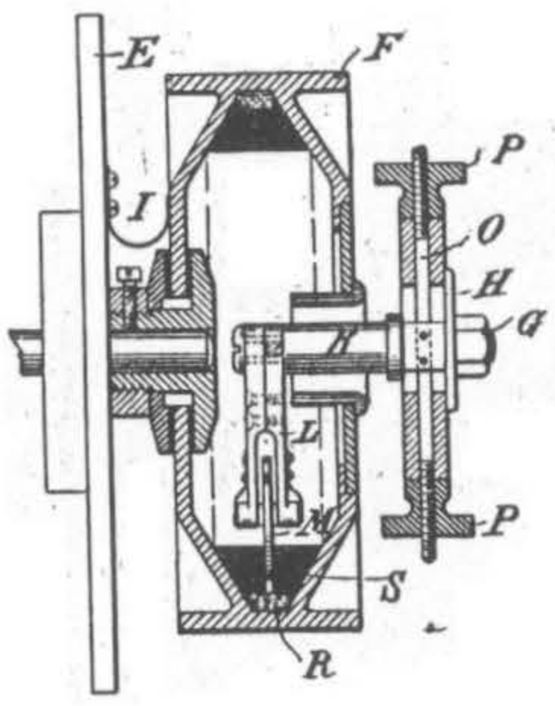

FIG. 1.

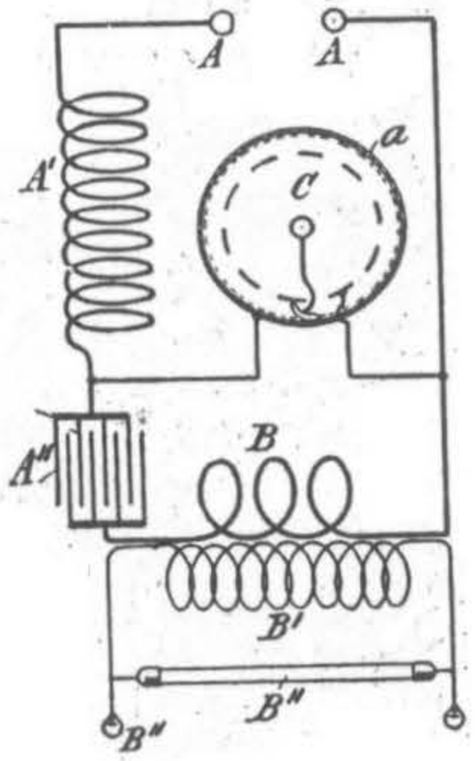

FIG. 3.

The distinguishing feature of the devices described below is the use of a liquid for one or both of the contacts of the make and break devices, this liquid preferably being mercury, acting in some instances in the form of a jet and in other cases as a surface with which a solid conductor makes and breaks a contact. Ingenious applications are also made of other principles, such as the use of a liquid dielectric between the contacts, inert gases under high pressure, jets meeting each other, etc.; and all the instruments are worked out with great perfection of detail for continuous and practically frictionless running, such as to require a minimum of attention.

The requirements of such an instrument are well stated in the patent specifications, as follows: The capability of effecting an extremely rapid interruption and completion of the circuit, the latter being positive and abrupt; the apparatus not to be liable to derangement, and capable of prolonged use without attention or adjustment.

Of the various types described the first is that shown in cross section in Fig. 1. This consists of an inclosing shell, *F*, arranged to be rapidly rotated by means of a motor coupled to the shaft shown at the left, and containing two liquids of different specific gravities, that with the higher specific gravity being a conductor and the other an insulator; preferably the conductor is mercury, the insulator being some hydrocarbon. When the shaft and shell mentioned are rapidly rotated the mercury flies to the periphery by centrifugal force and forms a ring shown at *R*, the other liquid forming an inner ring, as shown at *S*. Within the shell is an arm, *L*, supported on a non-rotating shaft, *H*, carrying a wheel, *M*, with projecting points sufficiently long to touch the mercury, *R*. As the liquids revolve they rotate this wheel at high speed, the points of which successively and repeatedly dip into the mercury rim and leave it again, the relative motion being a hypo-cycloid. The insulating liquid, under considerable pressure, owing to centrifugal action, forces itself between the mercury and the points as the lat-

ter recede and extinguishes the arcs which tend to form across these gaps. Other figures attached to the same patent show the machine assembled with a motor, condenser and transformer.

The next patent describes the waste of energy which occurs during the periods of make and break, or both, due to the passage of the current through an arc formed between the terminals; this loss of energy is said to be generally such as to render impossible a practical and economical conversion of considerable amounts of electrical energy by means of ordinary make and break devices, particularly in cases where a high frequency is required. Experiment and investigation have led Mr. Tesla to recognize the following laws governing this waste of energy: First, that the loss in any device for making and breaking a circuit, other conditions being the same, is inversely proportional rather to the square than to the first power of the relative velocity of the terminals in approaching and receding from one another in case the current curve is not so steep as to materially depart from one which may be represented by a simple sine function of the time; but such a case seldom obtains in practice; on the contrary, the current curve resulting from a make and break is generally very steep and particularly so when the circuit controller effects the charging and discharging of a condenser, and consequently the loss of energy is still more rapidly reduced by increased velocity of approach and separation.

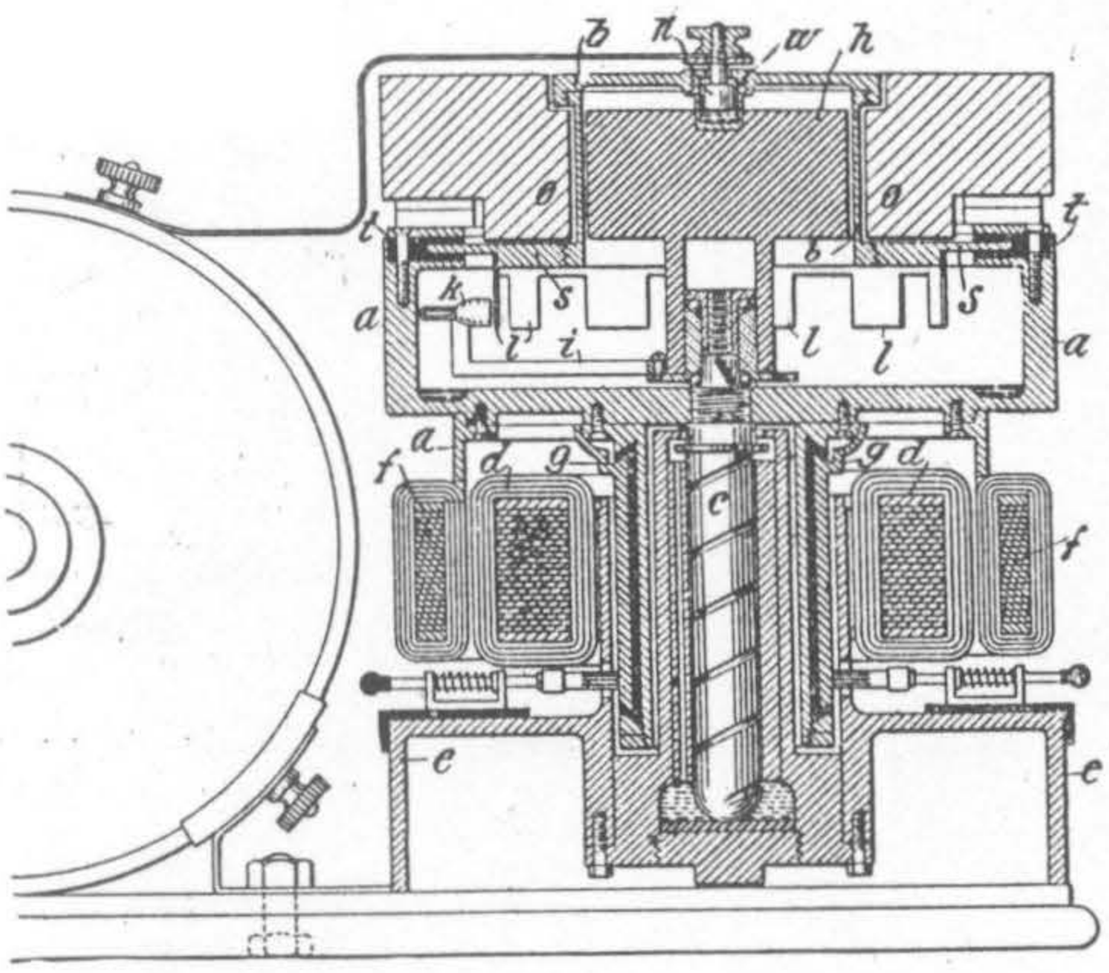

Fig. 2.

With a view to securing an interrupter in which not only the relative speed of the terminals but also the frequency of the interruption should be very high, the instrument shown in Fig. 2 was designed; this consists essentially of a shell, *a*, attached to the external armature, *f*, of a direct-current motor with a commutator, *g*, and field magnets, *d*, by which means the shell, *a*, is rotated at high speed on a self-oiling spindle, *c*. Projecting downward from the upper lid of the shell is a series of teeth, *l*, and within the case is a nozzle, *k*, arranged to throw a jet of mercury against these teeth; the nozzle is attached by means of an arm, *i*, to an armature, *h*, which is prevented from rotation by means of the field of force of an external non-rotating magnet, *o*, this field acting through the shell of the rotating case on the armature within. When mercury is placed within this case and the latter is revolved the mercury rises by centrifugal force against the outer wall and is caught by an open mouth or scoop attached to the non-rotating nozzle, *k*, and directed by the latter against the teeth, *l*. The main circuit is open between this nozzle and these teeth, and is intermittently closed by the jet of mercury.

For the further reduction of arcing others have used contacts made in a high vacuo, but Mr. Tesla claims that only a moderate improvement is secured in this manner, and this can be greatly exceeded by the use of certain fluids inert chemically maintained at a high pressure in the make and break chamber. It is found that in such a case the arc, when formed, is restricted to a small cross section or is, in other words, prevented from expanding laterally, and is therefore more quickly raised to a high resistance, choking back the current to such an extent that the arc is more promptly extinguished.

Fig. 4 shows an apparatus designed to make use of this principle. Here *F* is the laminated field ring or primary of a rotary field motor, the secondary of which is wound upon the rotatable core, *E*, mounted on the shaft, *D*, within the gas-tight shell, *A*, which is closed by the insulated and gas-tight cover, *B*. The rotating field of force obviously acts through the shell, *B*, which should be an insulating material or high-resistance metal, and rotates the parts within which carry a crown of downwardly pro-

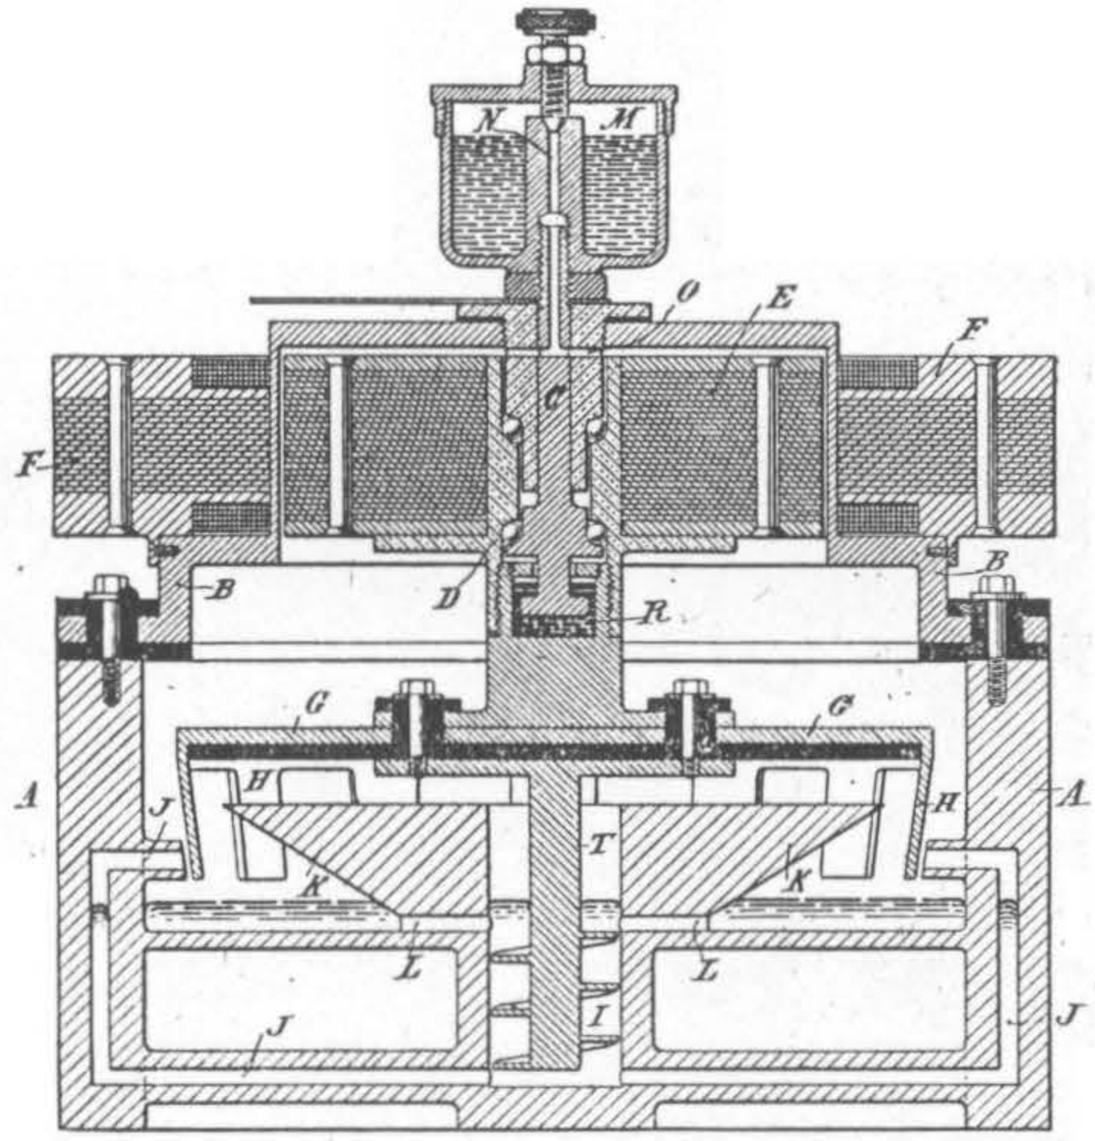

Fig. 4.

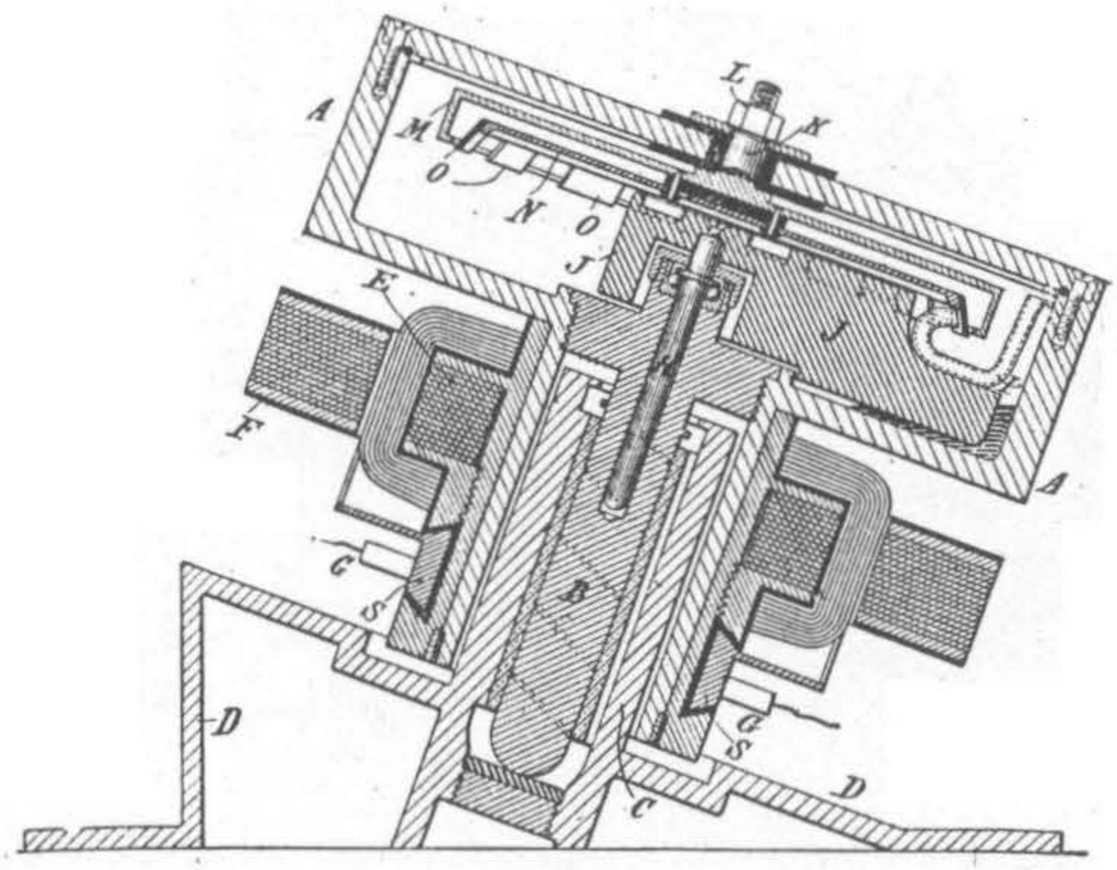

Fig. 5.

jecting teeth, *H*, and on the lower end of the shaft a screw pump, *I*. This screw pump acts upon the mercury in the lower part of the vessel, forcing it outwardly through tubes, *J*, from which it emerges in jets against the teeth, *H*; these jets and teeth make and break the circuit as in the apparatus described above, the whole being kept under pressure by an inert fluid shown in the cup, *M*, at the top of the apparatus; this liquid may be such a one as anhydrous ammonia, giving, at ordinary temperatures, a high pressure, due to its restricted evaporation and low boiling point. The gas is carried down into the chamber through the tube, *N*, in the fixed internal part of the ball bearing, *C*.

A means of accomplishing the same result without the use of a magnetic field acting through a fixed gas-tight wall, utilizing instead the force of gravity, is shown in Fig. 5, where *A* is again a gas-tight case supported upon an inclined spindle, *B*, and arranged to be rotated by a direct-current motor with outside armature similar to that shown in Fig. 2. Within this case is an eccentric weight, *K*, mounted on a self-oiling spindle, *J*, with a ball thrust bearing to avoid its being dragged around by friction. Owing to the inclination of the rotating axis of the system from the vertical, this weight, *K*, tends to remain at the low side and not to revolve with the case. Attached to this non-rotating weight, *K*, is an arm, *L*, carrying another ball bearing shaft, *N*, supporting a

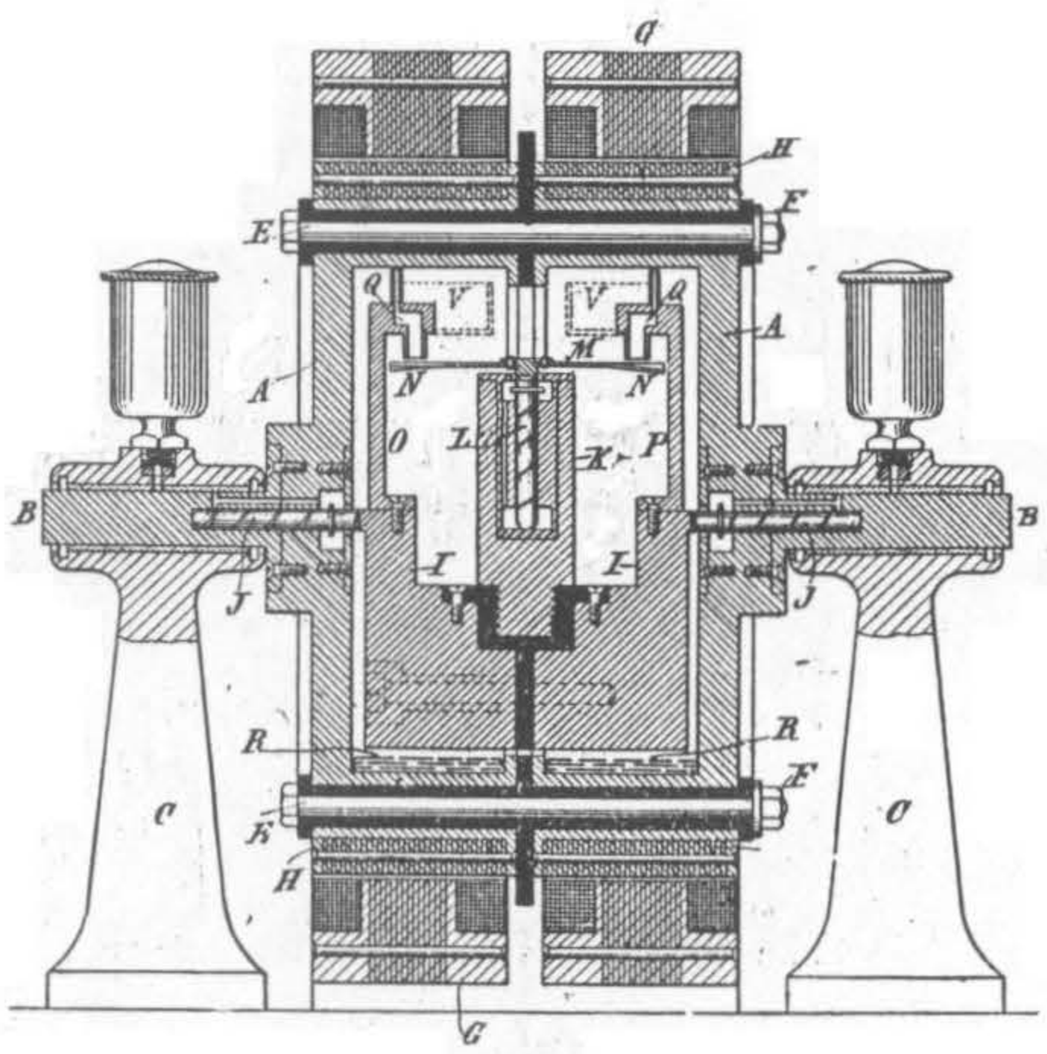

FIG. 6.

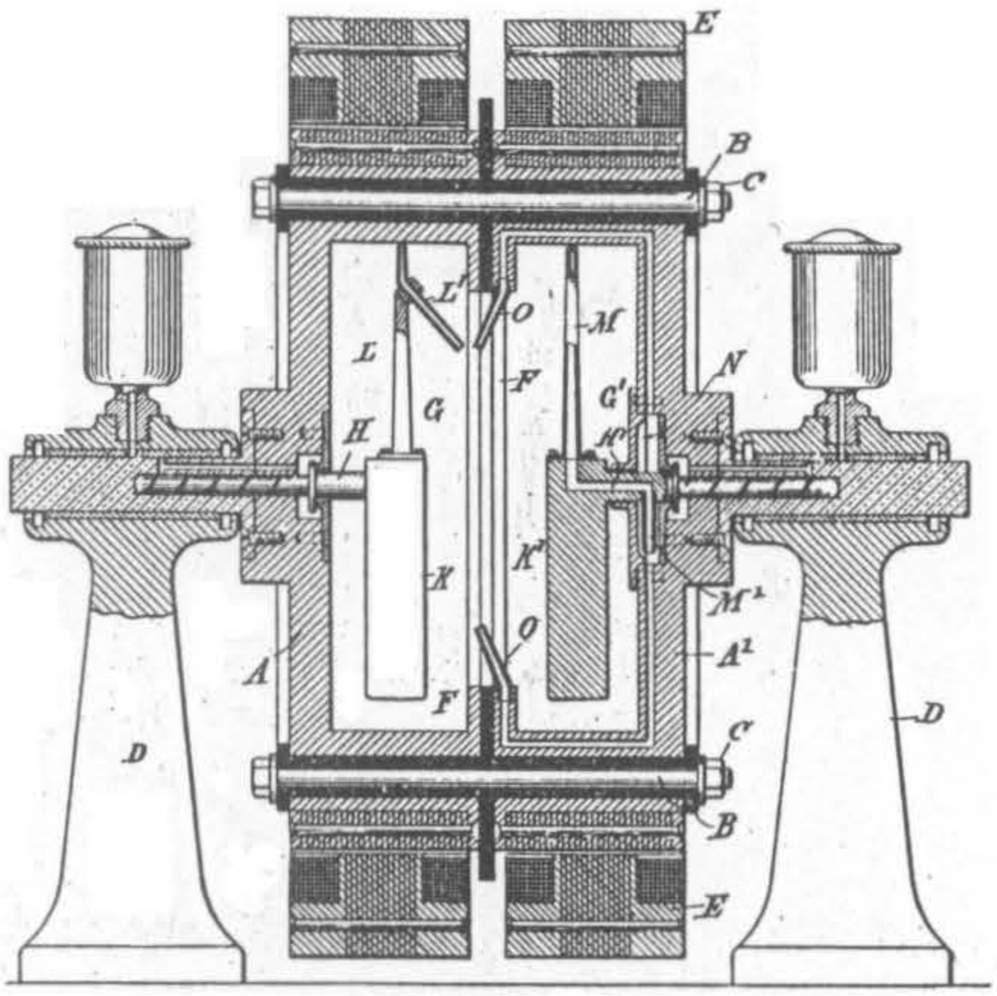

FIG. 7.

number of vanes, *Q*. When the case is revolved the mercury contained therein is maintained by centrifugal force in the form of a ring against the outside wall, into which ring the vanes, *Q*, dip and are rotated at high speed, making and breaking a contact between themselves and the mercury.

Still another device for obtaining a rapid make and break in a gas-tight chamber, this time utilizing both the rotary field and the eccentric weight, is shown in Fig. 6, where *G G* are two stationary primaries of the induction motor, which in this case is arranged in a vertical plane of rotation, *H H* being two secondary rotors, the necessity for two elements being the division of the rotating part by insulating gaskets into two sections. Within this rotating chamber, *A*, are mounted two eccentric weights, *I I*, fastened together by an insulating joint and supported on the spindles, *J J*. Fastened also to them is the central vertical journal, *K*, in which rotates the spindle, *L*, carrying a wheel, *M*, and inclined helically bent blades, *N N*. As before mercury placed in the revolving case is carried around by centrifugal force and, meeting the spouts attached to the nozzles, *Q*, is driven by its own inertia through them against the blades, *N N*, which, owing to their inclination, are given a rapid rotary motion about the spindle, *L*. The claims of novelty made for this combination are the facts that the action of the jets themselves puts in motion the solid terminals of the make and break device, with a speed very high compared with that of the shell, and that the motion of the vanes acts gyroscopically to prevent oscillation (and hence variation of the frequency) of the eccentric weights, *I I*.

A similar make and break device, in which, however, both terminals are liquid jets, is shown in Fig. 7. Here, as in Fig. 6, are the two rotary field motors rotating in a vertical plane with eccentric weights, *K K'*, the scoop attached to the former directing a jet from the nozzle, *L'*. The scoop attached to the other is intended to direct the liquid through the tube, *M*, to the axis of rotation, whence it is distributed through passages in the rotating case to the nozzels, *O O*. These jets striking that from *L'* make and break the circuit between the two insulated halves of the shell,

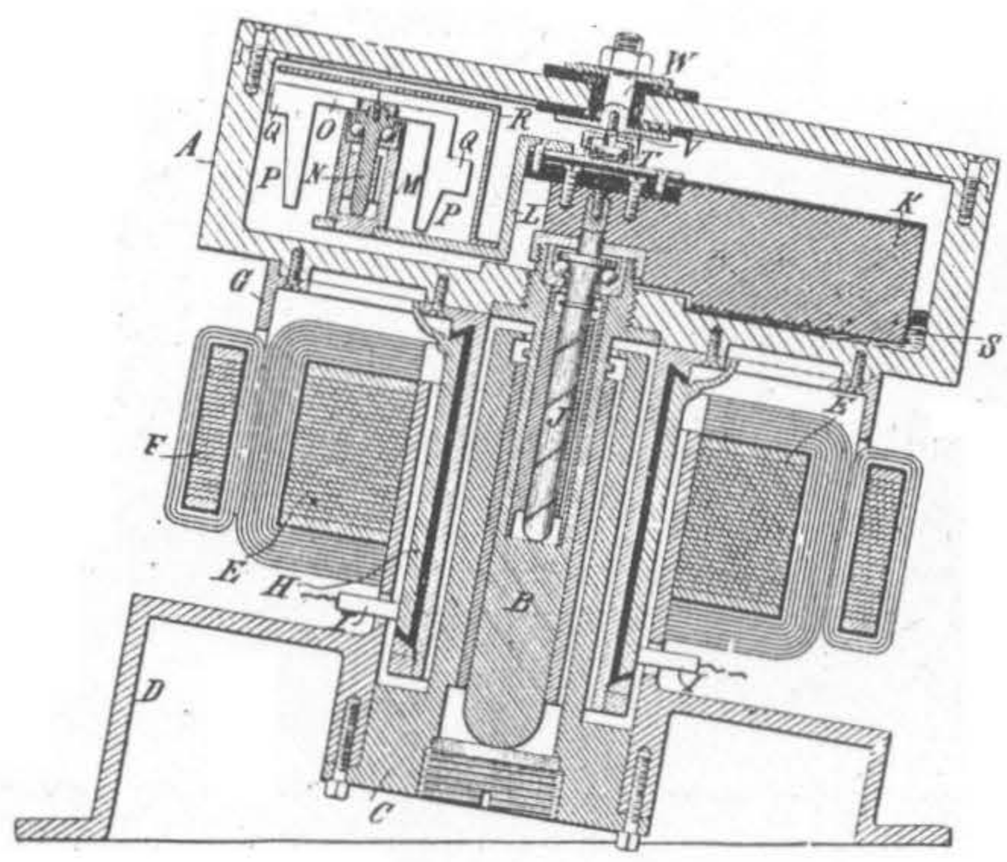

FIG. 8.

thus giving liquid contacts at both terminals of the make and break device.

Another interesting variation of the inclined axis arrangement shown in Fig. 5, giving mercury terminals in another way, is shown in Fig. 8, the essential features of which are a rotating shell, *A*, eccentric weight, *J*, carrying a tube, *P*, with scoop and nozzle and an unbroken solid metal terminal, *M*, with which the mercury makes contact. Rotating with the shell is a crown of downwardly projecting teeth, *O O*, these teeth being in this instance insulators preferably non-organic and vitreous. These insulating teeth cut off the stream of mercury intermittently, giving a rapid make and break with mercury terminals.

A further modification by which higher frequency is obtained is shown in Fig. 9, the frequency being doubled by means of rotating both terminals of the make and break device in opposite directions. This is effected by means of one rotary field generated by the primary, *H*, actuating the rotatable secondary, *G*, which carries on spindle, *C*, the gas-tight shell, *D*, through the upper part or cap of which, *F*, still another rotary field acts upon the secondary wound upon *Q*, which in turn is rotatable on spindle, *P*, and carries by means of arms, *T*, the mercury scoops and jets, *V*. These move in one direction while the teeth, *L L*, rotate with the case, *D*, in the opposite direction, thus giving double the frequency obtainable with the same angular velocity and one member stationary.

A most curious modification is shown in Fig. 10, in which the winding of the secondary of one of the elements, instead of being a copper short-circuited squirrel cage, as in the induction motors described above, consists of the mercury itself, this being arranged

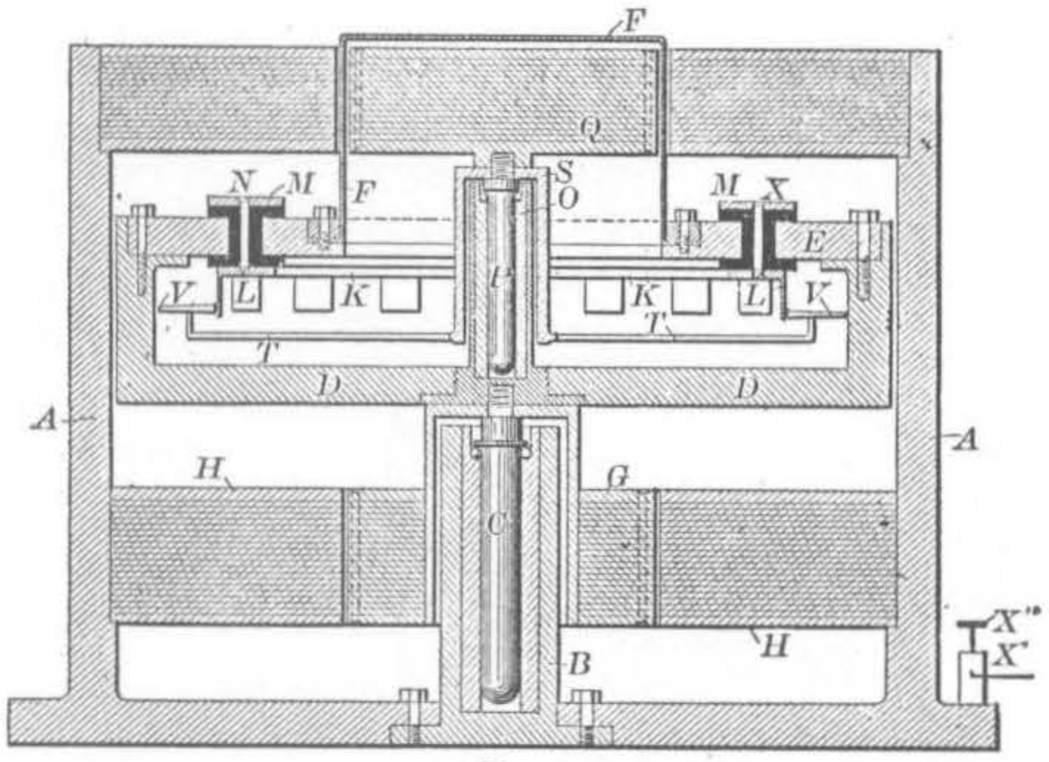

Fig. 9.

in two rings, *B B'*, forming the two terminals. A powerful rotating field, generating Foucault currents in these rings, will rotate them with a high velocity, the field completing itself through the stationary core, *E'*. Above is another rotary field actuating the secondary, *N'*, which carries the star wheels, *L' L''*, whose teeth

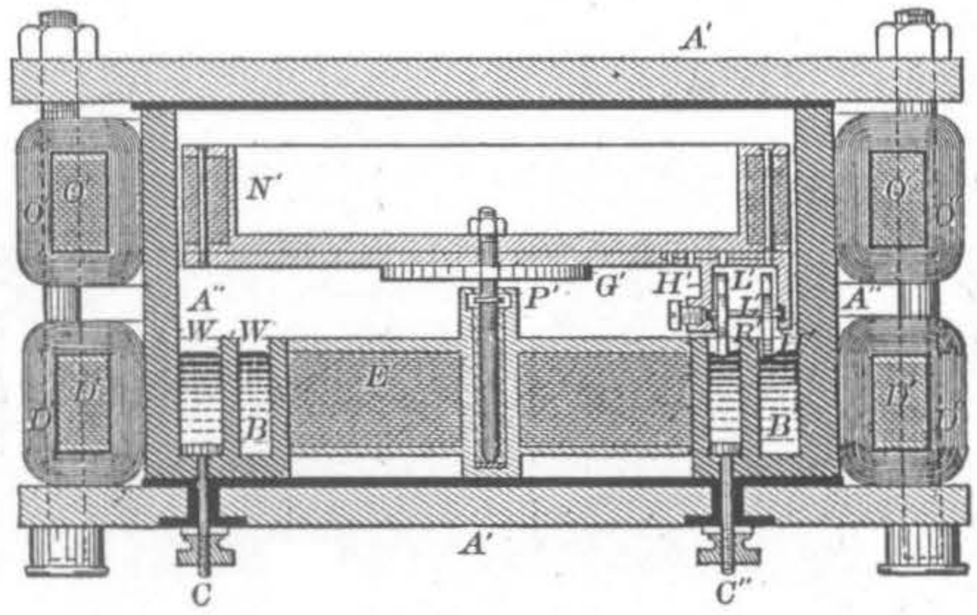

Fig. 10.

dip into the mercury rings below. The element carrying these wheels is supposed to rotate in the opposite direction from the rings of mercury, giving the star wheels a high peripheral velocity and a correspondingly high frequency of make and break.

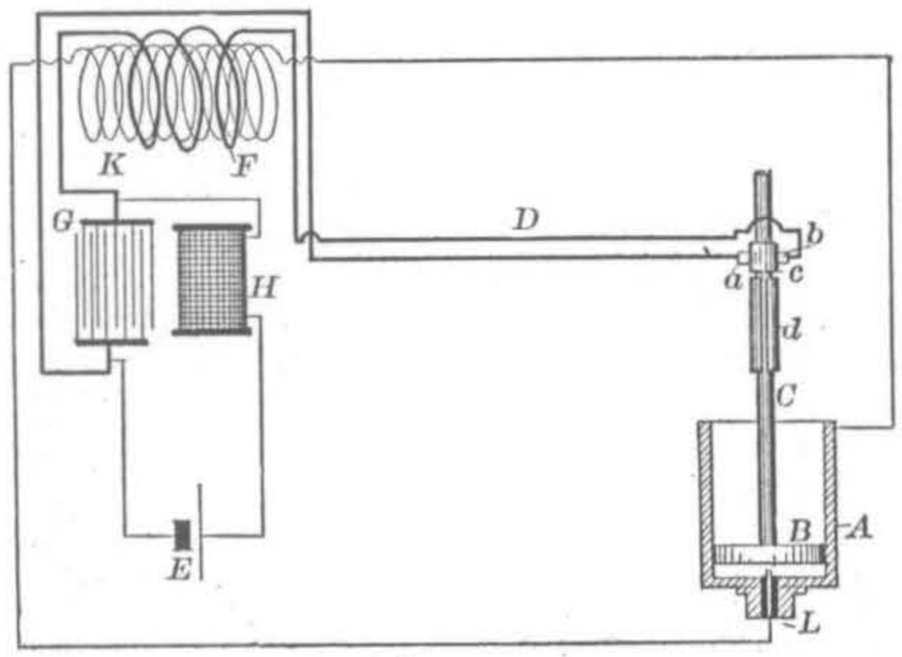

Fig. 11.

Another patent issued simultaneously with those described above and by the same inventor covers an improvement in electrical igniters for gas engines, as shown in Fig. 11, the principle being the use of an oscillatory discharge in the cylinder of the engine, the primary impulse being obtained at the proper instant from a contact actuated by the motion of the engine parts.

In the figure, *E* is the source of current, *H* an inductive coil, *G* a condenser, and *K* the transformer; at *a* is shown the contact for short-circuiting the primary and condenser at the proper time, thus causing a discharge from the secondary between the terminal, *L*, and the piston, *B*.

Remarkably broad claims on these various mechanical combinations have been obtained, the most important being briefly as follows: a rotating receptacle and independently mounted terminal, making contact with the fluid therein; a jet making contact with spaced conductors in combination with self-contained means for maintaining a circulation of the fluids (the use of a jet contact being well known in the art was not broadly patentable); an interrupter surrounded in a closed receptacle by an inert insulating medium under pressure; the use of jets for both terminals and the use of a jet intercepted intermittently by insulating solids.

MISCELLANEOUS

Tesla Circuit Controllers for Obtaining Oscillatory Currents of High Frequency.

ON August 16 a very ingenious and apparently significant group of patents was issued to Mr. Nikola Tesla, comprising several types of current-interrupting devices for obtaining oscillatory currents of very high frequency. Mr. Tesla has called them "electrical circuit controllers" and their use and construction may be understood by the following introductory remarks, taken from the patent specification referring to the class of circuits for which they were designed. We present also several illustrations showing the latest forms developed by Mr. Tesla, whose persistent investigations along the high frequency line entitle him to much praise and credit.

In every form of electrical apparatus involving a means for making and breaking more or less abruptly, a circuit, a waste of energy occurs during the periods of make or break, or both, due to the passage of the current through an arc formed between the receding or approaching terminals or contacts, or, more generally, through a path of high resistance. The tendency of the current to persist after the actual disjunction or to precede the conjunction of the terminals exists in varying degrees in different forms of apparatus, according to the special conditions

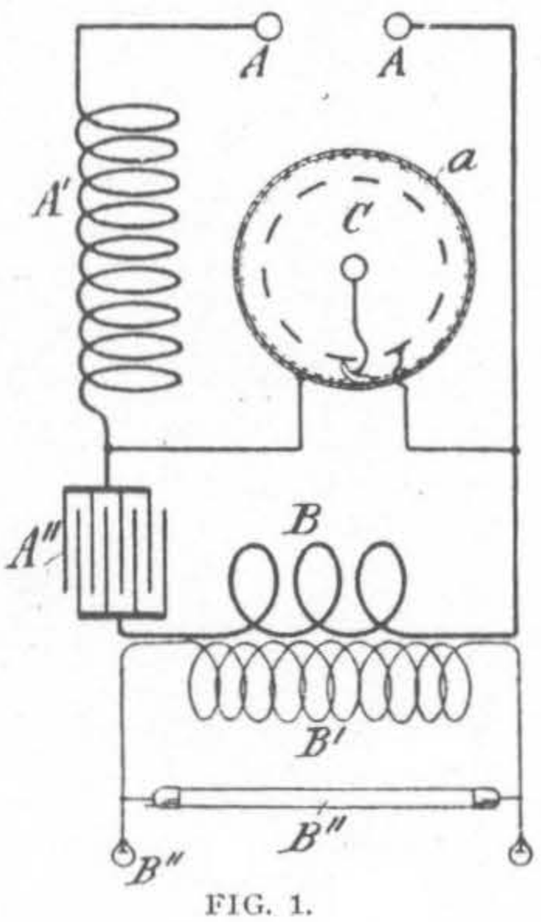

FIG. 1.

present. For example, in the case of an ordinary induction coil the tendency to the formation of an arc at the break is, as a rule, the greater, while in certain forms of apparatus in which the discharge of a condenser is utilized this tendency is greatest at the instant immediately preceding the conjunction of the contacts of the circuit-controller which effects the discharge of the condenser.

The loss of energy occasioned by the causes mentioned may be very considerable and is generally such as to greatly restrict the use of the circuit-controller and render impossible a practical and economical conversion of considerable amounts of electrical energy by its means, particularly in cases in which a high frequency of the makes and breaks is required.

Extended experiments and investigation conducted with the aim of discovering a means for avoiding the loss incident to the use of ordinary forms of circuit-controllers have led Mr. Tesla to recognize certain laws governing the waste of energy and making it dependent chiefly on the velocity with which the terminals approach and recede from one another and also more or less on the form of the current-wave. Briefly stated, from both theoretical considerations and practical experiment, it appears that the loss of energy in any device for making and breaking a circuit, other conditions being the same, is inversely proportional rather to the square than to the first power of the speed or relative velocity of the terminals in approaching and receding from one another in an instance in which the current-curve is not so steep as to materially depart from one which may be represented by a sine function of the time; but such a

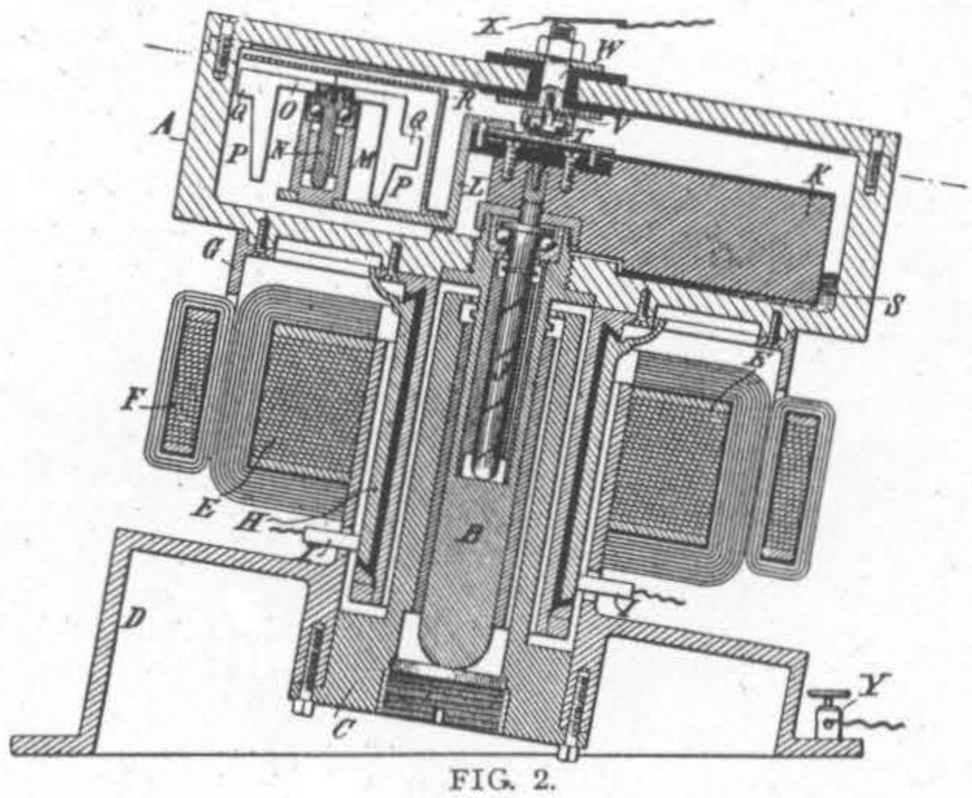

FIG. 2.

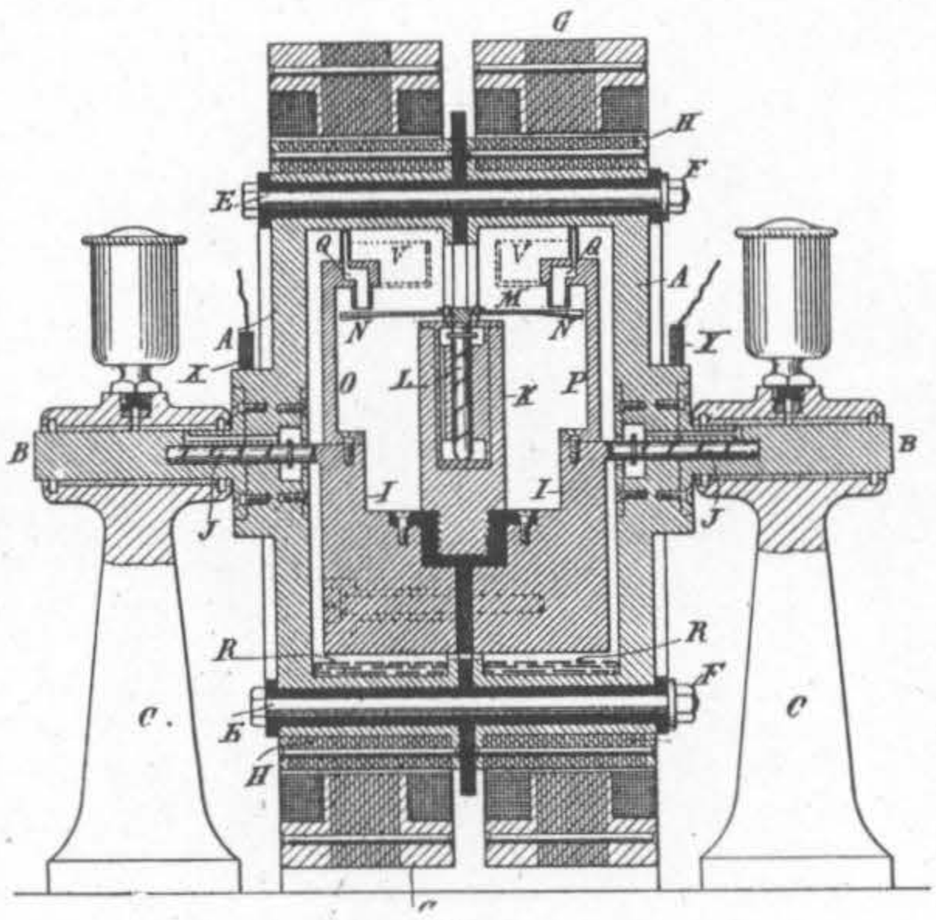
case seldom obtains in practice. On the contrary, the current-curve resulting from a make and break is generally very steep, and particularly so when, as in Mr. Tesla's system, the circuit-controller effects the charging and discharging of a condenser, and consequently the loss of energy is still more rapidly reduced by increased velocity of approach and separation. The demonstration of these facts and the recognition of the impossibility of attaining the desired results by using ordinary forms of circuit-controllers led Mr. Tesla to invent other means for making and breaking a circuit in which he has utilized a conducting fluid, such as mercury, as the material for one or both of the terminals and devised novel means for effecting a rapidly-intermittent contact between the fluid and a conductor or series of conductors forming the other terminal.

In this apparatus one of the members or terminals is a conducting fluid which is caused to issue from an orifice against a series of spaced conductors in rapid succession. For this purpose the series of conductors, or it may be a single conductor, is moved transversely through the stream or jet of fluid, or the jet is moved so as to impinge upon the conductors, or both jet and conductors are moved. This is preferably accomplished



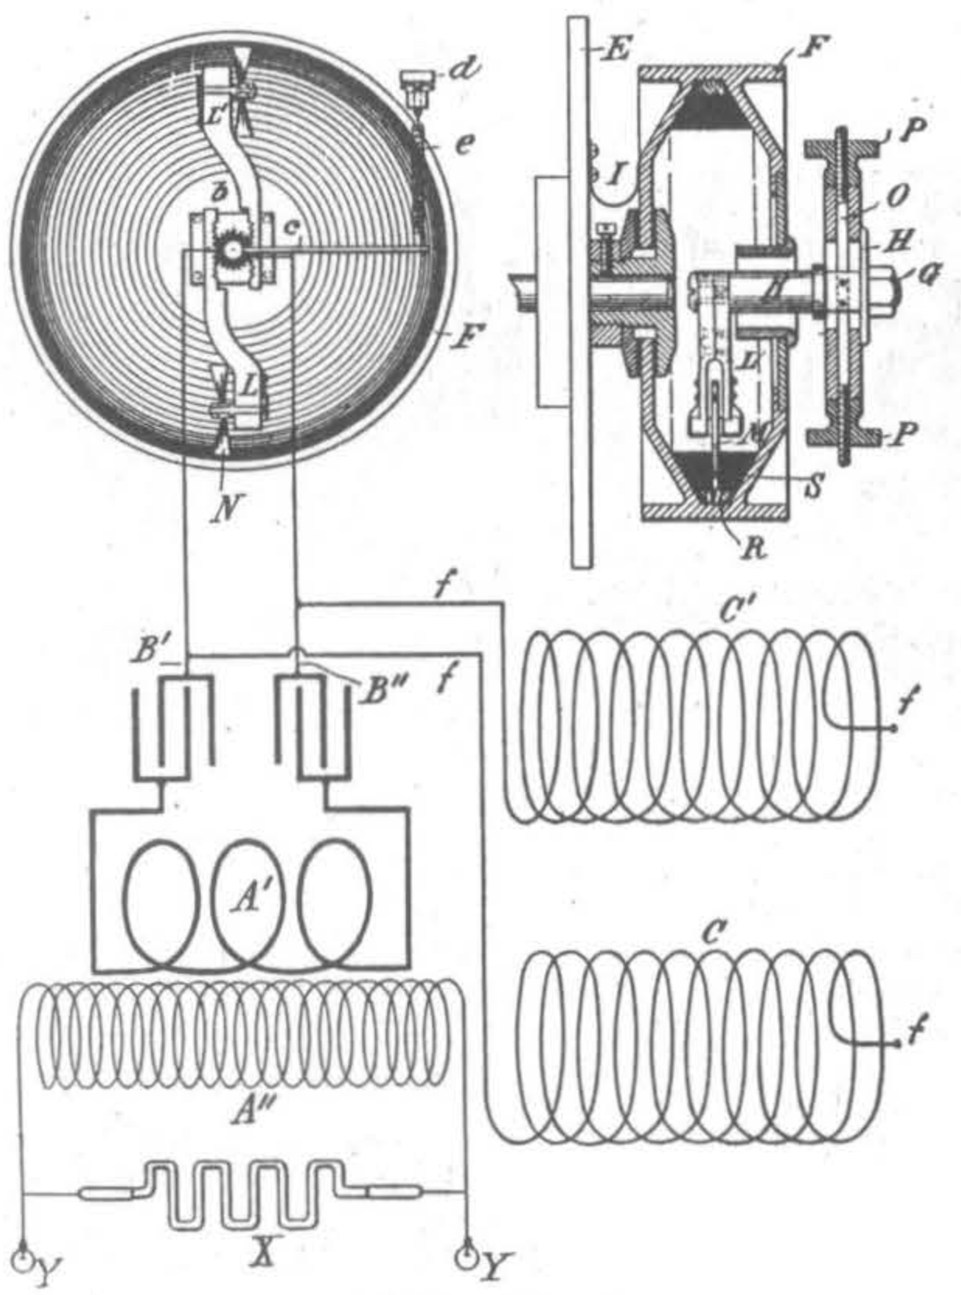


FIG. 3.

by mounting the conductors and the tube or duct from which the fluid issues concentrically and revolving one or both.

The plan adopted for maintaining the stream or jet of conducting fluid consists in utilizing the same power that actuates or drives the circuit-controller in effecting the necessary rela-

tive movement of its terminals to maintain the proper circulation of the conducting fluid by combining the two mechanisms (the controller and the means for maintaining a circulation of the conducting fluid) in one. This feature is of great practical advantage and may be effected in many ways. A typical arrangement for this purpose is to provide a tube or duct having an orifice at the end directed toward the spaced conductors and its other end in a position to take up a portion of the rapidly-rotating body of conducting fluid, divert it through the duct, and discharge it against the conductors. With this object when a closed receptacle is used a holder for the tube is employed, mounted within the receptacle and concentrically therewith, and this holder, when the receptacle is revolved, is held or influenced by any suitable means, as by magnetic attraction exerted from the outside or otherwise, in such manner as to keep it either in a fixed position or impress upon it a velocity different from that of the rotated fluid.

The general scheme of the system for use with which the circuit-controllers are more especially designed will be understood by referring to Fig. 1. In this figure A A represent the terminals of a source of current. A′ is a self-induction or choking coil included in one branch of the circuit and permanently connected to one side of a condenser A″. The opposite terminal of this condenser is connected to the other terminal of the source through the primary B of a transformer, the secondary B′ of which supplies the working circuit containing any suitable translating devices, as B″.

FIGS. 4 AND 5.

The circuit-controller C, which is represented conventionally, operates to make and break a bridge from one terminal of the source to a point between the choking-coil A′ and the condenser A″, from which it will result that when the circuit is completed through the controller the choking-coil A′ is short-circuited and stores energy which is discharged into the condenser when the controller-circuit is broken, to be in turn discharged from the condenser through the primary B when these two are short-circuited by the subsequent completion of the controller-circuit.

Six different constructions of circuit controllers have been patented by Mr. Tesla in this group referred to in the beginning of this article, but we have selected three of them which illustrate fairly well the various types for which patents were granted.

Referring to Fig. 2, the operative portions of the circuit-controlling mechanism are contained in a closed cylindrical receptacle A, of iron or steel, mounted on a spindle B in a suitable socket or support C to permit it to be freely and rapidly rotated. The socket C is secured to or forms a part of a base or stand D.

As a means of producing the proper rotation of the receptacle A, a field-magnet E is shown, mounted on or secured to the base D, and an armature F, supported by a bracket G from the under side of the receptacle A. The same bracket also carries a series of commutator-segments H, upon which bear brushes I, these parts being arranged to constitute an electromagnetic motor with stationary field and rotating armature. Any other suitable means, however, may be employed to rotate the receptacle and the fluid.

In the spindle B and concentric with its axis is a spindle J in bearings specially constructed to reduce friction in order that the spindle J may be as little as possible influenced by the rotation of the main spindle and receptacle which it carries. A suitable provision is made to oppose or prevent the rotation of the spindle J during the rotation of the receptacle. For this purpose the following has been devised.

The spindle B is held by its bearings at an angle to the vertical, and a weight K is secured eccentrically to the spindle J and tends to hold the spindle always in one position. The inclination of the axes of rotation necessary for this result may be as shown, and should not be greater, for the reason that it is especially advantageous to preserve the spindles and bearings as nearly as practicable vertical on account of lesser friction and easier lubrication.

Attached to the spindle J or weight K is an insulated bracket L, carrying a standard or socket M, in which is mounted on antifriction-bearings a spindle N. Secured to this latter is a plate with radial arms O, from which depend vanes or blades P, with projections Q extending radially from it. A shield or screen R incloses the vanes, except on the side adjacent to the inner periphery of the receptacle A.

A small quantity of a conducting fluid S is placed in the receptacle, and in order to secure a good electrical connection between the vanes P and a terminal on the outside of the receptacle a small mercury-cup T, in metallic contact with the vanes through the bracket L and socket M, is secured to the weight K. A metal stud V, set in an insulated bolt W, projects into the cup T through a packed opening in its cover. One terminal of the circuit-controlling mechanism will thus be any part of the metal receptacle and the other the insulated bolt W. The apparatus may be connected up in circuit by connecting the wires of the circuit to a brush X, bearing on the bolt W, and to a binding-post Y in contact with the base D.

To operate the apparatus, the receptacle is set in rotation, and as its speed increases the mercury or other conducting fluid which it contains is carried by centrifugal force up the sides of the inner wall, over which it spreads in a layer. When this layer rises sufficiently to encounter the projections Q on the blades or vanes P, the latter are set in rapid rotation, and the electrical connection between the terminal of the apparatus is thereby made and broken, it may be, with very great rapidity.

The projections Q are preferably placed at different heights on the vanes P, so as to secure greater certainty of good contact with the mercury film when in rapid rotation.

Fig. 3 is a central vertical cross-section of another type, which involves two salient features of novelty, one that it provides for maintaining in a rotating receptacle a stationary jet or jets which by impinging on a rigid conductor maintain the latter in rotation, thereby securing the requisite rapidly-intermittent contact between the two, and the other that it utilizes the rotation of such rigid conductor as a means for opposing or preventing the movement of its own supports in the direction of rotation of the receptacle, thereby securing, among other things, an approximately constant relative movement between the parts, a feature which in devices of this kind is often very desirable.

Referring to the figure, A designates a receptacle, usually of iron or steel and mounted in any suitable manner, as by trunnions B B, having bearings in standards C C, so as to be capable of rapid rotation about a horizontal axis.

The receptacle is divided into two parts insulated by a washer D and held together by insulated bolts E with nuts F. These two parts are electrically connected, respectively with the two terminals of the apparatus, and by means of brushes X Y, bearing at any suitable points on the two parts of the receptacle, the circuit-controller is connected with the wires of a circuit.

Any convenient means may be employed to rotate the receptacle; but a simple way to effect this is to surround the same with a field-magnet G and to make the receptacle itself the armature of an electric motor or else to secure to it armature-cores, as H.

A body I is supported by trunnions J, having bearings in the ends of the receptacle and concentric with the axis of rotation of the same. The weight of the body I being eccentric to this axis tends to oppose its turning about the axis when the receptacle is rotated.

Upon the body or support I, but insulated therefrom, is secured a vertical standard K, in which there is a freely-rotatable spindle L, carrying a disc M, with radial arms inclined to the plane of the disc, so as to form vanes N. Arms O P are also secured to the body I and are formed with or carry at their ends ducts or tubes Q, with one end directed toward and opening upon the vanes N, and the other end close to the inner wall of the receptacle and opening in the direction opposite to that of the rotation of the receptacle.

A suitable quantity of mercury R is placed in the receptacle before the latter is sealed or closed.

The operation of the device is as follows: The receptacle is started in rotation, and as it acquires a high velocity the mercury or other conducting fluid R is caused by centrifugal action to distribute itself in a layer over the inner peripheral surface of the receptacle. As the tubes or ducts Q do not take part in the rotation of the fluid, being held at the start by the weighted body I, they take up the mercury as soon as it is carried to the points where the ducts open and discharge it upon the vanes of the disc M. By this means the disc is set in rapid rotation, establishing the contact between the two sides of the receptacle which constitute the two terminals of the circuit-controller whenever the two streams or jets of fluid are simultaneously in contact with the vanes, but breaking the contact whenever the jets discharge through the spaces between the vanes. The chief object of employing more than one insulated jet is to secure a higher velocity of approach and separation. The disc M, having acquired a very rapid rotation, operates to prevent by gyrostatic action any tendency of the body I to rotate or oscillate, as such movement would change the plane of rotation of the disc. The movement of the parts, therefore, and the operation of the device as a whole are very steady and uniform, and a material practical advantage is thereby secured. The speed of the disc will be chiefly dependent on the velocity of the streams and pitch of the blades, and it is of course necessary in order to produce a constant speed of rotation of the disc that the velocity of the streams be constant. This is accomplished by rotating the receptacle with a constant speed; but when this is impracticable and the uniformity of motion of the disk very desirable special means are resorted to to secure this result, as by providing overflowing-reservoirs V V, as indicated by dotted lines, from which the fluid issues upon the vanes with constant velocity, though the speed of the receptacle may vary between wide limits.

In Fig. 4 is shown a central vertical section of an improved circuit controller and Fig. 5 represents the latest and most preferred form, showing it in connection with the remaining parts of the apparatus illustrated diagrammatically. In these forms the receptacle contains both a conducting and a non-conducting fluid, the former being the heavier, and the terminals are maintained in such relations that the electrical connection between them is made and broken by the successive immersion of the contact-points into and their withdrawal from the conducting through the non-conducting fluid. These relations are best maintained by such construction of the receptacle that the distribution of the two fluids necessary for the proper operation of the device may be preserved by centrifugal action and the rotation of the other terminal effected by the movement of the fluids in relation to it.

To secure the conditions necessary for the accomplishment of the objects of the invention, various mechanical expedients may be resorted to; but the best and most practicable device for the purpose appeared to Mr. Tesla to be a hollow wheel or drum mounted so as to be rotated at any desired speed and containing a conducting fluid, such as mercury or an electrolyte, which by the rotation of the drum is thrown by centrifugal force outward to the inner periphery of the same, and a sufficient quantity of a lighter non-conducting or poorly-conductive fluid, such as water or oil, which by the centrifugal action is maintained on the surface of the heavier conducting fluid and tends to prevent the occurrence of arcs between the contact-points and the conducting fluid.

A central opening is formed in one side of the drum, through which enters an arm carrying a disc with peripheral projections or vanes which when the drum is rotated project to a sufficient extent toward or into the conducting fluid to effect the makes and breaks of the circuit.

The motion of the fluid within the drum causes the disc to rotate and its projections or vanes to make and break the circuit with a rapidity which may be very great. In fact, when the drum is rotated at a high rate of speed, the fluid conductor may become in its effect similar to a solid body, upon which the conducting disc rolls so that the conducting fluid might be dispensed with.

In order to insure the proper immersion of the projections into the fluid to compensate for wear and at the same time to secure a yielding pressure between the fluid and the disc, it is desirable to employ for the disc some form of spring connection or support which will exert a force tending to force it in contact with the fluid.

Referring to Fig. 4, the various parts are mounted on a base, which contains the condenser, and comprise a transformer with primary and secondary coils, one or more self-induction coils, a small electromagnetic motor D, and the circuit-controller, which is driven by the motor.

The shaft of the motor D extends through a stationary disc E, and to its end is keyed a hollow wheel or drum F, which rotates with it. Two standards G are secured to the disc E and connected by a cross-bar H, from which extends an arm K into the interior of the drum F through a central opening in its side.

To the end of the arm K is secured an arm L, carrying at its free end a disc M with peripheral teeth or projections N. The disc is mounted on any suitable bearings in the arm L, so as to be capable of free rotation.

It is desirable that the disc should admit of adjustment with respect to the inner peripheral surface of the drum, and for this purpose the arm K is secured to a rod O, which passes through supports in the cross-bar H and is adjustable therein by means of threaded nuts P.

The interior of the drum F is tapered or contracted toward the periphery so as to form a narrow trough in which the fluid is confined when the drum is rotated.

R designates the conducting fluid, and S the lighter non-conducting fluid, which are used in the drum. If the proper quantities and proportions of these fluids be introduced into the drum and the latter set in rapid rotation, the two fluids will distribute themselves under the action of centrifugal force around the drum in the manner shown in the figure. The arm K is adjusted so that the teeth or projections on the disc M will just enter the conducting fluid, and by the action of either or both the disc will be rapidly rotated. Its teeth are so arranged that no two are simultaneously in contact with the conducting fluid, but come into the same successively. If, therefore, one part of the circuit be connected to the drum, as by a contact strip or brush T, and the other part to the disc M, or to any part, as the standards G, which are insulated from the frame of the apparatus and in metallic connection with the disc M, the circuit will be made and broken with a rapidity which may obviously be made enormously high. The presence of the non-conducting fluid on the surface of the other operates to prevent the occurrence of sparks as the teeth N leave the latter and also to prevent the current from leaping across the space between the teeth and the conductor as the two approach.

The diagram of circuit connections shown in Fig. 5 will serve to illustrate the purpose and mode of operation of the latest device. Let f f be the conductors from a source of current, each including a self-induction coil C C′ and connected with the arms L and L′ and with two conductors B′ B″, respectively. Then during the periods when the circuit is completed between the two arms L L′ the coils C C′ store energy, which on the interruption of said circuit rushes into and charges the condensers. These latter during the periods when the circuit is closed between arms L and L′ discharge through the primary A′ and induce by such discharge currents in the secondary A″, which are utilized for any purpose for which they may be suited, as in operating vacuum-tubes X or suitable lamps Y. It will be understood that the rotating drum may be mounted in a horizontal or other plane.

INJURIOUS EFFECTS OF THE ROENTGEN RAYS.

BY JOHN T. PITKIN, M. D

It is safe to say that no scientific discovery was ever received with greater rejoicing by suffering humanity than the enunciation by Professor Roentgen of the possibilities he had discovered that the x-ray possessed which could be utilized to photograph the living dense structures of the human body and thereby determine their physiological and pathological condition.

An army of scientific men including many of the medical profession hastened to become his disciples.

Static machines and induction coils or step up transformers of every conceivable size and description were suddenly very much in requisition.

An era of experimentation and investigation with x-rays galore was inaugurated, all of which was productive of many glowing accounts of what was seen and done through their instrumentality.

But this new variety or degree of light, too rapid in its rate of etherial vibrations to be perceived by the visual organs also failed to impress the nerves of tactile sensibility and thereby warn us of its dangerous and destructive qualities, consequently many untoward results have been experienced through which the ser-services of the Roentgenian have been brought into disrepute and his great field of usefulness thereby unduly limited.

Many who have been exposed to the Roentgen rays have suffered as sequelae all conceivable varieties and degrees of burns. The loss of an eye, the detachment of an external ear, the sloughing of a lower extremity, alopecia of a large portion of the head are among the alleged injuries sustained [redacted] one exposure of the brain to the rays for a period of thirty-minutes at a distance of one and one-half inches from the tube was in all probability contributory to death.

Although not any one operator of the rays may even hope to determine all of their mysterious properties, still each by careful observation may be able to add a little knowledge toward the enhancement of their usefulness on the one hand and the limitation of their destructiveness on the other. It is in this spirit that the writer who has had an experience from almost daily employment since their inception, nearly three years ago, concluded to communicate the tabulated results of his investigations.

DESCRIPTION OF THE X-RAY BURN.

Not any disagreeable feeling is experienced in the parts during the exposure, only a gentle breeze caused by bombardment of parts by the particles of electrified air repelled from the outer surface of the Crookes' tube. A period of incubation lasting from one to twenty-one or more days in which the parts functionate as usual and are devoid of discoloration or discomfort. Small erythematous spots with itching and dull pain deep seated become manifest, the redness extends, the pain increases in severity, is worse at night, and at times almost unbearable. The epidermis becomes separated from the derma by a transfusion of watery serum forming large blebs which coalesce, break down and discharge profusely. The epidermis desquamates layer after layer much as we can remove the outer coatings from an onion, the parts are much swollen, stiff, hot, angry looking, bleed easily and are very painful. If the fingers or toes are attacked the nails lose their brightness, as they grow out the line of demarkation between the new and old

texture becomes apparent. The stage of ulceration supervenes characterized by its indolence, severe pain and being usually devoid of suppuration, its depth depends upon the severity of the exposure and the vulnerability of the tissues, it may involve all of the subjacent structures even the bone participating in the inflammation. After several weeks or even months of chronicity, the parts very slowly repair, the destroyed parts are often regenerated and functional activity may be entirely restored but the new integument will be devoid of hair and hair follicles.

TREATMENT OF X-RAY INJURIES.

Treatment is of little avail—showering the parts with cold water reduces the temperature and for the time mitigates the pain. A rubber bandage loosely applied will hasten repair and afford a little relief, a solution of cocaine muriate will benumb the nerves, slightly raising the parts afford relief, but if raised too high, the suffering is intensified. Hot applications augment the discomfort of the patient.

THE CAUSE AND HOW TO AVOID THE DANGER.

If in accordance with the general consensus of opinion we concede that the rays in and of themselves are devoid of dangerous properties, that all of the bad results are attributable to the electricity unconsumed in their generation, it becomes obvious that as the x-ray can not be obtained without the electrical currents every precaution must be taken to keep the patient's body out of their field of operation.

In the atmosphere in the immediate neighborhood of every excited Crookes' tube two separate fields of force, the electrical and x-radial can be investigated, a portion of the former travels the dialectric air along the conductors to and from the tube, another portion which concerns us most is repelled from its exterior traveling a varying distance into space but incessantly tends to return to the generating apparatus by the path or paths of least resistance, this field of force constitutes the danger zone and can be explored by a floating feather or silken fabric which will travel through the areal electrical pathway. The x-radiance can be traced through this electrical field into the apartment by the aid of the fluoroscope, it will be observed to diverge from the deflecting target in the Crookes' tubes spreading out in a conoidal manner, rectilenear in propagation.

X-ray injuries may follow the employment of any variety of exciting apparatus but are by far more common from the unidirectioned than the oscillatory discharges, because the latter neutralizes its own potential with each pulsation in the immediate vicinity of the Crookes' tube, *i. e.*, has a smaller danger zone whereas, with the unidirectioned current the tendency is to select the patient's body as a path for a portion of the return flow.

Employment of the metallic grounded screen as recommended by Nikola Tesla as a protective measure is of extreme importance.* With the modern static machines capable of developing a pressure of several millions of volts, the employment of additional spark gaps increases the electrical dissemination, raises the resistance, developes amperage, increases the electrification of the patient and thereby adds to the danger.

Although it may seem paradoxical, the same strength of current from a large static machine delivering an electro-motor force of three million volts capable of causing severe x-ray injuries with the Crookes' tube attached, can be employed to bombard a patient's body placed directly in the circuit, after the tube has been removed, as a therapeutic proceed-

*See Electrical Review, May 5th, 1897.

ure, with only beneficial results, the skin may be reddened for a few hours immediately following the exposure, but no delayed impairment need be anticipated.

Insulating the body of the patient exposed to the x-rays, lessens his electrical transmissibility, and hence, decreases the danger.

Untoward results are in inverse ratio to the distance from the excited tube, the time of exposure and the efficiency of the apparatus—in other words the Crookes' tube, like the red hot stove, will not burn us unless we are brought into too close relationship therewith, but unlike the stove the excited tube will not warn us of its destructiveness and such manifestations are not immediate but delayed.

X-RAYS AND LUPUS.—It is reported from Vienna that Dr. Schiff has successfully treated cases of lupus vulgaris by means of the x-rays. His process is to set up an independent inflammation in the lupoid area by exposing the part to a very intense radiation. So far, investigations into the germicidal effects of the x-rays have gone to show that their activity in this respect is not greater than that of ordinary light. But Dr. Schiff's result is not a germicidal one, and we know that inflammation, and even necrosis may result from exposure in certain cases, although we do not know the determining factor which leads to iujury in some cases but not in others under apparently similar conditions. It is not, however, altogether improbable that Dr. Schiff's results may be due to a direct germicidal action of the x-rays on the tubercle-bacillus. Light, we know, is deleterious to this organism, and Dr. Finsen, of Copenhagan has reported cases of cure in lupus by protracted exposure to concentrated light, so arranged that the ultra-violet rays predominated.—*British Medical Journal.*

THE CAUSE OF THE EFFECTS PRODUCED BY EXPOSURE TO THE ROENTGEN RAYS.

BY ALFRED C. PRENTICE, A. M., NEW YORK.

When Dr. Wm. Konrad Roentgen discovered the x-rays he gave them this name because he did not know what they were, and the algebraic sign for an unknown quantity aptly signified his limited knowledge of their nature. It is significant that the name is still applicable. Dr. Roentgen's first reports were published in January, 1895, since which time scientists have eagerly crowded into this field of discovery. Much has been learned of the phenomena exhibited by the x-rays, but many difficult questions remain unanswered as yet by scientific facts. Very like the phenomena of electricity itself, the exact nature of which is still an enigma, the results produced by that form of electrical discharge in the vacuum tube, viz., the cathode rays and the x-rays, have found many new and varied applications in practical science, while many conflicting theories attempt to explain their action. Nor is the evidence brought forward as yet conclusive as to their exact nature.

The most important use of the x-rays is in medical and surgical diagnosis, but this has been involved with troublesome results in some cases. From their early use, and even now occasionally, there has followed a severe lesion at first apparently of the skin, but later involving the deep tissues as well. The constitutional disturbances have been most severe, and the process of healing is always protracted and exceedingly painful. Although cases of the "x-ray burns" so-called have become less frequent, and of the patients exposed to the rays, probably only a small fraction of one per cent experience any such results, nevertheless the uniform severity of the lesion and its obstinacy in healing can not but

qualify as more or less dangerous any exposure to their action. Notwithstanding these objections, the use of the x-rays in surgical diagnosis is destined to become general. Cases are on record (1) in which even the courts are required to accept the skiagraph as corroberative evidence of expert testimony.

The theories adduced to account for the injuries resulting from the application of the x-rays, inducing the "x-ray burn," have not as yet afforded either a remedy for the lesion or a way to avoid it.

The following series of experiments* have been conducted by the writer during the past six months in the study of the problem.

The x-rays were produced by means of the static electric current from a Wimshurst or influence machine having eight circular plates of blown glass each twenty-eight inches in diameter, revolv- at a high rate of speed between an equal number of stationary plates. The power was supplied by an one-half horse-power motor of the Crocker-Wheeler type connected with the current used for lighting the building. The apparatus is supplied with Leyden jars, in circuit or not, accessory spark gaps, and all adjustments for perfect regulation to secure the best results from the vacuum tubes. The tubes used were fourteen inches in length, having each a bulb three and one-half inches in diameter, enclosing aluminum cathodes and platinum anticathodes, also provided with an auxiliary potash tube to be connected in circuit by a shunt, so as to reduce the vacuum when it became too high. In this manner the tubes could be so adjusted to the potential of the current as to produce x-rays of the greatest brilliancy and penetration, and maintain their uniform production for an indefinite period without danger of breakage by perforation.

Two guinea pigs kept upon the same conditions of food, etc., were used—one for the experiments and one for the purpose of normal comparisons. Exposed a pig to the x-rays at a distance of three inches from the tube for a period of twenty minutes in order to accustom her to the slight annoyances of noise, etc., incident to the following experiments.

The only effect of the exposure was a slight drowsiness, which gradually passed away. No further effects of the exposure became apparent during the following week. Accordingly the pig was again exposed to a low vacuum tube giving x-rays of a poor quality, at a distance of one inch from the surface of the tube, for ten minutes; and again to a high vacuum tube emitting intensely brilliant x-rays, at the same distance, for a period of two hours. During this time the pig was confined in a pasteboard box perforated by a window one and one-half inches square, directly opposite the pig's right lateral thoracic wall. She remained quiet in her box except at intervals she would shift her position as if uncomfortable, but would immediately return to her former position. Three or four times she appeared to act as if something annoyed her belly and endeavored to reach the spot with her nose, but after some slight effort subsided into quiet.

During this time the table on which the pig rested became strongly electrified, and no doubt the pig was electrified as well.

She acted entirely normal, and no cutaneous or other effects were noticeable for one week after the exposure.

The fur was then clipped from a region one inch square, over the right lateral thoracic wall, which had been previously exposed, and again submitted to action of rays of greatest brilliancy for a

*The experiments mentioned in this paper were conducted in the photographic and x-ray laboratories of the Department of Pathology in the College of Physicians and Surgeons, Medical department of Columbia College in the City of New York, under the guidance of Dr. Edward M. Leaming, F.R P.S., instructor in photography, photomicography and skiagrapny in the above institution. The microscopic data here presented were supplied by the courtesy of Dr Frederick S. Ward, assistant in Normal Histology in the Department of Pathology.

period of seventy minutes at a distance of one inch.

In this exposure, although neither the pig nor table came in contact with the electrical apparatus, both became so strongly electrified that a spark was produced between the edge of the table and my finger held near; and the pig started and squirmed when I touched her, as if pricked with a pin, while I could feel the pricking sensations at the tips of my fingers, on touching her body. By the end of the week from the time of this exposure, there appeared on the clipped area two or three dry vesicles of exfoliating epidermis. The lesion gradually grew deeper and continually worse, until at the end of the second week the animal was very ill, showing marked ccnstitutional symptoms of fever and depression. Examination revealed a characteristic "x-ray burn." The skin had vesiculated and peeled off in flakes, leaving a pale, raw surface, moistened with serous exudation. Not much, if any, inflammation was evident, but the lesion was quite sensitive and apparently very painful. Only the small area which had been clipped was at first affected, but the injury rapidly extended, and on the night after the fifteenth day following the exposure the pig died.

On picking up the body by the fur at the back of the neck, a large bunch came out, permitting the body to fall. Body was dissected and portions were reserved for histological examination. The following is Dr. Ward's report:

Examination of Injury to Thoracic Wall of Guinea Pig Due to Prolonged Exposure to Action of X-Rays.

"*Macroscopical.*—Over a circular area of about four c. m. in diameter the hair and skin had been removed and the exposed surface was parched, the subcutaneous tissue and thoracic muscles feeling as though they were partially dried to the underlying ribs.

Microscopical.—Portion for examination taken through the seat of injury and including entire thickness of thoracic wall. Fixed in formalin five per cent; alcohol, ninety-seven per cent. Decalcified in acid. Imbedded in celloidin. Stained with Gage's haemotoxylin and alcoholic eosin. The skin and subcutaneous tissue had all disappeared. In the central portion the superficial layers of muscles did not stain. No striations were visible. The blood-vessels were shrunken and contained very little blood. Approaching the margin, the staining of the specimen improved, striations and cell nuclei of the connective tissue were visible. The deep, muscular layers of the central portion were slightly stained with eosin, and the nuclei took on a pale-purple color, but in neither case was the staining that of normal muscle. At the edge of the affected area, about blood-vessels and between muscles, there was a moderate amount of infiltration of small, round cells.

Anatomical diagnosis is that all the structures at the site of the injury have lost their vitality and have become dried. In the closely adjacent parts there is a very moderate amount of inflammation."

The sensation of drowsiness has been mentioned by other writers as following an exposure to x-rays. The statement of Professor J. J. Thomson that "all bodies traversed by Roentgen radiations become conductors of electricity" is perhaps a hint. It is supported by Professors Trowbridge and Burbank. (2) We know that twice were the animal and table charged in our experiments. Tesla states (3) that "by means of an enormous potential and high frequency, the tube was surrounded by a violet luminosity or halo," and that "Lenard also obtained a similar phenomenon in front of the aluminum window."

Mr. Rollin states (4) that the burning from vacuum tubes *not generating x-rays* may be severe, the tube being exhausted to such a degree that no Roentgen light could be produced with the voltage used.

Professor Thomson, of Harvard, demonstrates (5) by experiments upon himself that if the x-rays are ether vibrations of great rapidity, known as ultra-violet light, as we are now led to believe, they could not have produced the "burn" which he induced upon his finger by exposing at one and one-half inches distance from a vacuum tube of blue glass

in which was a transparent window of clear German glass, the injury which followed occurred only on that portion opposite the clear glass window, and the part covered, as it were, by the blue glass was unaffected, marked off by a sharp line of demarcation. He says the blue glass would have been transparent to the ultra-violet rays.

In another case (6) of purposely induced dermatitis, no effect was produced where the skin was covered with lead and tin foil, the lesion appearing only on the uncovered area, although exposed at a distance of only five-eighths of an inch. It would appear that only the electricity attacking the area covered by the foil was conducted away, while that attacking the uncovered area was the ultimate cause of the injury. Certainly the x-rays would have penetrated the foil as if it had been paper.

Dr. Monell is authority for the statement (7) that "nothing is more certain than that a sufficiently energetic electric current passing to tissues which it can reach and enter only after electrical energy has been transferred into heat by resistance, such as dry and hair-covered skin or clothing, will vesicate and can be made to produce intense and deep inflammatory action."

All these statements combined with the evidence of direct experiment tend to the conclusion that not the x-rays themselves, but the direct actions of the electric currents upon the fluids and tissues are the real factors in the damage done.

Tesla has stated (8) that he "believes the hurtful action is not due to the x-rays, but to the ozone generated in contact with the skin. Ozone," he says, "attacks the cutaneous surface, its action, no doubt, being heightened by the heat and moisture of the skin. This generation of ozone ceases at a definite distance from the electrical terminal, and the same is true regarding the production of this irritation." He also believes, or did believe that the electrodes became gradually disintegrated by the bombardment of the cathode rays, and that these metallic particles penetrate the walls of the tube. He said, (9) "I am getting more and more convinced that we have to deal with a stream of material particles which strike the sensitive plate with great velocities. If these observations be confirmed by men of keener insight, I shall be still more convinced that material streams of matter actually penetrate the skull. Thus it may be possible to project a suitable chemical into any part of the body."

Professor Ames (10) states: "The radiation in an x-ray tube may be divided provisionally into three classes: Ether waves, which may have wave-lengths from 150 to 800 m. m. approximately; cathode rays, which undoubtedly are streams of matter electrically charged; and x-rays, about whose nature there is no conclusive evidence at the present time. If the walls of the tube are thin enough, and of suitable material, all these radiations will emerge and pass into the surrounding air. It is a matter of doubt if the cathode rays observed outside the vacuum tube are the same as those inside; but the inner ones undoubtedly cause the outer ones. There is no evidence that the x-rays carry with them particles of matter, or that they directly cause a stream of particles; in fact, all known facts serve to point to the belief that they are ether waves of extreme shortness."

If this last statement holds true, then Professor Thompson has proven that the x-rays themselves do not burn. That the "cathode rays are streams of matter electrically charged," gives Dr. Gilchrist (11) sufficient reason to assume that the lesions may be due to the entrance of material particles—of platinum in his case—into the tissues, and that the cathode rays which accompany the x-rays, may be the cause of the trouble and not

the x-rays themselves. He endeavored to show that these particles had so accumulated in a given case as to produce an ostitis and periostitis, acting like foreign bodies in the tissues. He produced in evidence of this a skiagraph of the part taken after the injury was developed, which he said showed a marked increase in the density of the bones. He laid no emphasis on a chemical analysis of the exfoliated skin, which, however, gave a negative result.

Campbell Swinton, Esq., of London, writes: "Cathode rays are generally believed in this country to consist of atoms or molecules of risidual gas, which, being similarly electrified to the cathode, are repulsed by the latter, and travel at an average velocity not much less than one-twentieth that of light, the velocity depending upon the exact potential of the cathode and the molecule at the moment the latter leaves the former, and also upon the degree of the exhaustion of the tube, upon which depends the free path of the molecules, that is, the distance a molecule can travel without coming in contact with another molecule."

It seems strange that Dr. Gilchrist should have so confused the material particles of the cathode rays, which, as we have seen, can be nothing but residual gas, with the unique theory of Tesla, who spoke of metallic particles of the electrodes—aluminum or platinum, as the case might be—which he believed were projected through the walls of the tube and into the densest tissues. Tesla has also informed us (12) that if the part of the body exposed to the x-rays be placed between a metal plate and the tube, the injury would be on the side of the part on which was the metal plate. But that if a thin plate of aluminum, which is practically transparent to the x-rays, or a sheet of wire gauze, be placed between the tube and the exposed part, and at the same time the *metal screen be electrically connected with the ground*, the disturbance to the tissues will be avoided. His latest suggestion (13) is that it is possible for the "electro-static influence" which generates the ozone to "decompose the sodium chloride in the tissues, thus giving rise to irritants." It would appear that his statements of the violet halo or brush-discharge around the tube connected with the practical value of a metal screen in dispersing the injurious agents when electrically grounded, and its concentrative power, if placed on the far side of the part and not grounded, point directly to the action of electric currents and nothing else.

Dr. Charles a Lenard (14) states directly that the "burn" is the result of induced electric currents in the tissues, which will be induced capable of destroying their vitality, if the patient is approached sufficiently near to the x-ray tube.

Dr. Monell speaks of the "electrical energy transformed into heat by resistance of dry skin, etc., as causing dermatitis and inflammation. Professor E. Dorn (15) has demonstrated that x-rays do exert very slight heat effects, and he has measured their quantity, but this element is of so small amount as not to be appreciable.

A remarkable fact in nearly all cases of the "burn" is that no sensations of heat are felt at the time of exposure, and only in some cases is there noted any immediate symptoms whatever, as of "a sense of prickling heat, or a tingling followed by itching;" but there is uniformly no sensitiveness or pain. Another characteristic is the time which elapses from the exposure to the appearance of the first symptoms—usually a week to nine or ten days, or even a month or more in some cases. These facts have called forth the statement from several authorities (16) that the lesion is "not a burn," inasmuch as the accepted defini-

tion (17) of a burn is "an injury produced by the action of too great heat." It is also useful to note that ichthyol usually gives relief from pain in an ordinary burn, but Dr. Tuttle (18) found that it aggravated the pain of an x-ray injury. Cold water also proves soothing to burns, but in this case it was found the pain increased when moist dressings were applied of a temperature lower than 85 deg. Fahrenheit. Also, in certain cases, where skin grafting had been employed, the severe neuralgic pain still persisted after the part had healed.

It may not be improbable that electrical energy attacking the tissues is transformed into another form of energy than heat, as perhaps electrolysis of chemical substances. Dr. Bardeen (19) regards it justifiable to consider that one of the main causes of death after burns (ordinary) is to be sought in a toxaemia caused by alterations in the blood and tissues, the direct effect of the elevation of temperature; "a view which is further strengthened by chemical evidences and the experimental work of Kijanitzen and others." Since the pathological condition of the tissues in the "x-ray burn" correspond very nearly to, only are worse than those of a severe burn produced by heat, it does not seem unreasonable to suppose that similar chemical alterations and decompositions might be produced by electrical energy or electrolysis as are supposed to be produced by mere action of heat. Tesla hinted at this phase of the question in speaking of the decomposition of the sodium chloride.

It is well known that the static discharge in air produces ozone in a more or less considerable amount. The fact that a sufficient amount to detect by the odor is often produced and inhaled with impunity to the mucus lining of the respiratory passages would cast some discredit on the theory that it might irritate a warm and moist skin.

Tesla has demonstrated, however, that metallic particles of the anticathode do become deposited upon the inside of the tube, by breaking the tube and analyzing the deposit noticed. This deposit is especially noticeable in the tubes that have been in use for some time and at so high tension as to render the anticathode red or white hot. But whether these particles could penetrate the tube and enter the tissues to produce irritation as foreign bodies, is another question.

In order to test this matter, I exposed to the rays of maximum brilliancy four photographic plates superposed, so that if the metallic particles should strike the sensitive film or even pass through it, and one or more of the four glass plates and gelatine films, just as in human tissues Tesla supposed them to do, they would be apt to lodge, some of them at least, in one or more of the films. The exposure in this case was timed and adjusted exactly as in the last exposure of the guinea pig, viz., for seventy minutes at a distance of one inch. If the metallic particles caused the lesion which developed a week later in the case of the pig, they would certainly be deposited in the films of the plates. I therefore removed all the films, after having dissolved out the unchanged silver-salt in a solution of hyposulphite of sodium, and evaporated to dryness. Reduced the residue to an ash which was then digested in aqua regia (HCL, 3 parts to HNO_3 1 part, concentrated), forming from any metallic platinum present, soluble platinic chloride, $PtCl_4$. I then treated this solution with stannous chloride, $SNCl_2$ which reduces platinic salts to platinous salts. The latter are soluble in dilute hydrochloric acid, (HCl) giving a characteristic deep cherry red colored solution. I accordingly added HCl, but no color reaction took place. At the same time, for a check test, I dissolved in 10 c.c. of water two or three small granules of potassium, chloroplatinite,

and tested for platinum, as already indicated. The color reaction was characteristic, intense and permanent, in fully 20 c.c. of solution. This experiment proves conclusively that the particles of platinum are not projected into surrounding objects.

It is of quite recent demonstration (20) that the silver salt of the photographic plate which is sensitive to white light, is not affected by the x-rays. Experiments made upon the sensitized collodion film and the Daguerreotype plate produced no image whatever, while upon the gelatin coated plate or film the negative image was produced in the usual manner.

The conclusion drawn was that the x-rays did not produce an electrolytic effect upon the silver salt, nor even the partial decomposition as produced by ordinary light directly; but they did produce a fluorescence of the gelatine film and perhaps of the glass support, if it were of a fluorescent material, which in turn acted upon the silver salt suspended in it, just as ordinary light does. Incidentally the statement was made that plates most sensitive to ordinary light are not necessarily most sensitive to the x-rays, since the result depends upon the kind of gelatine used, and the period of cooking to which the emulsion was subjected. This fact was apparently confirmed by a series of comparative tests conducted by the writer in which he was convinced that the particular brand of plates which happened to be cheapest in the market produced the best x-ray negatives in the shortest time of exposure.

Little attention has been given to the comparative value of the static and induced currents in the production of the x-rays, and it may be worthy of note in this connection that in the great majority of cases reported as "x-ray burns," the current has been generated by the induction coil apparatus. Such an equipment of high potential, even a ten or twelve-inch spark-gap, requires less room, and is less expensive; but the current is characterized by much greater amperage than the static current of the same or even greater potential in volts. The amperage of the static current is very low, while the potential is almost unlimited under proper conditions. Also the distance of the exposed part from the tube in those reports which mention the distance has been invariably small, from three or four to six or eight inches.

The length of the spark-gap is directly proportional to the internal resistance of the tube (21), and is also directly dependent upon the voltage (22), and not the amperage. The greater the internal resistance, the more penetrative are the x-rays produced. Thus it is seen the production of x-rays of the highest penetrative value is directly dependent upon the voltage utilized. And consequently, the lower the amperage, the less danger attends the use of the tube, because a less quantity of electricity per unit of time is free to act upon the tissues; and with a current of higher potential and lower amperage the greater may be the distance from the tube, and only the voltage is important to produce x-rays.

Since the intensity of the x-rays varies inversely as the square of the distance, it follows that the higher the potential in volts, the greater may the distance be, to produce the same results of penetration. I have not been able to see any penetration by the skiascope, from a tube supplied by an induction coil having a six-inch spark gap at a distance of eight feet. While with a tube supplied by the static machine working at a similar sparking interval, the bones of my hand could be seen at a distance of thirty-six feet.

Professor Thomson has already demonstrated that a "burn" may be induced by the use of the static current in the vacuum tube, but no cases on record, to my knowledge, in which injuries have

been sustained at so short a distance as six inches, using the static current, while one case I recall was burned by the induction current x-ray tube at a distance of eighteen inches.

If the intensity of the brush discharge is governed by the same law as other form of radiated energy, it would require an exposure of some thirty-two hours at a distance of twelve inches, and fifty-seven hours at a distance of sixteen inches, to produce a lesion as Professor Thomson did while using the static current in his tube for half an hour at one and one-half inches distant, making no allowance, of course, for idiosyncrasies of patients.

The radical treatment that has been employed consists in a complete excision of the lifeless tissues, as in gangrene, thereby producing a healthy granulating surface in the wound, which rapidly heals. One surgeon claims to have cured twenty-five or thirty cases by cutting down clear through the affected part, and then dressing with carbolic acid until granulation sets in. Balsam of Peru was then applied, and healing took place by granulation. Of course the necrotic tissues had to be sloughed off in this latter treatment.

In noting the conclusions of this paper it will be valuable to compare results strikingly similar of a series of experiments (23) by Oudin, Barthelemy and Darier, of Paris.

CONCLUSIONS.

1. The general character of the tissues affected in the "x-ray burn" is that of absolute necrosis and more or lesss exudative inflammation. The resulting alopecia is more or less marked in lesions involving hair follicles.

2. The x-rays themselves exert no appreciable heating effects, and consequently do not burn. All evidence seems to point to the conclusion that the lesion is due to the direct effects of the electric currents upon the tissues and fluids. The nature of this effect is as yet wholly speculative.

3. The ozone irritation theory is not supported by evidence.

4. Metallic particles of the platinum anode are not projected into substances near to x-ray tube.

5. X-rays do not decompose the silver salt of the photographic plate directly, but produce in the gelatine film a fluorescence which in turn acts upon the silver salt as ordinary light.

6. The use of the static rather than the induced electric current in producing the x-rays is less liable to result harmfully, (*a*) because it is of low amperage, and (*b*) being of very high potential comparatively, does not necessitate so short distance between the tube and the exposed part.

7. In all cases where exposure is required at a distance less than twelve inches from the tube an aluminum screen, electrically grounded, should be placed between the tube and the exposed part.—*Medical Review of Reviews*, N. Y.

THEORY OF ROENTGEN RAYS. Lond. *Elec. Rev.*, May 13.—Stokes suggested a theory several years ago, according to which these rays are aperiodic electromagnetic waves caused by the impact against the anti-cathode of the charged particles in the cathode stream; this theory was recently developed by J. J. Thomson (*Phil. Mag.* page 172). Lord Rayleigh, in *Nature*, April 28, protests against the acceptance of this theory, as it does not carry with it some of the consequences which have been deduced as the distinction between Roentgen rays and ordinary luminous and non-luminous radiation; he does not agree that Roentgen rays are not very short waves, but impulses; he favors the view that the waves differ from ordinary light only in the shortness of their waves.

IF one wishes by a simple optical illusion to obtain an almost perfect imitation of the wonders of radiography, he may take a small turkey feather, and, holding it close to the eye, look through the radiating ribs at the end of the feather at the ends of the outstretched fingers of his hand, held against the window. This done, the flesh will appear to be transparent, with the opaque bone running down in the center as shown by true radiography. If gas light is used, a piece of ground glass must be held before the flame, to diffuse the light.—*Inter-Ocean.*

CATHODE AND ROENTGEN RAY TUBES. Villard. *L'Eclairage Elec.*, May 28; *Electrical World*, New York.—An abstract of a French Physical Society paper describing improvements. One of these is an anticathode which does not blacken the tubes; iridium is very satisfactory if quite pure, but the commercial variety is not pure enough; the new anti-cathode is in the form of a paraboloid with a lateral opening through which the cathode rays enter; this will not blacken the tube, because it never acts as a cathode for the reversed currents; the form of the anode, creating an electrical field which is practically zero in its interior, totally prevents the formation of these new rays. He also describes a tube which may be regenerated; part of the tube consists of a small tube of platinum closed at one end and joined at the open end with a glass tube; nickel or palladium will also answer; to regenerate the tube this metallic tip is heated in a Bunsen flame; at about 1,000 deg., hydrogen passes through the platinum, but it is absolutely impenetrable to air. He also mentions some magic screens on which the images are preserved, but the description is not quite clear.

TREATMENT OF LUPUS WITH ROENTGEN RAYS AND CONCENTRATED LIGHT.—Dr. Kummel (Hamburg) claimed that in selected cases these means were successful, but experience with them was yet too limited to absolutely state the indications and contraindications. He exhibited two advanced cases almost cured, in which he expected a continuance of the treatment to cure radically.

TRANSPORTABLE X-RAY APPARATUS. Levy. *Elec. Zeit.*, July 7.—A reprint of a brief, illustrated paper describing a simple, portable apparatus, devised by him.

Mr. Tesla's Circuit Interrupter.—When a charged condenser is discharged through a circuit possessing high induction and low resistance electrical oscillations are produced, the frequency of these being given by $2\pi\sqrt{KL}$, where K and L respectively represent the capacity of the condenser and the coefficient of self-induction in the charging circuit. Under the most favourable conditions which can be realised experimentally the train of waves produced by a single discharge is quickly damped, owing to the dissipation of energy due to the resistance of the circuit. Thus with oscillations possessing a frequency of several hundred thousand per second, if after 200 oscillations the electric waves have been so far damped as to be negligible, there will be a current flowing through the circuit for only an inappreciable fraction of the whole time, unless the condenser be charged and discharged many times per second. The primary object of several recent patents due to Mr. Tesla is to obtain an arrangement which is capable of doing this in an efficient manner. The actual arrangement of the electrical apparatus is somewhat as follows: The terminals of a condenser of suitable capacity are connected with the electric mains, one terminal through a coil of wire possessing an iron core, the other terminal through a few turns of wire of small resistance, forming the primary of a trans former with an air core. The condenser is also capable of being short-circuited through the above-mentioned low-resistance coil by a mechanical contact-maker effecting as many as 1,000 contacts per second. As a consequence, electric oscillations will be produced in the condenser circuit, and these will be transformed to an exceedingly high voltage by means of the transformer. The general principles of the circuit interrupter employed may be understood from an example. An arm hangs vertically from a stationary horizontal spindle, a star wheel being attached to the end of the arm so as to be capable of free rotation. The spindle passes through the centre of an airtight case, which can be rotated at a high speed by means of a motor. Mercury is placed in this case, and will be driven, by centrifugal force, to form a ring around that part of the case furthest from the axis of rotation; a non-conducting liquid, less dense than mercury, forms an interior ring owing to the same cause. The quantity of mercury is so adjusted that the points of the star wheel alternately dip into it, and are withdrawn from it as the wheel revolves. The methods of using this arrangement to make and break a circuit are obvious. A number of other ingenious contrivances are also described, in some of which mercury jets are used to make contacts, whilst high-pressure gases are employed to diminish sparking. Important applications of the high-tension currents of great frequencies may be anticipated, both in regard to lighting and the formation of chemical substances, such as ozone.

DOCTORS IN CONVENTION.

Electro-Therapeutic Association Begins Its Sessions in the Library

The eighth annual convention of the American Electro-Therapeutic Association was called to order in the rooms of the society of Natural Sciences in the Library building this forenoon.

Although the attendance at this morning's session was small, it is expected that fully 100 men, who stand high in the medical profession in this country, will be here before night. They are coming on trains from the four points of the compass.

About 25 members were present in the Library building when Dr. Charles Rea Dickson of Toronto, president of the association, rapped for order at 10:30. He briefly announced the purpose of the association and outlined the important features of the meeting. Rev. O. P. Gifford of the Delaware Avenue Baptist Church was then introduced and delivered an eloquent prayer. The reading of the minutes of the last meeting was dispensed with and the report of the executive council was submitted by President Dickson.

On motion of Dr. William T. Bishop of Washington the privileges of the floor were extended to all members of the medical profession. Mayor Diehl was introduced and extended a warm welcome to the visitors. He spoke of the rapid strides that had been made in the growth and development of electrical treatment for disease. He referred to the way electricity was operating the street cars of this city and advisd the visiting phycians to inspect the plant of the Buffalo Railway Company. Dr. Bishop responded to the Mayor's welcome in fitting terms. Guests were then introduced. Dr. Henry McClure of Cromer, England; Dr. Holland of Hot Springs, Dr. A. D. Rockwell of New York and other physicians of note were presented and made short remarks. Letters were read from Dr. Georges Apostoli of Paris, Dr. Felice La Torre of Rome, Dr. Georges Gautier of Paris and several others, expressing their regret at being unable to attend the meeting.

Reports of committees were then presented and discussed. Dr. Margaret A. Cleaves read the report of the committee on meters, Dr. Dickson the report from the committee on electrodes, John J. Carty of New York the report on electric light apparatus for X rays.

Several physicians who were scheduled to read papers were not present and are expected later in the session. Dr. Cleaves read an interesting report on "Phlebitis; A Clinical Study." This afternoon several other papers will be read. Dr. Apostoli has sent a paper on "New Uses of the Sinusoidal Current in Gynaecology," Dr. La Torre on "Electricity in the Treatment of Uterine Fibromata," and Dr. Gautier on "Electro-Therapeutics in Gynaecology." These papers will be read by a member of the association.

Tonight a reception will be given at the University of Buffalo. Addresses will be delivered by Dr. Henry R. Hopkins, Dr. O. P. Gifford, Dr. Wende and others.

DOCTORS IN CONVENTION.

Electro-Therapeutic Association Begins Its Sessions in the Library.

(From Yesterday's Last Edition.)

The eighth annual convention of the American Electro-Therapeutic Association was called to order in the rooms of the society of Natural Sciences in the Library building this forenoon.

Although the attendance at this morning's session was small, it is expected that fully 100 men, who stand high in the medical profession in this country, will be here before night. They are coming on trains from the four points of the compass.

About 25 members were present in the Library building when Dr. Charles Rea Dickson of Toronto, president of the association, rapped for order at 10:30. He briefly announced the purpose of the association and outlined the important features of the meeting. Rev. O. P. Gifford of the Delaware Avenue Baptist Church was then introduced and delivered an eloquent prayer. The reading of the minutes of the last meeting was dispensed with and the report of the executive council was submitted by President Dickson.

On motion of Dr. William T. Bishop of Washington the privileges of the floor were extended to all members of the medical profession. Mayor Diehl was introduced and extended a warm welcome to the visitors. He spoke of the rapid strides that had been made in the growth and development of electrical treatment for disease. He referred to the way electricity was operating the street cars of this city and advisd the visiting physcians to inspect the plant of the Buffalo Railway Company. Dr. Bishop responded to the Mayor's welcome in fitting terms. Guests were then introduced. Dr. Henry McClure of Cromer, England; Dr. Holland of Hot Springs, Dr. A. D. Rockwell of New York and other physicians of note were presented and made short remarks. Letters were read from Dr. Georges Apostoli of Paris, Dr. Felice La Torre of Rome, Dr. Georges Gautier of Paris and several others, expressing their regret at being unable to attend the meeting.

Reports of committees were then presented and discussed. Dr. Margaret A. Cleaves read the report of the committee on meters, Dr. Dickson the report from the committee on electrodes, John J. Carty of New York the report on electric light apparatus for X rays.

Several physicians who were scheduled to read papers were not present and are expected later in the session. Dr. Cleaves read an interesting report on "Phlebitis; A Clinical Study." This afternoon several other papers will be read. Dr. Apostoli has sent a paper on "New Uses of the Sinusoidal Current in Gynaecology," Dr. La Torre on "Electricity in the Treatment of Uterine Fibromata," and Dr. Gautier on "Electro-Therapeutics in Gynaecology." These papers will be read by a member of the association.

Tonight a reception will be given at the University of Buffalo. Addresses will be delivered by Dr. Henry R. Hopkins, Dr. O. P. Gifford, Dr. Wende and others.

ELECTRICITY IN MEDICINE.

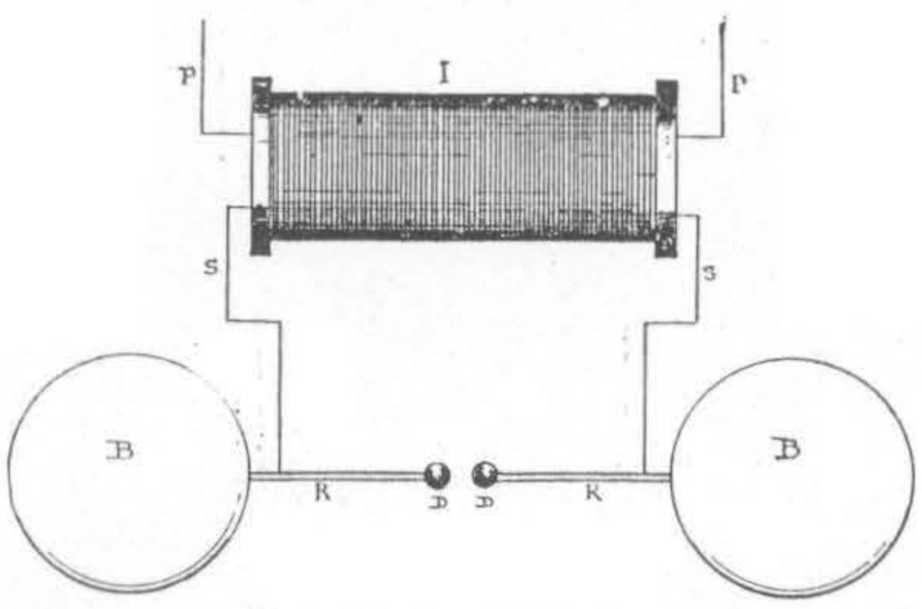
Electro-Therapeutic Physicians Close Their Session With an Excursion.

Dr. Charles R. Dickson of Toronto, president of the American Electro-Therapeutic Association, spoke at considerable length at yesterday afternoon's meeting of the association on the uses of electricity as a therapeutic agent. He declared that the necessity of such an association as the one in session was due to the fact that in the colleges nothing worthy of the subject is taught concerning electricity.

Electricity, he averred, is an agent powerful for weal or woe. Educators have hitherto been lethargic concerning it and the sooner they awake the better it will be for the reputation of surgery as an enlightened, progressive scientific profession. Electricity has too long been left to the charlatan, the incompetent and the unscrupulous. It is the association's aim to cultivate and promote knowledge of it wherever it can be of service to medicine.

Papers were read at the afternoon session by Dr. G. Betton Massey of Philadelphia, Dr. Robert Newman of New York, Dr. A. D. Rockwell of New York and others.

In the evening Dr. Lucien Howe entertained the delegates at dinner. Officers were elected at the night session as follows:



President, Dr. Francis B. Bishop of Washington; first vice-president, Dr. Ernest Wende of Buffalo; second vice-president, Dr. W. H. White of Boston; secretary, Dr. John Gerin of Auburn; treasurer, Dr. Richard T. Nunn of Savannah, Ga.; executive council, Dr. Robert Newman of New York and Dr. G. Belton Massey of Philadelphia (three years), Dr. A. D. Rockwell and Dr. William J. Morton of New York (two years), Dr. Charles R. Dickson of Toronto and Frederick Shavior of Stamford, Conn., (one year.)

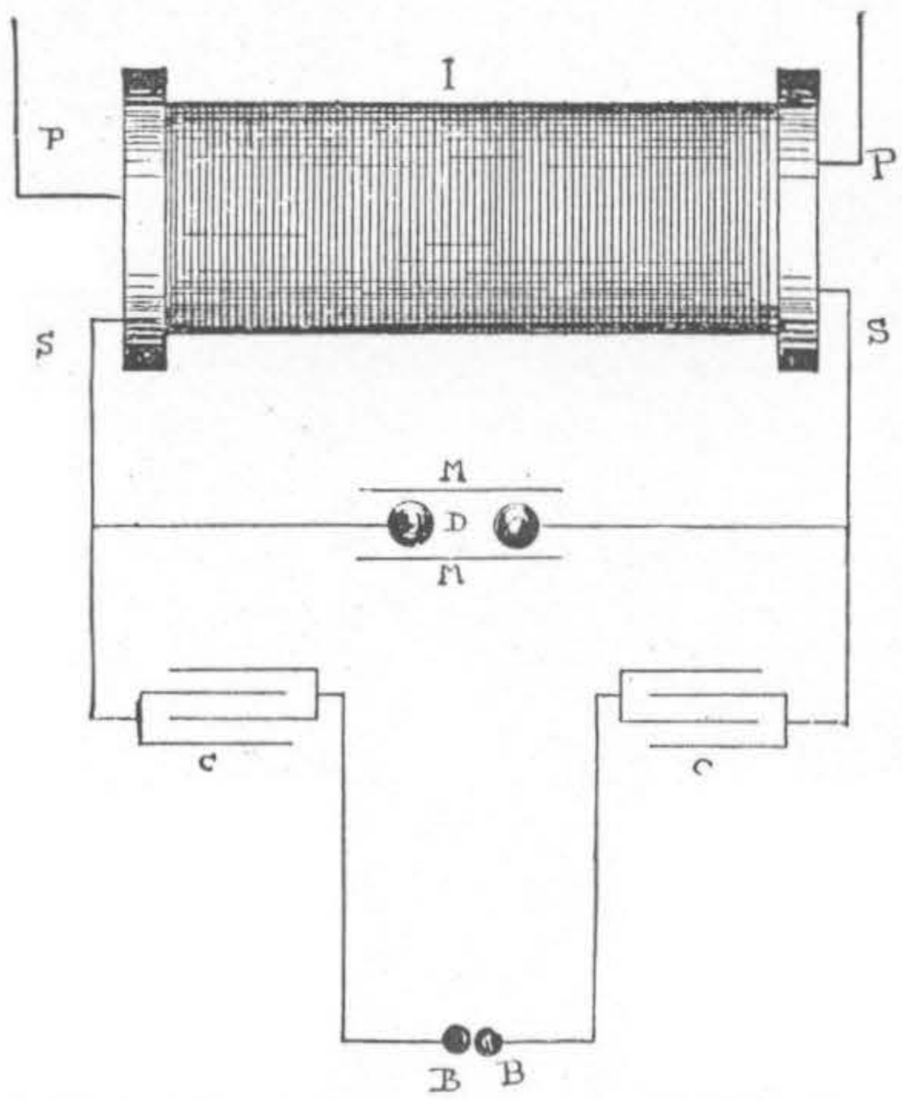
This morning's sesssion ended the convention. The next annual gathering will be held at Washington a year hence. This afternoon the delegates go down the river on the yacht Huntress.

TESLA AND HERTZ EFFECTS.

The currents of high frequency used by Tesla in his researches are produced by electrical rather than mechanical means. The alternating current dynamo used by him renders a current of 10,000 alternations per second, but the actual current necessary to the performance of the luminous effects has a frequency of millions of oscillations per second, produced by the discharge of Leyden jars or condensers.

Dr. Oliver J. Lodge, in his "Modern Views of Electricity," shows that the discharge of the Leyden jar is in

Hertz Electric Resonator.



general oscillatory; the apparently single and momentary spark, when analyzed in a very rapidly rotating mirror, is shown to consist of a series of alternating flashes, rapidly succeeding one another and lasting individually less than one hundred thousandth of a second. The capacity of the condenser and inertia of the circuit regulate the rapidity of these oscillations. A 1 microfarad condenser discharging through a coil of large self-induction, such as one having an iron core, may oscillate only a few hundred times per second. On the other hand, a Leyden jar of the 1-pint size discharging through a short circuit will set up oscillations, perhaps ten million per second; and a still smaller jar would give oscillations away up in the billions. But these small jars are quickly discharged, and require a constant replenishing.

The discharge actually consists of a principal discharge in one direction, and then several reflex actions back and forth, becoming feebler until their cessation. In their vibration they generate waves in the surrounding medium, similar in many respects to sound waves, but of infinitely higher velocity. Their length depends on the rate of vibration of the source and their velocity. The microfarad discharge before mentioned will have a wave length of perhaps 1,200 miles, the small jar not over 70 feet; and yet the true light wave has only an average length of one fifty thousandth of one inch. These waves travel into space until they either die out from exhaustion or are absorbed by some suitable body; but they possess the quality of resonance in a degree like those of sound. Two tuning forks of the same pitch will influence one another—that is, one on being vibrated will start the other in vibration, even at a considerable distance, but the electric waves far surpass them in this respect.

Dr. Hertz made the first practical experiments in this direction with his electric resonator (Fig. 51). This apparatus consisted of a 3-inch spark induction coil, *I*, the secondary wires *S S* being connected to the copper rods *R R*, provided with metal balls *B B*, nearly 11 inches in diameter. The discharging balls *D D* were approximated until a satisfactory discharge passed between them. A large wire ring having a spark gap in its circuit was so influenced by the resonance as to show minute sparks passing across this gap, even when the ring was situated in a distant room. In many experiments with a rapidly vibrating induction coil current, a sparking has been noticed in metallic objects in the same room, in one instance it being discovered in the metallic designs on a wall-paper.

The "Tesla" Effects.

In exploring the comparatively new field opened up by Professor Crookes, Nikola Tesla has stimulated research

Tesla Arrangement with a Ruhmkorff Coil.

into the mysteries of high tension and frequency currents and their effects. In the majority of his experiments Tesla uses alternating currents generated by machinery of his own design, but in a large number of cases his effects can be duplicated with an induction coil suitably energized. In the latter case the apparatus consists of a battery, a Ruhmkorff coil, two condensers, and a second specially constructed induction or disruptive coil, with some few subsidiary implements. The contact-breaker or rheotome must be one giving interruptions of very rapid sequence.

Fig. 52 shows a diagram of the Tesla arrangement with a Ruhmkorff coil. The terminals of the secondary coil of the Ruhmkorff coil *I* terminate at the condensers *C. C.* Bridged across the wires before they reach the condensers is the discharger *D*. The second terminals of the condensers are led through the split primary of the disruptive coil, terminating at the points *B B* of the second discharger. The secondary of the disruptive coil is either outside or inside the primary coil. The condensers are of special design, being small, but of high insulation. They each consist of two plates of metal a few inches

square immersed in oil and arranged so they can be brought nearer together or further apart, as necessary. Within limits, the smaller these plates are the more frequent will be the oscillations of their discharge. They also fulfil another purpose; they help nullify the high self-induction of the secondary coil by adding capacity to it.

The discharger tips are preferably metal balls under 1 inch in diameter. Tesla uses various forms of dischargers, but for experimental purposes the two metal balls will answer. They are adjusted when the whole apparatus is working according to the results desired. The mica plates serve to establish an air current up through the gap, making the discharge more abrupt, an air blast being also used at times for the furtherance of this object. The device (Fig. 53)consists of an electro-magnet, *C*, set with its poles *P* across the air gap, helping to wipe out the spark, as in a well-known form of lightning arrester. This form, described by Tesla, has the pole pieces *P* shielded by mica plates *M* to prevent the sparks jumping into the magnets. Fig. 53 is an elevation and Fig. 54

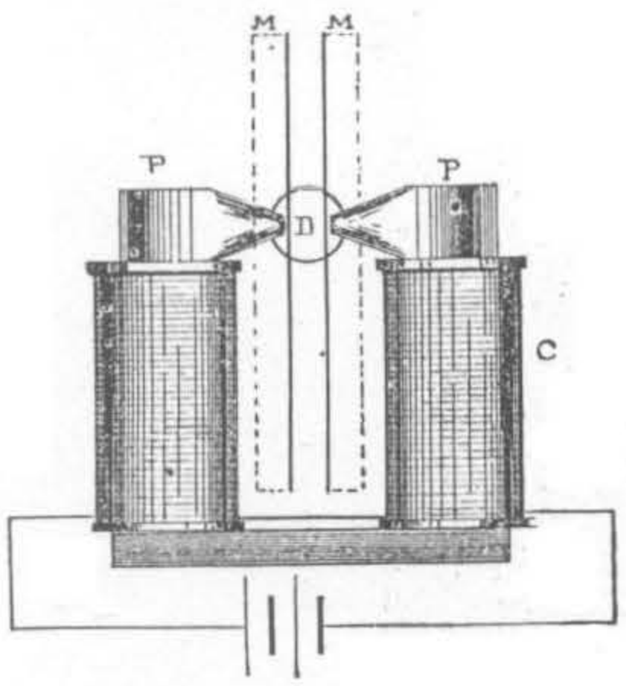


Fig. 53—Tesla's Spark Destroy r.

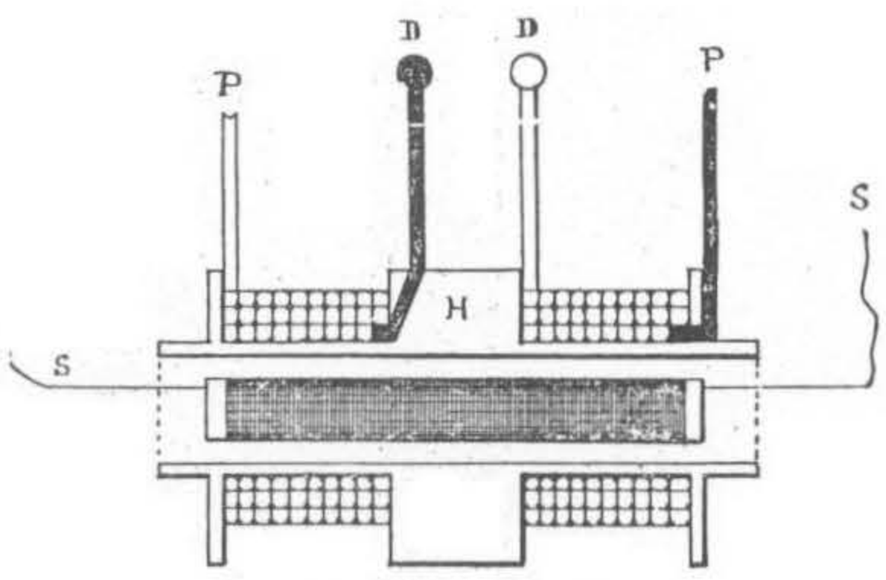

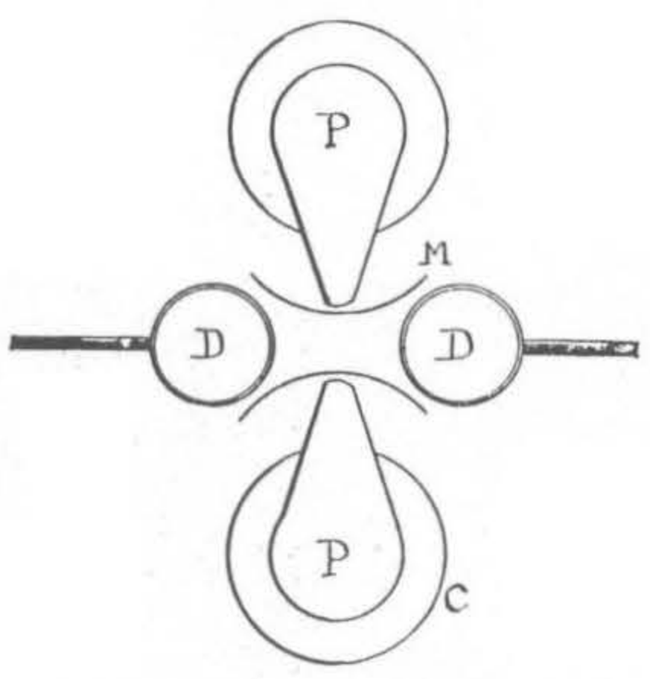

Fig. 55—Disruptive Coil.

Tesla's Spark Destroyer Shielded by Mica Plates, M M.

a plan of this device. The terminals from the condenser are led to the primary of the disruptive coil, or, as in Fig. 52, to two discharger balls *B B*. The disruptive coil (Fig. 55) is easily made, and will give good results with careful handling.

The secondary coil *S* of 300 turns of No. 30 silk-covered magnet wire, wound on a rubber tube or rod ½ inch in diameter, with the ends brought out in glass or rubber tubes. The primary coils are wound on a second rubber tube, *H*, at least 1-10 inch thick, and large enough inside to slip easily over the secondary coil S. It must be long enough to project 2 or 3 inches over the ends of the secondary coil turns. The primary has 50 turns in each coil of No. 18 B. & S. gutta-percha covered wire. The four ends, *P P P P*, of this coil are brought out in rubber or glass tubes, two to the condenser and two to the discharger *D D*. Each layer of these coils must be separated by rubber cloth or even cotton cloth. The further apart the layers the less the inductive effect, but the better the insulation. The whole coil is immersed in a glass or wooden vessel containing boiled-out linseed or petroleum oil. A perfect coil should have all the air bubbles drawn out of it after being immersed by putting it under an air-pump, but for many experimental uses this is not absolutely necessary; but extreme care must be taken to insulate the coils and their terminals. This will be apparent when the current is turned on.

The resonance effects obtained during the operation of a Tesla coil are very marked, and their study may lead to the solution of the problems of communication between distant points without the use of other conducting media than the atmosphere. But the main use to which the Tesla currents have been put is that of artificial illumination. These currents have enabled experimenters to obtain a high luminosity in vacua by the aid of only one conducting wire—in fact, in some cases without the utilization of any conductor than the air. An ordinary incandescent lamp connected to one terminal of the coil will show in a fair degree some of the luminescent phenomena. The brush effects from the terminals of the secondary coils are extremely marked and interesting; but to detail the experiments that can be performed with the Tesla disruptive coil would be an impossibility here. Reference is recommended to the published works of Nikila Tesla, which, happily, are readily procurable.

These currents of high frequency have of late been turned to account in electro-therapeutics, principally for the stimulation they exert on the nutritive process. They also exert a very great influence on the vasomotor centres, as is evidenced by the reddening of the skin and exudation of perspiration. This result is readily obtainable by placing the patient in connection with one electrode on an insulating stool, and terminating the other electrode at a large metal plate situated a few feet distant; or the patient may be surrounded by a coil of wire in connection with the coil of sufficient diameter, however, to prevent contact.—H. S. Norrie, in "Ruhmkorff Induction Coils," by permission of Spon & Chamberlain.

COMBINATION OF THE WALKER AND WESTINGHOUSE INTERESTS.

Two of the largest manufacturing concerns in this country, the Westinghouse Electric & Manufacturing Company, of Pittsburg, Pa., and the Walker Company, of Cleveland, O., have combined and formed what is probably the largest electrical combination in the world. The Walker Company has been very successful in obtaining large contracts for electric railway installations, but has been greatly hampered by litigation with the Westinghouse Company. The combination, therefore, of the two corporations will result in their working on a more profitable basis than heretofore, unhampered by ruinous competition.

Third Day—Thursday, September 15th.

The Alternating Dynamo Current.—Dr. F. B. Bishop presented a paper in which he described a simple step-down transformer for use in this connection. He said that he had treated several cases of writer's cramp with this current. The patients had been previously treated with the galvanic current, and of their own accord had spoken of how much easier they felt after the alternating current. By means of the transformer the voltage was reduced from 104 to 4. The patient placed both hands in jars containing warm water in which salt or soda had been dissolved.

The Electric Arc Bath: A Clinical Report.—Dr. Margaret A. Cleaves presented in this report detailed clinical accounts of cases treated by the electric arc bath. Among these were cases of eczema, psoriasis, bronchial asthma, and pulmonary phthisis. Her observations in connection with the last-named disease were especially interesting. As she very pertinently remarked, it had long been known that sunlight was inimical to the growth of tubercle bacilli, and the value of sun baths had been demonstrated again and again. The electric-light bath closely approximated the sun bath, and, in addition, there was the production of ozone. A greater quantity of ozone was generated from the alternating current. She preferred the arc light because of this production of ozone, and also because of the fact that the rays from this light embraced a large part of the violet end of the spectrum. There could be no doubt, she said, that in man, as in plants, protoplasmic activity was increased by exposure to electric light. Her cabinet, she said, was six feet long, two and one-half feet wide, and seven feet high, and was lined with zinc, painted white. At each end were glass compartments containing the electric arc lights. The patient reclined on a wire-mattress cot. Each lamp had a reflector which allowed focussing the light on special parts. The patient was preferably nude, and the eyes were protected by dark glasses. The maximum of nutritional activity was usually observed at the end of the second week, and this would be expected from theoretical considerations as to the action of ozone.

Dr. Nunn said that the paper was interesting as emphasizing the old-time truth regarding the sanitary value of sunshine. Of course, where sunshine could be readily obtained, it must be admitted to be superior to artificial light. As modern chemistry had shown the atmosphere to be such a complex substance, it did not seem to him wise to say very much regarding ozone.

Mr. John J. Carty, electrical engineer, suggested that some of the effect might be due to radiation and some to emanations from the arc. In the latter connection it should be borne in mind that the carbon rods were commonly of complex composition, and not pure carbon, and, furthermore, that they were coated with copper.

Dr. F. B. Bishop said that he had had an opportunity of seeing the working of Dr. Cleaves' cabinet, and had been impressed with the rapidity with which the ozone had been generated and its quantity. As he had himself secured some excellent results in the treatment of the early stages of pulmonary phthisis by means of the ozone bath, he was inclined to attribute Dr. Cleaves' success chiefly to the ozone generated in connection with the arc light.

Dr. Massey spoke of the striking effect of sunlight on the vegetable world, and the mistake of modern civilization in so generally excluding the sun from dwellings.

Dr. Cleaves, in closing the discussion, said that she wished it to be understood that she did not know what it was that gave her these good results, though the clinical fact remained. In only the one case reported had there been a complete disappearance of the tubercle bacilli, but in all of the cases so treated there had been gratifying improvement.

Some Suggestions on the Possibilities of Cataphoresis.—Mr. John J. Carty, E.E., of New York, presented this paper, which was founded on some experiments that he had made regarding the use of cataphoresis in the attempt to secure painless dentistry. It did not seem to him that there was any part of the body which physicians should despair of reaching by cataphoric medication. A novel suggestion which he made was to use an O'Dwyer tube as the positive pole, and apply the negative pole to the neck in the form of a collar in cases of diphtheritic laryngitis.

Dr. Massey said that cocaine cataphoresis never failed in dentistry if properly conducted. The principal causes of failure were: (1) improper apparatus; (2) imperfect technique, such as not properly drying the tooth cavity; and (3) lack of willingness on the part of dentists to give the necessary time to the use of this method. The suggestion about using the intubation tube seemed an excellent one, and if this tube was of zinc and was freshly amalgamated at the time, he thought it would prove still more efficient, as the oxychloride of mercury formed was one of the most powerful antiseptics known.

A High-Frequency Oscillation for Electro-Therapeutic Purposes.—Mr. Nikola Tesla, E.E., of New York, in a paper with this title described his now well-known experiments with high-frequency currents, dwelling particularly on the construction of the apparatus and the possibilities of the future in the therapeutic application of this form of electricity.

Officers.—The following officers of the association were elected: *President*, Dr. Francis B. Bishop, of Washington, D. C.; *Vice-Presidents*, Drs. Ernest Wende, of Buffalo, and W. H. White, of Boston; *Secretary*, Dr. John Gerin, of Auburn; *Treasurer*, Dr. R. J. Nunn, of Savannah, Ga.

The next meeting will be held in Washington, D. C., on September 19, 20, and 21, 1899.

The Mechanical Engineer.

Rival Systems of Electric Driving.

IT cannot be doubted that electric transmission of energy over long and short distances has made remarkable progress during the past few years. Even in this country, which is commonly reputed to be slow in adopting new methods, electric driving is being extensively used, and it will not be surprising to find the system eventually adopted in the majority of those works where the process of manufacture necessitates somewhat wide areas. The natural enthusiasm of the electrical engineer has infected to a great extent manufacturers and power users; but in spite of the obvious merits of electrical systems, and the very high efficiency that usually obtains, it must not be assumed that economy can be exhibited under all conditions.

A system of power transmission which embraces long lengths of steam pipes and small scattered engines would be clearly uneconomical, and it is not surprising when such a method is superseded by electric transmission that some very marked economies should ensue. In the case of Messrs. Richardson's works at West Hartlepool, where long steam pipes were carried through extensive shops and yards, electric transmission scored a complete triumph by demonstrating a saving of 100 tons of coal per week. Messrs. Dorman and Long again have, by adopting electricity, saved 32 tons of coal per week; while in the case of Messrs. Gray and Son the saving of fuel consequent upon introducing electric driving realised the large sum of £3,000 per annum. Electrical men could not be blamed for proclaiming such results to the whole world, but while these instances demonstrate beyond all cavil the economy of electricity, it clearly proves the extremely wasteful nature of the previous methods. It would be impossible to conceive a more inefficient means of transmitting energy than that formerly employed at Messrs. Richardson's, and almost any system of mechanical transmission, hydraulic or compressed air, would have shown marked economy over it. Therefore, without desiring in the least degree to depreciate the value of electricity as an economical transmitting agent, one is inclined to view the foregoing cases as somewhat extreme ones.

It is true that hydraulic systems are not very efficient at light loads, and that long distances and leakage considerably impair the efficiency of compressed air. Moreover, while the addition of 100 horse power to an existing installation on these systems would call for a much larger conductive agent, it would make but slight difference to the cross-section of an electric conductor. Notwithstanding these drawbacks, however, electrical engineers are somewhat prone to disregard the good features of rival systems. Moreover, we think they are apt to overstate the losses that arise in shafting, and frequently they have cited shafting losses, though doubtless unwittingly, which really represented the combined losses of shafting and gearing. This was especially noticeable in a recent paper presented by Mr. Geipel to the recent meeting of the British Association. There is undoubtedly a good deal of confusion as to the exact losses that arise in shafting. Probably there are cases where they may reach as high as 75 per cent, but it must not be forgotten that mill engineers have given considerable attention to the design of shafting, and on the whole we should be inclined to accept Prof. Kennedy's statement that for 100 horse power of useful work in shafting it required 145 indicated horse power at the engine. No doubt a well-designed electrical system could show better results than that, but it is, after all, only a series of links between the prime mover and the machine to be driven, and is, consequently, subject to certain losses of its own. The most efficient electrical plant could not show a much greater efficiency than 76 per cent at the place where power was demanded; there are the dynamo losses which might be 6 or 7 per cent; the conductors would absorb

2 per cent; while the motors would represent a loss of 12 per cent. It is true that the losses of an electric system are not continuous in the same sense as those of shafting, but even electric motors do not always abolish shafting.

While there is very properly a strong tendency among power users to accept electric driving as an economical agent, there is a disposition among electrical engineers to quarrel among themselves as to which is the best system, and the recent discussion at the British Association took a somewhat acrimonious tone. In fact, it seems to be a revival in a modified form of the old battle of the systems. These discussions, while highly diverting and even of some interest in an academic sense, might tend to somewhat perplex the prospective user of electric driving.

There is, after all, very little to quarrel about, for an unbiassed investigation into the various systems will show that each has its special sphere of usefulness. For practical purposes electric driving may be divided into three classes—continuous current, single-phase alternating, and three-phase alternating.

The continuous current motor has been widely adopted in this country, and it owes much of its development to the central station engineer, who, in an endeavour to obtain a day load for his lighting plant, has created quite a small revolution in the condition of small power users. How marked the development has been in this direction is shown in such towns as Manchester, where 257 motors, aggregating 696 horse power, are connected to the public mains, while even in a non-industrial centre, such as Edinburgh, 167 motors, aggregating 343 horse power, are employed. In the early days of electric lighting one heard a good deal as to the evil effects that would be created on the lighting circuits by the throwing on and off of electric motors, but though some trouble may have been originally experienced, a stage is soon reached when the trouble ceases. The interference caused by motors decreases in exact proportion to the increase of the load, and the starting and stopping of motors causes a minimum of disturbance; especially is this the case in three and five wire systems of distribution when the motors are connected across the outer wires. It is not alone on public supply circuits, however, that continuous current motors have been adopted; indeed, until comparatively recently the system was the only one employed on private systems in this country. Even now the greater proportion of new electric driving schemes embrace direct-current motors.

It is not easy to say what is the precise stage at which it pays to employ private plant to generate electricity for power purposes, rather than purchase from a public supply, if such be available. As a matter of fact, public supply companies and municipal authorities have not gone far beyond the small consumer, or one whose demand is greater than 50 horse power; but it is almost established that a public supply could even now supply electricity cheaper for power purposes than it could be generated even on a large scale by private plant. Many towns are now able to sell electricity for power purposes at 1½d. per Board of Trade unit, and that this is probably cheaper than it could be generated by a private plant is shown by the case of Messrs. Siemens Bros., of Charlton, who, employing electrical driving on a very large scale, find the cost to be 2d. per unit. In other words, if Messrs. Siemens were obtaining their supply of electricity from public mains they would probably save £2,000 per annum. With such apparent economies the development of a public supply of electricity for power purposes is bound to be rapid.

Considering the continuous current motor in a comparative sense, it can scarcely be denied, even by the most ardent advocate of three-phase principles, that it has the merit of simplicity. Theoretically the commutator and brushes ought to give trouble, but in practice they do not. With the general adoption of carbon brushes continuous current motors may be left for days, and even weeks, without any attention whatever. So reliable is this type considered to be in some works that it is frequently fixed in somewhat inaccessible places, a sufficient indication of the little attention required.

For all practical purposes the single-phase alternating current motor may be considered out of court. It is true that marked improvements have been effected during the past twelve months, but it is doubtful whether the problem has been really solved. We are inclined to agree with Mr. Alexander Siemens, when he says, "If a reliable alternate current motor had been invented there is little doubt that this system of transmitting power would be the dominating one at the present time, but unfortunately alternate current motors up to now refuse to start without being first synchronised by external means. They are liable to stop abruptly when they are overloaded, and their speed cannot be varied."

As a matter of fact, there are few motors on the mains of alternating supply stations, and those are of quite insignificant size; indeed the engineers of such stations do not, as a rule, countenance their introduction upon the lighting circuits. That the present alternating stations cannot satisfactorily meet a motor load is shown by the County of London and Brush Co., which, owning an alternating supply station in the City of London, has, in order to meet the demand that exists for motors, laid down continuous current machinery and special mains. The City of London Company has decided to proceed on almost similar lines.

When we come to speak of three-phase alternating motors, we are again in the region of practical accomplishment, for some of the most ambitious and most interesting electrical driving has been carried out on this system. The chief development, however, has taken place on the Continent, and when we say that three-phase motors of 1,000 horse power each have been erected, one obtains an indication of the possibilities that lie before electric transmission. Some of the objections urged in this country against three-phase motors were that it was impossible to overload them, and that it was difficult to place such motors on lighting circuits.

The Brooklyn Eagle October 4, 1898

WILL TESLA'S PATENTS BE USED EXCLUSIVELY?

Consolidation of the Electric Companies Said to Mean This.

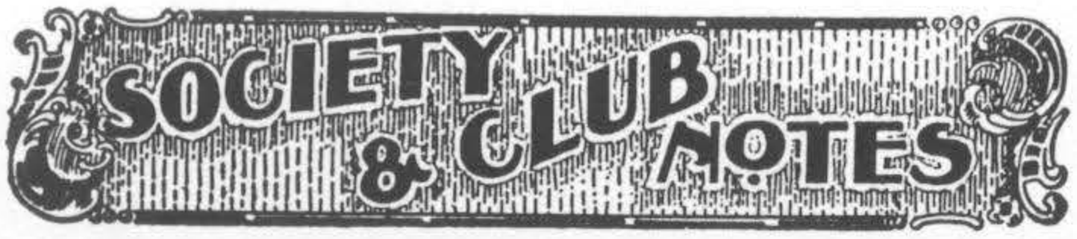
THE COMBINATION ASSURED.

Over 90 Per Cent. of Edison Stockholders Have Deposited Their Shares and the Physical Consolidation Will Be Effected Within a Few Months—All Power Houses but the New Water Front Plant of Kings County to Be Closed—This Is Equipped With Tesla's Inventions—Financial Details.

The combination of the four principal electric light companies of this borough into one large corporation, and securing what is practically the control of that industry here, has now become assured through the formal consent of nearly the entire stock issue of the Edison Electric Company. According to Vice President Royal C. Peabody, over 91 per cent. of the capital stock of $5,000,000 has been deposited with the Central Trust Company and there is every reason to believe that every share will finally go in. This transfer makes the Kings County Electric Light and Power Company the owner of the Edison, the latter in turn controlling the Citizens' Lighting Company and the Municipal Lighting Company; or substantially all of the electric light business of Brooklyn.

While the consolidation of the electric interests is now practically settled, yet there are so many details and legal matters to be attended to that Vice President Peabody said this morning that it would be two or three months before the physical and actual combination of the companies would be effected. It would take at least this time, he said, to close up the financial questions and until that has been done, Mr. Peabody was not prepared to discuss the policy of the new consolidated company, how it would be operated, its new management, etc. In fact, Mr. Peabody added, these questions had not been definitely decided as yet, the financial matters engrossing so much of the attention of the men behind the consolidation.

When this consolidation becomes a fact the new company will find itself in control of three immense plants in addition to the sub-stations established throughout the borough and on Long Island by the Edison Company. It is not to be expected that all of these plants will be operated and a director of one of the companies is the authority for the statement that all the plants will be closed, when the new company takes hold, and that the new water front plant of the Kings County Company will be used to manufacture all the power necessary to supply Brooklyn. This, the reporter's informant said, it was well able to do and much cheaper than the power is now being manufactured by the present plants, including even the new million dollar South Brooklyn station of the Edison.



The water front plant of the Kings County Company has been completed for some time, but it has not been in operation; the consolidation deal of the companies making it unnecessary that there should be any actual competition. When the Kings County Company was organized and the construction of its power house was well advanced, it was currently reported that this new power house was going to be the perfection of electrical art and, through the fact that the company had secured control of a number of new patents by that well known expert, Tesla, it was said that they could manufacture power so cheaply that with the accompanying cut in rates that would be possible, the other electric companies would be driven to the wall. The men interested in the Kings County Company were in the habit of talking most mysteriously in regard to these new patents, but the only positive information ever obtained was to the effect that they did control a system which could greatly reduce the cost in transmitting power long distances.

If the consolidation company uses this new plant exclusively even to the abandonment of that admittedly modern South Brooklyn power house, men interested say it will be conclusive proof that there is something in the Tesla invention stories, which, by the way, have generally been regarded as bluffs, after all. It is certainly true that the Edison Company feared the competition of the Kings County, as the latter was able to bring about a consolidation on what is regarded as most favorable terms, especially after taking into consideration the large business and almost monopoly enjoyed by the Edison for so many years. There will be no change in the local electrical situation for several months and for the present it is impossible to secure any information as to executive heads of the consolidated company, the directors, etc., and the officers themselves say these questions have not even been discussed.

According to the terms of the agreement, the $5,000,000 of the Edison capital stock, which has lately been increased by an additional 25 per cent. of the original $4,000,000 issue, and for which the stockholders had the privilege of subscribing, is to be exchanged, par for par, for $5,000,000 second mortgage 99 year gold 6 per cent. bonds, to be issued by the Kings County Company.

These bonds of the Kings County Company will be secured by vendor's lien on the Edison shares to be reserved by the Central Trust Company and by a purchase money mortgage, which, beside being a first lien on the Edison shares, will be a general lien on property, present and future, of the Kings County Company, subject only to its present first mortgage for $2,500,000. They will also be secured by deposit with the Central Trust Company of $1,000,000 cash, to be invested in securities approved by the Edison stockholders' committee, which consists of George Foster Peabody, Ethan Allen Doty and Edwin M. Bulkley.

It is proposed that the Edison first consolidated mortgage, recently authorized for $5,000,000, in 5 per cent. bonds, shall be authorized instead to an amount not exceeding $10,000,000 in forty year 4 per cent. bonds. This mortgage will be secured by a first lien on all of the Edison property, subject only to the existing first mortgage bonds, which are to be paid off and canceled in 1900. The first issue of these Edison first consolidated bonds was of $2,000,000 to provide funds to pay for the stock of the municipal company. Of the remainder, $1,875,000 will be reserved to retire the $1,500,000 of existing first mortgage bonds, which will be called for payment at 110 and interest in 1900. The rest of the $10,000,000 of bonds will be issued from time to time as required, for extensions, additions and other property, which, when acquired, will become subject to the lien of the mortgage.

Eighth Annual Meeting of the American Electro-Therapeutic Association, Buffalo, N. Y., September 13, 14 and 15, 1898.

SHORTLY after 10 a. m. Dr. Charles Rea Dickson, of Toronto, Canada, president of the American Electro-Therapeutic Association, called together the eighth annual meeting of the association in the rooms of the Buffalo Society of Natural Sciences.

President Dickson introduced Dr. Conrad Diehl, Mayor of Buffalo, who extended to the members of the association the freedom of the city. He spoke of the growth and development of electrical treatment since the time it was first adopted by the medical profession, as an important part of the professional apparatus. Dr. Diehl said that the street cars of Buffalo were now run by electric power from Niagara Falls, and urged the members of the association to inspect the electrical plant of the Buffalo Railway Company.

Dr. Francis B. Bishop, of Washington, responded to the Mayor's welcome on behalf of the American Electro-Therapeutic Association.

Reports of standing committees on scientific questions were next in order. Dr. Margaret A. Cleaves, of New York, presented her report on meters. The report was accepted and the committee requested to continue its labors. Dr. Cleaves announced that the committee was not willing to continue its work, but desired the appointment of a new committee on meters.

On constant current generators and controllers the report was asked for from the chairman of the committee, Dr. William J. Herdman, of Ann Arbor, Mich., but in his absence an auxiliary report was presented by another member of the committee, Dr. Robert Newman, of New York, who in 1896 was president of the American Electro-Therapeutic Association.

John J. Carty, electrical engineer, of New York, made a brief report of progress. He is chairman of the committee on electric light apparatus for diagnosis and therapy and the Roentgen X-ray.

Dr. Margaret A. Cleaves, of New York, read a paper on "Phlebitis, a Clinical Study," in which she gave a number of instances which had come under her professional supervision.

Dr. A. D. Rockwell read his paper on "The Diagnostic and Therapeutic Relations of Electricity to Diseases of the Central Nervous System."

AFTERNOON SESSION.

Shortly after 2 p. m. the second session of the American Electro-Therapeutic Association was called to order by President Dickson. The first paper on the programme was by an honorary fellow of the society, Dr. Georges Apostoli, of Paris. The subject was "New Uses of the Undulatory Current in Gynaecology." The paper was translated from French into English and was read by Dr. G. Betton Massey, of Philadelphia.

"Electricity in the Treatment of Uterine Fibromata" was the subject of a paper by Dr. Felice La Torre, of Rome, Italy, read by Dr. John Gerin, of Auburn, secretary of the association. Then came a paper on "Electro-Therapeutics in Gynaecology," by Drs. Georges Gautier and J. Larat, of Paris, France, read in English by Dr. Dickson, president of the association, followed by "The Treatment of Uterine Fibroids by Small Currents, Administered Percutaneously," by Dr. Richard J. Nunn, of Savannah, Ga.

Dr. W. H. White, of Boston, read a paper by Dr. Adelstan de Martigny, of Montreal, on "Treatment of Menorrhagia by Weak Current and Silver Internal Electrode."

This was the concluding paper on the afternoon programme. An early adjournment was taken in order that members of the association might avail themselves of the tally-ho ride about the city, planned by the committee on arrangements.

An invitation to the association to visit the storage battery of the Buffalo Railway Company was sent by Superintendent Danforth at the request of Mayor Diehl.

RECEPTION FOR THE VISITORS.

At 8:30 p. m. a public reception in honor of the members of the American Electro-Therapeutic Association was held in Alumni Hall, University of Buffalo Building, which was largely attended, many medical men of Buffalo being present.

Dr. Henry R. Hopkins, of Buffalo, a member of the local committee on arrangements, spoke of the earnest work of the medical men in this country. Dr. Charles Rea Dickson, of Toronto, president of the American Electro-Therapeutic Association, made a few remarks, in which he spoke of the fraternal feeling existing between the two great English-speaking nations at the present time.

Dr. Robert Newman, of New York, made a brief address, as did Dr. G. Sterling Ryerson, of Toronto, Deputy Surgeon General of the Canadian Militia.

SECOND DAY'S SESSION.

An executive session of the American Electro-Therapeutic Association was held at 9 a. m.

The report of the executive council on the revision of the constitution and by-laws was adopted, making some important changes in the governing rules of the association.

The first paper was presented by Dr. Lucien Howe, of Buffalo, who represented the Erie County Medical Society and also the New York State Medical Society at the convention. Dr. Howe's subject was "The Method for Using Cataphoresis in Certain Forms of Conjunctival Inflammation."

Dr. Howe illustrated his address by means of a number of his patients. His lecture was received with great interest and considerable discussion followed. Many questions were asked Dr. Howe concerning his methods of treatment.

Dr. Robert Newman, of New York, presented an able paper on "Electricity in Deafness and Stricture of the Eustachian Tube." In his address Dr. Newman rehearsed the history of a peculiar case which came under his professional care. He also cited a number of other cases, which had been reported by other physicians.

The discussion which followed Dr. Newman's paper was led by Dr. Howe, followed by Dr. A. D. Rockwell, of New York.

Dr. Grover W. Wende, of Buffalo, read a paper on "Electricity in Acne Vulgaris and Acne Rosaceae."

Dr. G. Betton Massey, of Philadelphia, led the discussion of Dr. Wende's paper, followed by Dr. Margaret A. Cleaves, of New York.

Dr. G. Sterling Ryerson, of Toronto, Deputy Surgeon General of the Canadian Militia and the accredited delegate of the Ontario Medical Association, was introduced by President Dickson, and spoke briefly, giving a number of instances of the effect of lightning-stroke causing diseases of the eye, in which the results were not permanently serious.

Dr. Francis B. Bishop, of Washington, presented a paper on "High Tension Current in Neuritis," which was followed by considerable discussion.

The final paper of the morning session was by Dr. Charles Rea Dickson on "Electricity in the Treatment of Goitre."

At 1 o'clock the convention adjourned until 2 p .m.

AFTERNOON SESSION.

President Dickson delivered his annual address, a part of which is as follows:

"The necessity for the existence of such an association as ours has been questioned not only here, but elsewhere, hence it may be necessary to explain our position. It has been asked 'Why should there be such an association?' Electricity is only one of many therapeutic agents, and it would be absurd to have a separate association to consider each therapeutic agent. At first

glance this may seem a quite rational question. Our colleges teach us how to administer opium and its various derivatives, therefore the necessity for an opium society does not exist, but do our colleges teach us anything about electricity worthy of the subject? The answer to this question is quite unnecessary in the presence of the members of our association. Anyone should be depended upon to prescribe and administer the ordinary, or even extraordinary, remedies to carry out any regulation form of treatment. But I, for one, should fear to trust myself to the tender mercies of the general practitioner of to-day did he, in his wisdom, consider it necessary to use this agent, electricity, unless he had paid some special attention to the mastery of it. The contention is an absurdity unworthy of America, the vaunted land of progress, and of Buffalo, the Electrical City. In my own benighted land, even, we are more enlightened than that. This is an age of specialism.

"The old-time practitioner, then the physician and surgeon, seems passing away. Surgery is being divided and subdivided, until at one time we feared that we were to be confronted with an appendix surgeon. Our patients are reaping the benefit of all this. Why, then, should we call a halt? No! Let onward be our cry. The time is past when a physician, the proud possessor of a solitary magneto-electrical machine, turned by a crank, considered his armamentarium electricum quite complete. One has but to glance at our programme to see to what extent electricity may be used to advantage. A programme such as ours should prove a perfect revelation to him who has not kept well up to this progressive age. Could such a programme or one-hundredth part of it be intelligently discussed in any other existing society to-day not dealing distinctly with the subject? No, I greatly fear it would be a hidden book, a stumbling block.

"The hope of the future lies in those who are now thronging wisdom's halls, and it is a subject for congratulation that this association is to be asked to take action, bringing the needs of the hour before the authorities competent to deal with them. The student with mind as yet unwarped by prejudice must be in a position to obtain a comprehensive, intelligent grasp of the whole subject, that he may turn his theories to practical account in his professional career. But even he, unless endowed by these inestimable blessings, common sense, patience and gentleness, will find his efforts unavailing, and he must be a close observer of Nature and her laws, seeking to assist rather than to combat her. Electricity is an agent most powerful for weal or woe. A great responsibility rests upon our educators, and the sooner they awake from their strange lethargy the better will it be for our reputation as an enlightened, progressive, scientific profession. The commercial world has taken such advantage of the rapid strides of electricity as a science with fixed laws that we have laid ourselves open to the charge of neglect. Let us hasten to make amends for the past and remove some of the reproaches that rest on this, the noblest profession in this fair world.

"Our association was organized some eight years ago, because it was felt that the subject of electro-therapeutics could not be discussed in any existing society in a scientific and practical manner without controversial digressions of no value whatever. It was felt, and felt strongly, that electricity had been left too long to the charlatan, the incompetent and the unscrupulous. It was also felt that we had another foe of hardly less dangerous character, the over-zealous.

"To combat all these and cultivate and promote knowledge of electricity wherever it can be of service in medicine and surgery is the object of our association. It must be admitted that we are setting about this in the most practical manner possible. In fact, I know of no other association in which more practical or more useful work is being done. To carry out this idea successfully we have associated with us other than purely medical practitioners, and the association has proved a most happy one, and fruitful of nothing but good. Thus the electrical engineer and expert study electricity's laws and note its action upon inert matter. The biologist and physicist go a step farther and study these laws in their action upon living tissue, and their labors are turned to practical account by the physician and surgeon. The curative and palliative powers of the agent are available to all who have access to my clinics.

"The clouds are breaking on our horizon. On my side of that imaginary boundary line we find increasing interest being manifest, and it gives me the greatest satisfaction to say that my own warmest friends in the city of my adoption are the men who stand in the front ranks of medicine and surgery, and electrotherapy has a recognized standing, inasmuch as special departments devoted to it are to be found in our public hospitals. I have had the honor to organize and now to preside over four such departments in as many hospitals, and more intelligent inquiries are being made by the students of the various medical colleges, all of whom have access to my clinics.

"A rock we must avoid is that on which many a stronger society than our own has come to grief, the clique. And the furtherance of personal ambition or personal designs must be shunned."

All the suggestions embodied in the address were referred to the executive council of the association.

The programme for the afternoon was made up of a series of ten-minute talks on "Electro-Therapy," and the subject was one to attract a widespread interest among members of the medical fraternity.

Dr. G. Betton Massey, of Philadelphia, presented a paper on "The Galvanic Current in Gynaecology." The next paper was "Surgical Uses of Electricity," by Dr. Charles Rea Dickson, president of the association.

Dr. Robert Newman, of New York, presented a paper on "Electricity in Genito-Urinary Diseases." Dr. G. Betton Massey spoke on "Treatment of Malignant Growths by Means of Electricity."

A paper by Dr. Louis A. Weigel, of Rochester, on "Orthopædic Uses of Electricity," was followed by a paper by Dr. Rockwell on "Functional Diseases of the Nervous System Treated by Electricity."

The association adjourned at 4:30 p. m. and proceeded by special car to visit the power house and storage batteries of the Buffalo Railway Company.

A short business session of the American Electro-Therapeutic Association was held from 8 to 9 p. m., at which the following officers were elected: President, Dr. Francis B. Bishop, of Washington; first vice-president, Dr. Ernest Wende, of Buffalo; second vice-president, Dr. W. H. White, of Boston; secretary, Dr. John Gerin, of Auburn; treasurer, Dr. Richard T. Nunn, of Savannah, Ga.; executive council, Dr. Robert Newman, of New York, and Dr. G. Betton Massey, of Philadelphia, three years; Dr. A. D. Rockwell and Dr. William J. Morton, of New York, two years; Dr. Charles R. Dickson, of Toronto, and Dr. Frederick Schavoir, of Stamford, Conn., one year. Washington was selected for the convention next year, to be held September 19-21, 1899.

Dr. Lucien Howe entertained the men of the association at the conclusion of the business meeting. A smoker was given at Dr. Howe's home, corner of Delaware avenue and Huron street, which was largely attended.

THIRD DAY'S SESSIONS.

A vote of thanks was tendered to Dr. Wende, chairman of the local committee on arrangements; to the Buffalo Commercial for its kindness, not only during the convention, but in publishing the preliminary news of the association; to Dr. Howe, for his entertainment last evening; to Mayor Diehl, to the Buffalo Railway Company, Buffalo Historical Society, Fine Arts Academy, president and secretary of the association, and Dr. Newman, of New York, and to the press generally.

The congratulations of the American Electro-Therapeutic Association were extended to the University of Buffalo for its progress in establishing a chair of electro-therapeutics in the medical college.

A general vote of thanks was also adopted, expressing the association's deep appreciation of the courtesy and hospitality extended to the members during the convention in Buffalo.

At 10 o'clock the executive session adjourned and President Dickson called the scientific session to order. The first two papers on the programme were read by title. They were both by Drs. Georges Gautier and J. Larat, of Paris, France, the first on "The Hydro-Electric Bath with Sinusoidal Current in Disease," the second on "The Use of Hot Air and Light Bath in Disease."

A paper was read by the newly-elected president of the association, Dr. Francis B. Bishop, of Washington, on "Alternating Dynamo Currents."

Dr. Margaret A. Cleaves, of New York, read a paper on "The Electric Arc Bath."

A paper by Dr. J. H. Kellogg, of Battle Creek, Mich., on "The Electric Light Bath" was read by title. The next paper was by John J. Carty, of New York, on "Some Suggestions on

the Possibilities of Cataphoresis." Mr. Carty gave a short, practical talk, which was very interesting.

A paper by Dr. G. Herbert Burnham, of Toronto, Canada, on "Electricity in the Treatment of Certain Diseases of the Eye," was read by title.

Then came a paper by Nikola Tesla, read by Dr. White, of Boston. The subject was "A High Frequency Oscillator for Electro-Therapeutic Purposes."

The following papers were read by title: "The Effect of High Tension Discharges Upon Micro-Organisms," Drs. J. Inglis Parsons and C. Slater, London, England; "The Action of X-Rays Upon Tuberculosis," Dr. J. Bergonie, Bordeaux, France; "Two Years of Practice in Radiotherapy," Drs. Georges Gaultier and J. Larat, Paris, France.

Dr. Newman, of New York, and Dr. Nunn, of Savannah, Ga., were appointed a committee by the president to conduct the president-elect, Dr. Bishop, of Washington, to the chair. Before turning over to his successor the gavel and other insignia of office Dr. Dickson took occasion to thank the association for its kindness and courtesy to him during his term of office.

The afternoon was devoted to an excursion and reception under the direction of the local committee of arrangements.

On Friday afternoon the members were conducted over the power house of the Niagara Falls Power Company by Coleman Sellers, E. D., president and chief engineer, who made the visit a most interesting and instructive one. On returning to the hotel a meeting was held and Dr. C. R. Dickson was requested to convey to Dr. Sellers the thanks of the association for his courtesy.

Those who remained visited on Saturday morning Power Station No. 2 of the Niagara Falls Hydraulic Power and Manufacturing Company, being conducted over it by the chief electrician, who fully explained all the appliances.

A most interesting exhibition of electrical apparatus for diagnostic, therapeutic and radiographic purposes was held in the room adjoining the meeting hall. The following manufacturers exhibited: Van Houten & Ten Broeck, New York; Chloride of Silver Dry Cell Battery Company, Baltimore, Md.; Jerome Kidder Manufacturing Company, New York; Edison Manufacturing Company, New York; Waite & Bartlett Company, New York; Dow Electric Assistant Company, Boston, Mass.; the American Electro-Neurotone Company, Niagara Falls, N. Y.; the Standard Cold Electric Lamp Company, Washington, D. C.; the Spencer Lens Company, Buffalo, N. Y.; the Detwiller, Biddle Company, Buffalo, N. Y.; W. J. Shields & Co., New Wilmington, Pa.; Rochester Fluorometer Company, Rochester, N. Y.

The eighth annual meeting was unanimously conceded the most successful and enjoyable that has been held, and the prospects for the association were never brighter or more encouraging.

[94183.]—**Tesla's Experiments.**—By means of an induction coil or other transformer, which charges a condenser or Leyden jar, which, in its turn, sends its discharges through a second highly-insulated coil or transformer, which at once raises the potential and increases the frequency of the induced current. You will find illustrations of the necessary apparatus in the ENGLISH MECHANIC for Sept. 11, 1896. S. BOTTONE.

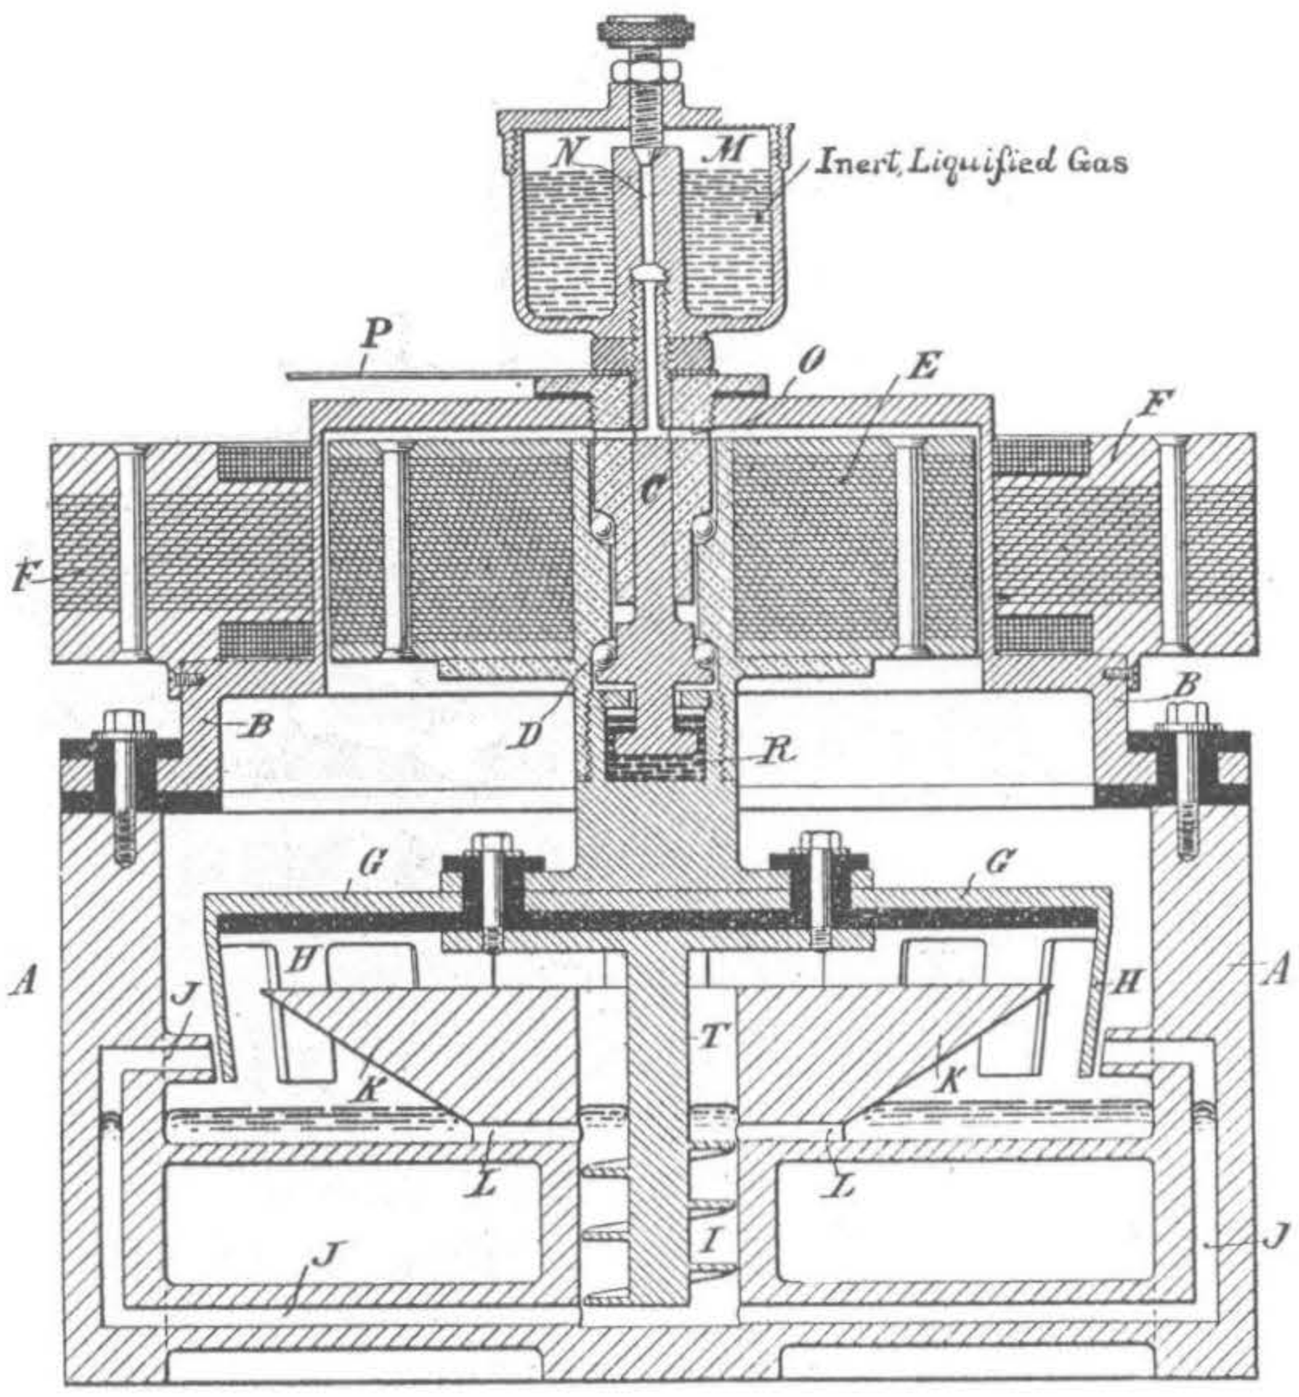
MR. TESLA'S NEW CIRCUIT CONTROLLER.

Unusual interest attends all of the work of Mr. Nikola Tesla, but more particularly that in connection with his system of vacuum tube lighting. On another page we present a description of an electric circuit controller, one form of a series of developments in this line for which patents were recently issued to him, several of which were previously noted in the ELECTRICAL REVIEW. This invention seems to us to possess mechanical efficiency of a high order, and, like the author's work in general, marks an advanced step, and will undoubtedly possess a wide field of usefulness.

Improved Circuit-Controller for Vacuum Tube Lighting and Other Purposes.



A patent was issued to Nikola Tesla October 4 relating to improvements in electric circuit controllers. The details of this invention are presented herewith, with illustration, the interesting description being in full in the language of the author, as follows:

In order to secure a more efficient working of circuit-controllers, particularly in their use in connection with my system of electrical-energy conversion by means of condenser discharges, I have devised certain novel forms of such appliances, comprising as essential elements a body of conducting fluid constituting one of the terminals, a conductor or series of conductors forming the other terminal, and means for bringing the two into rapidly-intermittent contact with each other. These devices possess many desirable qualities, particularly that of being eminently adapted for making and breaking at a very rapid rate an electric circuit and thus reducing to a minimum the time of passage of the current through an arc or path of high resistance and diminishing thereby the losses incident to the closure and interruption of the circuit. Continued experimentation with these appliances has led me to make further important improvements by causing the make-and-break to be effected in an inert medium of very high insulating power.

It is a fact, which was fully demonstrated by Poggendorff and utilized by him to improve the operation of induction-coils, that when the contact-points of a circuit-breaker are enclosed in a vessel, and the latter exhausted to a high degree, the interruption of the current is rendered more sudden, as if a condenser were connected around the break. Furthermore, my own investigations have shown that under such conditions the closure also is more sudden, and this to even a greater degree than the break, which result I attribute to the high insulating quality of the vacuous space, in consequence of which the electrodes may be brought in very close proximity before an arc can be formed between them. Obviously these facts may be utilized in connection with my novel circuit-controllers; but inasmuch as only a very moderate improvement is secured in this manner, and as the high vacuum required is quickly destroyed and can not be maintained, unless by a continuous process of rarefaction and other inconvenient measures, I have found it desirable to employ more effective and practical means to increase the efficiency of the devices in question. The measures I have adopted for this purpose have resulted from my recognition of certain ideal qualifications of the medium wherein to effect a make-and-break. These may be summed up as follows: First, the medium by which the contact-points are surrounded should have as high an insulating quality as possible, so that the terminals may be approached to an extremely short distance before the current leaps across the intervening space; second, the closing up or repair of the injured dielectric, or, in other words, the restoration of the insulating power, should be instantaneous in order to reduce to a minimum the time during which the waste principally occurs; third, the medium should be chemically inert, so as to diminish as much as possible the deterioration of the electrodes and to prevent chemical processes which might result in the development of heat, or, in general, in loss of energy; fourth, the giving way of the medium under the application of electrical pressures should not be of a yielding nature, but should be very sudden and in the nature of a crack, similar to that of a solid, such as a piece of glass when squeezed in a vice, and, fifth, most important, the medium ought to be such that the arc when formed is restricted to the smallest possible linear dimensions and is not allowed to spread or expand. As a step in the direction of these theoretical requirements I have employed in some of my circuit-controlling devices a fluid of high insulating qualities, such as liquid hydrocarbon, and caused the same to be forced, preferably with great speed, between the approaching and receding contact-points of the circuit-controller. By the use of such liquid insulator a very marked advantage was secured; but while some of the above requirements are attained in this manner, certain defects still exist, notably that due to the fact that the insulating liquid, in common with a vacuous space, though in a less degree, permits the arc to expand in length and thickness, and thus pass through all degrees of resistance and causing a more or less considerable waste of energy. To overcome this defect and to still more nearly attain the theoretical conditions required for most efficient working of the circuit-controlling devices, I have been finally led to use a fluid insulating medium subjected to great pressure.

The application of great pressure to the medium in which the make-and-break is made secures a number of specific advantages. One of these may be obviously inferred from well-established experiental facts, which demonstrate that the striking distance of an arc is approximately inversely proportional to the pressure of gaseous medium in which it occurs; but in view of the fact that in most cases occurring in practice the striking distance is very small, since the difference of potential between the electrodes is usually not more than a few hundred volts, the economical advantages resulting from the reduction of the striking distance, particularly on approach of the terminals, is not of very great practical consequence. By far the more important gain I have found to result from an effect which I have observed to follow from the action of such a medium when under pressure upon the arc—namely, that the cross-section of the latter is reduced approximately in an inverse ratio to the pressure. As under conditions in other respects the same the waste of energy in an arc is proportional to its cross-section, a very important gain in economy generally results. A feature of great practical value lies also in the fact that the insulating power of the compressed medium is not materially impaired even by considerable increase in temperature, and, furthermore, that variations of pressure between wide limits do not interfere notably with the operation of the circuit-controller, whereas such conditions are fatal drawbacks when, for instance, Poggendorff's method of insulating the terminals is used. In many other respects, however, a gas under great compression nearly fulfills the ideal requirements above mentioned, as in the sudden breaking down and quick restoration of the insulating power, and also in chemical inertness, which by proper selection of the gas is easily secured.

In carrying out my invention the medium under pressure may be produced or maintained in any proper manner, the improvement not being limited in this particular to any special means for the purpose. I prefer, however, to secure the desired result by enclosing the circuit-controller, or at least so much of the same as shall include the terminals, in a chamber or receptacle with which communicates a small reservoir containing a liquefied gas.

TESLA'S NEW CIRCUIT-CONTROLLER.

While the improvement is applicable generally to circuit-controllers, the best results will be secured by the use of devices in which a high relative speed between the terminals is obtainable, and with this special object in view I have devised a novel circuit-controller, which, though belonging to the class of which I have shown a typical form in my application for patent filed December 2, 1897, Serial No. 660,518, differs in certain particulars of construction, which will be understood from the following comparison: In the previously-described form of said circuit-controllers a rotary receptacle, carrying within it a series of spaced conductors, is driven at a high speed by a suitable motor. Mounted within and concentrically with the receptacle, but capable of free independent rotation with respect thereto, is a body which during the rotation of the receptacle is retarded or restrained against rotation by the application of a suitable force. This body carries a tube or duct, which takes up at one end a fluid conductor contained in the receptacle and rotating with the same, and discharges it from the other end against the rotating spaced conductors.

While an apparatus thus constructed is very efficient and performs the work required of it in a highly satisfactory manner, it is nevertheless subject to certain limitations, arising mainly from the amount of work which the conducting fluid is required to perform and which increases with the speed. With the object of overcoming objections that might lie to this form of circuit-controller in the particular referred to, I devised the form of instrument shown herein. The features which more particularly distinguish this form are the following: I employ a closed stationary receptacle within which is mounted a body that is capable of being rotated in any way—as, for example, by the drag or pull upon it of an external field of force or a magnet rotated bodily. The rotary body imparts rotation to a series of spaced conductors within the receptacle and also operates as a pump to maintain a flow of conducting fluid through one or more stationary ducts and from the same against the rotating conductors.

The details of this apparatus will be described by reference to the accompanying drawing, which is a vertical central section of the circuit-controller complete.

A is a receptacle, of iron, steel or other proper material, with a head B, secured by a gas-tight insulating-joint. Within this receptacle is contained the circuit-controller, which, in so far as the main feature of my present invention is concerned, may be of any desired construction, but which, for the reason stated above, is of the special character shown. A spindle C is screwed or otherwise secured centrally in the head B, and on this is mounted on antifriction-bearings a body to which rotary motion may be imparted. The construction of the device in this particular and the means for imparting rotation to the said body may be greatly varied; but a convenient means for accomplishing this is to secure to the rotary sleeve D a laminated magnetic core E and place around the portion of the head B which contains it a core F, provided with coils and constituting the primary element of a motor capable of producing a rotary field of force which will produce a rapid rotation of the secondary element or core E. To the depending end of the sleeve D is secured a conductor G, usually in the form of a disk with downwardly-extending teeth or peripheral projections H. To the sleeve or the disk G is also attached, but insulated therefrom, a shaft T having a spiral blade and extending down into a well or cylindrical recess in the bottom of the receptacle. One or more ducts or passages J lead from the bottom of this well to points near the path of the conducting teeth H, so that, by the rotation of the screw I, a conducting fluid, which runs into the well from the receptacle, will be forced up through the duct or ducts, from which it issues in a jet or jets against the rotating conductor. To facilitate this operation the well is surrounded by a flange K, containing passages L, which permit the conducting fluid to flow from the receptacle into the well, and having beveled sides, which serve as a shield to deflect the fluid expelled from the ducts through the spaces in the conductor to the bottom of the receptacle.

M is any suitable reservoir communicating with the interior of the main receptacle and containing a liquefied gas, such as ammonia which maintains a practically inert atmosphere under pressure in the receptacle.

Preferably, though mainly as a matter of convenience, the receptacle M is a metal cup with a hollow central stem N, the opening for the passage of gas being controlled by a screw valve in the top of the cup. The said cup is screwed onto the end of the spindle C, through which is a passage O, leading into the interior of the receptacle A.

The receptacle A and the conducting fluid, which is generally mercury, being normally insulated from the head B and the parts attached and supported thereby, are connected to one part of the circuit to be controlled. The other circuit connection is made by a conductor P to any part of the head, so that when the core E and conductor G are rotated the circuit will be completed between the two insulated parts of the receptacle through the jet or jets of conducting fluid whenever they impinge upon the said conductor.

To ensure a good electrical connection between the sleeve D and the spindle C, I provide in the former a small chamber R, which contains mercury, and into this the end of the spindle C extends.

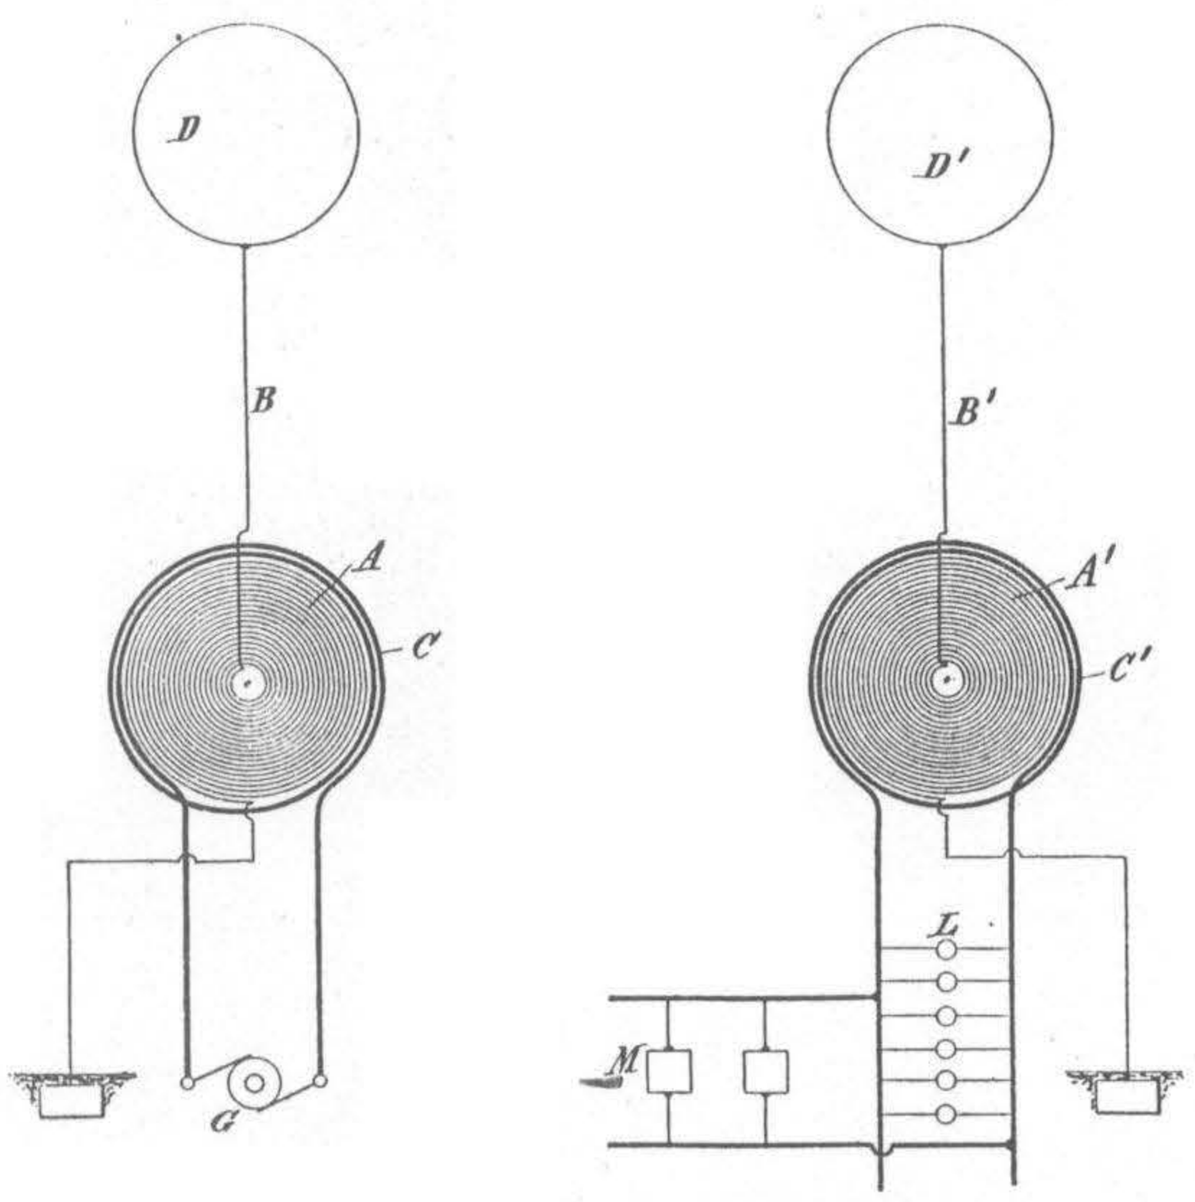
TESLA'S SYSTEM OF ELECTRIC POWER TRANSMISSION THROUGH NATURAL MEDIA.*



On this novel system patents have been obtained in various countries, and the following is freely quoted from the inventor's own text :

It has been well known heretofore, that if the air enclosed in a vessel be rarefied, its insulating properties are impaired to such an extent that it becomes what may be considered as a true conductor of electricity, although one of admittedly high resistance. The practical information in this matter, however, has been derived from observations manifestly subject to limitations imposed by the character of the apparatus or means heretofore known, and the quality of the electrical effects producible thereby.

It has also been known, particularly since the investigations of Heinrich Hertz, that certain transverse electrical waves or radiations may be transmitted through the atmosphere, and these have been found capable of affecting certain delicate receiving instruments at a limited distance from the source of the electrical disturbance.

The invention which forms the subject of the present application comprises a novel method or system for the transmission of electrical energy without the employment of metallic line conductors, and is primarily designed for use in cases where large amounts of electrical energy are to be transmitted to considerable distances, but the results arrived at are of such character and magnitude, as compared with any heretofore secured, as to render indispensable the employment of means and the utilization of effects essentially different in their characteristics and actions from those before used or investigated.

To be more explicit, the transmission of electrical energy, which forms a part of my present invention, demands for the attainment of practically useful results the production and conversion of excessively high electrical pressures. Heretofore, it has been possible, by means of the

DIAGRAMS ILLUSTRATING TESLA'S SYSTEM OF ELECTRIC POWER TRANSMISSION THROUGH THE AIR.

apparatus at command, to produce only moderate electrical pressures, and even these not without some risks and difficulties, but I have devised means whereby I am enabled to generate with safety and ease electrical pressures measured by hundreds of thousands, and even millions, of volts, and in pursuing investigations with such apparatus, I have discovered certain highly important and useful facts which render practicable the method of transmission of electrical energy hereinafter described.

Among these, and bearing directly upon the invention, are the following: First, that with electrical pressures of the magnitude and character which I have made it possible to produce, the ordinary atmosphere becomes, in a measure, capable of serving as a true conductor for the transmission of the current. Second, that the conductivity of the air increases so materially with the increase of electrical pressure and degree of rarefaction, that it becomes possible to transmit through even moderately rarefied strata of the atmosphere electrical energy up to practically any amount and to any distance.

The system of transmission comprised in my present invention and which, as above stated, was rendered possible only by the production of apparatus of a character radically new and different from any before known, and which is based upon discoveries made in the investigation of the results produced thereby, consists then in producing at a given point a very high electrical pressure, conducting the current caused thereby to earth and to a terminal at an elevation at which the atmosphere serves as a conductor therefor, and collecting the current by a second elevated terminal at a distance from the first.

In order to attain this result it is necessary to employ an apparatus capable of generating electrical pressures vastly in excess of any heretofore used, and to lead the current to earth and to a terminal maintained at an elevation where the rarefied atmosphere is capable of conducting freely the particular current produced; then, at a distant point, where the energy is to be utilized, to maintain a terminal at or about the same elevation to receive the current and to convey it to earth through suitable means for transforming and utilizing it.

The apparatus which I have invented, and by means of which this method of transmission may be effected, is represented in the accompanying drawing, which is a diagrammatic illustration of the system, each transformer comprising a spiral conductor with many turns shown in fine lines surrounded by a conductor indicated in heavy lines with a very few convolutions.

The secondary coil is built up as usual, the wire being wound around an insulating core or spool until its convolutions fill up the space and form one complete layer. The winding is continued in the same way until another layer is formed, and so on. When the desired length of secondary or high-tension coil is thus obtained, the primary or low-tension coil is wound outside of it, but this latter coil is composed of only a very few turns of wire or conductor, which is of much larger diameter of cross-section than the secondary wire.

The transformer thus consists simply of two concentric coils, the inner coil having very many turns of fine wire, the outer coil a very few turns of coarse wire.

From this plan of construction it follows that one of the high-tension terminals is at the center of the secondary coil, and in the use of the coil the other terminal, whether it be connected to ground or not, is electrically connected to the primary, in order that there may be no material difference of potential between the latter and the adjacent convolutions of the secondary.

Assuming that it appears from the above that, in the general plan of construction of the coils, only common and well known methods have been pursued, it remains then to consider the length of the secondary coil. This should be approximately one quarter of the wave length of the electrical disturbance in the circuit, and the reason for it is that the highest possible electrical pressures may be secured at the center terminals of the secondary coils.

A is a coil, generally of many turns and of very large diameter, wound in spiral form either about a magnetic core or not, as may be desired. C is a second coil formed by a conductor of much larger size and smaller length wound around in proximity to the coil A.

In the transmitting apparatus the coil A constitutes the high-tension secondary, and the coil C the primary of much lower tension of a transformer. In the circuit of the primary C is included a suitable source of current G.

One terminal of the secondary A is at the center of the spiral coil, and from this terminal the current is led by a conductor B to a terminal D, preferably of large surface, formed of or maintained by such means as a balloon at an elevation suitable for the purposes of transmission as before described. The other terminal of the secondary A is connected to earth and, preferably, to the primary also, in order that the latter may be of approximately the same potential as the adjacent portions of the secondary, thus insuring safety.

At the receiving station a transformer of similar construction is employed, but in this case the long coil A^1 constitutes the primary, and the short coil C^1 the secondary of the transformer. In the circuit of the latter are arranged lamps L, motors M, or other devices for utilizing the current. The elevated terminal D^1 connects with the center of the coil A, and the other terminal of said coil is connected to earth and preferably also to the coil C^1 for the reasons above stated.

The length of the high-tension coil of each apparatus should be approximately one-quarter of the wave length of the electrical disturbance in the circuit, this estimate being based on the velocity of propagation of the electrical disturbance through the coil itself and the circuit with which it is designed to be used. To illustrate, in accordance with accepted views, if the rate at which the current traverses the circuit, including the two high-tension coils, be 185,000 miles per second, then a frequency of 925 per second would maintain 925 stationary waves in a circuit 185,000 miles long, and each wave would be 200 miles in length. For such a frequency I should use in each high-tension coil a conductor 50 miles in length, or in general, with due allowance for the capacity of the leading wires and terminals, such length of conductor as would secure the highest electrical pressures at the terminals under the working conditions.

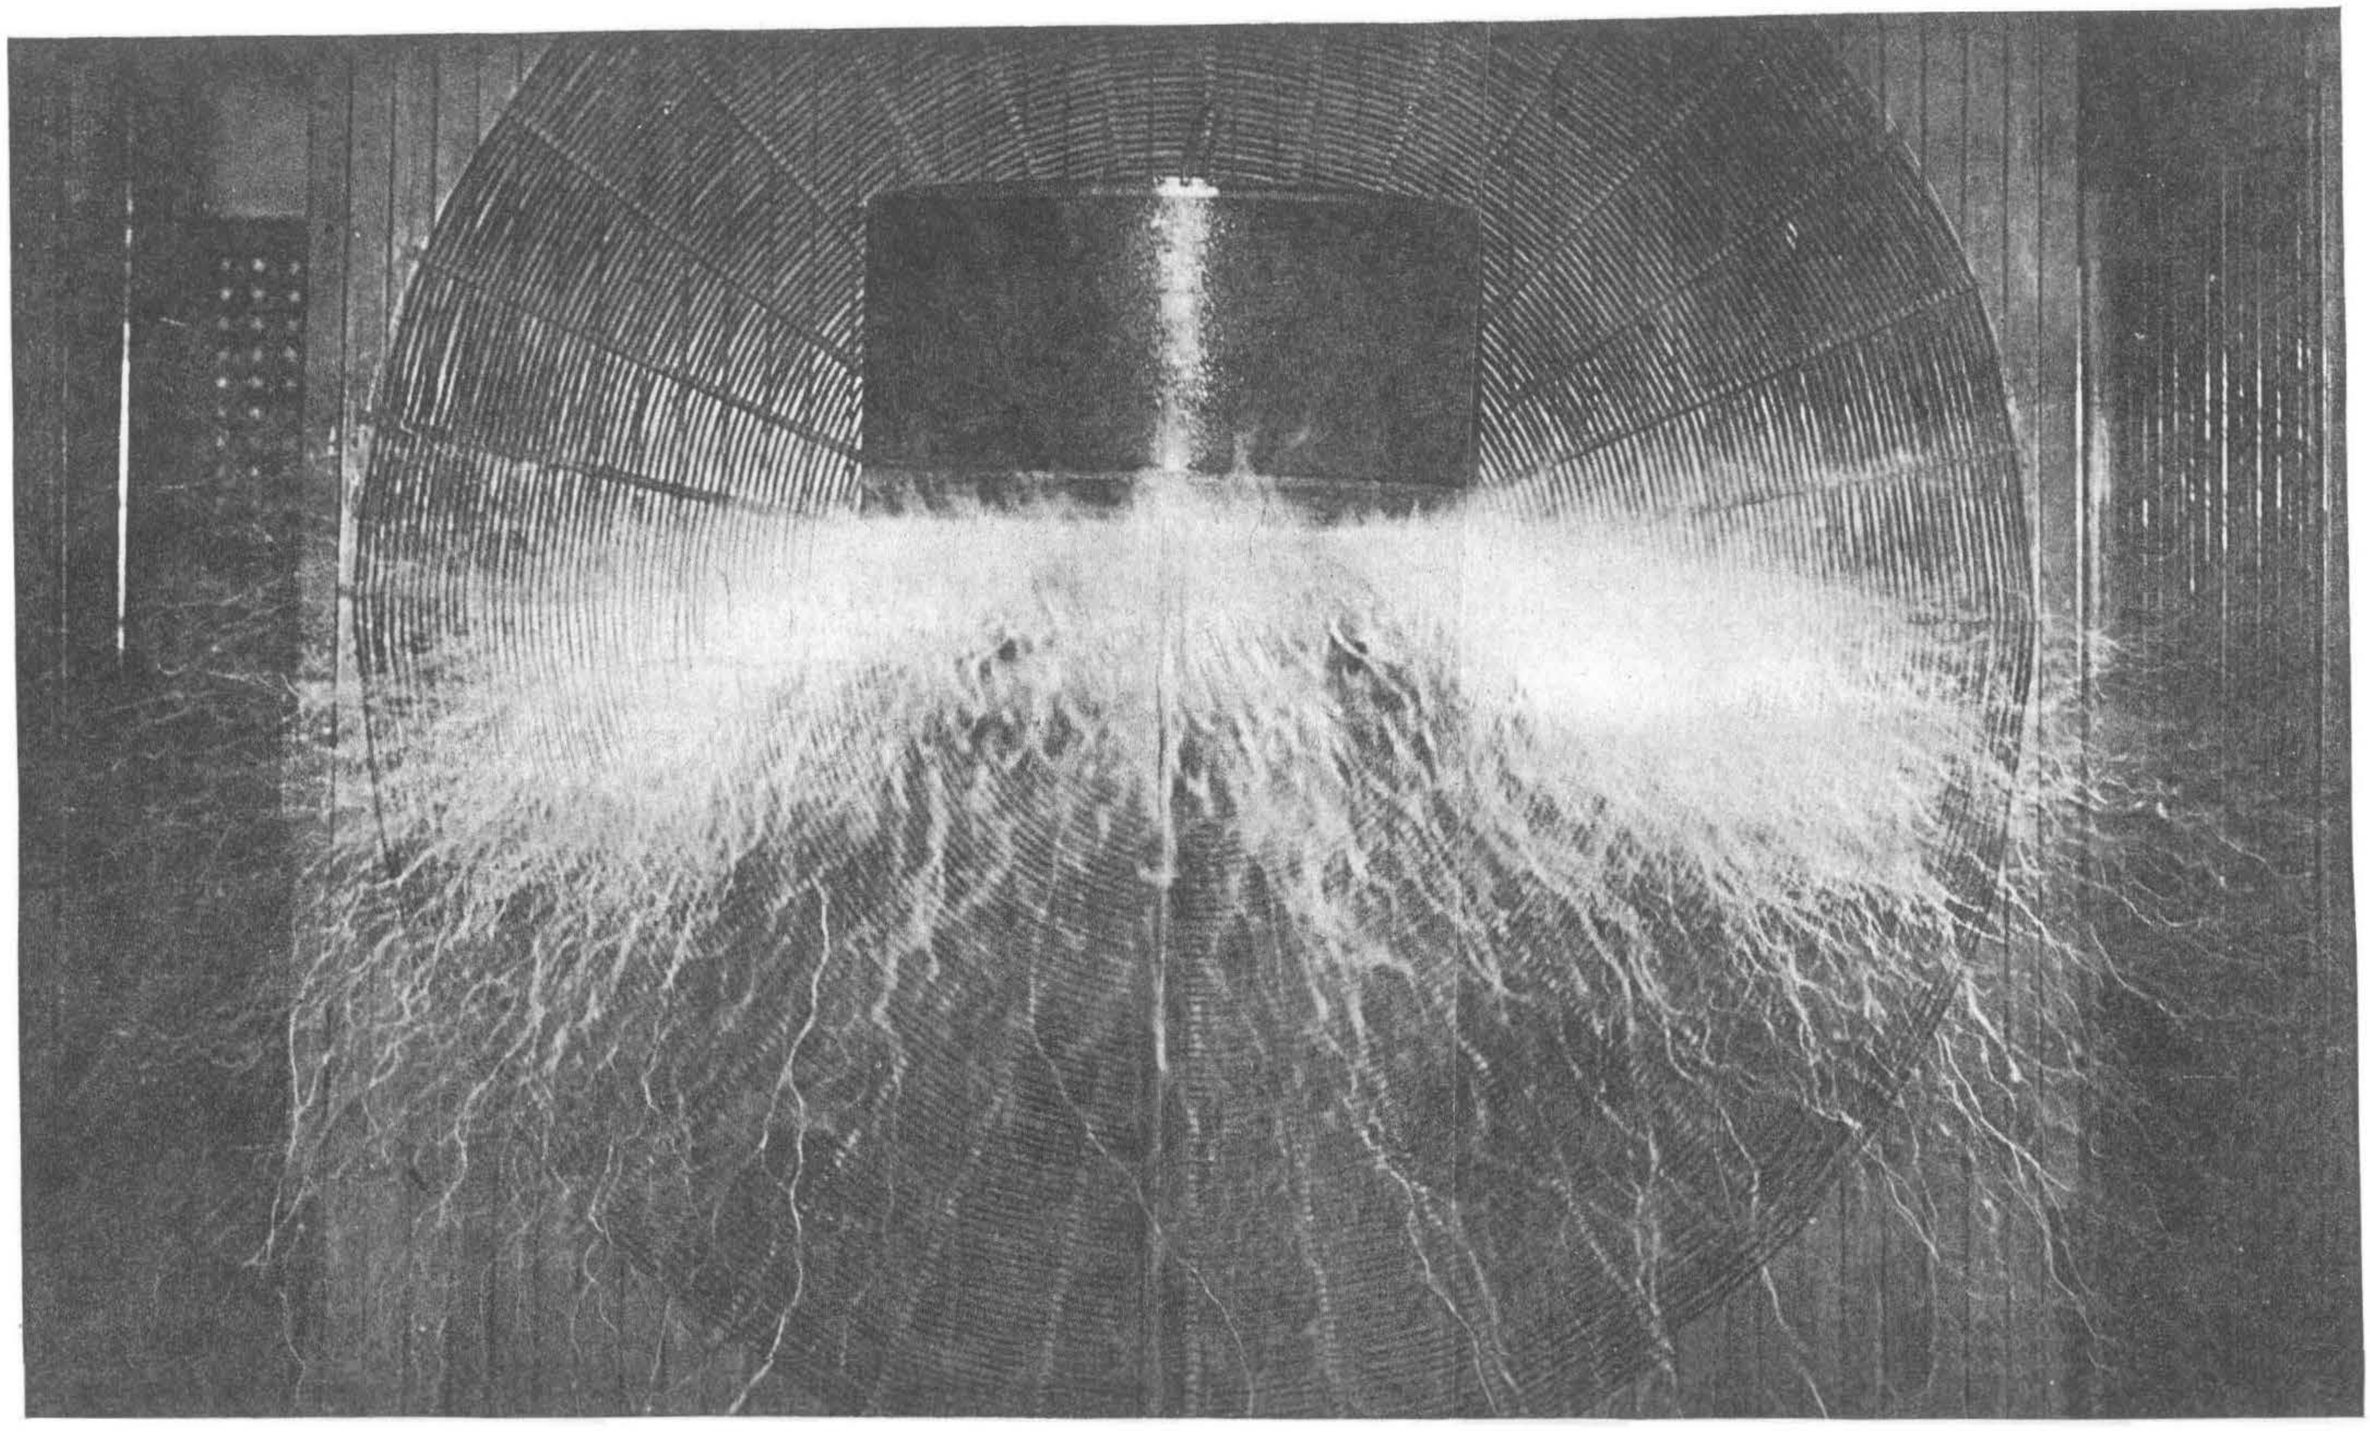
It will be observed that in coils of the character described the potential gradually increases with the number of turns, and the difference of potential between adjacent turns is comparatively small, and a very high potential, impracticable with ordinary coils, may be successfully obtained.

As the main object of the invention is to produce a current of extremely high potential, this object will be facilitated by using a primary current of very considerable frequency, but the frequency of the current is, in large measure, arbitrary, for if the potential be sufficiently high and the terminals of the coils be maintained at a proper elevation where the atmosphere is comparatively rarefied, the intermediate stratum of air will serve as a conductor for the current produced, and the latter will be transmitted through the air with, it may be, even less resistance than through an ordinary copper wire.

The apparatus described, it may be observed, is useful as a means for producing currents of very high potential for other purposes than that of the present system, as, for instance, the coils may be used singly for producing extremely high electrical potentials for any purpose, or used generally in the same manner as other electrical transformers for the conversion and transmission of electrical energy.

It will be understood that either or both of the coils or transformers and terminals may be movable, as, for instance, when carried by vessels floating in the air, or by ships at sea. In the former case the connection of one terminal with the ground might not be permanent, but might be intermittently or inductively established without departing from the spirit of the invention.

As to the elevation of the terminals D, D^1, it is obvious that this is a matter which will be determined not only by the condition of the atmosphere, but also by the character of the surrounding country.



Thus, if there be high mountains in the vicinity the terminals should be at a greater height, and generally, they should always be at an altitude much greater than that of the highest objects near them in order to reduce the loss by leakage. Since, by the means described, practically any potential that is desired may be produced, the currents through the air strata may be very small, thus reducing the loss in the air.

It will be observed that the phenomenon here involved in the transmission of electrical energy is one of true conduction, and is not to be confounded with the phenomena of induction or of electrical radiation which have heretofore been observed and experimented with, and which, from their very nature and mode of propagation, would render practically impossible the transmission of any considerable amount of energy to such distances as would be of practical importance.

Of the claims the following may be quoted:

1. The method of transmitting electrical energy herein described, which consists in producing at a given point a very high electrical pressure, conducting the current caused thereby to earth and to a terminal at an elevation at which the atmosphere serves as a conductor therefor, and collecting the current by a second elevated terminal at a distance from the first, as set forth.

2. A system for the transmission of electrical energy, comprising in combination a source of current of very high pressure, connected respectively with the earth and with a terminal at an elevation where the atmosphere forms a conducting path for the current produced, a second elevated terminal at a distance from the first for receiving the current transmitted therefrom and means for utilizing the said current, as set forth.

"Tesla's System of Electric Power Transmission Through Natural Media."—View of Model Transformer, or "Oscillator," Photographed in Action.—Actual Width of Space Traversed by the Luminous Streams Issuing from a Circular Single Terminal over Sixteen Feet.—Area Covered by the Streamers Approximately Two Hundred Square Feet.—Estimated Effective Electrical Pressure Two and One-half Million Volts.

While we are naturally pleased at the reiterated evidence that the ELECTRICAL REVIEW is the most widely quoted electrical publication in the world, we respectfully suggest to our daily contemporaries that care in assigning proper credit for borrowed matter will be appreciated, not only by ourselves, but by our electrical contemporaries.

A WONDERFUL POSSIBILITY IN ELECTRIC POWER TRANSMISSION.

As civilization advances and our needs multiply, the demands on the toilers in the various departments of science constantly increase, and naturally the activity in the direction of providing new resources becomes more and more intense. But the severest burden is undoubtedly on the engineer, mechanic or inventor, whose task it is to produce motive power. The problem of providing economical power has ever taxed the inventive mind, and with the introduction of electricity a great stride in advance has been effected. But still, many limitations were encountered in the difficulties of efficiently transmitting the energy of great sources of power, which exist in abundance in Nature, to remote places of utilization.

Here it is that Nikola Tesla did his first great work by discovering the rotating magnetic field, and applying it to a practical system of electric power transmission, now used in all parts of the world.

As we were then, so now we are privileged to record another forward step, which, if successful on a large scale, will prove of astounding consequences, for it will open up unlimited resources of practically costless power. Tesla now proposes to transmit, without the use of any wires, through the natural media—the earth and the air—great amounts of power to distances of thousands of miles. This will appear a dream—a tale from the Arabian Nights. But the extraordinary discoveries Tesla has made during a number of years of incessant labor, which are authoritatively described and illustrated in our present issue, make it evident that his work in this field has passed the stage of mere laboratory experiment, and is ready for a practical test on an industrial scale. The success of his efforts means that power from such sources as Niagara will become available in any part of the world regardless of distance.

The photographic reproduction contained in our present issue, which is explained in its title, illustrates one of the remarkable effects produced by Tesla's improved apparatus.

The New York Herald October 27, 1898

TESLA WOULD USE AIR AS CONDUCTOR

Announces Discovery of Method for Transmission of Electrical Energy Without Wires.

SAYS PLAN AVOIDS LOSS.

Terminals Raised Above All Surrounding Objects Communicate Through Rarefied Atmosphere.

Nikola Tesla, who has added much to the world's knowledge of electricity and electrical phenomena, announces in the current issue of the Electrical Review his discovery of a new method of transmitting large quantities of electrical energy to any distance without the employment of wires or other metallic conductors, and with a loss in transmission so small as to be practically inappreciable. The only conductor used is the atmosphere at great altitudes, where it is extremely rarified.

Mr. Tesla's discovery differs from others exploited as methods of telegraphing without wires and so forth, it is contended, in that it transmits any quantity of energy generated up to millions of volts, and without loss.

SAYS IT IS NOT INDUCTION.

He asserts that by his plan there is true conduction, and not, as in the case of other methods referred to, an induction or electrical radiation. Phenomena accompanying these methods preclude the transmission of any considerable quantity of energy and involve a great loss of power, so that, it is urged, they are of little practical importance.

It has long been known that if air enclosed in a vessel be rarefied it becomes a true conductor of electricity, though of high resistance. Mr. Tesla has discovered, however, that the conductivity of air increases rapidly with the increase of electrical pressure and its degree of rarefication, and the purpose of the apparatus which he has devised is to turn this discovery to account.

Stripped of technicalities, this apparatus comprises a line connecting a transformer, which communicates with the source of electrical energy, and a terminal high in the air. This terminal is a metallic globe of large surface.

SUSPENDED BY BALLOONS.

It is suspended by a balloon at such an altitude that the air is extremely rarefied and performs the function of projecting the electrical energy. If there be high mountains in the neighborhood the terminal must be above their crests to prevent leakage of energy. At the receiving end is a similar apparatus. Here, however, the terminal performs the function of collecting the energy projected from the first terminal mentioned and transmits it to the transformer, from which it can be distributed for use.

The transformer comprises an insulating core or spool, around which are wound many thicknesses of fine wire, forming in the transmitting apparatus the secondary or high tension coil, and around it are wound a few turns of coarse wire, forming the primary or low tension coil. In the receiving apparatus the fine wire constitutes the primary and the coarse wire the secondary coil.

No rule can be laid down as to the degree of elevation required for the terminals, which depends entirely on the condition of the atmosphere and the character of the country. They must, however, be much higher than the highest objects surrounding them.

This method of transmitting energy, Mr. Tesla says, can be used by ships at sea or by vessels floating in the air. It can be used to transmit power over high mountains when the stringing of wires or laying of other conductors would be difficult or impossible, or by projecting energy across rivers or lakes, saving the trouble and expense of submarine cables.

While not designed primarily for telegraphing, but for the transmission of power in large quantities, he says the method can be applied to telegraphic purposes also, as a current of very low power can be transmitted as easily and practically without loss.

TESLA'S LAST INVENTION.

TO TRANSMIT POWER GREAT DISTANCES BY NATURAL MEDIA.

Earth and Air the Only Means of Transmission—The Inventor Says He Can Generate with Safety and Ease Electrical Pressures Measured by Millions of Volts.

Tesla has pushed his investigations of the possibilities of electrical transmission through natural media far into the realm of what even in these days might almost be called fairyland since the public last heard of his then latest discoveries, inventions and visions. "Wireless telegraphy," luminous cylinders diffusing radiance throughout a room without visible wires, or familiar forms of illuminers, seem like tame achievements compared with what he now proposes, the transmission of great power, without other media than the earth and the air, to distances of hundreds of miles, over mountains, over sea—only a little less than launching thunderbolts in the ether to distribute their energy under men's guidance at remote points. This latest advance of the electrician in the possibilities of his science, the *Electrical Review*, in which he records it to-day, says "will, if successful on a large scale, open up unlimited sources of practically costless power. The success of his efforts means that power from such sources as Niagara will become available in any part of the world, regardless of distance."

His work in this field, the *Review* says, has passed the stage of mere laboratory experiment and is ready for a test on an industrial scale.

His last invention is, briefly, the apparatus for the production of great electric power and for the collection and utilization of that power at a point distant from the seat of its production after the power, or the electric current in which it is comprised, has traversed without wires the intervening atmosphere at an altitude such that the rarefaction has made the air of that stratum a conductor of the electric fluid.

The invention, he points out, was based partly upon, or was in part the outgrowth of, the observations heretofore recorded and well known, that the air in a closed vessel, if rarefied, suffered an impairment of its insulating properties to such an extent as to become a true conductor of electricity, though one of high resistance. This much known, with the fact of the rarefaction of the atmosphere high above the earth, and the further fact, which has before been demonstrated, "that certain transverse waves or radiations may be transmitted through the atmosphere, and have been found capable of affecting certain delicate receiving instruments at a limited distance from the source of the electrical disturbance," gave the groundwork upon which Tesla built his hypothesis and developed the invention that is its demonstration. The practical information at his command was necessarily derived from observations manifestly subject to limitations imposed by the character of the apparatus heretofore known, and the quality of the electrical effects producible by it. He needed high electrical pressures, for his problem involved the transmission of great electrical energy long distances.

"I have devised means whereby I am able to generate with safety and ease electrical pressure measured by hundreds of thousands and even millions of volts," he says, and adds that with pressures of such magnitude and character he has found that the ordinary atmosphere becomes in a measure capable of serving as a true conductor for the transmission of the current.

A second highly important fact which he came upon in pursuing his investigation was "that the conductivity of the air increases so materially with the increase of electrical pressure and degree of rarefaction that it becomes possible to transmit through even moderately rarefied strata of the atmosphere electrical energy up to practically any amount and to any distance."

With these facts he constructed his apparatus, a part to develop the electrical energy, of very high pressure, then to lead the current to earth and also "to a terminal at an altitude where the rarefied atmosphere is capable of conducting the particular current produced," and another part to provide and maintain another terminal, at or about the same elevation, at a distant point, "to receive the current and convey it to earth through suitable means for transforming and utilizing it."

The apparatus consists of "a transformer comprising a spiral conductor with many turns, surrounded by a conductor with a very few convolutions," or, in other words, a coil of fine wire wound in many layers, surrounded by a lesser coil of heavier wire, the former the secondary coil, the latter the primary. In the circuit of the primary is included the source of the current.

The outer terminal of the secondary coil is connected with the earth, the inner to a conductor which carries the current to a terminal up in the air, "maintained there by such means as a balloon." At the receiving point there is a similar contrivance; the high terminal there receiving the current that has been conducted to it by the rarefied air. The coils there perform reverse service, the long coil being the primary and the short one the secondary. In the circuit of the secondary are placed lamps or motors or such device as may be desired for utilizing the current. Tesla says: "It will be understood that either or both of the coils or transformers and terminals may be movable, as, for instance, when carried by vessels floating in the air or by ships at sea."

The New York Tribune October 27, 1898

TESLA'S LATEST INVENTION.

TRANSMITTING ELECTRICITY THROUGH THE AIR WITHOUT WIRES.

Extensive quotations are made by "The Electrical Review" this week from patents recently taken out by Nikola Tesla, the object of which is the transmission of large quantities of electricity from one point to another through the air without the aid of wires. Just now, to convey a current from the Niagara Falls dynamos to Buffalo a costly pole line is in service, the copper conductors being nearly or quite an inch in diameter, and three of them being used for each five thousand horse-power dynamo. Now, if this power could be sent without any such medium great economy would be secured. This is the central idea of Mr. Tesla's invention.

He has found from laboratory experiments that the conductivity of air, which is ordinarily so poor that it might be considered an insulator rather than a conductor, is improved if the air be rarefied. Hence, if a current of the right kind could be led up from the earth to a comparatively rare stratum, and then suitable receiving apparatus be placed at a distance, the current, he believes, would flow from the one piece of apparatus to the other. Then it would be conducted down to earth again and used at that point.

An essential part of the scheme is that the current, from any suitable source, shall be so manipulated as to acquire a very high "voltage," or "potential." The voltage is raised for this particular purpose by a transformer of original design, and the transformer is the chief feature of the new system. Those who are interested in technical details will find them in "The Electrical Review."

Mr. Tesla emphasizes the fact that his method involves the conduction of the current by the air, exactly as if metal were substituted. He does not make use of the imponderable ether which conveys the Hertzian waves in wireless telegraphy. He thinks that if the air is sufficiently rarefied, and the potential of the current is high enough, the conductivity will be at least as great as that of copper wire. He does not make it entirely clear how far apart he would have his stations, or how high above the earth he would put the terminals of his apparatus. But he talks about transmitting current for "considerable distances," by which he probably means scores, perhaps hundreds, of miles at one leap. Nor in the portion of the patent papers reproduced by "The Electrical Review" is there any suggestion as to the means by which he would suspend in air the terminals. He is, however, confident that there would be no leakage of electricity. The enterprising periodical that makes this announcement remarks that, "if successful on a large scale, this latest discovery will prove of astounding consequences. . . . The success of his efforts means that power from such sources as Niagara will become available in any part of the world, regardless of distance."

Tesla's Aerial Power Transmission.

TO THE EDITOR OF ELECTRICAL REVIEW:

This end of the century has been so replete with scientific discoveries, both electrical and otherwise, that the old motto, *nil admirari*, becomes revivified, and truly we wonder at nothing.

When one reads the account of Mr. Tesla's latest work in electric power transmission the mental question arises, "and why not?" Once he had accomplished wireless telegraphy, to his restless activity it was but a step to wireless transmission, merely devising ways and means for transmitting wagonloads instead of thimblefuls.

Nature herself has done this in what is probably her most awe-inspiring manifestation of power, the lightning. Who has not seen the tremendous bolt dart from one end of a long cloud to earth and at the other end flash back from earth as the "return stroke?" And who will say the cloud, though many miles in length, has not constituted an aerial circuit in such case?

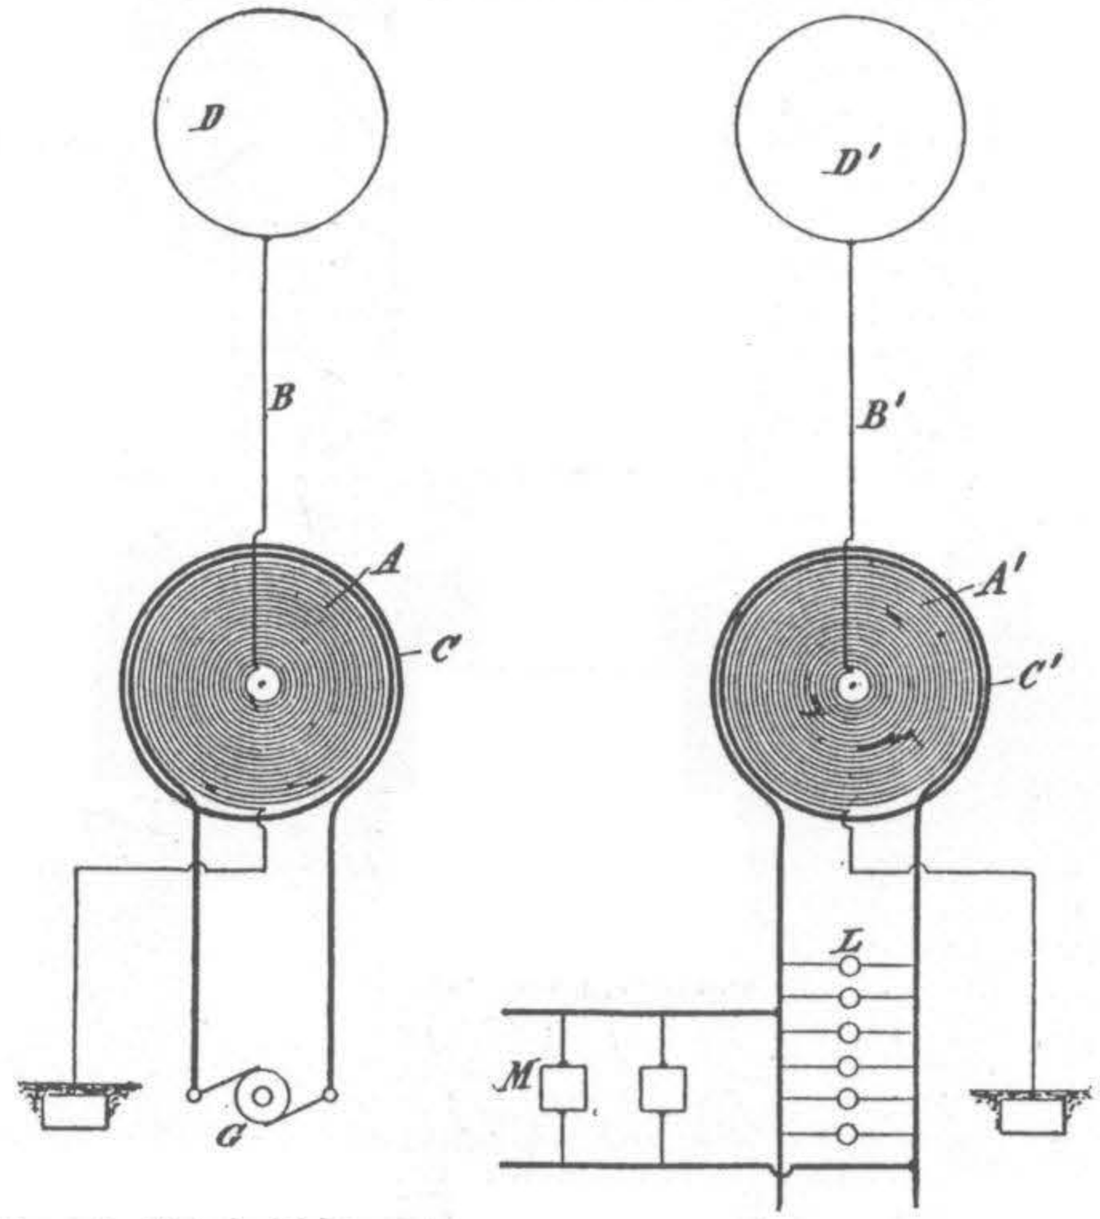
It is my belief that the upper strata are constantly carrying electrical currents of high potential.

An old-fashioned apparatus for the study of electrical phenomena was a globe of sulphur or glass, which, when rotated under slight friction of the dry hands, produced the desired effect in the shape of a snappy spark. Such a globe was about one foot diameter. What, then, should be the effect of the earth rotating at its enormous speed under the friction of the atmosphere—a globe billions of times the surface of the archaic electric machine?

It is no wonder that our most advanced meteorologists go astray in their forecasts, when they have no means of learning what is going on in the upper strata.

Tesla's balloon terminals may prove a boon to meteorology, while serving their own purpose also; for they can be used as a source of information of the various phenomena continually taking place above us. And, as the ELECTRICAL REVIEW has often pointed out, meteorology will never reach the pedestal of an exact science till observations are regularly conducted at an elevation consistent with the conditions.

There is nothing inconceivable in Tesla's transmission scheme, wonderful as it may seem; on the contrary, it is consistent with all that has gone before. He has simply gone after tarpon when others have been content with sprats. T. J. M.



New York, October 29.

SCIENTIFIC

Tesla's New Marvel

NICOLA TESLA, in the *Electrical Review*, New York, October 26. Condensed for PUBLIC OPINION

My invention comprises a novel method or system for the transmission of electrical energy without the employment of metallic line conductors, and is primarily designed for use

From the Electrical Review.

DIAGRAM OF TESLA'S NEW TRANSMITTER

in cases where large amounts of electrical energy are to be transmitted to considerable distances, but the results arrived at are of such character and magnitude, as compared with any heretofore secured, as to render indispensable the employment of means and the utilization of effects essentially different in their characteristics and actions from those before used or investigated. I have devised means whereby I am enabled to generate with safety and ease electrical pressures measured by hundreds of thousands, and even millions, of volts, and in pursuing investigations with such apparatus, I have discovered certain highly important and useful facts which render practicable the method of transmission of electrical energy hereinafter described. Among these, and bearing directly upon the invention, are the following: First, that with electrical pressures of the magnitude and character which I have made it possible to produce, the ordinary atmosphere becomes, in a measure, capable of serving as a true conductor for the transmission of the current. Second, that the conductivity of the air increases so materially with the increase of electrical pressure and degree of rarefaction, that it becomes possible to transmit through even moderately rarefied strata of the atmosphere electrical energy up to practically any amount and to any distance.

The system of transmission comprised in my present invention and which, as above stated, was rendered possible only by the production of apparatus of a character radically new and different from any before known, and which is based upon discoveries made in the investigation of the results produced thereby, consists then in producing at a given point a very high electrical pressure, conducting the current caused thereby to earth and to a terminal at an elevation at which the atmosphere serves as a conductor therefor, and collecting the current by a second elevated terminal at a distance from the first. In order to attain this result it is necessary to employ

an apparatus capable of generating electrical pressures vastly in excess of any heretofore used, and to lead the current to earth and to a terminal maintained at an elevation where the rarefied atmosphere is capable of conducting freely the particular current produced; then, at a distant point, where the energy is to be utilized, to maintain a terminal at or about the same elevation to receive the current and to convey it to earth through suitable means for transforming and utilizing it. The apparatus which I have invented, and by means of which this method of transmission may be effected, is represented in the accompanying drawing, which is a diagrammatic illustration of the system, each transformer comprising a spiral conductor with many turns shown in fine lines surrounded by a conductor indicated in heavy lines with a very few convolutions.

The secondary coil is built up as usual, the wire being wound around an insulating core or spool until its convolutions fill up the space and form one complete layer. The winding is continued in the same way until another layer is formed, and so on. When the desired length of secondary or high-tension coil is thus obtained, the primary or low-tension coil is wound outside of it, but this latter coil is composed of only a very few turns of wire or conductor, which is of much larger diameter of cross-section than the secondary wire. The transformer thus consists simply of two concentric coils, the inner coil having very many turns of fine wire, the outer coil a very few turns of coarse wire. From this plan of construction it follows that one of the high-tension terminals is at the center of the secondary coil, and in the use of the coil the other terminal, whether it be connected to ground or not, is electrically connected to the primary, in order that there may be no material difference of potential between the latter and the adjacent convolutions of the secondary. It will be understood that either or both of the coils or transformers and terminals may be movable, as, for instance, when carried by vessels floating in the air, or by ships at sea. In the former case the connection of one terminal with the ground might not be permanent, but might be intermittently or inductively established without departing from the spirit of the invention.

TESLA AND POWER.

THE very latest from America is that Mr. Nikola Tesla has invented a means of transmitting electricity to the distance of thousands of miles without loss of power or the use of wires, and there seems to be no limit to the power so transmitted, for the announcement states that the power of Niagara will now be available in any part of the world. Of course, such statements as this are naturally received with a considerable amount of caution; in fact, would not be taken any notice of were not Mr. Tesla's name mentioned in connection with them. We are told, however, the why and the wherefore, and are given a considerable amount of detail. The rarefied air at high altitudes is said to be a conductor of electricity, though of very high resistance, but the resistance is said to decrease rapidly as the electrical pressure increases. Tesla proposes to use electricity of millions of volts pressure, and to conduct it to a large metallic globe kept suspended high in the air by means of a balloon, and to have another globe similarly suspended at a receiving station perhaps some thousands of miles away. We have seen and heard in this our generation so much of the ostensibly impossible becoming the usefully possible, that it would be rash to assert that Tesla, or his American interpreter, say the thing which is not. But we manifest no undue incredulity when we say that no method of generating electricity of millions of volts pressure has yet been devised; while there is not any conceivable means of insulating the necessary apparatus. To the scientific use of the imagination the world is indebted for much. Tesla may find himself anticipated by some one who, instead of making lightning by the aid of Niagara, will utilise it as we find it ready made by nature's own apparatus.

Our Modern Franklin==Nikola Tesla

He Tells "Success" the Story of his Struggles and Triumphs—The Firefly as a Model—Two Hundred Inventions and More Coming

FRANCIS LEON CHRISMAN

"THE secret of success is hard work." The speaker was Nikola Tesla, the great electrician; and the place, his laboratory, at 46 East Houston street, New York.

I had called upon Mr. Tesla in order to learn from his own lips, for the readers of SUCCESS, the secret of his rapid progress toward the pinnacle of fame.

"To be successful in this world," continued the great electrician, "one must perform the hardest kind of work. You must peg away night and day, and not stop a minute. There is no royal road. This has been the plan I have followed for years.

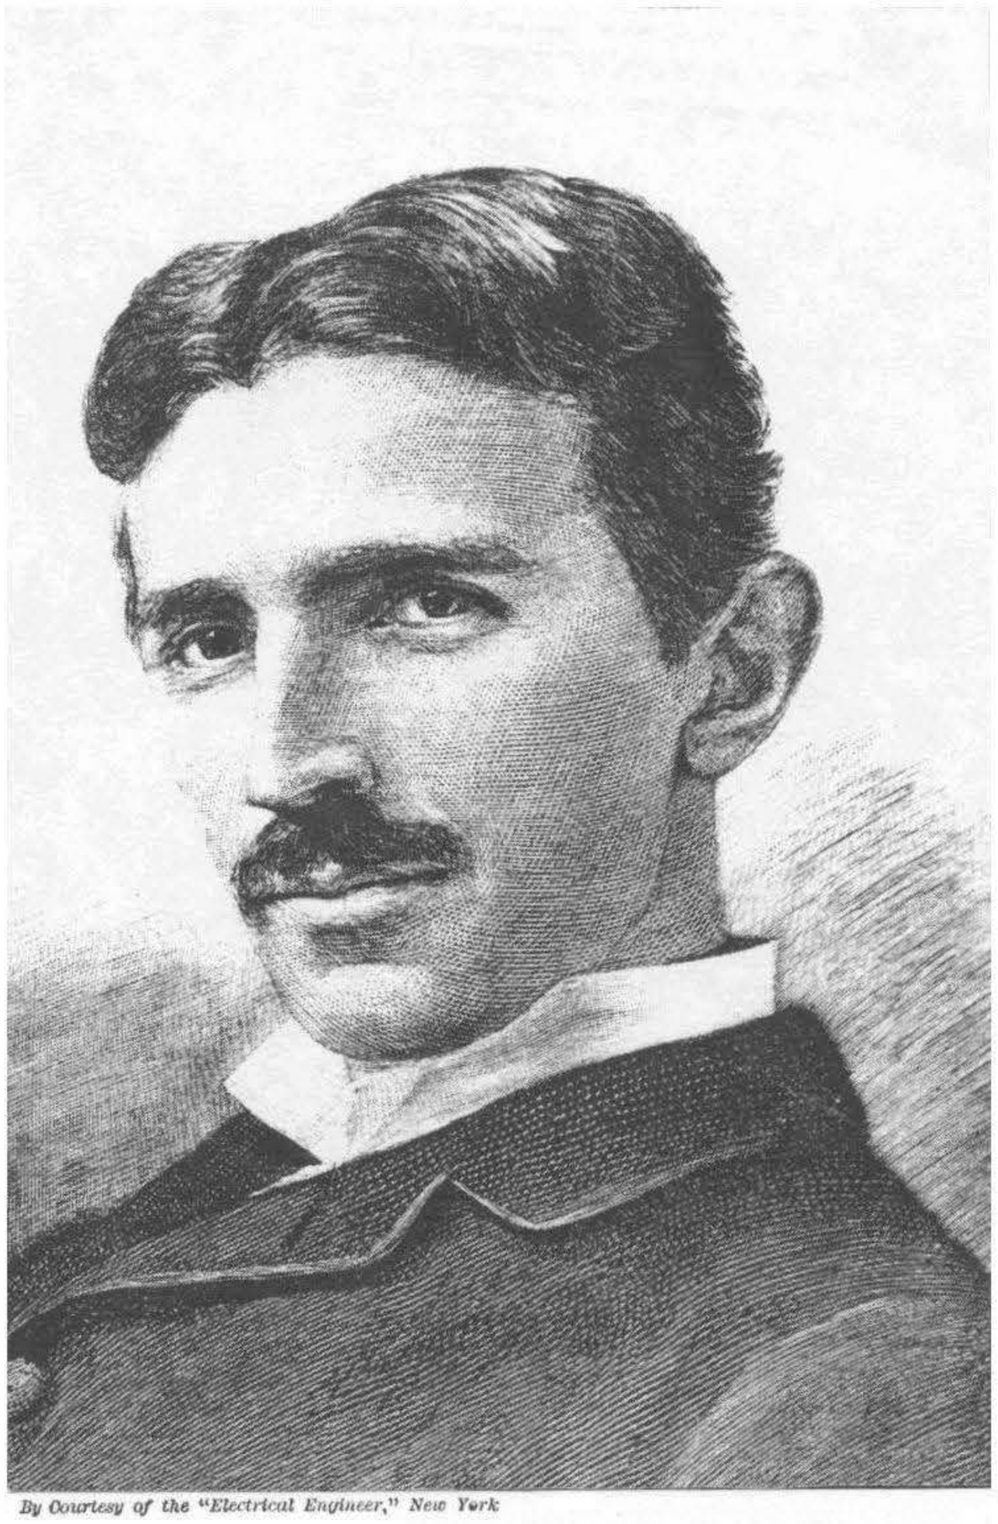
"Why! I am even blamed for being lazy by some people, because I do not perfect all my inventions; although I work from sixteen to twenty hours out of the twenty-four.

Replicating the Firefly's Light

"It may interest you to know that my system of vacuum-tube lighting is a success. It is now almost ready to be given to the public, and I expect soon to make an announcement on the subject. I have been watching very carefully what other inventors have been doing in this direction, and can assure you that my light will meet all requirements."

The aim and ambition of electricians is to actually manufacture artificial daylight. At first thought, it seems a very easy matter to duplicate the light of the firefly. Nevertheless, for ages, the little bug has successfully kept the secrets of its phosphorescent [illegible]on-house, baffled the brains of the world, and proved as elusive to electricians as the will-o'-the-wisp is to us all. Of late, several electricians have been making remarkable headway,—notably Tesla, Edison, [illegible]ore, and Haines. All have been devoting their time to vacuum tubes. Mr. Tesla showed his friends, a year or two ago, what he could accomplish with a single tube, and produced a good photograph made at a distance of four feet with only two minutes' exposure. It was while working on the problem presented by the firefly that he found time to harness Niagara Falls, and transmit its energy by an alternating current to the surrounding cities and towns. In the meantime, too, he developed the "Tesla Oscillator" for producing currents of tremendous potential, and at the same time made a machine for measuring the electric discharges from the earth, thus suggesting the possibility of "calling up" and communicating with the planet Mars one day by means of signals.

Modern Benjamin Franklin



Mr. Tesla is the modern Benjamin Franklyn and has sent his electrical kite to the sky for studying the secret of light. That he has at last succeeded in producing artificial sunlight which will stream from long glass tubes, is not surprising, in view of the long years of patient experiment and field work. The points in favor of the Tesla light are beautiful illumination, the absence of deadly wires, and the non-employment of any kind of filament in the tubes.

Mr. Tesla's hours are crammed with experiments and scientific investigations. In personal appearance he is tall and commanding. Like Cassius, he has a "lean and hungry look," and "thinks too much." He has already patented some two hundred inventions, has a similar number in various stages of evolution in his laboratory, and is dreaming daily of new worlds to conquer.

The friends of Mr. Tesla say that he is even fonder of solitude than Lincoln was. Few ever cross the threshold of his laboratory, and you can nearly always find him dining alone at the Waldorf-Astoria any evening at nine o'clock.

The distinguished inventor was born in 1858, at smiljan, Lika, on the borderland of Austro-Hungary. His mother had great ingenuity, and delighted in the construction of looms and churns. His father was a clergyman in the Greek Church, and intended that his son should succeed him in the sacred office. There were many children in the family, of whom Nikola was one of the youngest, and the most remarkable. He always dominated his brothers and sisters in their home and at school he had a decided aptitude for his studies. At school, one day, the master was expermenting in mechanics before the class. The children were gathered round the desk, Nikola in the front row. The teacher proceeded to demonstrate what he considered one of the main principles of electricity. He explained just why the lever moved, and had almost finished when Nikola, who had been listening intently, interrupted him. "That can't be true," he said, quietly. The master looked at him in astonishment, and demanded an explanation of his words. "Well, I say that isn't true," said Nikola, again; "I can't tell you why to-day, but I will to-morrow."

The master dismissed the class, and warned Nikola that, if he did not prove his assertion before the week was out, he would have to answer for his impudence. The young student went home and confidently began his experiments to prove that the master was wrong. All night long he worked, becoming more hopeful every moment. Before daylight he had finished his model, and went to bed triumphant. He declares that, when he went up to the desk and showed his machine to the teacher, he felt more triumphant than he has ever felt since, and when he was openly commended before the school, his joy was supreme. It was not long before the whole town knew that Nikola Tesla was destined for a great electrician, and his career had begun.

NIKOLA TESLA

The Race of Genius

Young Tesla's early studies were in electricity and magnetism. Later, he went to Prague and Buda-Pesth to study languages. He then entered the laboratory of a great inventor at Vienna; but, becoming dissatisfied, went to Paris, and engaged in the labor of furnishing that city with electric lights. Then he went to other cities, ever rising in his profession, making new improvements, new discoveries, and adding continually to his fame. His name became known all over the continent, and in London. The king of Servia, proud of such a subject, decorated him, and the emperor of Austria did likewise. His rise was almost phenomenal, and many places in Europe were open to him.

Tesla was a lover of liberty. He looked with longing eyes toward America, where there is such a promising field for electricians. He had read of Edison, and determined to come to New York and seek a place with the great inventor. Edison gladly received him, and for many years the two worked together, each relying to a certain extent on the other, and each profiting by the other's knowledge. Gradually their ideas began to differ, and it was decided that they would better separate.

Mr. Tesla is in his laboratory at half past eight every morning, and spends a long day there, planning, experimenting, and making models. He puts an enormous amount of energy into his work, and never stops until he has hit upon the idea he is after. He has a corps of clever assistants, but is careful to do all the important work himself.

Superior to Discouragement

On the morning of March 13, 1895, Mr. Tesla met with a bitter experience in the entire destruction of his fine laboratory on South Fifth Avenue by fire. It was a hard blow to the inventor, who cried like a child. The work of years had gone up in smoke, and two tottering walls, like tumbling monuments, marked the place where he had spent years of toil and tribulation in trying to wrest the secrets from nature. But before the ashes were fairly cold, he was planning for new quarters on East Houston street. While the valuable papers, notes, and data for years were destroyed, the man was still alive.

"More divine, the master of all these."

The new laboratory soon grew, and is now one of the best equipped in the country. Mr. Tesla's inventions cover many things, and are contained in big volumes. He believes that his discovery of the rotating magnetic field is the invention by which he will be best known. The "Oscillator" is a blending of the dynamo and the steam engine, the idea being to get the electric current directly from steam. He has also met with great success in experiments looking to the long-distance transmission of water-power. "Some day," he asserts confidently, "New York, Washington, Pittsburg, and Chicago, will be supplied with power generated from Niagara Falls."

Mr. Tesla has tried to harness the electrical discharge of the earth, and has made some interesting discoveries in this connection. Before he took up the subject, the alternating current had no recognized place. Now it is used everywhere, and has cheapened light and power. Mr. Tesla is a great genius, survey him as you will. To everyone he is courteous and Chesterfieldian. He always inspires you by his noble character, for he fully believes that "a firm faith is the best divinity;" a good life, the best philosophy; a clear conscience, the best law; honesty, the best policy; and temperance, the best physic. His achievements in electrical science have already marked him as one of the greatest benefactors to civilized society which our age has produced.

with the same conducting strata by means of any suitable device, such as that used by the illustrious Benjamin Franklin, or, preferably, as stated in the patent, by means of a balloon, the earth being utilized as a ground return.

The fact is set forth that the atmosphere at 15 pounds to the square inch, or other pressures common near the surface of this mundane sphere, is a good insulator, while at lower pressures, as is well known by manufacturers of 200-volt lamps, it becomes quite a fair conductor. By a rigid suppression of the reasoning faculties and a little freedom of the imagination, fancy pictures a conductor poked up through the insulating sheath at Niagara, establishing an alternating difference of potential between the superincumbent ether and this ball of solid matter below protected by an atmospheric dielectric, which difference of potential can be tapped, so to speak, at any desired location, such as the large cities, or by express trains with electric locomotives towing balloon trolleys, making contact with an overhead conductor from which they cannot readily slip off. The use of several great sources of natural power will, of course, necessitate generators of the same frequency running in synchronism with each other, as they are all, so to speak, connected across the same bus bars, and lacking the third bus bar, multiphase systems will go out of fashion.

The system might, however, give other results more valuable than those of power transmission. With transmitting and receiving stations at Niagara Falls and New York city, respectively, the State of New York would possibly be illuminated by a gigantic Geissler tube overhead that would turn night into day, put to shame the aurora borealis, and make the advocates of diffused illumination shout for joy.*

Mr. Tesla should certainly be enjoined from putting his polished ball terminals too high, or a Crookes-tube effect might be obtained, emitting a profusion of X-rays which would disclose altogether too much to anyone with fluorescent spectacles, and might make it necessary for mortals to carry leaden umbrellas to prevent the skin being burned from the tops of their heads.

The patent gives no data as to the estimated height to which it would be necessary to elevate the terminals. It is obvious that a height sufficient for a very marked difference in the specific resistance must be attained, otherwise the voltage would be necessarily so high that fatal leakage through the extended sheet of insulating medium would ensue. No such marked change of resistance occurs at the highest elevations yet attained by man, several miles upward, and the atmospheric pressure falls off somewhat more slowly even than by a logarithmic law, so that scores or hundreds of miles of elevation would be necessary. The methods of ballooning at this elevation and supporting conductors of this length are not explained in the patent.

With a circuit looped about so many square miles of space, it is not explained how the self-inductive choking of the comparatively high-frequency currents proposed (about 1000 cycles per second) could be eliminated, and no explanation is made of the precautions to be taken against lightning. The advocates of that light-weight material, aluminum, for current-conducting purposes must take a back seat, as the ether has a lower specific gravity than anything hitherto proposed for this service. Mr. Tesla, if correctly reported, previously proposed to wabble the earth's charge for man's ignoble uses, but he now, if these things can be taken seriously, has designs on the universe. The price of copper remains in the neighborhood of 11 cents. however.

*The writer reserves all rights to the use of interplanetary space as a vacuum tube for lighting purposes.

BOUNDLESS SPACE A BUS BAR.

One of the American electrical journals has recently taken some of Mr. Nikola Tesla's patents undoubtedly more seriously than the inventor himself intended them, and advanced the ideas there tentatively proposed as a revolutionary invention comparable with those of the same inventor in the rotary-field line, and has, with the aid of the gullible daily press, given the public in general another false impression of the wonders of electricity. The idea proposed comprises nothing more nor less than a high-tension step-up transformer feeding into a vertical conductor with a terminal at such an elevation above the earth as to reach a strata of rarefied atmosphere which has a comparatively low electrical resistance, a similar step-down transformer to be connected at any desired point

TESLA DECLARES HE WILL ABOLISH WAR.

Magician of Electricity Announces That He Has Perfected an Application of the Current Which Will Make Possible the Destruction of Battle Ships at Any Distance from an Operating Base.

PROJECTS CONTROLLING IMPULSES THROUGH ATMOSPHERE

Exhibits a Working Model, the Propelling, Steering and Exploding Mechanism of Which Are Controlled at Will from a Distance Without the Intervention of Wires.

At the Paris Exposition the Inventor Intends to Exhibit a Model of a Vessel, All the Manoeuvres of Which Will Be Directed by Him from His Office in New York.

WONDERS NIKOLA TESLA SAYS HE CAN PERFORM.

Shows How He Proposes by Electricity, Without Wires, to Control the Movements of a Model at the Paris Exposition from His Office in New York, and by Similar Methods Blow Up Ironclads and Send Lifeboats to Shipwrecked Vessels.

At the moment when all the world is ringing with rumors of an impending colossal conflict there comes from the laboratory of one of the great magicians of science the announcement of the development of a power which he believes is destined immediately to usher in the era of universal peace by the demonstration of its ability to destroy, without the possibility of defence, the mightiest armaments of all the naval powers.

In the words of Nikola Tesla, uttered yesterday morning:—"War will cease to be possible when all the world knows to-morrow that the most feeble of the nations can supply itself immediately with a weapon which will render its coast secure and its ports impregnable to the assaults of the united armadas of the world. Battle ships will cease to be built, and the mightiest armorclads and the most tremendous artillery afloat will be of no more use than so much scrap iron. And this irresistible power can be exerted at any distance by an agency of so delicate, so impalpable a quality that I feel that I am justified in predicting that the time will come, incredible as it may seem, when it can be called into action by the mere exercise of the human will."

Unlimited Destructive Powers.

In brief, Mr. Tesla's latest and most startling miracle consists in an application of electricity whereby, without the interposition of any artificial medium of communication, one man can control and direct, with absolute exactitude, the movements of any type of vessel, balloon or land vehicle, at any distance that may be desired. From a station on shore, or from the deck of a vessel under way, a torpedo boat equipped with Mr. Tesla's controlling device may be propelled either on or below the surface, manoeuvred at will in any direction, and finally brought into contact and exploded against the side of a hostile vessel at any point within the range of the vision of the operator.

More than this, assuming that it were possible to accurately locate the position of the vessel which it is desired to destroy, the torpedo boat could be directed to it, even if the ship lay in the harbor of Southampton and the operator were stationed at Sandy Hook. With such marvellous possibilities of destruction it is hardly to be wondered that Mr. Tesla firmly believes that the days of the supremacy of sea power are numbered.

Mr. Tesla told me that some months had elapsed since he had fully developed his device, for which he has applied for a patent. When it was learned that Admiral Cervera was bottled up at Santiago it was his intention to apply his mechanism to several launches and similar small craft loaded with high explosives and annihilate the fleet at anchor. Admiral Cervera, however, came out and met his fate under the guns of the American fleet before the necessary arrangements could be made. Then Mr. Tesla planned a raid on the Spanish vessels in Havana Harbor, only to be thwarted by the proclamation of the suspension of hostilities.

Ironclads Doomed.

While the most important application of the device is unquestionably in the direction of destruction, it will also have countless peaceful uses, and it is Mr. Tesla's highest pride that by making war too terrible it will render it impossible.

When I saw Mr. Tesla yesterday morning in his laboratory in East Houston street he said:—"It gives me the greatest pleasure to announce to the world my last and my greatest invention through the medium of the HERALD. My imagination fairly reels when I attempt to contemplate its countless possibilities. Already I hear the knell of the battle ship and the monster gun. Their day has passed with the advent of a new and irresistible power, which gives to all nations an absolute power of defence against any attack.

"England has until now boasted of her mastery of the seas, but her superiority has vanished and she is now no stronger than the weakest of the maritime nations, so far as her offensive power is concerned. England, who is now so diligently preparing for war, will awake to this unwelcome discovery tomorrow and will be utterly confounded, and France, against whom her armaments have been reported to be preparing, will rejoice in the discovery that she possesses an all powerful weapon of defence.

"Hitherto," continued Mr. Tesla, "the only means of controlling the movements of a vessel from a distance have been supplied through the medium of a flexible conductor such as an electric cable, but this system is subject to obvious limitations such as are imposed by the length, weight and strength of the conductor which can be practically used; by the difficulty of maintaining, with safety, the high speed of the vessel or changing the direction of her movements with rapidity; by the necessity of effecting the control from a point which is practically fixed, and from many other drawbacks which are inseparably connected with such a system.

No Wires Required.

"The plan which I have perfected involves none of these objections, for I am enabled by the use of my invention to employ any means of propulsion, to impart to the moving body or vessel the highest possible speed, to control the operation of its machinery and to direct its movements from either a fixed point or from a body moving and changing its direction, however rapidly, and to maintain this control over great distances, without any artificial connections between the vessel and the apparatus governing its movements, and without such restrictions as these must necessarily impose.

"In a broad sense, then, my invention differs from all of those systems which provide for the control of the mechanism carried by a moving object and governing its motion, in that I require no intermediate wires, cables or other form of electrical or mechanical connection with the object save the natural media in space. I accomplish, nevertheless, similar results and in a much more practical manner by producing waves, impulses or radiations which are received through the earth, water or atmosphere by suitable apparatus on the moving body and cause the desired actions, so long as the body remains within the active region or effective range of such currents, waves, impulses or radiations.

"Having explained to you some of the possibilities of the device," continued Mr. Tesla, "I will now give you a practical example of the workings of the model before going into a detailed description of how I am able to produce these results."

Illustrated by a Model.

Elevated on stocks on a table in the centre of the laboratory stood a model of a screw propelled craft, about four feet long and somewhat disproportionately wide and deep. Mr. Tesla explained that it was merely a working model which he had had made in order to exhibit to President McKinley, and that no attempt had been made to follow the usual sharp lines of a torpedo boat. The deck was slightly arched and surmounted by three slender standards, the centre one being considerably higher than the other two, which carried small incandescent bulbs, a third bulb being fixed at the bow.

The keel consisted of a massive copper plate, the propeller and rudder being in the usual positions. Mr. Tesla explained that the boat contained the propelling machinery, consisting of an electric motor actuated by a storage battery in the hold, another motor to actuate the rudder and the delicate mechanism which performs the function of receiving through the central standard the electric impulses sent through the atmosphere from the distant operating station, which set in motion the propelling and steering motors, and through them light or extinguish the electric bulbs and fire the exploding charge in a chamber in the bow in response to signals sent by the operator.

"Now, watch," said the inventor, and, going to a table on the other side of the room, on which lay a little switchbox, about five inches square, he gave the lever a sharp turn. Instantly the little bronze propeller began to revolve at a furious rate. "Now I will send the boat to starboard," he said, and another quick movement of the lever sent the helm sharp over, and another movement turned it as rapidly back again. At another signal the screw stopped and reversed.

Will Abolish War.

"During the day," continued Mr. Tesla, his hand still on the lever, "we should steer our course by keeping the two standards in line, but at night we should depend on the electric lights, which would, of course, be screened so as not to be visible to the enemy," and at a signal both the tiny bulbs were illuminated.

"Now we will assume that the boat has arrived within striking distance of the vessel to be destroyed, and the bulb in the bow will serve to show that the explosion has taken place."

As he spoke he touched the lever again and the light flashed and was extinguished.

"Imagine, if you can," said Mr. Tesla as he went back to his desk, "what an irresistible instrument of destruction we have in a torpedo boat thus controlled, which we can operate day or night, on the surface or below it, and from any distance that may be desired. A ship thus assailed would have no possibility of escape.

"I can apply this system of control to any type of vessel and of any size. It is not even necessary to make a close approach to the vessel to be destroyed. At the distance of 100 feet the explosion of 200 pounds of dynamite will exert a shattering effect on a battle ship, but there is no reason why we should not load a vessel with 200 or 300 tons, or even more, of dynamite, which, exploded even a mile or so away, would raise a wave that would overwhelm the biggest ship ever built.

"But I have no desire that my fame should rest on the invention of a merely destructive device, no matter how terrible. I prefer to be remembered as the inventor who succeeded in abolishing war. That will be my highest pride. But there are many peaceful uses to which my invention can be put, conspicuously that of rescuing the shipwrecked.

"It will be perfectly feasible to equip our life saving stations with life cars, or life boats, directed and controlled from the shore, which will approach stranded vessels and bring off the passengers and crews without risking the lives of the brave fellows who are now forced to fight their way to the rescue through the raging surf. It may also be used for the propulsion of pilot boats, for carrying letters or provisions or instruments to inaccessible regions, for killing whales and for many other commercial or scientific purposes."

Controlled from Any Distance.

"Is there any limit," I asked, "to the distance at which the controlling device can be operated?"

"In the operations of war," replied Mr. Tesla, "the radius of control would usually be limited by the range of the vision of the operator, whether afloat or ashore, but otherwise there is no limit to the distance. In order to give a practical illustration of this it is my intention to exhibit a model of a torpedo boat at the Paris Exposition and direct all its movements from my office in New York, precisely as I have shown you the working of the model here to-day, except that in Paris I intend to exhibit it afloat in a tank."

Coming to the description of the details of his device Mr. Tesla prefaced his remarks by the explanation that the electrical disturbances proceeding from the centre of control were of an infinitesimally feeble character, and then made the startling statement that he believed that the time would come when it would be possible to bring them into play by the mere exercise of the will.

"But that time," he continued, "is probably far distant. I only mention the fact as illustrative of the delicate character of the impulses, and because the possibility of exciting them by mere will power is logically in accordance with the development of the system."

Continuing his description, Mr. Tesla said:—"As to that part of my invention which involves the production of suitable waves or radiations and the conveying of the same to a remote receiving apparatus capable of being operated or controlled by their influence, it may be carried out in various ways which are at the present time more or less understood. For example, I may pass through a conducting bath, preferably enclosing a large area, a rapidly varying current, and by electro-magnetic induction of the same affect a circuit carried by the moving body.

Methods of Operating.

"In this case the action at a given distance will be the stronger the larger the area enclosed by the conductor and the greater the rate of change of the current. If the latter were generated in the ordinary ways, the rate of change, and consequently the distance at which the action would be practically available for the present purpose, would be very small, but by adopting such means as I have devised—that is, either by passing through the conducting path currents of a specially designed high frequency alternator, or, better still, those of a strongly charged condenser—a very high rate of change may be obtained, and the effective range of the influence thus extended over a vast area, and by carefully adjusting the circuit on the moving body so as to be in exact electro-magnetic synchronism with the primary disturbances this influence may be utilized at great distances.

"Another way to carry out my invention is to direct the currents or discharges of a high frequency machine or condenser through a circuit one terminal of which is connected directly or inductively with the ground and the other with a body, preferably of large surface and at an elevation. In this case, if the circuit on the moving body be similarly arranged or connected, differences of potential on the terminals of the circuit either by conduction or electrostatic induction are produced, and the same object is attained.

"Still another way is to pass the currents simply through the ground by connecting both the terminals of the source of high frequency currents to earth at different and remote points, and to utilize the currents spreading through the ground for affecting the receiving circuit properly placed and adjusted.

A Sensitive Device.

"Finally, I may avail myself, in carrying out my invention, of electrical oscillations which do not follow any particular conducting path, but propagate in straight lines through space, of rays, waves, pulses or disturbances of any kind, capable of bringing the mechanism of the moving body into action from a distance and at the will of the operator by their effect upon suitable controlling devices.

"In any event—that is to say, whichever of the above or similar plans I may adopt—and particularly when the influence exerted from a distance upon the receiving circuit be too small to directly and reliably affect and actuate the controlling apparatus, I employ auxiliary sensitive relays, or, generally speaking, means capable of being brought into action by the feeblest influences, in order to effect the control of the movements of the distant body with the least possible expenditure of energy and at the greatest practicable distance, thus extending the range and usefulness of my invention."

In describing the device used for detecting the presence of the impulse from the controlling station, and transmitting it to the propelling and other mechanism of the boat Mr. Tesla said a great variety of devices for the detection of vibrations were known to scientific men and artisans, and mentioned, among others, the familiar lightning arrester in use in telegraph offices.

He had demonstrated, he said, the practicability of providing a large number of receiving currents of a special design—fifty or a hundred or more—each of which might be called up, or brought into action, whenever desired without the others being interfered with. This made it possible for one operator to direct simultaneously the movements of many bodies, each of which might have a distinct duty to perform, as well as to control the action of various devices located on the same body, such as the propelling, steering and exploding mechanism of a torpedo boat.

The Problem Solved.

"In regard to these sensitive devices," he said, "which may be broadly considered as belonging to one class, inasmuch as the operation of all of them involves the breaking down of a minute thickness of highly strained dielectric, it is necessary to make some provision for automatically restoring to the dielectric its original, unimpaired insulating qualities in order to enable the device to be used in successive operations.

This is usually accomplished by a gentle tapping or vibration of the electrodes or particles, or continuous rotation of the same, but in long experience with many forms of these devices I have found that such procedures, while suitable in simple and comparatively unimportant operations, as ordinary signalling, when it is merely required that the succeeding effects produced in the receiving circuit should differ in regard to their relative duration only—in which case it is of little or no consequence if some of the individual effects be altered or incomplete or even entirely missed—do not yield satisfactory results in many instances when it may be very important that the effects produced should all be exactly such as desired and that none should fail.

"To illustrate, let it be supposed that an official, directing the movements of a vessel in the manner described, should find it necessary to bring into action a special device on the latter, or to perform a particular operation, perhaps of vital moment, at an instant's notice, and, possibly when, by design or accident, the vessel itself or any mark indicating its presence is hidden from his view.

Guarding Against Failure.

"In this instance a failure or defective action of any part of the apparatus might have disastrous consequences, and such cases, in which the sure and timely working of the machinery is of paramount importance, may often present themselves in practice, and this consideration has impressed me with the necessity of doing away with the defects in the present devices and of producing an apparatus which, while being sensitive, will also be most reliable and positive in its action.

"In this arrangement these defects are overcome in a most satisfactory manner, enabling thousands of successive operations in all respects alike being performed by the controlling apparatus without a single irregularity or miss being recorded.

"The apparatus by means of which the operation of both the propelling and steering mechanisms is controlled involves, primarily, a receiving circuit, which, for reasons before stated, is preferably both adjusted and rendered sensitive to the influence of waves or impulses emanating from a remote source, the adjustment being so that the period of oscillation of the circuit is either the same as that of the source or a harmonic thereof.

"The receiving circuit proper comprises a terminal affixed on the central standard conductor, a sensitive device, and a conductor leading to the ground, conveniently through a connection to the metal keel of the vessel.

"The terminal should present a large conducting surface and should be supported as high as practicable on the standard.

How the Current Flows.

"The circuit, or path, also a part of a local circuit, which latter includes a relay magnet and a battery, the electro-motive force of which is so determined that although the dielectric layers in the sensitive device are subjected to a great strain, yet normally they withstand the strain and no appreciable current flows through the local circuit. But when an electrical disturbance reaches the circuit the dielectric films are broken down, the resistance of the device is suddenly and greatly diminished, and a current traverses the relay magnet."

The sensitive device which Mr. Tesla employs, and on which dependence is placed to effect connection between the impulses from the controlling station and the mechanism proper of the boat, consists of a metal cylinder, provided with insulating heads, through which passes a metallic rod. A small quantity of metallic grains of conducting material, consisting of particles of exactly uniform size and carefully oxidized, is placed in the cylinder, which is placed in connection with a small battery and a train of clockwork.

This mechanism operates to turn the sensitive cylinder, end for end, after the passage of the impulse which has started the battery current. The normal position of the cylinder is vertical, and when turned over the grains in it are simply shifted from one end to the other. As they always fall through the same space and are subjected to the same agitation, they are brought after each operation of the relay to precisely the same electrical condition, and offer the same resistance to the flow of the battery current, until another impulse from afar reaches the receiving current.

In addition to the mechanism described the vessel may carry any other device or apparatus which may be required for any special object and which may be set in motion in the same manner as the propelling and steering machinery. In practice the switch box by which the generation of the electrical impulses is controlled is similar to the one used by Mr. Tesla in his demonstration with the model, signals being conveyed by simple movements of the lever.

TESLA'S NEW WAR WONDER

HAS MODEL OF SHIP OPERATED BY MAGNETIC WAVES FROM SHORE.

Applies Principle of Electrical Transmission Without Wires to New Invention—Magnet Controls the Machinery—Can Direct Balloon or Wagon in Same Way.

Nikola Tesla, whose original discoveries in electrical science during the last ten years have placed him in the foremost ranks of science, and whose applications of his discoveries have made him recognized as one of the world's greatest inventors, makes public to-day his latest discovery and invention, which he believes is also his greatest one. In brief, Mr. Tesla believes that this invention will not only answer many useful purposes in ordinary life, but that it would make war so terrible, as well as expensive, as to make it prohibitory, and thus to assure peace between all the nations.

Mr. Tesla's latest invention consists of a combination of his devices for producing and projecting into the air currents of electricity of enormous voltages which will reach out for many miles, and a means for using electric waves thus projected for controlling the driving, steering and other machinery of a moving body. By fitting out a vessel, a balloon, or a wagon with his special mechanical devices, Mr. Tesla can control their movements on land or sea or in the air by the projection without wires of currents of electricity to great distances. If desirable that such a vessel should carry great quantities of explosives, bombs or other destructive devices, the operator at the distant point can direct discharge and explode them at will.

The idea of the invention came to Mr. Tesla years ago, and he has never lost sight of it since, but it was not until the war with Spain came and stirred him with patriotism—for Mr. Tesla is American to the backbone—that the scheme took definite form and shape. Then the idea completely possessed him and gave him no rest until the problem was worked out in its entirety.

"Years ago," said Mr. Tesla, in explaining what led to this latest invention, "I used to argue that the human organism was but a thermo-electric machine, whose operations were controlled by the impressions which came to it through the medium of the eye, the ear, the nose, the palate or the touch. Light falls upon the retina, I would argue, and conveys an impression to certain nerves, and these transmit a signal to some part of the mechanism further back, which sets in motion certain muscles or perhaps sends signals further along. Could I but make a machine which could receive impressions as does my eye, my ear or my other organs of sense, then I could make it do anything which I wished almost as if it were a sensate being which could reason as well as act."

That is what Mr. Tesla has succeeded in doing. In his laboratory in West Houston street stands the working model of a vessel whose every movement Mr. Tesla can control by the simple turning of a crank in another part of the room, with no other connection between him and the vessel than that formed by the atmospheric air or the wooden floor. At one turn of the crank the vessel's screw begins to revolve, her rudder swings until it is in whatever position Mr. Tesla desires, and then with another touch the rudder remains fixed while the screw drives away. Another touch and the rudder moves either way, little or much as desired, and at the will of the operator signal lights flash out from staffs on the vessel to tell just what position the rudder is in. A green light tells that it is to port, a red light that it is a-starboard; and the flash of red and green together gives true word that it is amidship. The lamps remain dark unless their signal warning is ordered by the operator's touch, or they flash for a second or remain glowing, just as is desired. At another touch a white light forward glows or flashes, as may be desired, without interfering in any way with the other operations, and this is used by Mr. Tesla to signify that a giant charge of guncotton has been projected or exploded, or that any other operation that might be needed has been performed. When, with Mr. Tesla's guiding hand to help, one looks into the interior of the three-foot model vessel, and sees how these operations and the stopping of the machinery or regulation of its speed to either of three degrees of speed are produced, it is at once apparent that there is no operation which goes on aboard the greatest warship or merchant vessel, in a fort or workshop, where automatic machines could replace the hand of man that could not be controlled by the master hand at the tiny crank with as much certainty and precision as if that hand were on board the vessel and in direct touch with a master machine there. There might be a hundred, a thousand, ten thousand operations to be done, and all would be under the entire control of the operator miles away as certainly as the quartermaster steers our great ships, by the touching of a mechanism so frail that it breaks like a toy, or as surely as the men aboard a modern warship turn and handle her enormous turrets by the pressing of a key or turning of a stopcock.

Air, earth or water is all that is needed to make the connection between the operator and the moving mechanism, be it vessel, wagon or whatever, and even some of these might be done away with under certain circumstances. In the model which Mr. Tesla has the power which controls the moving mechanism is electricity, and Mr. Tesla declares that he can exercise the control from as far away as a telescope could enable the operator to keep watch of the vessel. But it is not necessary to use electricity even to exercise such control. With devices which any expert mechanic could make the same control could be exercised by the notes of a whistle, or by other means which would produce measurable vibrations. Electricity is, however, the necessary agent by which the primary control of the machinery within the controlled object is made obedient; although beyond the primary device steam, compressed air or any other source of power can be used. In the model vessel Mr. Tesla uses a combination of storage batteries and clockwork to produce the movements. The use of these, however, is but a minor detail of mechanics. Balloons can be controlled and directed as readily as any other vessel and sent hither and yon at will, or caused to drop explosives whenever the operator might desire, and yet be free from earth.

The possibilities of the new invention are thus modestly described by Mr. Tesla in the application for a patent which he filed at the Patent Office at Washington on July 1:

"The invention which I have described will prove useful in many ways. Vessels or vehicles of any suitable kind may be used, as life, despatch, or pilot boats, or the like, or for carrying letters, packages, provisions, instruments, objects or materials of any description, for establishing communication with inaccessible regions and exploring the conditions existing in the same, for killing or capturing whales or other animals of the sea, and for many other scientific, engineering, or commercial purposes. But the greatest value of my invention will result from its effects upon warfare and armaments, for, by reason of its certain and unlimited destructiveness, it will tend to bring about and maintain permanent peace among nations."

It was when Cervera's fleet took refuge in Santiago harbor that the invention assumed form in Mr. Tesla's mind. Almost by inspiration, he says, the thing shaped itself into a complete whole, embodying in the complete device the use of a number of his previous discoveries and inventions and the accepted science of the world.

"I was prepared," said Mr. Tesla yesterday, "to go to Santiago then and make such a demonstration as would have astounded the world and have made it impossible for an intelligent man like Cervera to have stood out for a day after he saw what could be done. It was not my idea to kill any one, but to send word to Cervera that at a certain time, despite all he might do to prevent it, we should produce such a destructive effect right under the guns of the fleet and fortifications and within the harbor as would if otherwise directed have destroyed his entire fleet or the town. I proposed to send a submerged vessel into the harbor carrying perhaps 10,000 pounds of wet guncotton and explode it. No intelligent commander, knowing that his enemy had at command such forces, would be justified in holding out for a day afterward. I was delayed for a few days in getting ready to explain and demonstrate what I could do to President McKinley, and then Cervera's fleet made the attempt to escape and was destroyed by Admiral Sampson's fleet. With victory already on our side, I decided to do nothing more at that time, but I went on and completed my arrangements for the making of such a demonstration at Havana in case we had to take that city. Fortunately for the country we were saved from having to take Havana, and so the necessity for the demonstration ceased."

Mr. Tesla declares that almost every part of the working devices for putting afloat a fleet of automatic vessels of war can be bought in the markets, and that in the case of a war, for instance between France and England or any of the other great powers, it would take but a few days or weeks for any of these nations to have ready quantities of engines of war that would make the guns and armor of the war fleets useless for offence and defence. One fast, unarmored vessel, without a gun aboard her, but supplied with a fleet of little vessels whose movements could be controlled by an operator aboard of the big vessel, could destroy the fleet of any enemy without ever coming anywhere within the range of any of the destructive engines of present warfare, or could send vast quantities of explosives into a hostile harbor where their explosion would be almost as destructive as an earthquake. Such are the visions which Mr. Tesla sees of the possibilities of his invention, and these he believes would insure a universal peace.

If war came it would be a war with machines on none of which was there a man. His moving automatons could be made, if needed, to discharge at the will of the operator, bombs, cannon, torpedoes, or any other offensive weapons. With a fleet of such little vessels directed from one vessel, each would answer to the signals meant for it alone, and it would be impossible for the enemy to control any of them, because each would be attuned to answer only to certain definite electrical vibrations, which could be known only to the proper operator. An attempt to interfere with their operation by others would be like the attempt of a burglar to find the combination of a safe lock.

In his application for a patent Mr. Tesla describes the various ways which have been heretofore used to control such moving objects as automobile torpedoes, and says:

"In a broad sense, then, my invention differs from all of those systems which provide for the control of the mechanism carried by a moving object and governing its motion in that I require no intermediate wires, cables or other form of electrical or mechanical connection with the object save the natural media in space. I accomplish, nevertheless, similar results and in a much more practicable manner by producing waves, impulses or radiations which are received through the earth, water or atmosphere by suitable apparatus on the moving body and cause the desired actions, so long as the body remains within the active region or effective range of such currents, waves, impulses or radiations. These actions necessitated the designing of devices and apparatus of a novel kind, in order to utilize to the best advantage various facts or results which, either through my own investigations or those of others, have been rendered practically available."

He then describes a number of ways, well known to electricians, by which an electric effect could be transmitted to a distance without direct connection and says: "But by adopting such means as I have devised, that is, either by passing through the conducting path currents of a specially designed high frequency alternator, or, better still, those of a strongly charged condenser, a very high rate of change may be obtained, and the effective range of the influence thus extended over a vast area, and by carefully adjusting the circuit on the moving body so as to be in exact electro-magnetic synchronism with the primary disturbances, this influence may be utilized at vast distances."

The device which he has adopted for his model demonstration consists of currents of enormous voltage, which can be projected in waves at the will of the operator by the turning of a little crank. Two waves go forth at each half turn. The effect of these is like that of the vibrations produced by the voice in a telephone. On the little vessel to be controlled is a broken electrical circuit, loose particles of a metallic oxide being at the point of separation. A current is always endeavoring to pass through these, but fails. The magnetic waves produced by the operator bring together by magnetic action those particles, which thus have power to conduct an electric current. When the operator sends out his signal, this current is enabled to pass through the oxide, and does so, bringing down an armature upon a magnet. With the first move of the armature a clockwork starts and prepares to set the machinery of the vessel into action by closing other electric circuits as soon as it may be released. A second magnetic wave moves the armature again and the vessel's machinery begins to move. Then by special devices combinations of impulses coming from the operator are made to operate each and every part of the machinery in the vessel at the will of the operator.

Among the new things designed by Mr. Tesla in carrying out his purposes is an agitator for shaking up the metallic oxide at the end of each impulse, to break its conductivity, and a new way of making the powder to insure its uniformity of composition and size of its grains. A vessel built after the manner described could be made to dive or rise at will and could be directed by a chart and kept out of sight if desired. If it were desired to watch her progress, and still have her under water, her position could be determined by a slender rod poking up above water in the daytime or at night by flashes of light made up into the air at the will of the operator.

Electrical Review

[LARGEST ELECTRICAL WEEKLY IN THE UNITED STATES.]

TIMES BUILDING, 41 PARK ROW,

BOX 2339. NEW YORK.

NEW YORK, NOVEMBER 9, 1898.

A NEW MARVEL.

As we go to press an invention of Tesla's is announced which must produce a profound impression all over the world. Tesla has already identified himself with a number of most remarkable scientific advances, and great things may still be confidently expected as the fruit of his earnest and persistent labors, but it is difficult for us to see how he could ever produce a more beautiful result than he now makes known through a United States patent issued this week.

To direct and control to the minutest detail, by a subtle agent, the operations of a mechanism however complicated and ponderous, to change its speed and direction at will, to make it perform an unlimited number of movements, without any tangible connection and from a great distance, is indeed an achievement worthy of the closing days of this century of wonders.

When Bell transmitted the human voice over a wire so that the faintest of its modulations could be recognized, it was a marvelous triumph; when Edison showed his fascinating invention of the phonograph, this, too, was justly looked upon as a wonder; when Tesla first showed the phenomena of the rotating magnetic field, or when he presented the magical effect of a tube of glass brilliantly lighted in his hand, the world stood astonished; when Roentgen announced the epoch-making discovery of the rays bearing his name, the scientific world was thrilled as never before; but we believe that the beauty and importance of the invention Tesla has just announced, in its ultimate developments, will be such as to place it among the most potent factors in the advance and civilization of mankind. The fact that the invention has been thoroughly and practically developed makes its immediate application sure.

In this issue we begin the publication of the clear and exhaustive wording of Tesla's own description of this invention, which will be concluded next week.

TESLA'S LATEST INVENTION.

The following is the text of a patent issued this week to Nikola Tesla, which will undoubtedly prove of world wide interest. The language of the author is given in full:

The problem, for which the invention forming the subject of the present application affords a complete and practicable solution, is that of controlling from a given point the operation of the propelling engines, the steering apparatus and other mechanism carried by a moving object, such as a boat, or any floating vessel, whereby the movements and course of such body or vessel may be directed and controlled from a distance, and any device carried by the same, brought into action at any desired time.

So far as I am aware, the only attempts to solve this problem, which have heretofore met with any measure of success, have been made in connection with a certain class of vessels, the machinery of which was governed by electric currents conveyed to the controlling apparatus through a flexible conductor. But this system is subject to such obvious limitations as are imposed by the length, weight and strength of the conductor which can be practically used, by the difficulty of maintaining with safety a high speed of the vessel or changing the direction of movement of the same with the desired rapidity, by the necessity for effecting the control from a point which is practically fixed, and by many well understood drawbacks inseparably connected with such a system.

The plan which I have perfected involves none of these objections, for I am enabled by the use of my invention to employ any means of propulsion, to impart to the moving body or vessel the highest possible speed, to control the operation of its machinery and to direct its movements from either a fixed point or from a body moving and changing its direction, however rapidly, and to maintain this control over great distances, without any artificial connections between the vessel and the apparatus governing its movements, and without such restrictions as these must necessarily impose.

In a broad sense, then, my invention differs from all of those systems which provide for the control of the mechanism carried by a moving object and governing its motion, in that I require no intermediate wires, cables or other form of electrical or mechanical connection with the object, save the natural media in space. I accomplish, nevertheless, similar results, and in a much more practicable manner, by producing waves, impulses or radiations, which are received through the earth, water or atmosphere by suitable apparatus on the moving body and cause the desired actions, so long as the body remains within the active region or effective range of such currents, waves, impulses or radiations.

The many and difficult requirements of the object here contemplated, involving peculiar means for transmitting to a considerable distance an influence capable of causing, in a positive and reliable manner, these actions, necessitated the designing of devices and apparatus of a novel kind in order to utilize to the best advantage various facts or results which, either through my own investigations or those of others, have been rendered practically available.

As to the part of my invention which involves the production of suitable waves or radiations and the conveying of the same to a remote receiving apparatus capable of being operated or controlled by their influence, it may be carried out in various ways which are at the present time more or less understood. For example, I may pass through a conducting path, preferably enclosing a large area, a rapidly varying current and by electro-magnetic induction of the same, affect a circuit carried by the moving body. In this case the action at a given distance will be the stronger the larger the area enclosed by the conductor and the greater the rate of change of the current. If the latter were generated in the ordinary ways, the rate of change, and consequently the distance at which the action would be practically available for the present purpose, would be very small; but by adopting such means as I have devised, that is, either by passing through the conducting path currents of a specially designed high-frequency alternator, or better still, those of a strongly charged condenser, a very high rate of change may be obtained, and the effective range of the influence thus extended over a vast area, and by carefully adjusting the circuit on the moving body so as to be in exact electro magnetic synchronism with the primary disturbances, this influence may be utilized at great distances.

Another way to carry out my invention is to direct the currents or discharges of a high-frequency machine or condenser through a circuit, one terminal of which is connected directly or inductively with the ground and the other to a body, preferably of large surface and at an elevation. In this case if the circuit on the moving body be similarly arranged or connected, differences of potential on the terminals of the circuit, either by conduction or electrostatic induction, are produced, and the same object is attained. Again, to secure the best action, the receiving circuit should be adjusted so as to be in electro-magnetic synchronism with the primary source as before, but in this instance it will be understood by those skilled in the art that, if the number of vibrations per unit of time be the same, the circuit should now have a length of conductor only one half of that used in the former case.

[Concluded next week.]

DOUBTS VALUE OF TESLA DISCOVERY

Professor C. F. Brackett Says Electrical Scientist's Invention Would Not Work in Practice.

DENIES ITS ORIGINALITY.

Asserts That Naval Warfare Cannot Be Terminated in the Manner Suggested by the Inventor.

A. S. BROWN LESS DOUBTFUL.

Declares He Has Full Faith in the Inventor's Ability to Carry Out His Ideas.

Nikola Tesla's declaration, made in yesterday's HERALD, that he had discovered a system of applying an electrical current whereby such marvellous results might be obtained as the destruction of battle ships, balloons or land vehicles at a great distance, attracted deep interest not only on the part of the general public, but among electrical experts and scientists. In some quarters doubt was expressed as to the possibility of Tesla putting his invention to practical use. Others were confident that the inventor would in time be able to make good his declaration by practical demonstration.

One of those inclined to question the value of Tesla's discovery was Cyrus F. Brackett, professor of physics in Princeton University and head of the Henry electrical school of Princeton, N. J., who is author of a treatise on physics.

When seen yesterday he said he placed no confidence in Tesla's claims that by means of his appliance naval warfare would, of necessity, be abandoned. He believes that Tesla is a theorist, that his discoveries are useless and for the most part the reproduction under another form of the inventions of other scientists.

NOT A NEW DISCOVERY.

Professor Brackett said:—"The shortest, most correct and most complete criticism which I can make in reference to this bold boast is that what is new about it is useless, while that which is useful had all been discovered by other scientists long before Tesla made this startling announcement. You will find the whole theory which he has applied in any up to date text book. What Tesla has done is simply to make theoretical application, which would prove to be absolutely ridiculous in application, of inventions which had already been discovered.

"There is nothing new about this. The theory is perfect, but the application absurd. So throughout Tesla's whole elaborate scheme, the theory is not at fault, although there is nothing original about it, but the circumstances under which its application would be necessitated are such that the only result would be failure.

THE SCHEME NOT PRACTICABLE.

"Do you suppose that in the din of battle it would be possible to put into execution those minute and carefully adjusted mechanical experiments, all of which are presupposed by his theory, which require the quiet of an uninterrupted laboratory to work successfully?

"Or do you think that the enemy would co-operate with the attack and place their vessels in exactly the correct position to be hit or that they would remain stationary while the torpedo boat approached?

"His theory would have to assume an affirmative answer in order to be a success, and moreover the torpedo boat would have to be seen from the base of operations in order to direct it. It would be discovered by the doomed vessel long before it reached its destination, and would be exploded on the spot, so how great an advance is this on the present mode of warfare?

"I do not doubt the validity of the scientific truth of the principles which the theory involves, for the experiments have been made repeatedly in physical laboratories, and I believe that on a small model the desired effects could be made. In my classroom I perform experiments by which the actions of a body fitted with the proper electrical mechanism can be controlled without metallic communication through wave motion by means of a lever which Tesla has utilized in controlling the action of his model vessel.

"In application the whole phase of the matter is changed and the thing becomes an absolute impossibility, owing to the mechanical and natural impediments which would have to be overcome."

HAS FAITH IN TESLA.

A. S. Brown, chief electrical expert of the Western Union Telegraph Company, does not agree with Professor Brackett. He believes that Tesla's discovery may prove most important. When I saw him yesterday he said:— I have not had an opportunity to read closely the HERALD article which sets forth Tesla's discovery, but I may say that he is such a wonderfully inventive genius that we need not question the value and practicability of anything which he may discover. His is a wonderful mind, and his contributions to the cause of science have been most valuable and important.

"It has for some time been possible to produce a movement of a telegraphic sounder for a distance of some twenty miles without making use of a wire, but whether it is possible to extend this principle to a distance of three or four thousand miles, or say from New York to Paris, France, as Mr. Tesla says he will be able to do, remains to be seen. I do not question his ability to do so, for I know what a wonderfully inventive genius he is."

The New York Herald November 10, 1898

CHARY ABOUT TESLA'S PLANS.

Professor Dolbeer Says the Electrician Has Made Startling Announcements Before Without Result.

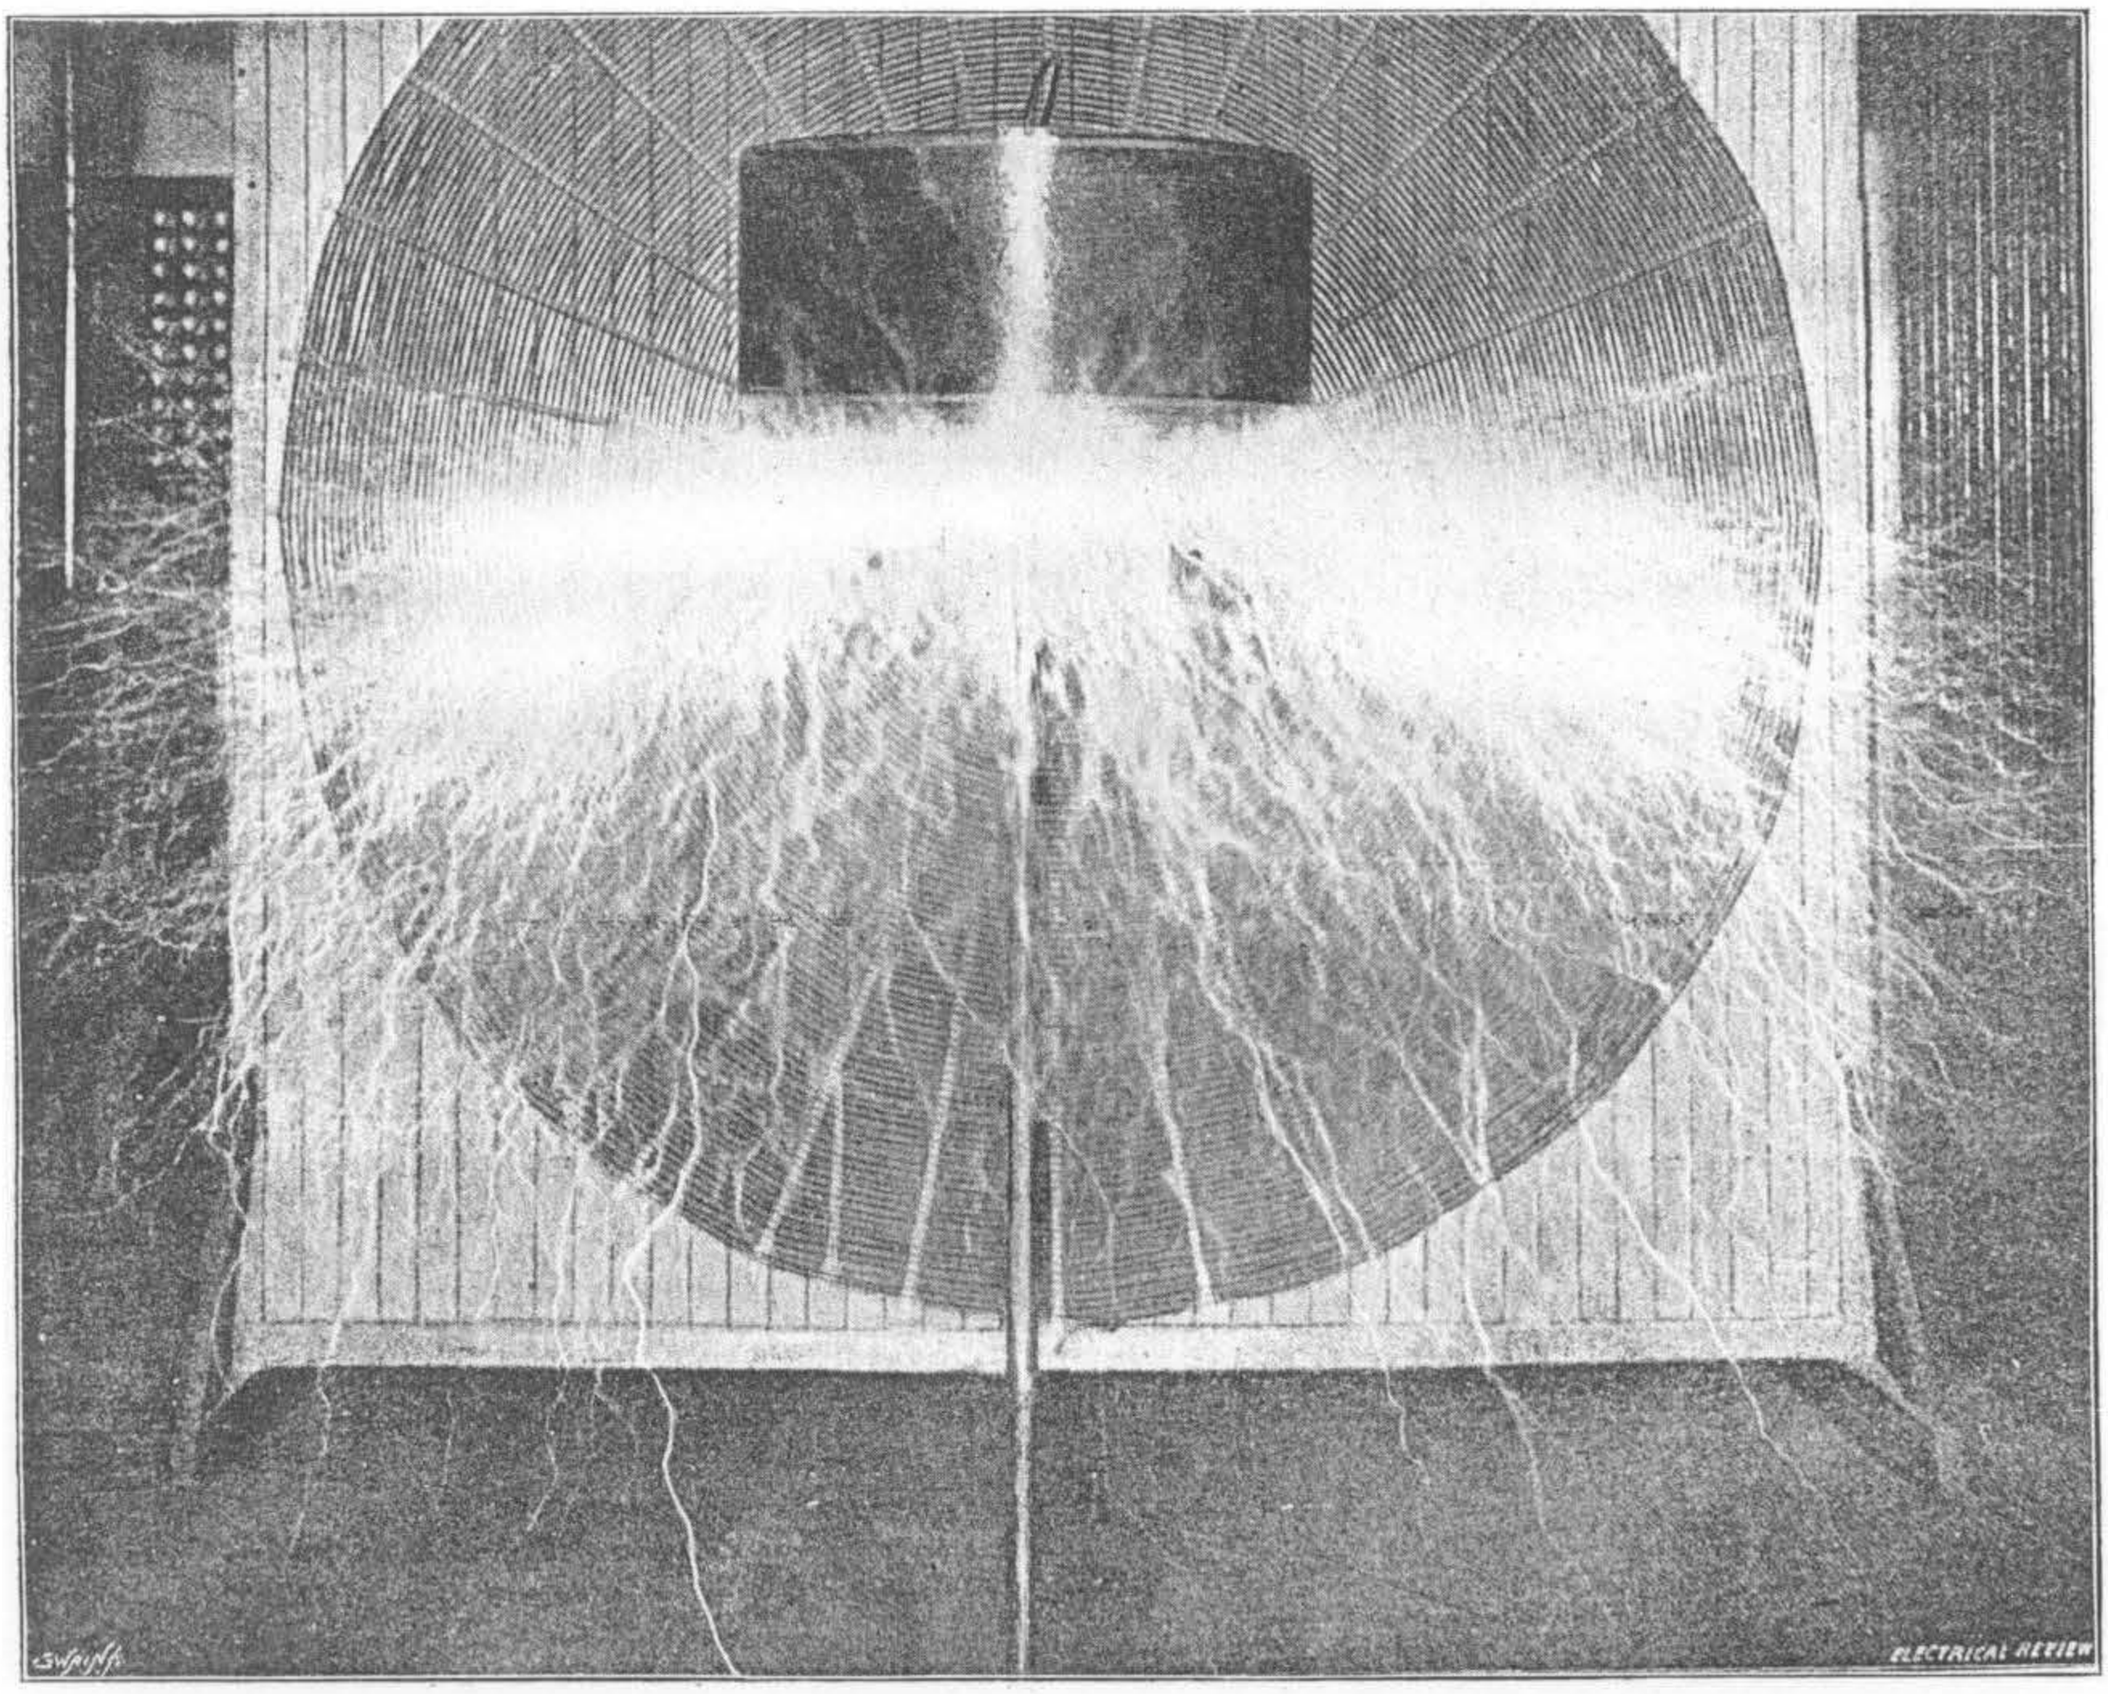
BOSTON, Mass., Wednesday.—Professor Dolbeer, of Tufts College, said to me to-day:—"This last so called invention of Nikola Tesla's is a very pretentious affair, and it is so incredible that the story is not to be believed until the work is actually done. If Tesla said all that the HERALD quotes him as saying, then his whole scheme and his manner of working is unintelligible to me. He even says that 'this power can be exerted at any distance by an agency of so delicate, so impalpable a quality, that I feel I am justified in predicting that the time will come when it can be called into action by the mere exercise of the human will.'

"That is getting a little outside of science, but you will notice that Tesla himself is only predicting that this will come true. There has been no accomplishment. He proposes to do great things, but he does not tell how he is going to do them, and he hasn't done them himself yet.

"The announcement is most amazing, and, coming as it does from Tesla, scientists are all the more chary about accepting it. During the last six years he has made so many startling announcements and has performed so few of his promises that he is getting to be like the man who called 'Wolf! wolf!' until no one listened to him. Mr. Tesla has failed so often before that there is no call to believe these things until he really does them. Meantime, we are all waiting with much patience and without solicitude. We will believe them when they are done."

TESLA'S SYSTEM OF ELECTRIC POWER TRANSMISSION THROUGH NATURAL MEDIA.

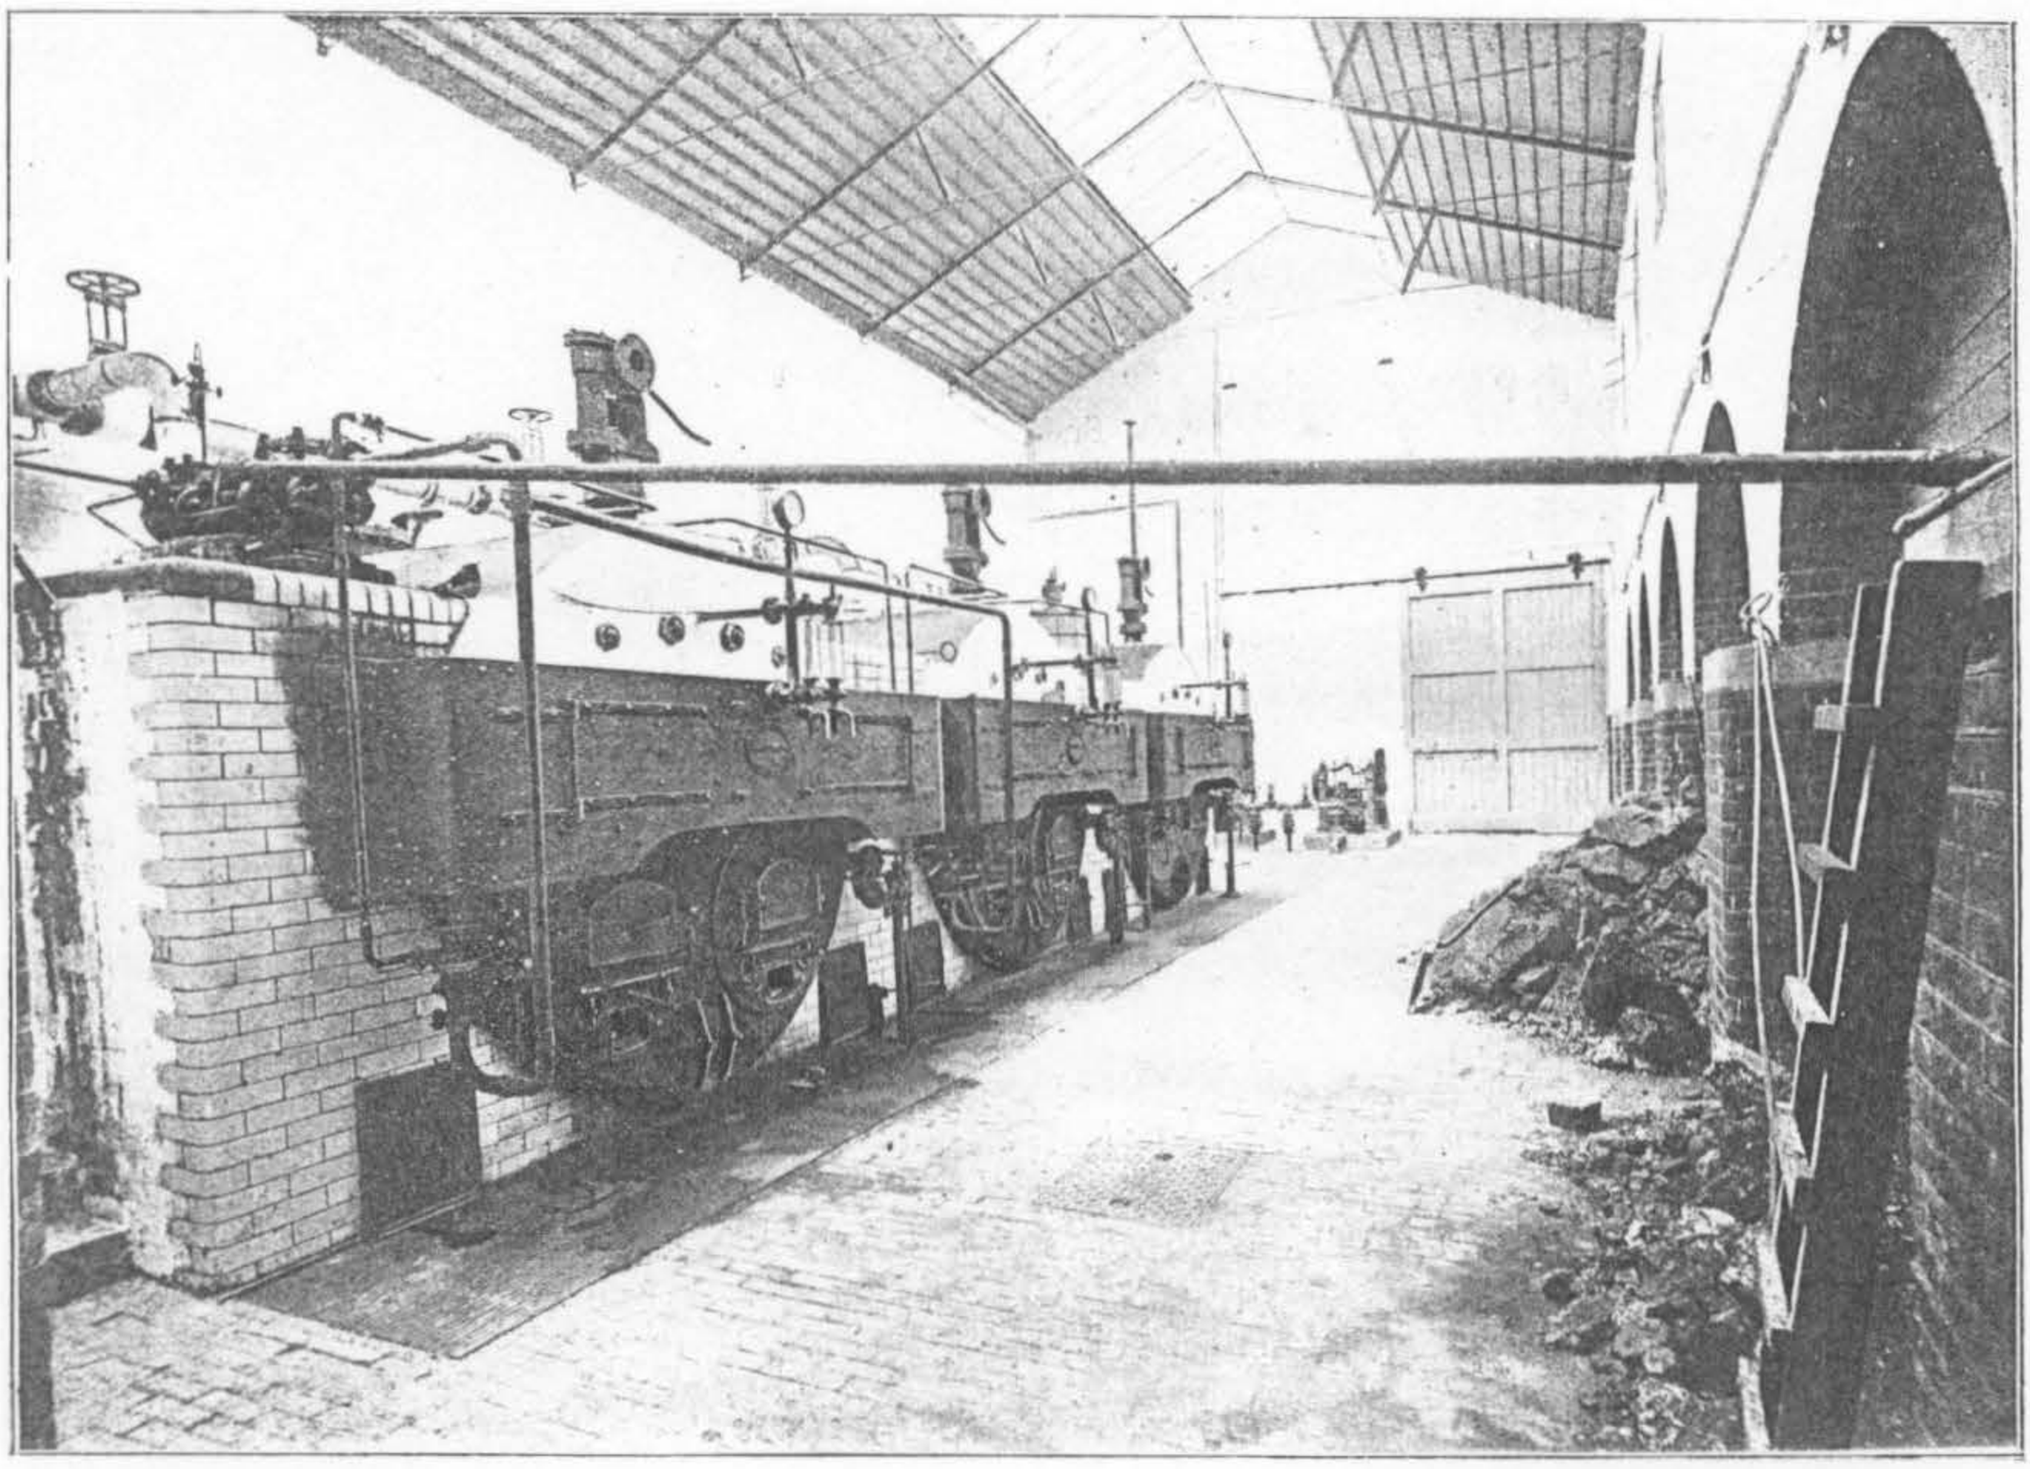
The *Electrical Review*, N.Y., of October 26th, gives a description of a new method of electric power transmission invented and patented by Tesla, the well-known electrician. The description appears to be taken from Tesla's patent specification, and is of a somewhat general nature; but is sufficient to enable us to understand the principle of the startling novelty which Tesla proposes to introduce into our methods of transmitting power by electricity. The following is a summary of our contemporary's article:—



It has long been known, that if air enclosed in an insulating vessel is rarefied, its resistance is reduced to such an extent, that it may be considered a true conductor of electricity, though one of admittedly high resistance. The practical information on this subject, has, however, been derived from observations, manifestly subject to limitations imposed by the character of the apparatus or means heretofore known, and the kind of electrical effects which could be produced.

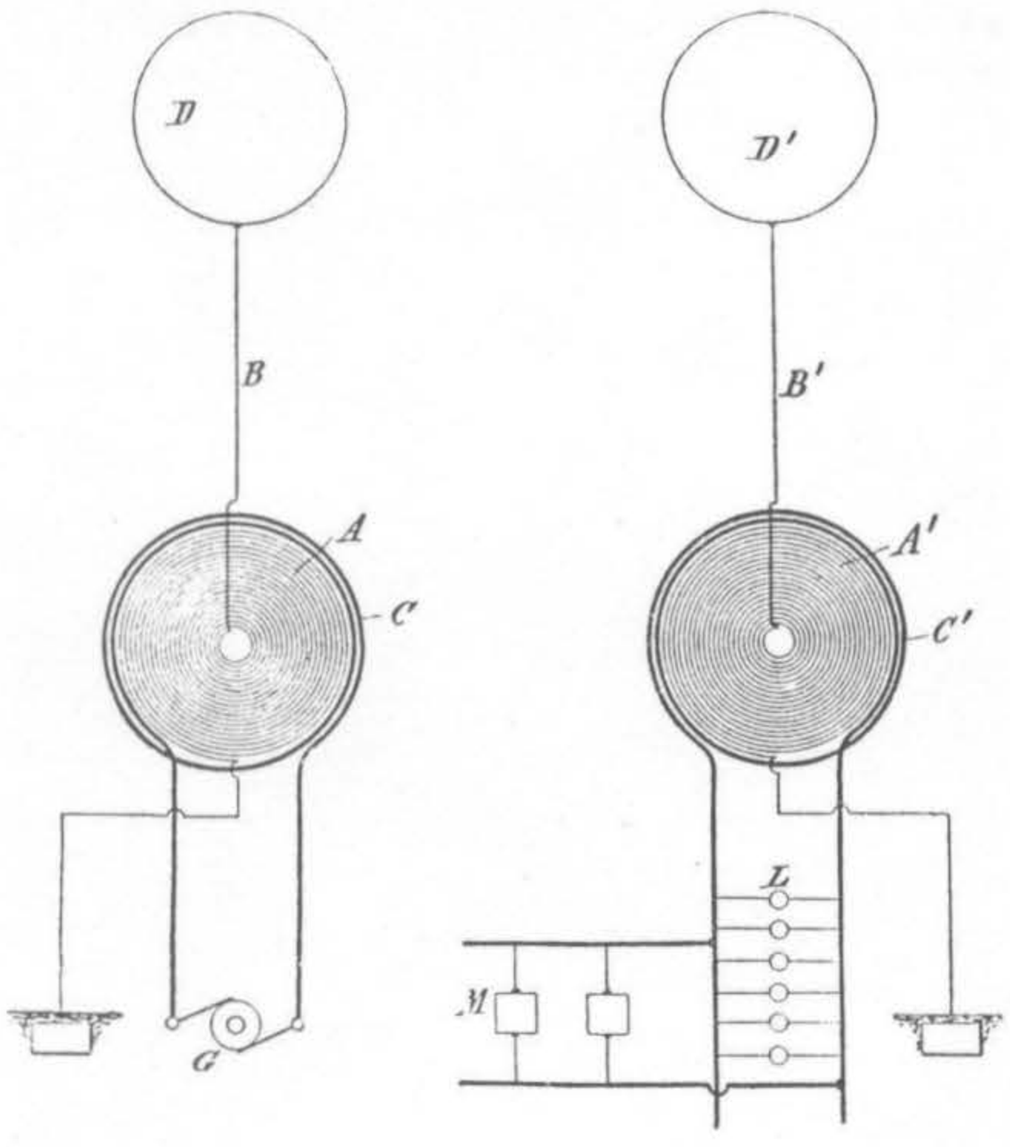
Tesla's invention consists in transmitting electrical power without the employment of metallic line conductors, by taking advantage of the conductivity of the layer of rarefied air which exists in the higher regions of the atmosphere. But in order to make this practicable, he has devised special apparatus for the production and conversion of excessively high electrical pressures.

Heretofore, it has been possible, by means of the apparatus at command, to produce only moderate electrical pressures, and even these, with considerable risks and difficulties. Tesla, however, claims that he has devised means, whereby he is enabled to generate with safety and ease, electrical pressures measured by hundreds of thousands, and even by millions of volts. He has also, during his investigations with such apparatus, discovered certain highly important and useful facts, which are said to render practicable his new system of transmitting electrical energy.



Among these are the following: first, that with electrical pressures of the magnitude and character which he has been able to produce, the ordinary atmosphere becomes, in a measure, capable of serving as a true conductor for the transmission of the current; second, that the conductivity of the air increases so materially with the increase of electrical pressure and the degree of exhaustion, that it becomes possible to transmit through even moderately rarefied strata of the atmosphere, electrical energy up to practically any amount and to any distance.

In order to carry out his system of power transmission, Tesla has designed special apparatus capable of generating electrical pressures vastly in excess of any hitherto made use of. One terminal of this generating apparatus is connected to earth, and the other terminal is maintained at an elevation, where the rarefied atmosphere is capable of conducting



View of model transformer, or "oscillator," photographed in action.—Actual width of space traversed by the luminous streams issuing from a circular single terminal, over 16 feet.—Area covered by the streamers, approximately 200 square feet.—Estimated effective electrical pressure, 2½ million volts.

freely the particular kind of current produced. Then at the distant point where the energy is to be utilised, a terminal is maintained at an equally high elevation, to receive the current and to convey it to earth through suitable means for transforming and utilising it.

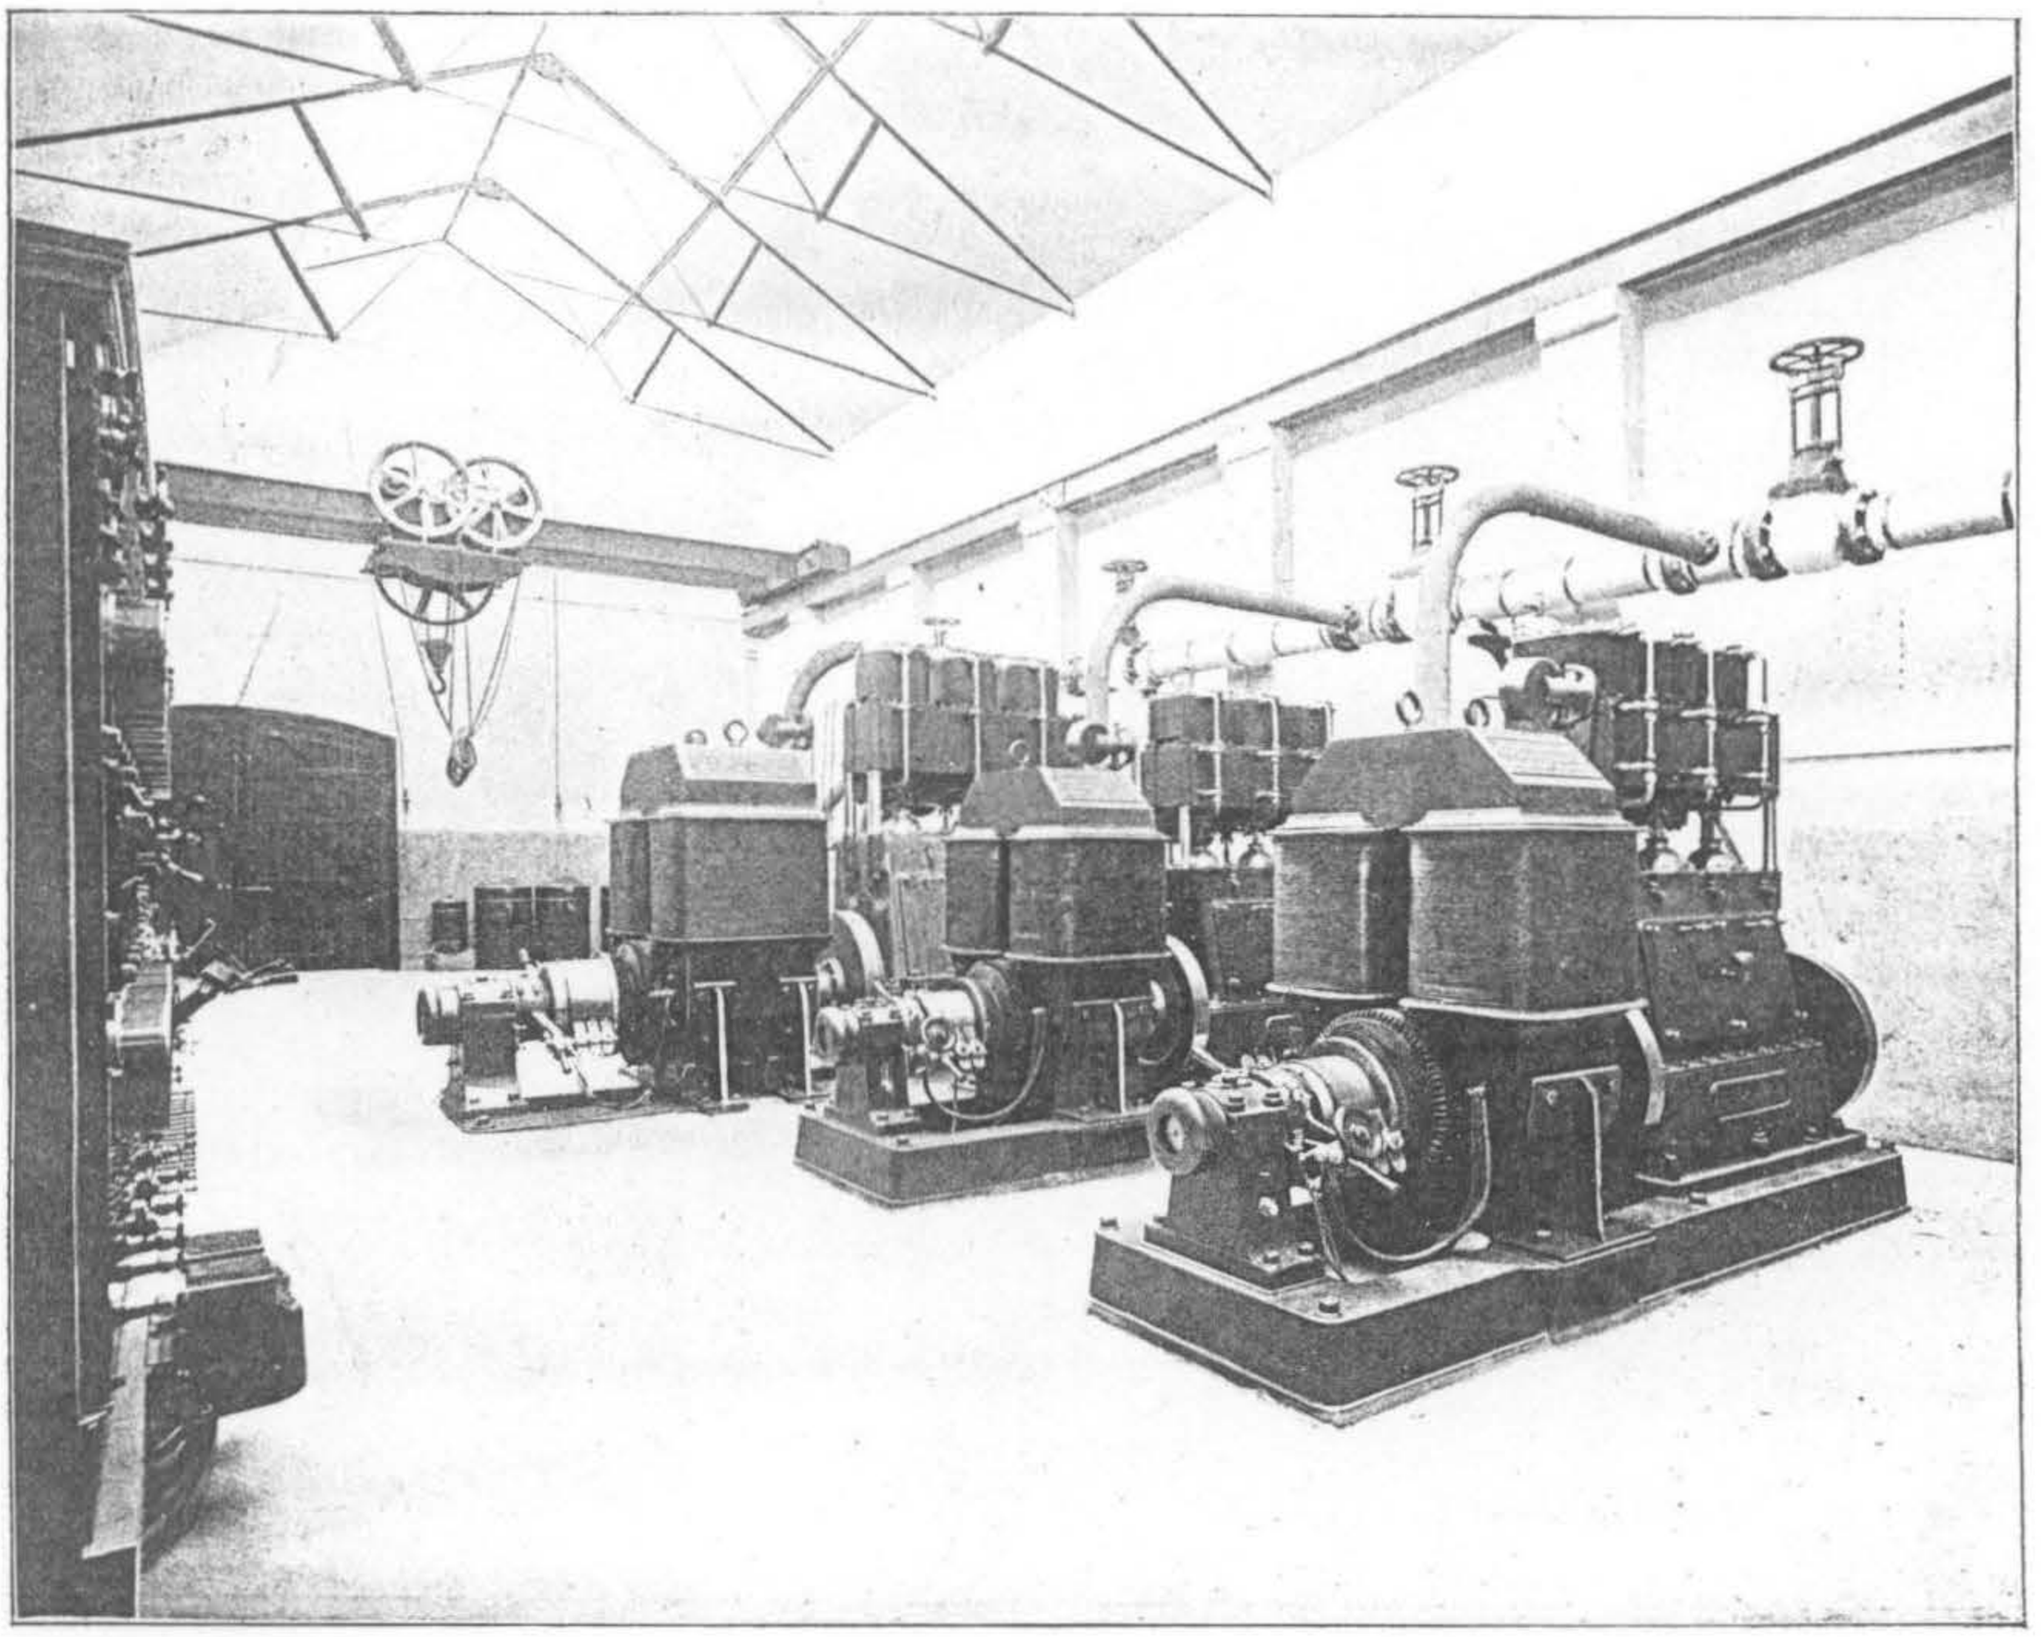
Folkestone.—View of Boilers.

The apparatus by means of which this method of transmission may be effected, is represented diagrammatically in the accompanying figure.

A is a coil, generally of many turns, and of very large diameter, wound in spiral form, either about a magnetic core or not, as desired. C is a second coil formed by a conductor of much larger size and smaller length, wound around in proximity to the coil A.

In the transmitting apparatus the coil A constitutes the high tension secondary, and the coil C the primary, of much lower tension, of a transformer. In the circuit of the primary, C, is included a suitable source of current G.

One terminal of the secondary, A, is at the centre of the spiral coil, and from this terminal the current is led by a conductor, B, to a terminal D, preferably of large surface, formed of, or maintained by such means as a balloon at an elevation suitable for the purposes of transmission as before described. The other terminal of the secondary, A, is connected to earth and, preferably, to the primary also, in order that the latter may be of approximately the same potential as the adjacent portions of the secondary, thus insuring safety.



At the receiving station a transformer of similar construction is employed, but in this case the long coil, A', constitutes the primary, and the short coil, C', the secondary of the transformer. In the circuit of the latter are arranged lamps, L, motors, M, or other devices for utilising current. The elevated terminal, D', connects with the centre of the coil, A, and the other terminal of said coil is connected to earth, and preferably also to the coil C', for the reasons above stated.

The length of the high tension coil of each apparatus should be approximately one quarter of the wave length of the electrical disturbance in the circuit, this estimate being based on the velocity of propagation of the electrical disturbance through the coil itself, and the circuit with which it is designed to be used. To illustrate this in accordance with accepted views, if the rate at which the current traverses the circuit, including the two high tension coils, be 185,000 miles per second, then a frequency of 925 per second would maintain 925 stationary waves in a circuit 185,000

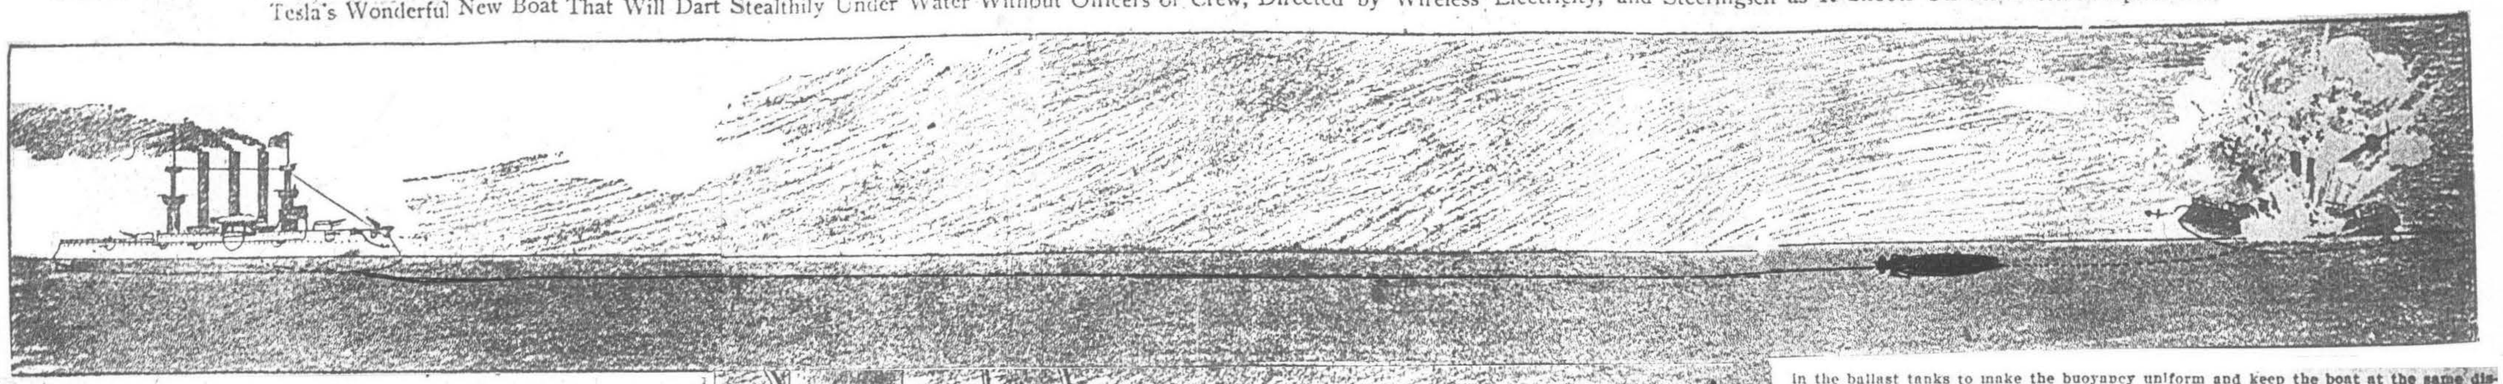
miles long, and each wave would be 200 miles in length. For such a frequency Tesla would use in each high tension coil a conductor 50 miles in length, or, in general, with due allowance for the capacity of the leading wires and terminals, such length of conductor as would secure the highest electrical pressures at the terminals under the working conditions.

It will be observed that in coils of the character described, the potential gradually increases with the number of turns, and the difference of potential between adjacent turns is comparatively small, and a very high potential, impracticable with ordinary coils, may be successfully maintained.

As the main object of the invention is to produce a current of extremely high potential, this object will be facilitated by using a primary current of very considerable frequency. But the frequency of the current is, in a large measure, arbitrary, for if the potential be sufficiently high and the terminals of the coils be maintained at a proper elevation

General View of Dynamo and Engine Room.

where the atmosphere is comparatively rarefied, the intermediate stratum will serve as a conductor for the current produced, and the latter will be transmitted through the air with, it may be, even less resistance than through an ordinary copper wire.



As to the elevation of the terminals D, D', it is obvious that this is a matter which will be determined not only by the condition of the atmosphere, but also by the character of the surrounding country. Thus if there be high mountains in the vicinity, the terminals should be at a great height, and generally, they should always be at an altitude much greater than that of the highest objects near them in order to reduce the loss by leakage. Since, by the means described, practically any potential that is desired may be produced, the currents through the air strata may be very small, thus reducing the loss in the air.

Tesla points out that the phenomenon involved in the transmission of electrical energy is one of true conduction, and is not to be confounded with the phenomena of induction or of electrical radiation which have heretofore been observed and experimented with, and which, from their very nature and mode of propagation, would render practically impossible the transmission of any considerable amount of energy to such distances as would be of practical importance.

Science

A SUBMARINE DESTROYER THAT REALLY DESTROYS—AND WITHOUT A SOUL ON BOARD TO GUIDE IT.

Tesla's Wonderful New Boat That Will Dart Stealthily Under Water Without Officers or Crew, Directed by Wireless Electricity, and Steeringself as It Shoots Off Its Terrific Explosives.

YESTERDAY Nikola Tesla gave to the Sunday Journal exclusively the news of his latest invention—a submarine torpedo boat. He has perfected his device after observing the defects of the torpedo boats in the recent war, and noting the fatalities of submarine boats invented up to date. His submarine boat will carry no lives to risk, but can be directed at a distance of miles from on shore or from the deck of a war ship. The power to do this will be the electric vibrations of the air used in wireless telegraphy. By this means a whole flotilla of submarine destroyers can be turned against a hostile fleet, and perhaps destroy it, without the enemy knowing how they were attacked. This seems almost incredible until the great magician of electricity explains his wonderful invention, point by point, in the following statement.

"My New Submarine Destroyer."

By Nikola Tesla.

I AM now prepared to announce through the Journal my invention of a submarine torpedo boat that I am confident will be the greatest weapon of the navy from this time on.

The almost utter uselessness of the present kind of torpedo boat has been conclusively demonstrated in the recent war. Neither the courage and skill of the Americans nor the desperate extremities of the Spaniards were able to bring the torpedo boats into successful action. These frail craft, of which so much was expected, simply made an easy target for land batteries and rapid-fire guns of opposing war ships.

The submarine boats, on the other hand, which have up to this time been built to carry torpedoes have proved death traps for men and were consequently ineffective. The submarine boat, or, more properly speaking, the submarine destroyer, which I have invented is as compact as a torpedo itself. In fact, it is simply an enlarged torpedo shell, thirty-six and a half feet long, loaded with other torpedoes to discharge. Like a torpedo, also, it has its own propelling device. But here the likeness stops. The ordinary torpedo, once launched, plunges head on blindly and no known power can turn it one way or another. It hits or misses, according to the trueness with which it is aimed at its launching.

But my submarine boat, loaded with its torpedoes, can start out from a protected bay or be dropped over a ship's side, make its devious way below the surface, through dangerous channels of mine beds, into protected harbors and attack a fleet at anchor, or go out to sea and circle about, watching for its prey, then dart upon it at a favorable moment, rush up to within a hundred feet if need be, discharge its deadly weapon and return to the hand that sent it. Yet all through these wonderful evolutions it will be under the absolute and instant control of a distant human hand on a far-off headland, or on a war ship whose hull is below the horizon and invisible to the enemy.

I am aware that this sounds almost incredible and I have refrained from making this invention public till I had worked out every practical detail of it. In my laboratory I now have such a model, and my plans and description at the Patent Office at Washington show the full specifications of it.

As to the mechanism which is to be stored in this submarine shell: The first and most essential thing is a motor, with storage battery to drive the propeller. Then there are smaller motors and batteries to operate the steering gear, on the same principle that an ordinary vessel is now steered by steam or electricity. Besides these there are still other storage batteries and motors to feed electric signal lights. But in order that the weight of machinery shall not be too great to destroy the buoyancy or make the boat go too deep in the water compressed air motors will also be used to perform certain functions, such as to fill and empty the water tanks which raise the boat to the surface or sink it to any required depth. Pneumatic air or motors will also fire the torpedoes and pump out the water that may leak in at any time.

This submarine destroyer will be equipped with six 14-foot Whitehead torpedoes. These will be arranged vertically in two rows in the bow. As one torpedo falls into position and is discharged by pneumatic force, another torpedo, by the force of gravity, falls into the position of the first one, the others above being held up by automatic arms. They can be fired as rapidly as a self-cocking revolver is emptied or at intervals of minutes or hours. The discharge takes place through a single tube, projecting straight ahead in the bow. The small amount of water which leaks through each time is caught by drain pipes and a compressed air pump instantly expels it. As each torpedo is expelled a buoyancy regulator will open the sea cocks and let enough water in the ballast tanks to make the buoyancy uniform and keep the boat at the same distance beneath the surface.

This submarine destroyer will carry a charge of torpedoes greater than that of the largest destroyers now in use. Those vessels of five hundred tons each which cost the Government $500,000, carry but three or four torpedoes, while this simple submarine destroyer, which can be built for $48,000 to $50,000 or less, will carry six torpedoes. It will have, also, the incalculable advantage of being absolutely invisible to an enemy, and have no human lives to risk or steam boilers to blow up and destroy itself.

All that is necessary to make this submarine boat subject to perfect control at any distance is to properly wire it, just like a modern house is wired so that a button here rings a bell, a lever there turns on the lights, a hidden wire somewhere else sets off a burglar alarm and a thermal device gives a fire alarm.

The only difference in the case of the submarine boat is in the delicacy of the instruments employed. To the propelling device, the steering gear, the signal apparatus and the mechanism for firing the torpedoes are attached little instruments which are attuned each to a certain electro-magnetic synchronism.

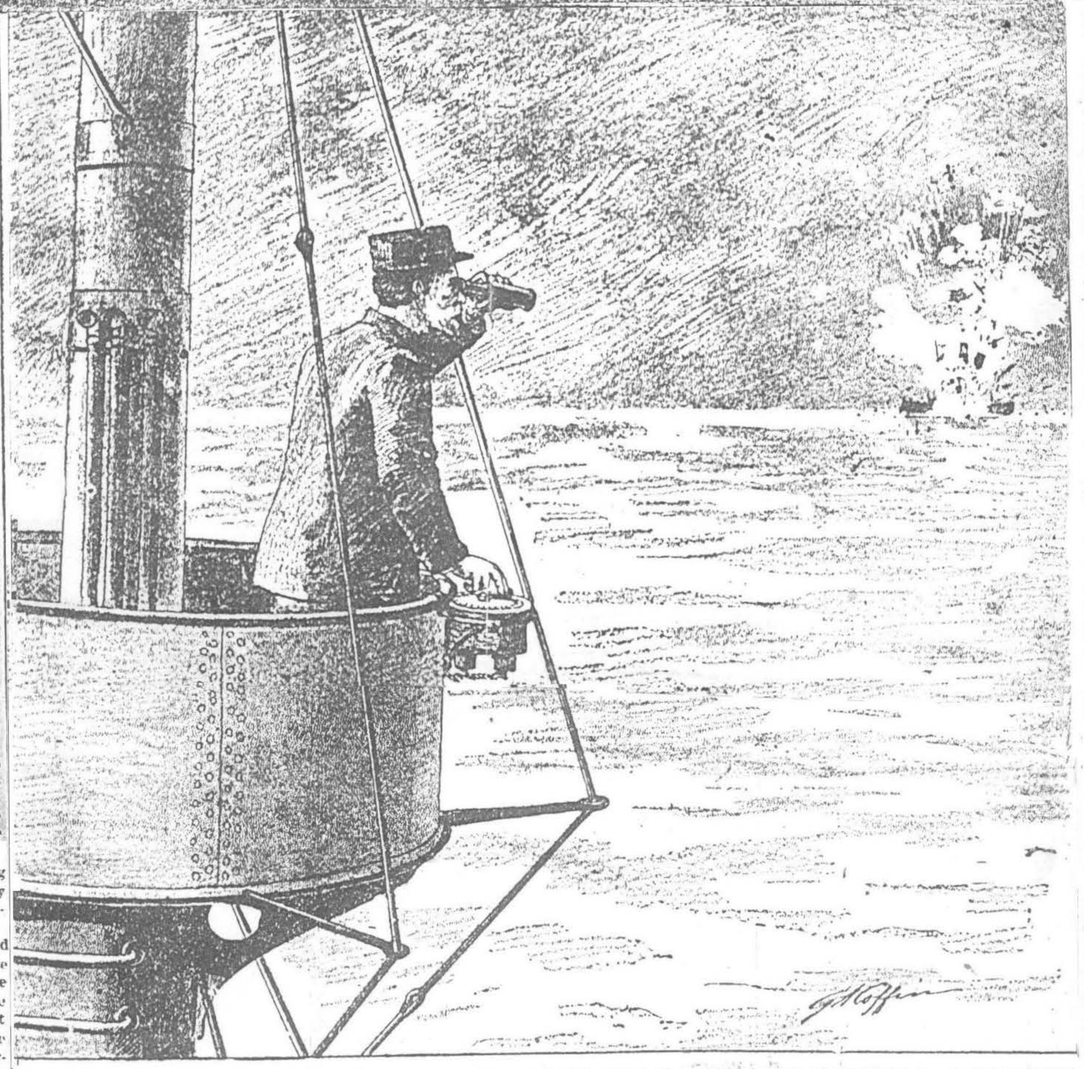
Then there is a similar set of synchronistic instruments all connected to one little switchboard, and placed either on shore or on an ordinary war ship. By moving the lever on the switchboard I can give the proper impulse to the submarine boat to go ahead, to reverse, throw the helm to port or starboard, rise, sink, discharge her torpedoes or return

It might be thought that some great power would be necessary to be projected across miles of distance and operate on the far-off boat. But no. The power is all stored in the submarine boat itself—in its storage batteries and compressed air. All that is needed to affect the synchronistic instruments is a set of high alternating currents, which can be produced by my oscillator attached to any ordinary dynamo situated on shore or on a war ship.

How such an apparently complicated mechanism can be operated and controlled at a distance of miles is no mystery. It is as simple as the messenger call to be found in almost any office. This is a little metal box with a lever on the outside. By moving the crank to a certain point it gives vibrating sounds and springs back into position, and its momentary buzzing calls a messenger. But move this same crank a third further round the dial and it buzzes still longer, and pretty soon a policeman appears, summoned by its mysterious call. Again, move the crank this time to the farthest limit of the circle and scarcely has its more prolonged hum of recoil sounded when the city fire apparatus dashes up to your place at its call.

Now, my device for controlling the motion of a distant submarine boat is exactly similar. Only I need no connecting wires between my switchboard and the distant submarine boat, for I make use of the now well-known principle of wireless telegraphy. As I move this little lever to points which I have marked on a circular dial I cause a different number of vibrations each time. In this case two waves go forth at each half turn of the lever and affect different parts of the distant destroyer's machinery.

How such submarine destroyers should actually be used in war I leave for naval tacticians to determine. But it seems to me that they could best be operated by taking a number on board a large fast auxiliary cruiser like the St. Louis or St. Paul, launch them, several at a time, like life boats, and direct their movements from a switch board placed in the forward fighting top.

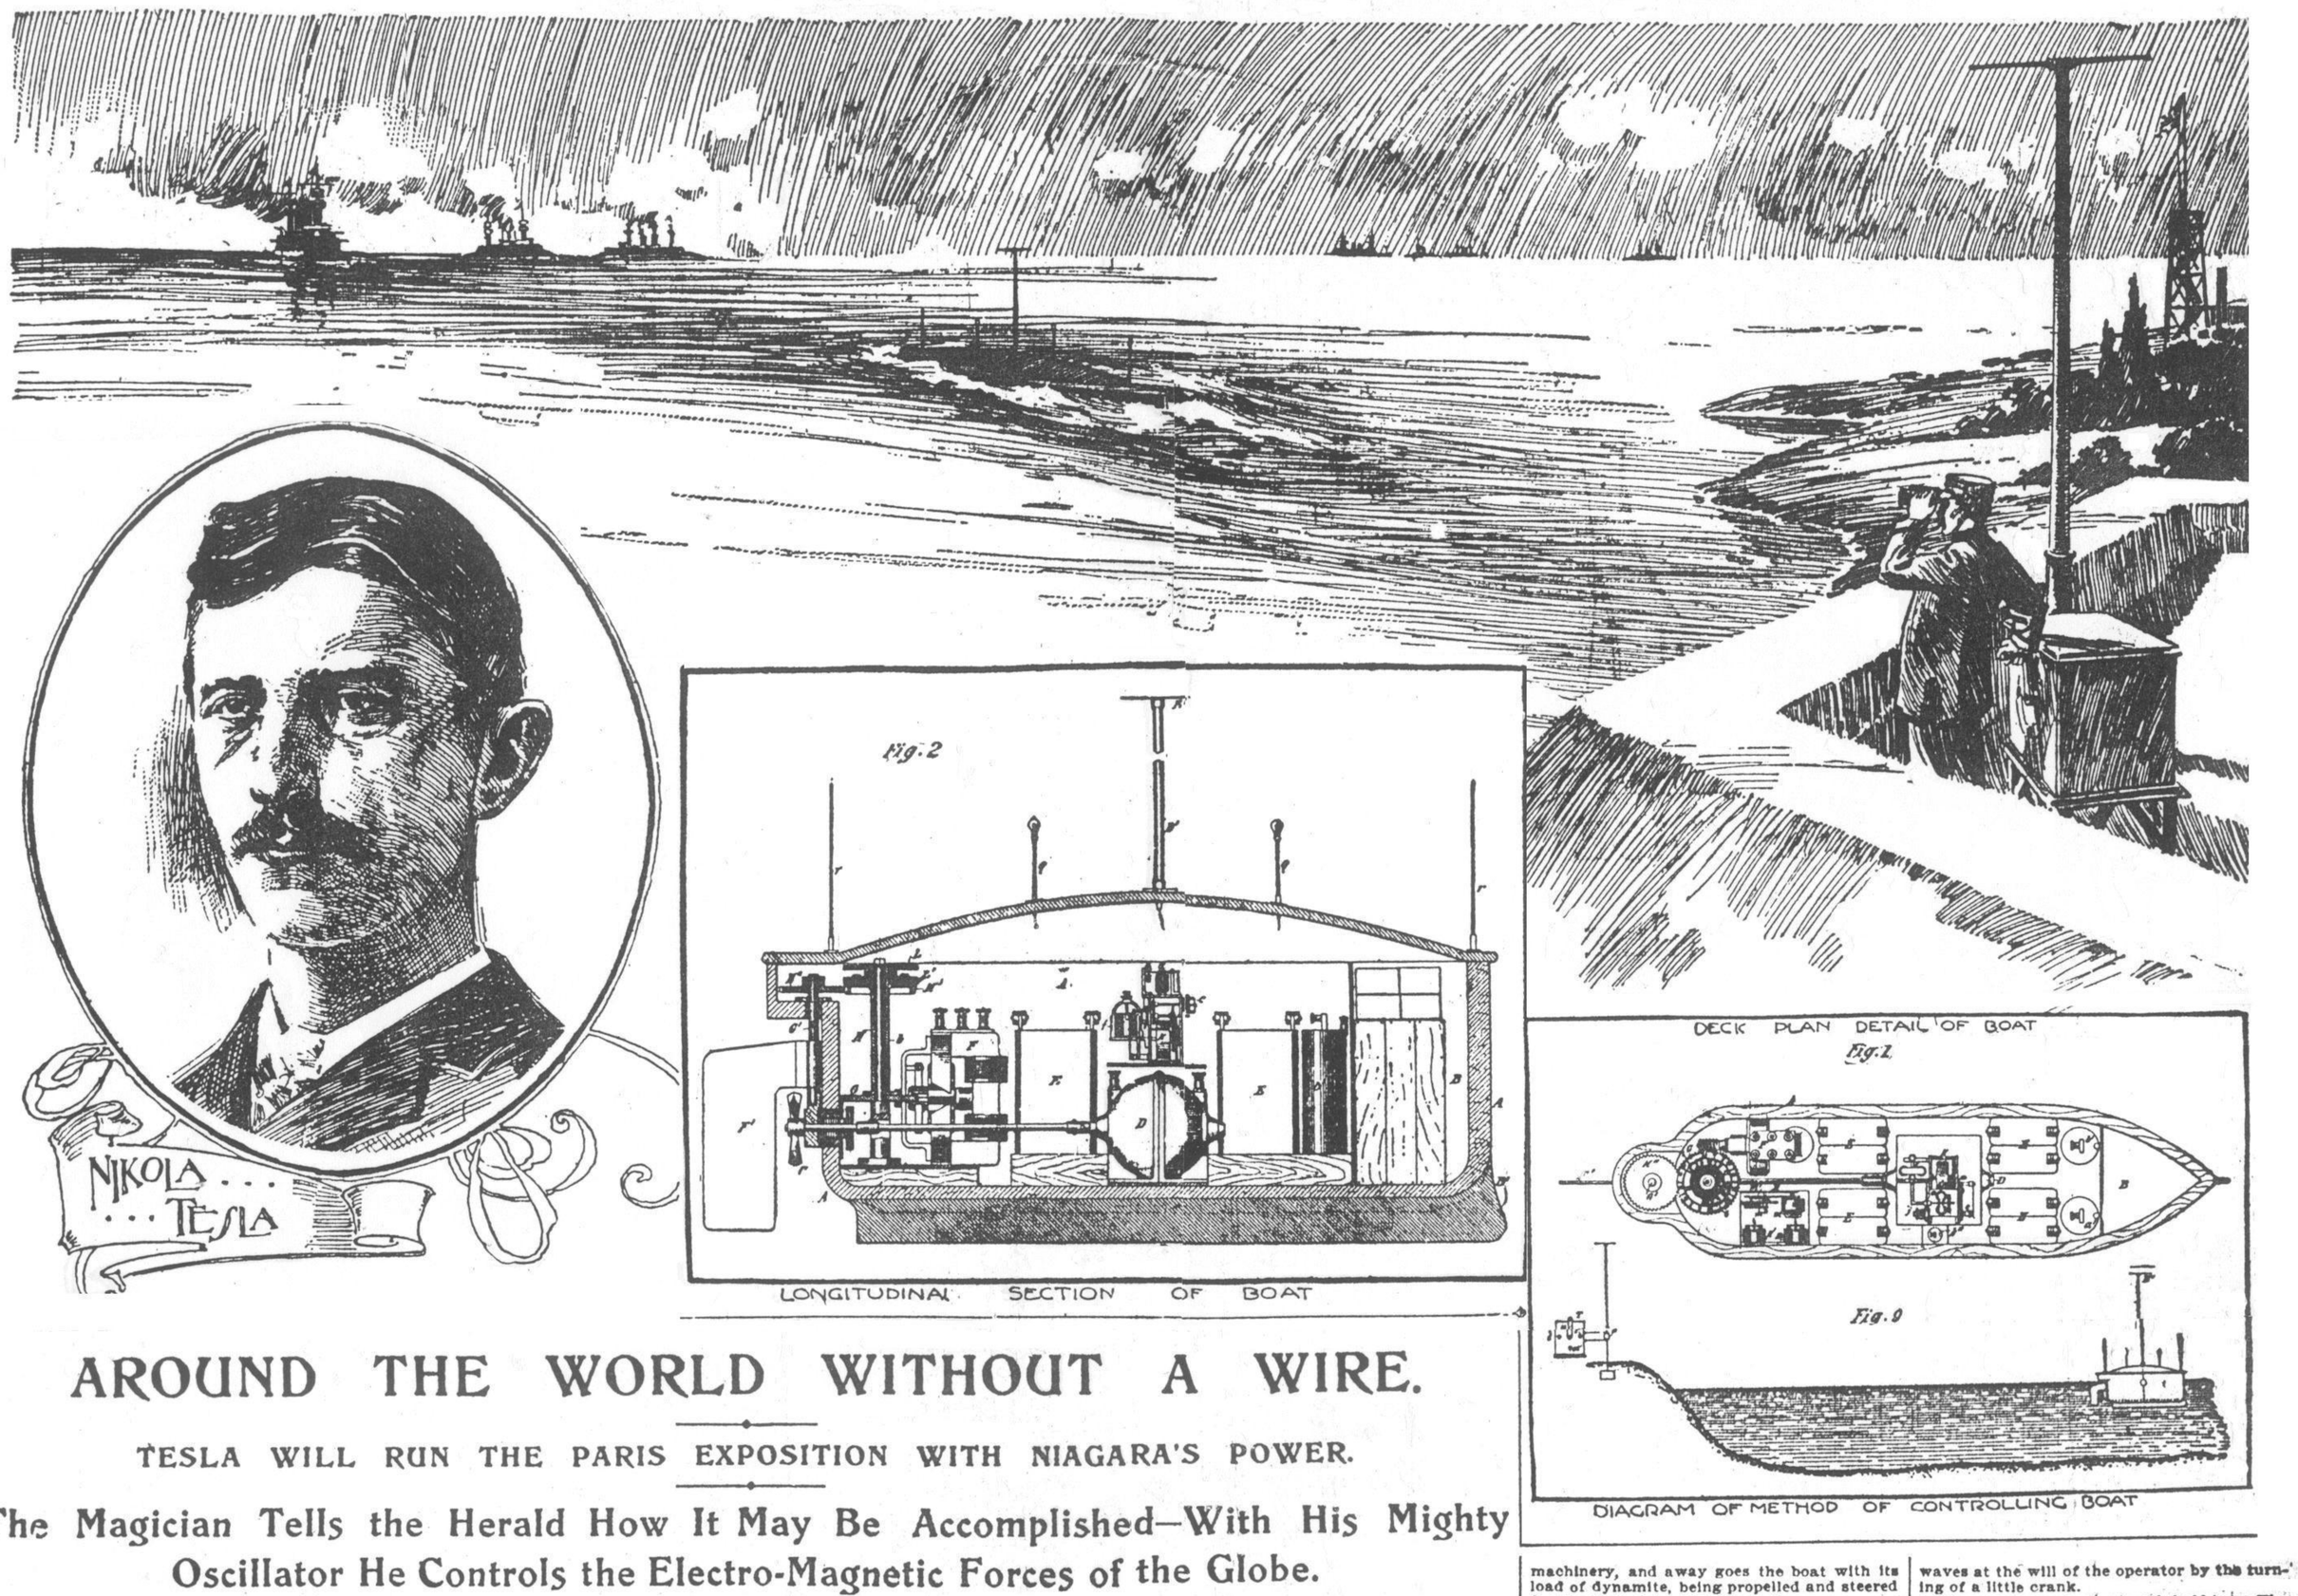


In order that the director of the submarine destroyer may know its exact position at every moment, two masts, at bow and stern, will project up just above the water, too minute to be seen or hit by an enemy's guns by day, and by night they will carry hooded lights.

The lookout placed in the fighting top could detect a hostile ship off on the horizon while the auxiliary cruiser's big hull is still invisible to the enemy. Starting these little destroyers out under direction of a man with a telescope, they could attack and destroy a whole armada—destroy it utterly—in an hour, and the enemy never have a sight of their antagonists or know what power destroyed them. A big auxiliary cruiser, used to carry these submarine destroyers, could also carry a cargo of torpedoes sufficient to conduct a long campaign and go half way around the world.

She could carry the gun cotton and other explosives needed to load the torpedoes in safe magazines below the water line, and do away with much of the danger of transporting loaded torpedoes. When necessary for use the war heads could be loaded, fitted to the torpedoes, and the submarine destroyers fully equipped.

A high, projecting headland overlooking a harbor and the sea would also be a good point on which to establish a station and have the destroyers laid up at docks below and ready to start.



That is the whole story of my latest invention. It is simple enough, you say. Of course it is, because I have worked all my life to make each one of the details so simple that it will work as easily as the electric ticket in a stock broker's office.

STATION IN A FIGHTING TOP FROM WHICH THE SUBMARINE DESTROYER IS DIRECTED

TESLA TO DESTROY NAVIES AND SHOOT MOTIVE POWER FROM NIAGARA TO EUROPE.

All this is done without metallic conductors. A wonderful feature is that with a little pocket oscillator distant war ships, forts and cities may be annihilated.

AROUND THE WORLD WITHOUT A WIRE.

TESLA WILL RUN THE PARIS EXPOSITION WITH NIAGARA'S POWER.

The Magician Tells the Herald How It May Be Accomplished—With His Mighty Oscillator He Controls the Electro-Magnetic Forces of the Globe.

TESLA proposes to run the machinery of the Paris Exhibition with electric power sent instantly across the world from Niagara Falls.

It is an astounding statement.

He has just patented his machine for transmitting electricity without wires. He says he can shoot thousands of millions of volts around and through the globe without metallic conductors.

The Electrical Review says "It is like a tale from the 'Arabian Nights,' and, if successful, it will open up unlimited resources of practically costless power."

If successful, it means that from the great falls of Niagara, of the Yellowstone, of Alaska and of the canyons of Colorado unlimited power of millions of volts can be delivered in New York, London, Paris, St. Petersburg and Pekin in a second of time. Mountains, rivers and oceans would thus be annihilated.

Tesla says his machinery works perfectly; that he has demonstrated the seeming miracle beyond all possibility of failure.

He said to me yesterday:—"I will supply the Paris Exhibition with Niagara's power. I will send it across the ocean without a wire. My invention is the crowning success of long years of thought and labor.

Tesla went on to explain how he invents. He first discovers the natural laws governing the secret he is after. Then he can predict just what his mechanism, when constructed in a certain way, will accomplish.

When the laws controlling their appointed work in the universe have been once mastered the making of the proper machine to act in harmony with the laws is comparatively an easy task.

When Tesla discovered the laws leading up to the invention of his famous oscillator he was convinced that if he made certain wires in the machine exactly of the required length the electricity of the globe would stream forth in flame.

A New Marvel.

He worked long and persistently, with no satisfactory result. Still, he said, he knew to a mathematical certainty—a certainty on which he would stake his life—that the flames must appear when once he found the right measurements.

At last he hit it, and the world now marvels at the results announced. When Lord Kelvin, the Shakespeare of European science, saw this machine in action, its awful flames shooting and exploding in veritable thunderbolts, it is said that his emotion was profound, for above and beyond its spectacular features he realized that it sent its currents around and through our universe of matter. Between each terrifying lightning stroke the globe is penetrated and encircled by the million volted force. With this seemingly divinely endowed oscillator Tesla, it is declared, instantly brings Paris and Hong Kong within the reach of his hand.

I saw the machine yesterday. At the touch of Tesla's finger it blossomed into lightning flame. In color and shape it was like a celestial morning glory flower, twenty feet in diameter, fringed with ten thousand purple thunderbolts—shooting into daggers and tongues of fire, continuously exploding with the roar of a cyclone.

It was like the spectacle on Sinai.

And what is this electric force that moves cars and machinery?

"Invisible light," says Tesla.

To Abolish War.

A still greater marvel is claimed. Tesla will destroy navies and abolish war. His invention to accomplish this sublime end is the subject of wide discussion. General Grant said:—"Make war terrible enough and you will have peace." This Tesla claims to have accomplished with his astonishing machinery.

But it is not by raining artificial thunderbolts on the enemy nor throwing shells by electricity. Tesla's plan is to steer swift dynamite boats at express train speed along the surface or under water against a ship or a fleet, against a fort or a city, and blow them up—annihilate them.

Tesla will handle his destroyers from shore or a distant ship as skilfully as would a captain with a picked crew of experts. By electric devices alone the engines will be controlled and the boat steered and run at any speed, its guns fired or the boat exploded. If a submarine boat it will be made to dive and move below the surface at any depth, coming up at the desired point to blow the enemy out of the water. All this and a hundred other things will be done, he claims, by electricity, without wires or any artificial means of communication.

More Wonderful Than Fiction.

It is a staggering statement to make. But the electrical machinery for doing it is fully described in the twenty-four typewritten pages of specifications covering the patent. There are eight thousand words in the document, showing the invention as a veritable engine of power for peace or war. Its action is largely automatic, and under the manipulation of the operator, stationed a mile or fifty miles away, it would seem almost instinct with human intelligence.

Tesla shows that his machine not only has the capacity for executing any number of orders, but it exhibits what practically amounts to intelligence.

It distinguishes from any number of signals that particular vital one which it has been previously "instructed" to select and obey.

Herein lies the proof of its almost omnipotent power for civilization, for peace or war. By its use war becomes annihilation and peace is the inevitable consequence.

Already rivals in electricity are criticising the claims of the patent, calling Tesla a laboratory dreamer. As usual, they say that sending electrical currents without a wire is nothing new in theory; that it will be impossible to achieve anything of a practical character on sea or land with the enemy vigilant, the weather stormy, the sea boisterous and battles raging. They claim that dynamite boats can never be steered and fleets blown up by an operator stationed miles away with no metallic means of communication.

But Tesla is no ordinary inventor. According to the records he stands in the front rank of geniuses. He was associated with Edison and his achievements are a part of the marvellous history of electrical discov- the marvellous history of electrical discovery.

Tesla Too Busy to Bother with Critics.

When I showed Tesla some of the things the critics had written about this last invention he smiled and said life was too short to enter into a defence of his work. He preferred to devote every hour to perfecting his inventions, leaving the results to vindicate his skill and judgment.

"I was many years in perfecting my electrical apparatus for transmitting power," he said. "Many were at work in that direction, but I invented the machine now used in this country, in Europe, Asia, and even in Zululand. It has revolutionized the whole system of transmitting power. It was not difficult to transmit power a short distance. To transmit power successfully and cheaply long distances required years of study and demonstration.

"But in regard to my invention for destroying cities, forts and fleets, which I have just patented, that is altogether beyond any question of doubt. I know just what I can do.

"It is a mistake to imagine that fleets can be destroyed without the operator knowing where they are. That is absurd. I never made such a claim. He must see the war ships with his unaided eye or through a telescope, or they must be otherwise located that he may know exactly where they are, and then direct his attacking boat, filled with dynamite or gunpowder, against the enemy to accomplish their destruction."

How the Miracle Is Accomplished.

And how does Tesla propose to do this without wire or any artificial means of communication?

He uses the earth and the atmosphere as his double wire and thus secures a complete electrical circuit. He has a thunderbolt producing machine, his famous "Oscillator." Instead of producing the few thousand volts used for electric lighting, propelling trolley cars or killing murderers at Sing Sing, it manufactures millions of volts. But the electricity is of such a character that when the machine fills a room with jagged lightning, flashing and thundering in a tornado of fiery storm, it does not kill anybody, yet it develops a force thousands of times greater than the biggest ordinary dynamo can produce.

With this machine creating a pressure of millions of volts, Tesla lashes the vast ocean of electricity of the earth into a cyclonic storm. Instantly the waves spread in all directions through the universe of matter.

And this electricity is as rigid as steel. It cannot be compressed nor condensed. Yet it is thousands of millions times lighter than the lightest air of the highest mountain tops. It is everywhere in the universe, in the earth, in the sea, in the air and in the vast abyss above the air. With it your eye penetrates material substance, as in using the X ray. In the presence of this divine fluid, electricity, the earth and the universe of matter in a sense no longer exist, yet on a spider web wire, on a sunbeam, on a cloud you can send a thunderbolt or a human whisper hurling through space.

Like Aladdin's Famous Lamp.

All science stands aghast before the secret of this inexplicable power, yet it is obedient to the red freckled telephone girl who works in accordance with its laws. And yet old Archimedes' lever which moves the world cannot condense a volume of electricity to the extent of a hair's width. If you had a bag reaching from Tammany Hall to Chicago filled with electricity, and you dimpled the bag in New York with your fist, it would instantly be dimpled in Chicago, eight hundred miles away. It can encircle the globe sixteen times in a second.

All the universe is a big bag of electricity. When Tesla's thunderbolt machine bombards it in New York, rippling waves break on the most distant electric shores of the world—in Chicago, San Francisco, Siberia, New Zealand, in our Philippines, at the poles north and south. This is Tesla's claim, that the electro-magnetic waves thus made sweep around and through the world in an instant.

How the Machines Work.

Now how can he send his message aboard ship from distant lands—reaching one particular vessel?

By having two electric circuits, one on shore and one on the vessel, both adjusted to be in exact unison. They may be likened to a pair of violins in perfect accord and tune. You play one and the other takes up the strain of music.

One of the most wonderful features of this invention is that the oscillator for producing these tremendous, far reaching electric waves can be almost tucked away in one's pocket, like a cigarette case.

When Tesla on shore wants the ship's engines to start he touches the code signal, which goes flying on the billows of electric ether through all space. If these duplicate machines were in every city every city would receive the message to start the engine, fire the guns, steer "port" or "starboard," go ahead or back, or whatsoever the message sent might be.

But the machine is deaf and blind to all other messages. Hence the enemy is powerless to thwart any attack.

So one ship alone of a fleet receives the electric message, the current "impulse," or whatever it may be termed.

A little armature or lever is released, the electric circuit is complete, the clock starts a more powerful electric machine connecting with the engines, as it does with the steering machinery, and away goes the boat with its load of dynamite, being propelled and steered for the fleet at terrifying speed.

McKinley's Great Feat.

Didn't McKinley press a button and start the great machinery of the big fair?

Tesla touches his code signal and the distant boat starts for the enemy's fleet.

Every day a similar feat is performed in the big hotels of the country. The visitor on the fifteenth floor of the Imperial wants writing material and a steak. He sets the electric machine to the proper index in his room.

Down in the hotel office it rings and points to the same articles on the same kind of a dial—bearing all the "calls" and dishes, lettered exactly the same as the twin machine in his room in the fifteenth floor.

In the big hotel the electricity travels over a double wire. Tesla's electricity travels through air and earth. They are his double wires.

In your house you pull your district messenger call for boy, fire engine or policeman. It is because of the peculiarity of the machine that the electricity obeys you—calling for boy or policeman as you wish.

So again with Tesla. The secret is in the peculiarity of the machines. His machines not only enable him to control the distant ship, on which there is no human being, but they pick out only the vibratory current originally sent flying by the machine creating it.

With a glass Tesla sees the enemy's fleet fifteen miles away. He adjusts the two machines—one on shore, one on the boat. He starts it, steers it, increases speed, rushes it against the fleet with its cargo of dynamite blowing the war ships to destruction.

If it is a diving submarine boat, he knows its course by bars of colored electric light which shoot from the depths to the sky from the speeding boat. If, on the surface, he uses colored lamps.

Besides ships, Tesla says he can direct balloons, or wagons—steering them in the same way.

Atlantic travellers know how easily the pilot steers the big steamship by merely pressing a button, operating the machinery connected with the ponderous steering mechanism. In a similar way Tesla would set his dynamite boat's machinery in motion. What matters it whether he is one or twenty miles away. Electricity laughs at distance.

How Tesla Describes It.

Here is a section of his own technical description of how he does it:—

"In a broad sense, my invention differs from all of those systems which provide for the control of the mechanism carried by a moving object and governing its motion in that I require no intermediate wires, cables or other form of electrical or mechanical connection with the object, save the natural media in space.

"I accomplish, nevertheless, similar results and in a much more practicable manner by producing waves, impulses or radiations which are received through the earth, water or atmosphere by suitable apparatus on the moving body and cause the desired actions, so long as the body remains within the active region or effective range of such currents, waves, impulses or radiations.

"These actions necessitated the designing of devices and apparatus of a novel kind, in order to utilize to the best advantage various facts or results which, either through my own investigations or those of others, have been rendered practically available."

About the Electric Waves.

Tesla describes a number of ways, well known to electricians, by which an electric effect could be transmitted to a distance without direct connection, and says:—

"But by adopting such means as I have devised, that is, either by passing through the conducting path currents of a specially designed high frequency alternator, or, better still, those of a strongly charged condenser, a very high rate of change may be obtained, and the effective range of the influence thus extended over a vast area, and by carefully adjusting the circuit on the moving body so as to be in exact electro-magnetic synchronism with the primary disturbances, this influence may be utilized at vast distances."

An expert thus describes the working of the electrical machine:—

"The device which he has adopted for his model demonstration consists of currents of enormous voltage, which can be projected in waves at the will of the operator by the turning of a little crank.

"Two waves go forth at each half turn. The effect of these is like that of the vibrations produced by the voice in a telephone. On the vessel to be controlled is a broken electrical circuit, loose particles of a metallic oxide being at the point of separation. A current is always endeavoring to pass through these, but fails. The magnetic waves produced by the operator bring together by magnetic action these particles, which thus have power to conduct an electric current.

Working the Signals.

"When the operator sends out his signal current it is enabled to pass through the oxide, a magnet. With the first move of the armature a clockwork starts and prepares to set closing other electric circuits as soon as it may be released.

"A second magnetic wave moves the armature again, and the vessel's machinery begins to move. Then by special devices combinations of impulses coming from the operator are made to operate each and every part of the machinery in the vessel at the will of the operator."

Many astounding facts in electricity have been discovered. It originally cost thousands of dollars for copper wire alone to carry comparatively weak currents a few miles to move machinery. It was finally discovered that a tremendous voltage could be sent on a mere thread of wire, thus reducing the cost to a trifling expense. Tesla first succeeded in transmitting power over one wire, now he abolishes all wires.

Regarding the Diagrams.

The accompanying illustrations, taken from Tesla's patent specification, show a top and side of his boat, Nos. 1 and 2 respectively. Also a view showing the operating boat out at sea and the electrical wave generator and controller on shore, where the operator stands directing the course of the vessel. This latter operation Tesla thus describes:—

"In this figure S designates any source of electrical disturbance or oscillations, the generation of which is controlled by a suitable switch contained in box T. The handle of the switch is movable in one direction only, and stops on four points—t t^1 u u^1—so that as the handle passes from stop to stop oscillations are produced by the source during a very short time interval. There are thus produced four disturbances during one revolution, and the receiving circuit is affected four times, but the rudder is moved only twice—once to right and once to left. Now I preferably place the handle of the switch so that when it is arrested on points t t^1—that is, to the right or left of the operator—he is reminded that the vessel is being deflected to the right or left from its course, by which means the control is facilitated. The normal positions of the handle are therefore at u u^1 when the rudder is not acted upon, and it remains on the points t t^1 only so long as necessary. Since the working of the apparatus is very sure, the operator is enabled to perform any such operations as provision is made for without even seeing the vessel.

"To blow up the boat or ram it into the enemy's fleet, the switch handle of the entire wave controlling machine is simply turned by the operator continually round and round for, say, ten or twenty seconds, sufficiently to accomplish the work designed."

In summing up the various uses of this invention Tesla says it will be invaluable in saving life at sea and in shipwrecks along shore. The operator can send out a lifeboat, scoop in the struggling swimmers from the water, turn the boat about and bring them safely to shore.

In his own words Tesla says of its merits:—

"The invention which I have described will prove useful in many ways. Vessels or vehicles of any suitable kind may be used, as life, despatch or pilot boats or the like, or for carrying letters, packages, provisions, instruments, objects or materials of any description, for establishing communication with inaccessible regions and exploring the conditions existing in the same, for killing or capturing whales or other animals of the sea, and for many other scientific, engineering or commercial purposes."

And he adds the following significant and prophetic remarks:—"But the greatest value of my invention will result from its effect upon warfare and armaments, for, by reason of its certain and unlimited destructiveness it will tend to bring about and maintain permanent peace among nations."

The New York Sun November 13, 1898

Nikola Tesla and His Quest.

NIKOLA TESLA has just made public some facts about an invention intended to make war too terrible to be prosecuted, and thus to insure peace between nations. The war with Spain drew Mr. TESLA'S mind aside for the time from the line of studies which has engaged him for years. Inspired and fired by patriotism he has applied to a war engine some of the principles which he discovered in following his inquiries into new methods of applying energy to the purposes of peace.

The success or failure of Mr. TESLA'S latest invention will not turn him away from the great project which has possessed his mind for years. This, as he puts it, is to harness the sun's power to do the work of mankind. He does not mean to catch the power of the sun's rays directly, but to utilize that enormous portion of their power which is expended upon the earth's surface in sucking from sea and lake waters which are afterward precipitated upon the higher parts of the land.

That there are waterfalls upon the earth which are capable of producing all the energy which mankind uses for power, heat and light is well known. The use of water powers, however, is limited within narrow margins, partly because of the investment cost of installment, but chiefly because the great waterfalls are remote from the seats of population and trade. Before Mr. TESLA began his researches there was no method known by which the power generated at a remote place could be transmitted to where it was wanted except at a loss of efficiency which was prohibitory. Since that time, by the use of currents of from 10,000 to 20,000 volts, it has become possible to send electric power successfully over wires for thirty-five miles or more, and one plant is now building to transmit power eighty-five miles.

But to utilize the great water powers of the world, the transmittal of energy for a distance of from fifty to one hundred miles is hardly more useful than a reach of eight or ten miles. Mr. TESLA designs to annihilate space. He would take the power of a Niagara, transform it into an electric current, and send this without appreciable loss to any place on earth where it was needed for use. Mr. TESLA has, accordingly, devised an electric oscillator which will receive the electric current from its source and give it an intensity which, as the inventor calculates, would enable a copper thread to carry 50,000-horse power across the ocean. Mr. TESLA claims to have discovered, furthermore, that at an altitude easily reached by balloons the rarefied air has a conductivity equal to copper, while the denser layer of air below is a non-conductor. He proposes to suspend one pole of his electric circuit in the air at Niagara Falls and the other at Paris, and to forward his current through the upper air to France, whence it shall return through the earth when its active energy has been expended in work. He believes that he will be able to make this demonstration in 1900 as an exhibit at the coming world's fair at Paris, and to drive all the machinery at that exposition with the power from our great waterfall. The significance of his success would be that coal would become a convenience instead of a necessity, and water power and electricity would replace coal and steam for the work of the world.

Another great quest which Mr. TESLA has been conducting side by side with this, and in fact leading along the same lines, is for the means of producing light from electricity without heat. It was well known when TESLA began his studies that a Crookes vacuum tube could be made to glow by passing through it currents of electricity at a high tension, but no electrician could evolve from these tubes more than a phosphorescent glow. To turn this into a white light which should shine like the face of the sun itself was the problem to be solved. All his investigations led Mr. TESLA to conclude that the thing which was needed was to be able to give to electrical currents voltages enormously beyond any which had ever been produced, and then to be able to handle and control the currents thus transformed. From this need grew his electrical oscillator, with which Mr. TESLA proposes to produce a current with an intensity of 800,000 volts, capable of transmission across the Atlantic. In Mr. TESLA'S laboratory the vacuum tubes glow like sunshine, and their introduction for use is waiting only for a reduction of the cost of their light to a commercial basis, a reduction which he says is near at hand.

Since Mr. TESLA began investigating the possibilities of such high tension currents as he produces by means of his oscillator he has made some startling announcements, such as that of his ability to use the whole earth as a conductor, and to telegraph to any part of its surface from any other part, sending messages jointly to many stations or separately to each at will. Perhaps because none of these late triumphs of Mr. TESLA'S genius have yet been brought into practical use, there are many persons who declare that he is a visionary and impractical. It must be remembered that his discovery of the rotating electric field was of as great importance in its day as are his later discoveries now. That was announced in 1882, yet it was nearly ten years before its value was fully recognized.

The personality of NIKOLA TESLA is as interesting as are the results of his scientific labors. His ways of work differ radically from the methods of those who study by experiment and elimination. TESLA seldom experiments, and when he does it is to prove a theory, not to form one. In eleven years, he says, only one of his experiments has failed. His processes are mental, and at times, he declares, his mind reaches out into fields so vast that he is afraid, and recalls it. He verifies his conclusions afterward by figures and experiments.

No other great scientific genius ever turned aside from his work to devise means for putting an end to war. Others have invented guns, armor, explosives, and other accessories of war, but even in these cases the inventions were in a line with work in which the inventors were already engaged. Mr. TESLA'S first design was to apply his method of control to such engines as automobile torpedoes and to use these to destroy the Spanish fleets, but as he went on, the broader idea came to him to make his war machine so irresistible as to render war itself improbable.

ECTRICAL REVIEW

AN ILLUSTRATED WEEKLY JOURNAL OF SCIENTIFIC AND ELECTRICAL PROGRESS.

TESLA'S LATEST INVENTION.

DETAILS OF AN INVENTION WHICH MAY ASSURE THE PEACE OF THE WORLD.

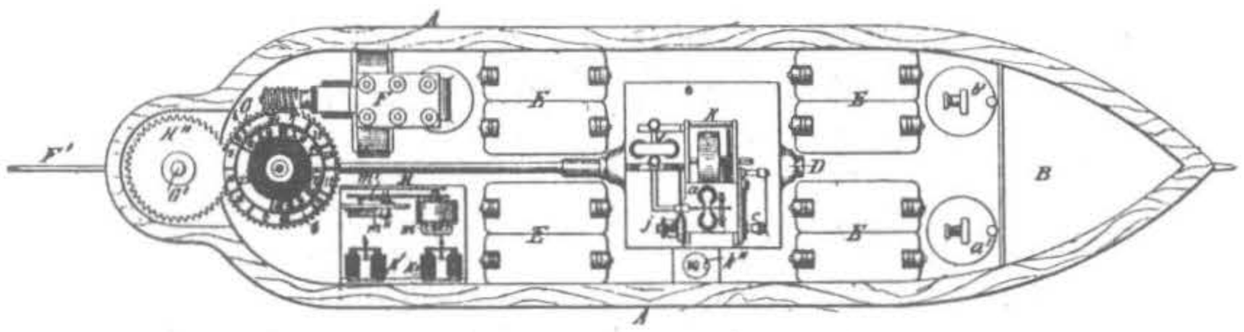

FIG. 1.—TESLA'S LATEST INVENTION—PLAN VIEW OF A VESSEL AND ITS CONTAINED MECHANISM.

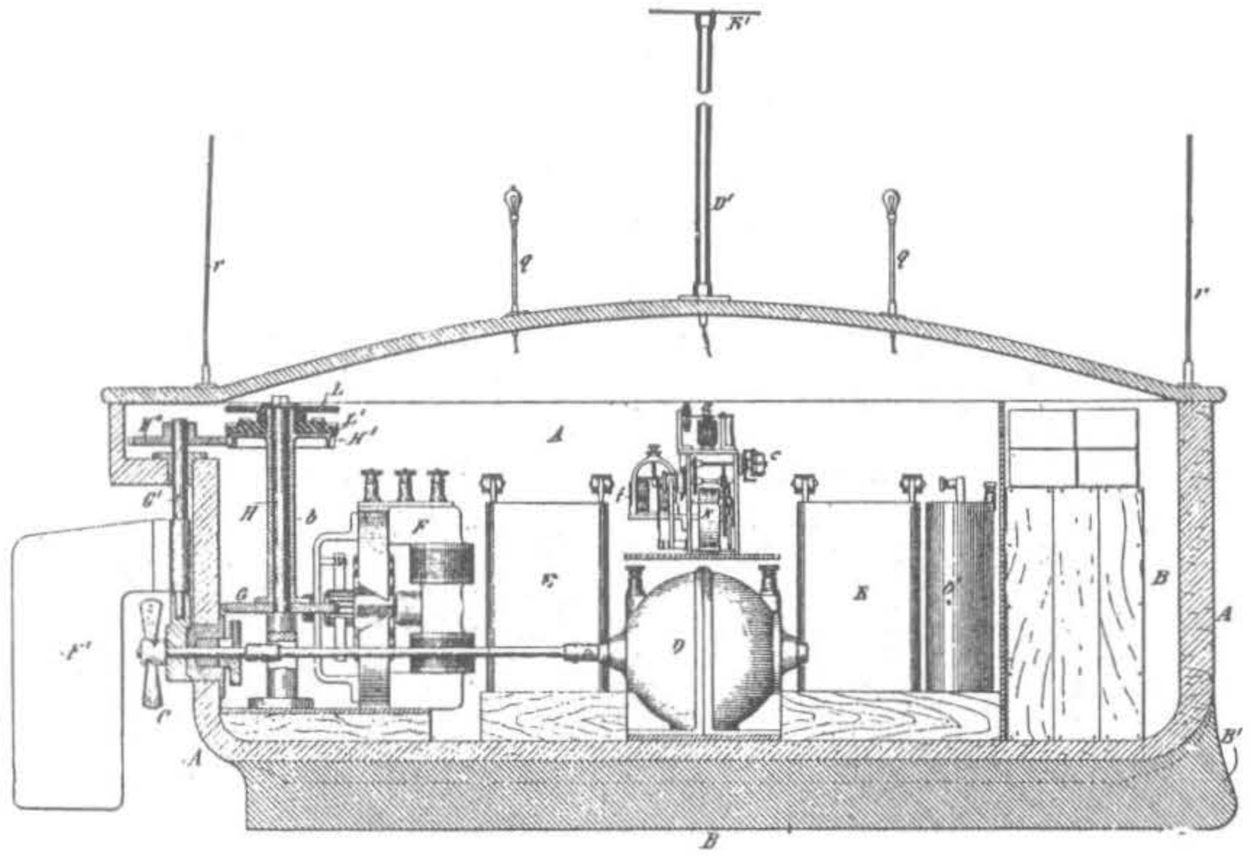

FIG. 2.—TESLA'S LATEST INVENTION—LONGITUDINAL SECTIONAL VIEW OF ELECTRICALLY CONTROLLED VESSEL AND ITS CONTAINED MECHANISM.

The ELECTRICAL REVIEW last week began the publication of a patent just issued to Nikola Tesla for the invention of means and apparatus for controlling from a given point the operation of the propelling engines, the steering apparatus and other mechanism carried by a moving object, such as a boat, or any floating vessel, whereby the movements and courses of the body or vessel may be directed and controlled from a distance, and any device carried by the same brought into action at any desired time. After stating that the production of suitable waves or radiations, and the conveying of the same to a remote receiving apparatus capable of being operated or controlled by their influence, may be carried out in various ways which are at the present time more or less understood, the specification, which is presented herewith in full, goes on to describe the apparatus used as follows:

Still another way is to pass the currents simply through the ground by connecting both the terminals of the source of high frequency currents to earth at different and remote points and to utilize the currents spreading through the ground for affecting a receiving circuit properly placed and adjusted. Again, in this instance, if only one of the terminals of the receiving circuit be connected to the ground—the other terminal being insulated—the adjustment as to synchronism with the source will require that under otherwise equal conditions the length of wire be half of that which would be used if both the terminals be connected or, generally, if the circuit be in the form of a closed loop or coil. Obviously also, in the latter case, the relative position of the receiving and transmitting circuits is of importance, whereas, if the circuit be of the former kind, that is, open, the relative position of the circuits is, as a rule, of little or no consequence.

Finally, I may avail myself, in carrying out my invention of electrical oscillations which do not follow any particular conducting path, but propagate in straight lines through space of rays, waves, pulses or disturbances

of any kind, capable of bringing the mechanism of the moving body into action from a distance and at the will of the operator by their effect upon suitable controlling devices.

In the following detailed description I shall confine myself to an explanation of that method and apparatus only which I have found to be the most practical and effectual, but obviously my invention, in its broad features, is not limited to the special mode and appliances which I have devised and shall here describe.

In any event, that is to say, whichever of the above or similar plans I may adopt, and particularly when the influence exerted from a distance upon the receiving circuit be too small to directly and reliably affect and actuate the controlling apparatus, I employ auxiliary sensitive relays, or, generally speaking, means capable of being brought into action by the feeblest influences, in order to effect the control of the movements of the distant body with the least possible expenditure of energy and at the greatest practicable distance, thus extending the range and usefulness of my invention.

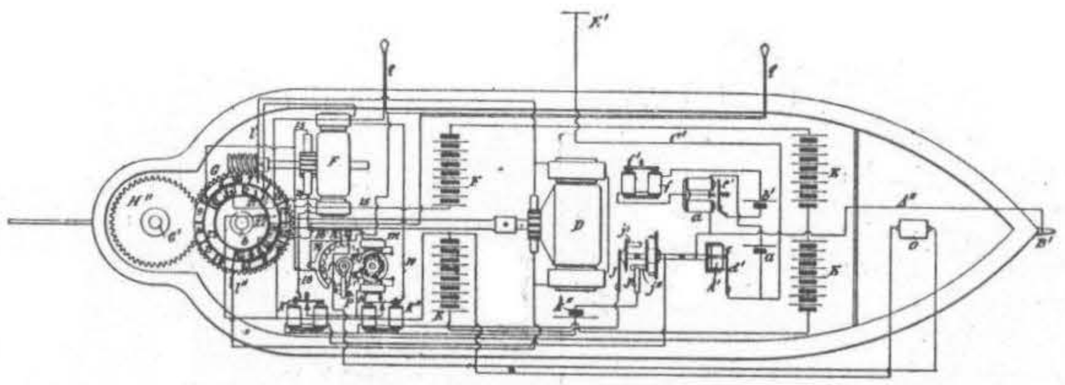
A great variety of electrical and other devices, more or less suitable for the purpose of detecting and utilizing feeble actions, are now well known to scientific men and artisans, and need not be all enumerated here.

Confining myself merely to the electrical as the most practicable of such means, and referring only to those which, while not the most sensitive, are, perhaps, more readily available, from the more general knowledge which exists regarding them, I may state that a contrivance may be used which has long been known and used as a lightning arrester, in connection with telephone switchboards for operating annunciators and like devices, and comprises a battery, the poles of which are connected to two conducting terminals separated by a minute thickness of dielectric. The electromotive force of the battery should be such as to strain the thin dielectric layer very nearly to the point of breaking down, in order to increase the sensitiveness. When an electrical disturbance reaches a circuit so arranged and adjusted, additional strain is put upon the insulating film, which gives way and allows the passage of a current which can be utilized to operate any form of circuit-controlling apparatus.

Again, another contrivance capable of being utilized in detecting feeble electrical effects, consists of two conducting plates or terminals which have preferably wires of some length attached to them and are bridged by a mass of minute particles of metal or other conducting material. Normally, these particles, lying loose, do not connect the metal plates, but, under the influence of an electrical disturbance produced at a distance, evidently owing to electro-static attraction, they are pressed firmly against each other, thus establishing a good electrical connection between the two terminals. This change of state may be made use of in a number of ways for the above purpose.

Still another modified device, which may be said to embody the features of both the former, is obtained by connecting the two conducting plates or terminals, above referred to, permanently with the poles of a battery, which should be of very constant electro-motive force. In this arrangement a distant electrical disturbance produces a two-fold effect on the conducting particles and insulating films between them. The former are brought nearer to each other in consequence of the sudden increase of electro-static attraction, and the latter, owing to this as well as by being reduced in thickness or in number, are subjected to a much greater strain which they are unable to withstand.

It will be obviously noted from the preceding that, whichever of these or similar contrivances be used, the sensitiveness, and, what is often still more important, the reliability of operation is very materially increased by a close adjustment of the periods of vibration of the transmitting and receiving circuits, and, although such adjustment is in many cases unnecessary for the successful carrying out of my invention, I nevertheless make it a rule to bestow upon this feature the greatest possible care, not only because of the above mentioned advantages which are secured by the observance of the most favorable conditions in this respect, but also, and chiefly, with the object of preventing the receiving circuit from being affected by waves or disturbances emanating from sources not under the control of the operator. The narrower the range of vibrations, which are still capable o perceptibly affecting the receiving circuit, the safer will the latter b against extraneous disturbances. T secure the best result, it is necessary as is well known to experts, to con struct the receiving circuit, or tha part of the same in which the vibra tion chiefly occurs, so that it wil have the highest possible self-induc tion and at the same time the leas possible resistance. In this manne I have demonstrated the practicability of providing a great number of such receiving circuits—50 or 100 or more—each of which may be called up or brought into action whenever desired, without the other being interfered with. This result makes it possible for one operator to direct, simultaneously, the movements of a number of bodies, as well as to control the action of a number of devices located on the same body, each of which may have a distinct duty to fulfill. In the following description, however, I shall show a still further development in this direction; namely, how, by making use of merely one receiving circuit, a great variety of devices may be actuated and any number of different functions performed at the will and command of the distant operator.



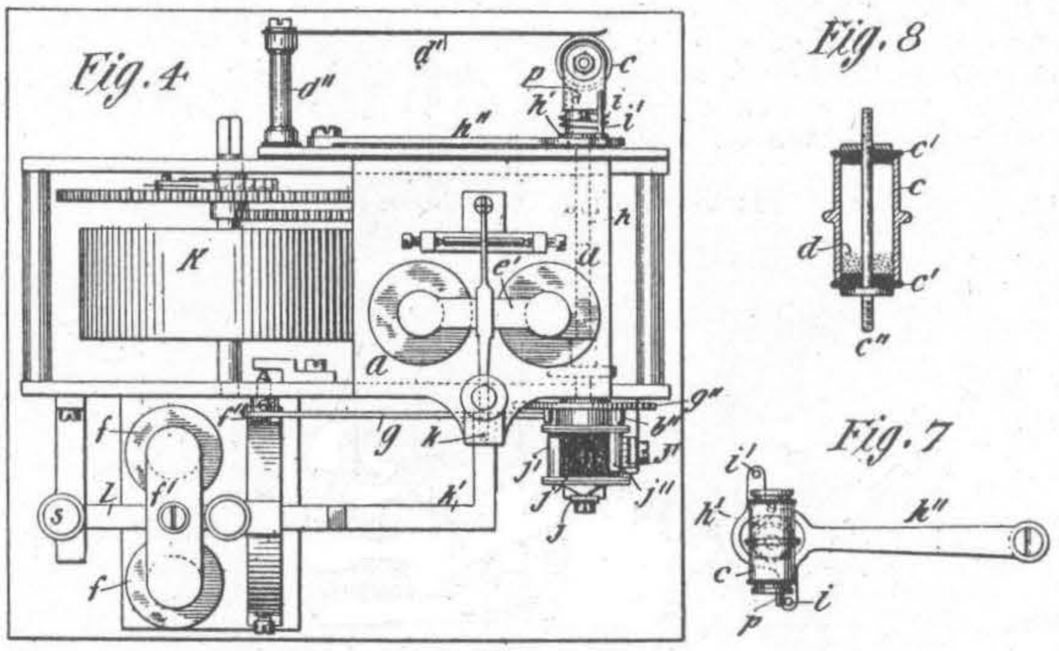


FIG. 3.—TESLA'S LATEST INVENTION—PLAN VIEW SHOWING ELECTRICAL CIRCUITS AND APPARATUS OF ELECTRICALLY CONTROLLED VESSEL.

FIGS. 4, 7 AND 8.—TESLA'S LATEST INVENTION.—DETAILS OF APPARATUS ON ELECTRICALLY CONTROLLED VESSEL.

It should be stated in advance, in regard to the sensitive devices above mentioned, which may be broadly considered as belonging to one class, inasmuch as the operation of all of them involves the breaking down of a minute thickness of highly strained dielectric, that it is necessary to make some provision for automatically restoring to the dielectric its original, unimpaired insulating qualities, in order to enable the device to be used in successive operations.

This is usually accomplished by a gentle tapping or vibration of the electrodes or particles, or continuous rotation of the same, but in long experience with many forms of these devices I have found that such procedures, while suitable in simple and comparatively unimportant operations, as ordinary signaling, when it is merely required that the succeeding effects produced in the receiving circuit should differ in regard to their relative duration only (in which case it is of little or no consequence if some of the individual effects be altered or incomplete or even entirely missed), do not yield satisfactory results in many instances, when it may be very important that the effects produced should all be exactly such as desired and that none should fail. To illustrate, let it be supposed that an official, directing the movements of a vessel in the manner described, should find it necessary to bring into action a special device on the latter, or to perform a particular operation, perhaps of vital moment, at an instant's notice, and possibly when, by design or accident, the vessel itself or any mark indicating its presence, is hidden from his view. In this instance a failure or defective action of any part of the apparatus might have disastrous consequences, and such cases, in which the sure and timely working of the machinery is of paramount importance, may often present themselves in practice, and this consideration has impressed me with the necessity of doing away with the defects in the present devices and procedures and of producing an apparatus which, while being sensitive, will also be most reliable and positive in its action. In the arrangement hereinafter described these defects are overcome in a most satisfactory manner, enabling thousands of successive operations, in all respects alike, being performed by the controlling apparatus without a single irregularity or miss being recorded. For a better understanding of these and other details of the invention as I now carry them out, I would refer to the accompanying drawings, in which

Fig. 1 is a plan view of a vessel and mechanism within the same.

Fig. 2 is a longitudinal section of the same showing the interior mechanism in side elevation.

Fig. 3 is a plan view, partially diagrammatical, of the vessel, apparatus and circuit connections of the same.

Fig. 4 is a plan view on an enlarged scale of a portion of the controlling mechanism.

Fig. 5 is an end view of the same.

Fig. 6 shows the same mechanism in side elevation.

Fig. 7 is a side view of a detail of the mechanism.

Fig. 8 is a central sectional view on a larger scale of a sensitive device forming part of the receiving circuit.

Fig. 9 is a diagrammatic illustration of the system in its preferred form.

Fig. 10 is a view of the various mechanisms employed, but on a larger scale and leaving out or indicating

conventionally certain parts of well understood character.

Referring to Fig. 1 and Fig. 2, A designates any type of vessel or vehicle which is capable of being propelled and directed, such as a boat, a balloon or a carriage. It may be designed to carry, in a suitable compartment B, objects of any kind, according to the nature of the uses to which it is to be applied. The vessel, in this instance a boat, is provided with suitable propelling machinery, which is shown as comprising a screw propeller C secured to the shaft of an electromagnetic motor D, which derives its power from storage batteries E, E, E, E.

In addition to the propelling engine or motor, the boat carries also a smaller steering motor F, the shaft of which is extended beyond its bearings and provided with a worm which meshes with a toothed wheel G. This latter is fixed to a sleeve *b*, freely movable on a vertical rod H, and is rotated in one or the other direction, according to the direction of rotation of the motor F.

The sleeve *b* on rod H is in gear through the cog wheels H′ and H″ with a spindle G′ mounted in vertical bearings at the stem of the boat and carrying the rudder F″.

The apparatus, by means of which the operation of both the propelling and steering mechanisms is controlled, involves, primarily, a receiving circuit which, for reasons before stated, is preferably both adjusted and rendered sensitive to the influence of waves or impulses emanating from a remote source, the adjustment being so that the period of oscillation of the circuit is either the same as that of the source or a harmonic thereof.

The receiving circuit proper, diagrammatically shown in Figs. 3 and 10, comprises a terminal E′, conductor C′, a sensitive device A′ and a conductor A″ leading to the ground, conveniently through a connection to the metal keel B′ of the vessel.

The terminal E′ should present a large conducting surface and should be supported as high as practicable on a standard D′, which is shown as broken in Fig. 2, but such provisions are not always necessary. It is important to insulate very well the conductor C′, in whatever manner it be supported.

The circuit or path just referred to forms also a part of a local circuit, which latter includes a relay magnet *a* and a battery *a′*, the electro-motive force of which is, as before explained, so determined that although the dielectric layers in the sensitive device A′ are subjected to a great strain, yet normally they withstand the strain and no appreciable current flows through the local circuit. But when an electrical disturbance reaches the circuit, the dielectric films are broken down, the resistance of the device A′ is suddenly and greatly diminished and a current traverses the relay magnet *a*.

The particular sensitive device employed is shown in general views and in detail in Figs. 4, 6, 7 and 8. It consists of a metal cylinder *c* with insulating heads *c′*, through which passes a central metallic rod *c″*. A small quantity of grains *d* of conducting material, such as an oxidized metal, is placed in the cylinder.

A metallic strip *d′*, secured to an insulating post *d″*, bears against the side of the cylinder *c*, connecting it with the conductor C′, forming one part of the circuit. The central rod *c″* is connected to the frame of the instrument and so to the other part of the circuit through the forked metal arm *e*, the ends of which are fastened with two nuts to the projecting ends of the rod, by which means the cylinder *c* is supported.

In order to interrupt the flow of battery current, which is started through the action of the sensitive device A′, special means are provided, which are as follows: The armature *e′* of the magnet *a*, when attracted by the latter, closes a circuit containing a battery *b′* and magnet *f*. The armature lever *f′* of this magnet is fixed to a rock shaft *f″*, to which is secured an anchor escapement *g*, which controls the movements of a spindle *g′*, driven by a clock train K.

The spindle *g′* has fixed to it a disk *g″*, with four pins *b″*, so that for each oscillation of the escapement *g* the spindle *g′* is turned through one-quarter of a revolution.

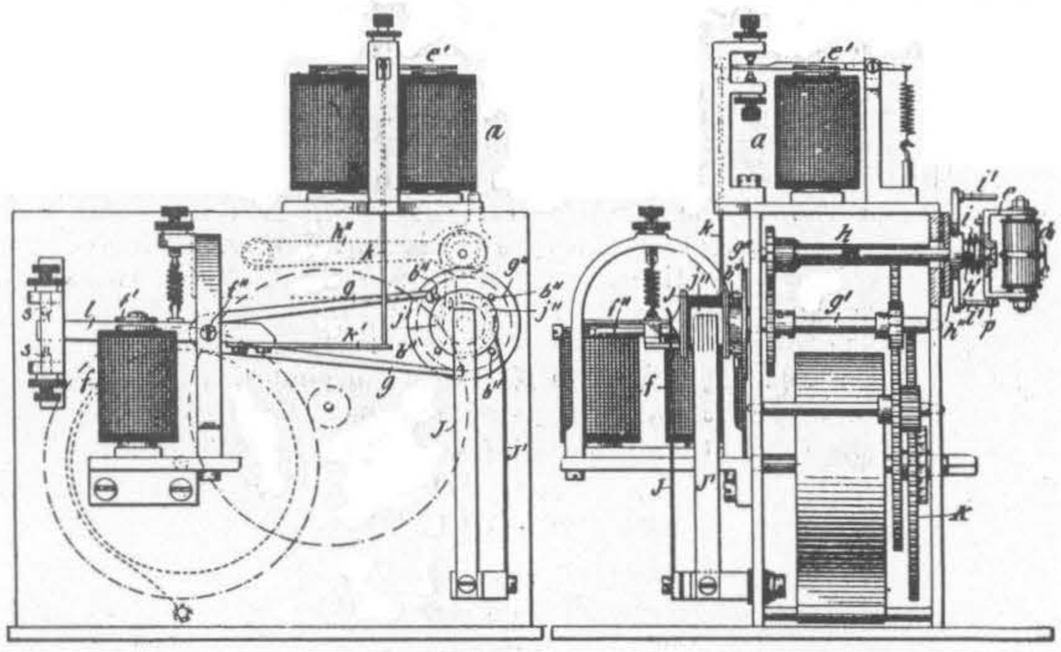
One of the spindles in the clock train, as *h*, is geared so as to make one-half of a revolution for each quarter revolution of spindle *g′*. The end of the former spindle extends through the side of the frame and carries an eccentric cylinder *h′*, which passes through a slot in a lever *h″*, pivoted to the side of the frame

The forked arm *e*, which supports the cylinder *c*, is pivoted to the end of an eccentric *h′*, and the eccentric and said arm are connected by a spiral spring *l*.

Two pins *i′ i″* extend out from the lever *h″*, and one of these is always in the path of a projection on arm *e*. They operate to prevent the turning of cylinder *c* with the spindle *h* and the eccentric. It will be evident that a half revolution of the spindle *h* will wind up the spring *i*, and at the same time raise or lower the lever *h″*, and these parts are so arranged that just before the half revolution of the spindle is completed, the pin *i″*, in engagement with projection or stop pin *p′*, is withdrawn from its path, and the cylinder *c*, obeying the force of the spring *i*, is suddenly turned end for end, its motion being checked by the other pin *i′*.

The adjustment relatively to armature *f′* of magnet *f* is furthermore so made that the pin *i″* is withdrawn at the moment when the armature has nearly reached its extreme position in its approach towards the magnet, that is, when the lever *l*, which carries the armature *f′*, almost touches the lower one of the two stops *ss*, Fig. 5, which limits its motion in both directions.

The arrangement just described has been the result of long experimenting with the object of overcoming certain defects in devices of this kind, to which reference has been made before.



These defects I have found to be due to many causes, as the unequal size, weight and shape of the grains, the unequal pressure which results from this and from the manner in which the grains are usually agitated, the lack of uniformity in the conductivity of the surface of the particles, owing to the varying thickness of the superficial oxidized layer, the varying condition of the gas or atmosphere in which the particles are immersed and to certain deficiencies, well known to experts, of the transmitting apparatus as heretofore employed, which are in a large measure reduced by the use of my improved high-frequency coils. To do away with the defects in the sensitive device, I prepare the particles so that they will be in all respects as nearly alike as possible. They are manufactured by a special tool insuring their equality in size, weight and shape, and are then uniformly oxidized by placing them for a given time in an acid solution of predetermined strength. This secures equal conductivity of their surfaces and stops their further deterioration, thus preventing a change in the character of the gas in the space in which they are enclosed. I prefer not to rarefy the atmosphere within the sensitive device, as this has the effect of rendering the former less constant in regard to its dielectric properties, but merely secure an air-tight enclosure of the particles and rigorous absence of moisture, which is fatal to satisfactory working.

The normal position of the cylinder *c* is vertical, and when turned in the manner described, the grains in it are simply shifted from one end to the other. But inasmuch as they always fall through the same space and are subjected to the same agitation, they are brought, after each operation of the relay, to precisely the same electrical condition, and offer the same resistance to the flow of the battery current until another impulse from afar reaches the receiving circuit.

The relay magnet *a* should be of such character as to respond to a very weak current and yet be positive in its action. To insure the retraction of its armature *e′*, after the current has been established through the magnet *f* and interrupted by the inversion of the sensitive device *c*, a light rod *k* is supported in guides on the frame in position to be lifted by an extension *k′* of the armature lever *l* and to raise slightly the armature *e′*. As a feeble current may normally flow through the sensitive device and the relay magnet *a*, which would be sufficient to hold, though not draw, the armature down, it is well to observe this precaution.

The operation of the relay magnet *a* and the consequent operation of electro-magnet *f*, as above described, are utilized to control the operation of the propelling engine and the steering apparatus in the following manner:

On the spindle *g′*, which carries the escapement disk *g″*, Fig. 4 and Fig. 6, is a cylinder *j*, of insulating material with a conducting plate or head at each end. From these two heads respectively contact plates or segments *j′ j″* extend on diametrically opposite sides of the cylinder. The plate *j″* is in electrical connection

FIGS. 5 AND 6.—TESLA'S LATEST INVENTION.—SIDE VIEW AND SIDE ELEVATION OF A PORTION OF THE CONTROLLING MECHANISM ON AN ELCTRICALLY CONTROLLED VESSEL.

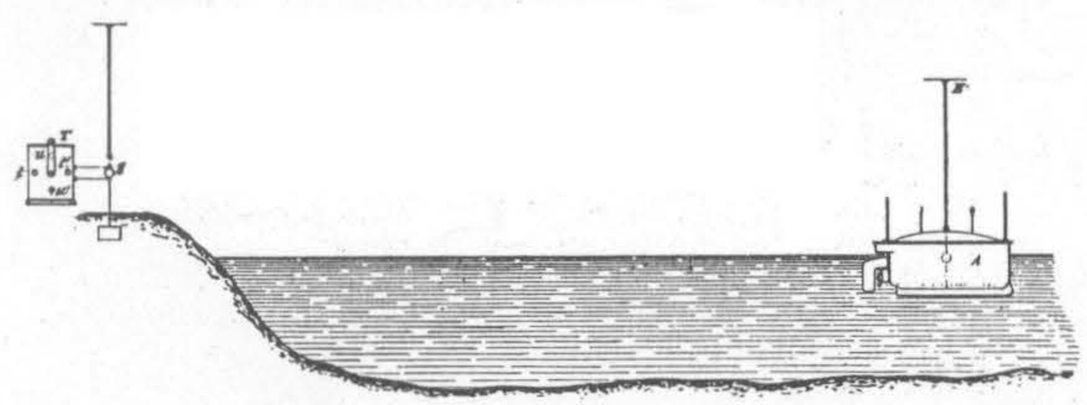


FIG. 9.—TESLA'S LATEST INVENTION.—DIAGRAM OF ELECTRICALLY CONTROLLED VESSEL SYSTEM.

with the frame of the instrument through the head from which it extends, while insulated strips or brushes J J' bear upon the free end or head of the cylinder and the periphery of the same respectively. Three terminals are thus provided, one always in connection with plate j', the other always in connection with the plate j'', and the third adapted to rest on the strips j' and j'' in succession or upon the intermediate insulating spaces, according to the position in which the commutator is brought by the clock train and the anchor escapement g.

K' K'', Figs. 1, 3 and 10, are two relay magnets, conveniently placed in the rear of the propelling engine. One terminal of a battery k'' is connected to one end of each of the relay coils; the opposite terminal to the brush J', and the opposite ends of the relay coils to the brush J, and to the frame of the instrument respectively. As a consequence of this arrangement either the relay K' or K'' will be energized, as the brush J' bears upon the plate j' or j'' respectively, or both relays will be inactive while the brush J' bears upon an insulating space between the plates j' and j''.

While one relay, as K', is energized, its armature closes a circuit through the motor F, which is rotated in a direction to throw the rudder to port. On the other hand, when relay K'' is active, another circuit through the motor F is closed, which reverses its direction of rotation and shifts the rudder to starboard. These circuits, however, are at the same time utilized for other purposes, and their course is, in part, through apparatus which I shall describe before tracing their course.

The fixed rod H carries an insulating disk or head L, Fig. 2, to the under line of which are secured six brushes, 1, 2, 3, 4, 5 and 6, Fig. 3. The sleeve b, which surrounds the rod and is turned by the steering motor F, carries a disk L', upon the upper face of which are two concentric circles of conducting contact plates Brushes 1, 2, 3 and 4 bear upon the inner circle of contacts, while the brushes 5 and 6 bear upon the outer circle of contacts.

The outer circle of contacts comprises two long plates, 7 and 8, on opposite sides of the disk, and a series of shorter plates, 9, 10, 11, 12, 13 and 14, in the front and rear. Flexible conductors l l' connect the plates 7 and 8 with the terminals of the propelling motor D, and the poles of the main battery E are connected to the brushes 5 and 6 respectively, so that, while the rudder is straight or turned up to a certain angle to either side, the current is conveyed through the brushes 5 and 6 and segments 7 and 8 to the propelling motor D.

The steering motor F is also driven by current taken from the main battery E in the following manner. A conductor 15, from one pole of the battery, leads to one of the commutator brushes, and from the other brush runs a conductor 16 to one of the contacts of each relay K' K''. When one of these relays, as K'', is active, it continues this circuit through a wire 19, through one field-coil or set of field coils on the motor F, and thence to the brush l. In a similar manner, when the other relay K' is active, the circuit is continued from wire 18, through a wire 20, the second or reversing set of field-coils, and to brush 2.

Both brushes 1 and 2, at all times when the rudder is not turned more than about 45 degrees to one side, are in contact with a long-conducting plate 21, and one brush, in any position of the rudder, is always in contact with said plate, and the latter is connected by a flexible conductor 22 with the opposite pole of the main battery. Hence the motor F may always be caused to rotate in one direction, whatever may be the position of the rudder, and may be caused to rotate in either direction whenever the position of the rudder is less than a predetermined angle, conveniently forty-five degrees from the center position.

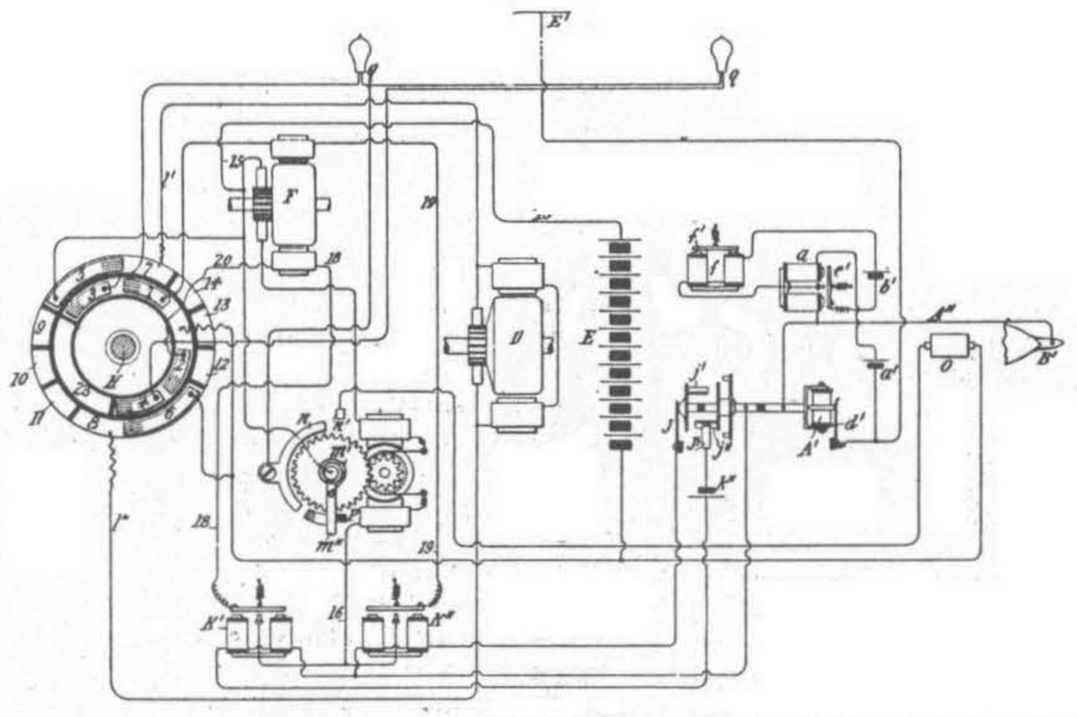

FIG. 10.—TESLA'S LATEST INVENTION—VIEW OF VARIOUS MECHANISMS EMPLOYED ON ELECTRICALLY CONTROLLED VESSEL.

In order, however, to prevent the rudder from being turned too far in either direction, the isolated plate 23 is used. Any movement of the rudder beyond a predetermined limit brings this plate under one or the other of the brushes 1, 2, and breaks the circuit of motor F, so that the rudder can be driven no further in that direction, but, as will be understood, the apparatus is in condition to turn the rudder over to the other side.

In like manner the circuit of the propelling motor D is controlled through brushes 5 and 6 and the segments on the outer circle of contacts of head L If the short segments on either side of the circle are insulated, the motor D will be stopped whenever one of the brushes 5 or 6 passes onto one of them from the larger segments 7, 8.

It is important to add that on all contact points where a break occurs, provision should be made to overcome the sparking and prevent the oscillation of electrical charges in the circuits, as such sparks and oscillations may affect the sensitive device. It is this consideration chiefly which makes it advisable to use the two relays K' K'', which otherwise might be dispensed with. They should be also placed as far as practicable from the sensitive device in order to guard the latter against any action of strong varying currents.

In addition to the mechanism described the vessel may carry any other device or apparatus as might be required for accomplishing any special object of more or less importance. By way of illustration, a small motor m is shown (Figs. 1 and 3), which conveniently serves for a number of purposes. This motor is shown connected in series with the armature of the steering motor F, so that, whenever either one of the circuits of the latter is closed through relays K' K'', the motor m is likewise rotated, but in all cases in the same direction. Its rotation is opposed by a spring m', so that, in normal operation, owing to the fact that the circuits of motor F are closed but a short time, the lever m'' which is fastened to one of the wheels of clockwork M, with which the armature of the motor is geared, will move but a short distance, and upon cessation of the current return to a stop P. But if the circuits of the motor F are closed and opened rapidly in succession, which operation leaves the rudder unaffected, then the lever m'' is moved to a greater angle, coming in contact with a metal plate n, and finally, if desired, with a post n'.

Upon the lever m'' coming in contact with plate n, the current of the main battery passes either through one or other or both of the lights supported on standards q q, according to the position of brushes 3 and 4 relatively to the insulating segment 23. But since the head L carrying the segments is geared to the rudder, the position of the latter is in a general way determined by observing the lights. Both of the lights may be colored, and by flashing them up whenever desired the operator may guide at night the vessel in its course. For such purposes also the standards r r are provided, which should be painted in lively colors, so as to be visible at great distances.

By opening and closing the circuits of motor F a greater number of times, preferably determined beforehand, the lever m'' is brought in contact with post n', thus closing the circuit of the main battery through a device o and bringing the latter into action at the moment desired. By similar contrivances, or such as will readily suggest themselves to mechanicians, any number of different devices may be operated.

Referring now to Fig. 9, which illustrates diagrammatically the system as practiced when directing the movements of a boat:

In this figure S designates any source of electrical disturbance or oscillations, the generation of which is controlled by a suitable switch contained in box T. The handle of the switch is movable in one direction only, and stops on four points, t, t', u, u', so that, as the handle passes from stop to stop, oscillations are produced by the source during a very short time interval. There are thus produced four disturbances during one revolution, and the receiving circuit is affected four times; but it will be understood from the foregoing description of the controlling devices on the vessel that the rudder will be moved twice, once to right and once to left. Now I preferably place the handle of the switch so that, when it is arrested on points t, t'—that is, to the right or left of the operator—he is reminded that the vessel is being deflected to the right or left from its course, by which means the control is facilitated. The normal positions of the handle are therefore at u, u' when the rudder is not acted upon, and it remains on the points t, t' only so long as necessary. Since, as before stated, the working of the apparatus is very sure, the operator is enabled to perform any such operations as provision is made for without even seeing the vessel.

The manner of using the apparatus and the operation of the several instrumentalities comprising the same is, in detail, as follows: Normally, the plate L' is turned so that brush 2 rests upon the insulated segment 23, and brush 6 upon one of the isolated short segments in the rear of the circle. Under these conditions the rudder will be turned to starboard and the circuit of motor D interrupted between brushes 5 and 6. At the same time, only one of the circuits of motor F—that controlled by relay K'—is capable of being closed, since brush 2, which connects with the other, is out of contact with the long segment 21.

Assuming now that it is desired to start the vessel and direct it to a given point. The handle T is turned from its normal position on u' to the point t on the switch-box. This sends out an electrical disturbance which, passing through the receiving circuit on the vessel, affects the sensitive device A' and starts the flow of current through the local circuit, including said device, the relay a and the battery a'. This, as has been previously explained, turns the cylinder j and causes the brush J' to pass from insulation onto the contact j'.

(Concluded on page 312.)

TESLA'S LATEST INVENTION.

(*Concluded from page 308.*)

The battery *k*'' is thus closed through relay K'', and the latter closes that circuit of the motor F which, starting from plate 22, which is permanently connected with one pole of the main battery, is completed through the brush 1, the field of motor F, wire 19, the armature of relay K'', wire 16, the motor *m*, the brushes and commutator of motor F, and wire 15 to the opposite terminal of the battery E. Motor F is thus set in operation to shift the rudder to port, but the movement of plate L', which follows, brings the brush 6 back onto segment 8 and closes the circuit of the propelling motor, which starts the vessel.

The motor F is permitted to run until the rudder has been turned sufficiently to steer the vessel in the desired direction, when the handle T is turned to the point *u*. This produces another action of the relay *a*, and brush J' is shifted onto insulation and both relays K' and K* are inactive.

The rudder remains in the position to which it has been shifted by the motor F. If it be then desired to shift it to starboard or in the opposite direction to that in which it was last moved, the handle T is simply turned to point *t'* and allowed to remain there until the motor F, which is now operated by relay K', the circuit of which is closed by strip J' coming into contact with plate *j**, has done its work.

The movement of handle T to the next point throws out both relays K' and K*, and the next movement causes a shifting of the rudder to port, and so on. Suppose, however, that after the rudder has been set at any angle to its middle position, it be desired to shift it still further in the same direction. In such case, the handle is moved quickly over two points, so that the circuit which would move the rudder in the opposite direction is closed for too short a time interval to produce an appreciable effect, and is allowed to rest on the third point until the rudder is shifted to the desired position, when the handle is moved to the next point, which again throws out both relays K' and K*. It will be understood that, if the handle be held for a sufficiently long time upon either point *t* or *t'*, the motor will simply turn the plate L' in one direction or the other until the circuits of motors D and F are broken. It is furthermore evident that one relay K' or K* will always be operative to start the motor F.

As previously explained the longest period of operation of which the motor F is capable, under ordinary conditions of use, does not permit the motor *m* to shift the arm *m'* into contact with the plate *n*. But if the handle T be turned with a certain rapidity a series of current impulses will be directed through motor *m*, but, as these tend to rotate the motor F in opposite directions, they do not sensibly affect the latter, but act to rotate the motor *m* against the force of the coiled spring.

The invention which I have described will prove useful in many ways. Vessels or vehicles of any suitable kind may be used as life, despatch or pilot boats or the like or for carrying letters, packages, provisions, instruments, objects or materials of any description, for establishing communication with inaccessible regions and exploring the conditions existing in the same, for killing or capturing whales or other animals of the sea, and for many other scientific, engineering or commercial purposes. But the greatest value of my invention will result from its effect upon warfare and armaments, for, by reason of its certain and unlimited destructiveness, it will tend to bring about and maintain permanent peace among nations.

Having now described my invention, what I claim is:

1. The improvement in the art of controlling the movements and operation of a vessel or vehicle herein described, which consists in producing waves or disturbances which are conveyed to the vessel by the natural media, actuating thereby suitable apparatus on the vessel and effecting the control of the propelling engine, the steering and other mechanism by the operation of the said apparatus, as set forth.

2. The improvement in the art of controlling the movements and operation of a vessel or vehicle, herein described, which consists in establishing a region of waves or disturbances, and, actuating by their influence exerted at a distance, the devices on such vessel or vehicle, which control the propelling, steering and other mechanism thereon, as set forth.

3. The improvement in the art of controlling the movements and operation of a vessel or vehicle, herein described, which consists in establishing a region of electrical waves or disturbances, and, actuating by their influence exerted at a distance, the devices on said vessel or vehicle, which control the propelling, steering and other mechanism thereon, as set forth.

4. The improvement in the art of controlling the movements and operation of a vessel or vehicle, herein described, which consists in providing on the vessel a circuit controlling the propelling, steering and other mechanism, adjusting or rendering such circuit sensitive to waves or disturbances of a definite character, establishing a region of such waves or disturbances, and rendering by their means the controlling circuit active or inactive, as set forth.

5. The combination with a source of electrical waves or disturbances of a moving vessel or vehicle, and mechanism thereon for propelling, steering or operating the same, and a controlling apparatus adapted to be actuated by the influence of the said waves or disturbances at a distance from the source, as set forth.

6. The combination with a source of electrical waves or disturbances of a moving vessel or vehicle, mechanism for propelling, steering or operating the same, a circuit and means therein for controlling said mechanism, and means for rendering said circuit active or inactive through the influence of the said waves or disturbances exerted at a distance from the source, as set forth.

7. The combination with a source of electrical waves or disturbances and means for starting and stopping the same, of a vessel or vehicle, propelling and steering mechanism carried thereby, a circuit containing or connected with means for controlling the operation of said mechanism and adjusted or rendered sensitive to the waves or disturbances of the source, as set forth.

8. The combination with a source of electrical waves or disturbances, and means for starting and stopping the operation of the same, of a vessel or vehicle, propelling and steering mechanism carried thereby, local circuits controlling said mechanisms, a circuit sensitive to the waves or disturbances of the source and means therein adapted to control the said local circuits, as and for the purpose set forth.

9. The sensitive device herein described comprising in construction a receptacle containing a material such as particles of oxidized metal forming a part of the circuit, and means for turning the same end for end when the material has been rendered sensitive by the passage through it of an electric discharge, as set forth.

10. The sensitive device herein described, comprising in combination a receptacle containing a material such as particles of oxidized metal forming a part of an electric circuit, an electromagnet in said circuit, and devices controlled thereby for turning the receptacle end for end when said magnet is energized, as set forth.

11. The sensitive device herein described, comprising in combination a receptacle containing a material such as particles of oxidized metal forming part of an electric circuit, a motor for rotating the receptacle, an electromagnet in circuit with the material, and an escapement controlled by said magnet and adapted to permit a half revolution of the receptacle when the said magnet is energized, as set forth.

12. The combination with a movable body or vehicle, of a propelling motor, a steering motor and electrical contacts carried by a moving portion of the steering mechanism, and adapted in certain positions of the latter to interrupt the circuit of the propelling motor, a local circuit and means connected therewith for controlling the steering motor, and a circuit controlling the local circuit and means for rendering said controlling circuit sensitive to the influence of electric waves or disturbances exerted at a distance from their source, as set forth.

13. The combination with the steering motor, a local circuit for directing current through the same in opposite directions, a controlling circuit rendered sensitive to the influence of electric waves or disturbances exerted at a distance from their source, a motor in circuit with the steering motor, but adapted to run always in the same direction, and a local circuit or circuits controlled by said motor, as set forth.

lectrical Review

D IST ELECTRICAL WEEKLY IN THE UNITED STATES.]

TIMES BUILDING, 41 PARK ROW,

BOX 2339. NEW YORK.

IEW YORK, NOVEMBER 16, 1898.

TESLA'S PEACE MANIFESTO.

We conclude in this issue the full text of the specifications of the patent issued to Nikola Tesla last week, and which excited such unusually widespread interest, more especially in military circles. Although Tesla contemplates in the description of his marvelous invention chiefly its uses in peace, its tremendous importance in regard to its powers in warfare did not escape the keen perceptions of our alert army and navy officials.

We think that the numerous press comments did not really bring out with sufficient clearness the revolutionary features of the invention, particularly in regard to the furtherance of the noble cause which the Czar of Russia voices in his stirring peace manifesto. Naturally our heroes are keenly disappointed at the prospect of having no wars, but the every-day citizen will hail with joy the success of Tesla's humane efforts.

The ability to control with precision, from a distance of a score of miles the movements of a vessel with no soul on board—to call any of its numerous appliances into play, at any desired moment—would of itself be a stupendous achievement. But when this vessel in addition has the power of distinguishing with almost human intelligence the orders which it receives from afar, though silent and invisible—obeying only those for which the builder designed it, and remaining unresponsive to all others—the imagination staggers when following the immediate consequences of such an unheard-of result. Inventions of a startling character have been made before, but most of them have been the result of gradual development. Here the inventor has given us an entirely new and wonderful art. There is something appalling, awe-inspiring in Tesla's invention.

The Electrical Engineer.

MISCELLANEOUS

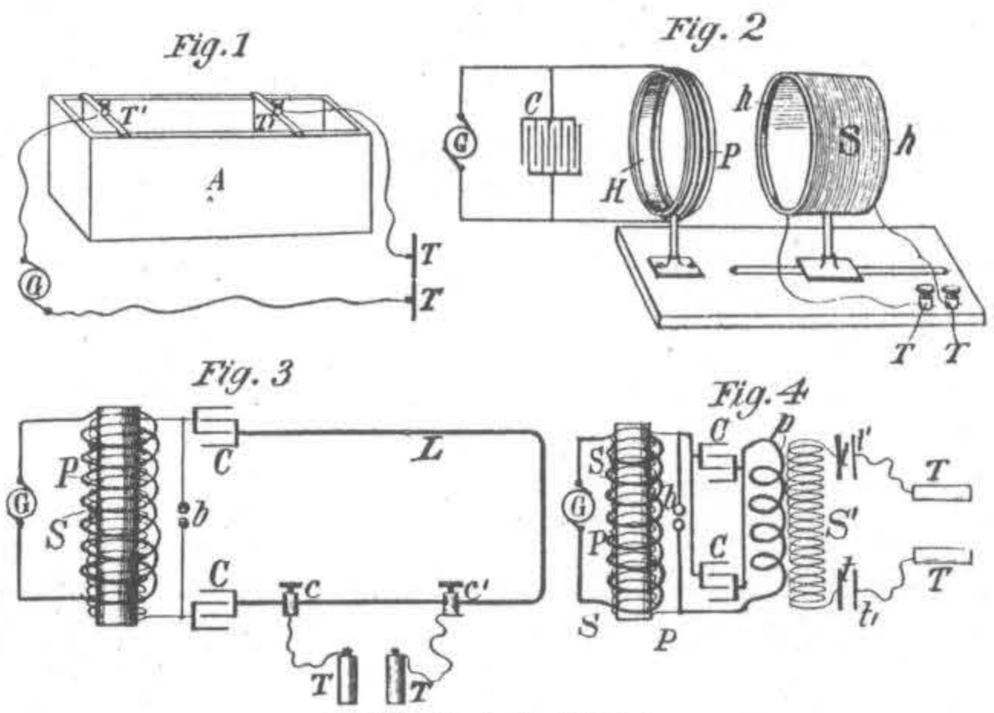
High Frequency Oscillators for Electro-therapeutic and Other Purposes.[1]

BY NIKOLA TESLA.

SOME theoretical possibilities offered by currents of very high frequency and observations which I casually made while pursuing experiments with alternating currents, as well as the stimulating influence of the work of Hertz and of views boldly put forth by Oliver Lodge, determined me some time during 1889 to enter a systematic investigation of high frequency phenomena, and the results soon reached were such as to justify further efforts towards providing the laboratory with efficient means for carrying on the research in this particular field, which has proved itself so fruitful since. As a consequence alternators of special design were constructed and various arrangements for converting ordinary into high frequency currents perfected, both of which were duly described and are now —I assume—familiar.

One of the early observed and remarkable features of the high frequency currents, and one which was chiefly of interest to the physician, was their apparent harmlessness which made it possible to pass relatively great amounts of electrical energy through the body of a person without causing pain or serious discomfort. This peculiarity which, together with other mostly unlooked-for properties of these currents I had the honor to bring to the attention of scientific men first in an article in a technical journal in February, 1891, and in subsequent contributions to scientific societies, made it at once evident, that these currents would lend themselves particularly to electro-therapeutic uses.

With regard to the electrical actions in general, and by analogy, it was reasonable to infer that the physiological effects, however complex, might be resolved in three classes. First the statical, that is, such as are chiefly dependent on the magnitude of electrical potential; second, the dynamical, that is, those principally dependent on the quality of electrical movement or current's strength through the body, and third, effects of a distinct nature due to electrical waves or oscillations, that is, impulses in which the electrical energy is alternately passing in more or less rapid succession through the static and dynamic forms.



Most generally in practice these different actions are coexistent, but by a suitable selection of apparatus and observance of conditions the experimenter may make one or other of these effects predominate. Thus he may pass through the body, or any part of the same, currents of comparatively large volume under a small electrical pressure, or he may subject the body to a high electrical pressure while the current is negligibly small, or he may put the patient under the influence of electrical waves transmitted, if desired, at considerable distance through space.

While it remained for the physician to investigate the specific actions on the organism and indicate proper methods of treatment, the various ways of applying these currents to the body of a patient suggested themselves readily to the electrician.

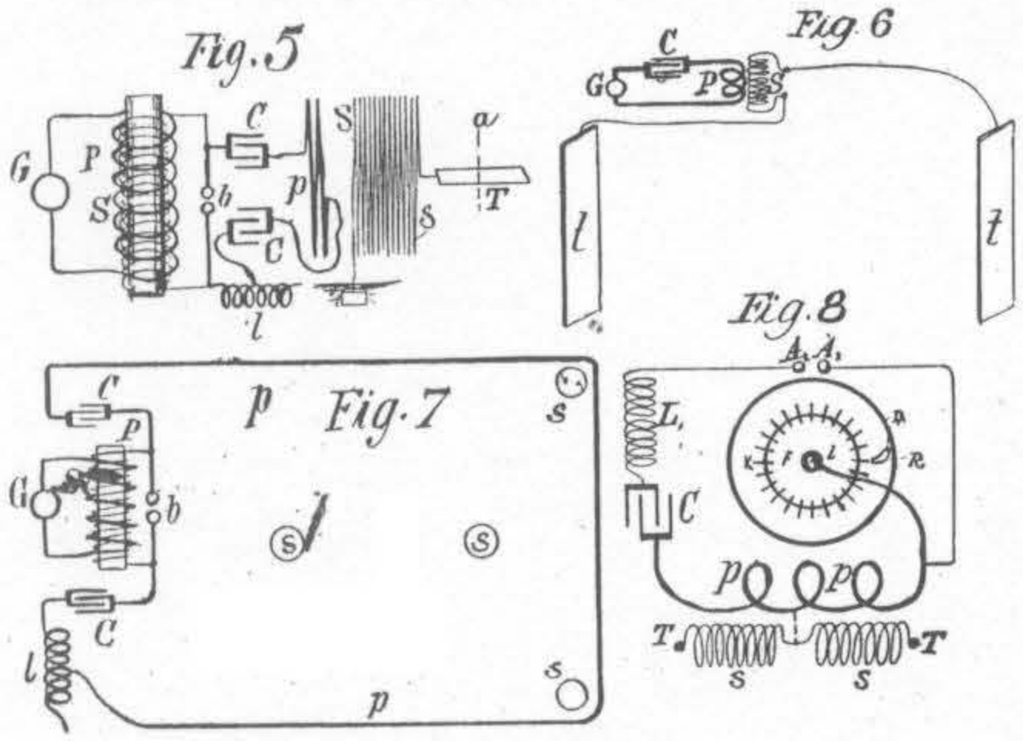
As one cannot be too clear in describing a subject, a diagrammatic illustration of the several modes of connecting the circuits which I will enumerate, though obvious for the majority, is deemed of advantage.

The first and simplest method of applying the currents was to connect the body of the patient to two points of the generator, be it a dynamo or induction coil. Fig. 1 is intended to illustrate this case. The alternator G may be one giving from five to ten thousand complete vibrations per second, this number being still within the limit of practicability. The electromotive force—as measured by a hot wire instrument—may be from fifty to one hundred volts. To enable strong currents to be passed through the tissues, the terminals T T, which serve to establish contact with the patient's body should, of course, be of large area, and covered with cloth saturated with a solution of electrolyte harmless to the skin, or else the contacts are made by immersion. The regulation of the currents is best effected by means of an insulating trough A provided with two metal terminals T' T' of considerable surface, one of which, at least, should be movable. The trough is filled with water, and an electrolytic solution is added to the same, until a degree of conductivity is obtained suitable for the experiments.

When it is desired to use small currents of high tension, a secondary coil is resorted to, as illustrated in Fig. 2. I have found it from the outset convenient to make a departure from the ordinary ways of winding the coils with a considerable number of small turns. For many reasons the physician will find it better to provide a large hoop H of not less than, say, three feet in diameter and preferably more, and to wind upon it a few turns of stout cable P. The secondary coil S is easily prepared by taking two wooden hoops h h and joining them with stiff cardboard. One single layer of ordinary magnet wire, and not too thin at that, will be generally sufficient, the number of turns necessary for the particular use for which the coil is intended being easily ascertained by a few trials. Two plates of large surface, forming an adjustable condenser, may be used for the purpose of synchronizing the secondary with the primary circuit, but this is generally not necessary. In this manner a

FIGS. 1, 2, 3 AND 4.

cheap coil is obtained, and one which cannot be easily injured. Additional advantages, however, will be found in the perfect regulation which is effected merely by altering the distance between the primary and secondary, for which adjustment provision should be made, and, furthermore, in the occurrence of harmonics which are more pronounced in such large coils of thick wire, situated at some distance from the primary.



The preceding arrangements may also be used with alternating or interrupted currents of low frequency, but certain peculiar properties of high frequency currents make it possible to apply the latter in ways entirely impracticable with the former.

One of the prominent characteristics of high frequency or, to be more general, of rapidly varying currents, is that they pass with difficulty through stout conductors of high self-induction. So great is the obstruction which self-induction offers to their passage that it was found practicable, as shown in the early experiments to which reference has been made, to maintain differences of potential of many thousands of volts between two points—not more than a few inches apart—of a thick copper bar of inappreciable resistance. This observation naturally suggested the disposition illustrated in Fig. 3. The source of high frequency impulses is in this instance a familiar type of transformer which may be supplied from a generator G of ordinary direct or alternating currents. The transformer comprises a primary P, a secondary S, two condensers C C which are joined in series, a loop or coil of very thick wire L and a circuit interrupting device or break b. The currents are derived

[1]Read at the eighth annual meeting of The American Electro-Therapeutic Association, Buffalo, N. Y., Sept. 13 to 15, 1898.

from the loop L by two contacts c c', one or both of which are capable of displacement along the wire L. By varying the distance between these contacts, any difference of potential, from a few volts to many thousands, is readily obtained on the terminals or handles T T. This mode of using the currents is entirely safe and particularly convenient, but it requires a very uniform working of the break b employed for charging and discharging the condenser.

Another equally remarkable feature of high frequency impulses was found in the facility with which they are transmitted through condensers, moderate electromotive forces and very small capacities being required to enable currents of considerable volume to pass. This observation made it practicable to resort to a plan such as indicated in Fig. 4. Here the connections are similar to those shown in the preceding case, except that the condensers C C are joined in parallel. This lowers the frequency of the currents, but has the advantage of allowing the working with a much smaller difference of potential on the terminals of the secondary S. Since the latter is the chief item of expense of such apparatus and since its price rapidly increases with the number of turns required, the experimenter will find it generally cheaper to make a sacrifice in the frequency, which, however, will be high enough for most purposes. However, he only needs to reduce proportionately the number of turns or the length of primary p to obtain the same frequency as before, but the economy of transformation will be somewhat

FIGS. 5, 6, 7 AND 8.

reduced in so doing and the break b will require more attention. The secondary S^1 of the high frequency coil has two metal plates t t of considerable surface connected to its terminals, and the current for use is derived from two similar plates t' t' in proximity to the former. Both the tension and volume of the currents taken from terminals T T may be easily regulated and in a continuous manner by simply varying the distance between the two pair of plates t t and t' t' respectively.

A facility is also afforded in this disposition for raising or lowering the potential of one of the terminals T, irrespective of the changes produced on the other terminal, this making it possible to cause a stronger action on one or other part of the patient's body.

The physician may find it for some or other reason convenient to modify the arrangements in Figs. 2, 3 and 4 by connecting one terminal of the high frequency source to the ground. The effects will be in most respects the same, but certain peculiarities will be noted in each case. When a ground connection is made it may be of some consequence which of the terminals of the secondary is connected to the ground, as in high frequency discharges the impulses of one direction are generally preponderating.

Among the various noteworthy features of these currents there is one which lends itself especially to many valuable uses. It is the facility which they afford for conveying large amounts of electrical energy to a body entirely insulated in space. The practicability of this method of energy transmission, which is already receiving useful applications and promises to become of great importance in the near future, has helped to dispel the old notion assuming the necessity of a return circuit for the conveyance of electrical energy in any considerable amount. With novel appliances we are enabled to pass through a wire, entirely insulated on one end, currents strong enough to fuse it, or to convey through the wire any amount of energy to an insulated body. This mode of applying high frequency currents in medical treatment appears to me to offer the greatest possibilities at the hands of the physician. The effects produced in this manner possess features entirely distinct from those observed when the currents are applied in any of the before mentioned or similar ways.

The circuit connections as usually made are illustrated schematically in Fig. 5, which, with reference to the diagrams before shown, is self-explanatory. The condensers C C, connected in series, are preferably charged by a step-up transformer, but a high frequency alternator, static machine, or a direct current generator, if it be of sufficiently high tension to enable the use of small condensers, may be used with more or less success. The primary p, through which the high frequency discharges of the condensers are passed, consists of very few turns of cable of as low resistance as possible, and the secondary s, preferably at some distance from the primary to facilitate free oscillation, has one of its ends—that is the one which is nearer to the primary—connected to the ground, while the other end leads to an insulated terminal T, with which the body of the patient is connected. It is of importance in this case to establish synchronism between the oscillations in the primary and secondary circuits p and s respectively. This will be as a rule best effected by varying the self-induction of the circuit including the primary loop or coil p, for which purpose an adjustable self-induction e is provided; but in cases when the electromotive force of the generator is exceptionally high, as when a static machine is used and a condenser consisting of merely two plates offers sufficient capacity, it will be simpler to attain the same object by varying the distance of the plates.

The primary and secondary oscillations being in close synchronism, the points of highest potential will be on a part of terminal T, and the consumption of energy will occur chiefly there. The attachment of the patient's body to the terminal will in most cases very materially affect the period of oscillation in the secondary, making it longer, and a readjustment of the primary circuit will have to be made in each case to suit the capacity of the body connected with terminal T. Synchronism should always be preserved, and the intensity of the action varied by moving the secondary coil to or from the primary, as may be desired. I know of no method which would make it possible to subject the human body to such excessive electrical pressures as are practicable with this, or of one which would enable the conveying to and giving off from the body without serious injury amounts of electrical energy approximating even in a remote degree those which are entirely practicable when this manner of applying the energy is resorted to. This is evidently due to the fact that the action is chiefly superficial, the largest possible section being offered to the transfer of the current, or, to say more correctly, of the energy. With a very rapidly and smoothly working break I would not think it impossible to convey to the body of a person and to give off into the space energy at the rate of several horse power with impunity, while a small part of this amount applied in other ways could not fail to produce injury.

When a person is subjected to the action of such a coil, the proper adjustments being carefully observed, luminous streams are seen in the dark issuing from all parts of the body. These streams are short and of delicate texture when the number of breaks is very great and the action of the device b (Fig. 5) free of any irregularities, but when the number of breaks is small or the action of the device imperfect, long and noisy streams appear which cause some discomfort. The physiological effects produced with apparatus of this kind may be graduated from a hardly perceptible action when the secondary is at a great distance from the primary, to a most violent one when both coils are placed at a small distance. In the latter case only a few seconds are sufficient to cause a feeling of warmth all over the body, and soon after the person perspires freely. I have repeatedly, in demonstrations to friends, exposed myself longer to the action of the oscillations, and each time, after the lapse of an hour or so, an immense fatigue, of which it is difficult to give an idea, would take hold of me. It was greater than I experienced on some occasions after the most straining and prolonged bodily exertion. I could scarcely make a step and could keep the eyes open only with the greatest difficulty. I slept soundly afterward, and the after-effect was

certainly beneficial, but the medicine was manifestly too strong to be used frequently.

One should be cautious in performing such experiments for more than one reason. At or near the surface of the skin, where the most intense action takes place, various chemical products are formed, the chief being ozone and nitrogen compounds. The former is itself very destructive, this feature being illustrated by the fact that the rubber inslation of a wire is destroyed so quickly as to make the use of such insulation entirely impracticable. The compounds of nitrogen, when moisture is present, consists largely of nitric acid which might, by excessive application, prove hurtful to the skin. So far, I have not noted injuries which could be traced directly to this cause, though on several occasions burns were produced in all respects similar to those which were later observed and attributed to the Röntgen rays. This view is seemingly being abandoned, having not been substantiated by experimental facts, and so also is the notion that these rays are transverse vibrations. But while investigation is being turned in what appears to be the right direction, scientific men are still at sea. This state of things impedes the progress of the physicist in these new regions and makes the already hard task of the physician still more difficult and uncertain.

One or two observations made while pursuing experiments with the apparatus described might be found as deserving mention here. As before stated, when the oscillations in the primary and secondary cirucits are in synchronism, the points of highest potential are on some portion of the terminal T. The synchronism being perfect and the length of the secondary coil just equal to one-quarter of the wave length, these points will be exactly on the free end of terminal T, that is, the one situated farthest from the end of the wire attached to the terminal. If this be so and if now the period of the oscillations in the primary be shortened, the points of highest potential will recede towards the secondary coil, since the wave-length is reduced and since the attachment of one end of the secondary coil to the ground determines the position of the nodal points, that is, the points of least potential. Thus, by varying the period of vibration of the primary circuit in any manner, the points of highest potential may be shifted accordingly along the terminal T, which has been shown, designedly, long to illustrate this feature. The same phenomenon is, of course, produced if the body of a patient constitutes the terminal, and an assistant may by the motion of a handle cause the points of highest potential to shift along the body with any speed he may desire. When the action of the coil is vigorous, the region of highest potential is easily and unpleasantly located by the discomfort or pain experienced, and it is most curious to feel how the pain wanders up and down, or eventually across the body, from hand to hand, if the connection to the coil is accordingly made—in obedience to the movement of the handle controlling the oscillations. Though I have not observed any specific action in experiments of this kind, I have always felt that this effect might be capable of valuable use in electro-therapy.

Another observation which promises to lead to much more useful results is the following: As before remarked, by adopting the method described, the body of a person may be supjected without danger to electrical pressures vastly in excess of any producible by ordinary apparatus, for they may amount to several million volts, as has been shown in actual practice. Now, when a conducting body is electrified to so high a degree, small particles, which may be adhering firmly to its surface, are torn off with violence and thrown to distances which can be only conjectured. I find that not only firmly adhering matter, as paint, for instance, is thrown off, but even the particles of the toughest metals are torn off. Such actions have been thought to be restricted to a vacuous inclosure, but with a powerful coil they occur also in the ordinary atmosphere. The facts mentioned would make it reasonable to expect that this extraordinary effect which, in other ways, I have already usefully applied, will likewise prove to be of value in electro-therapy. The continuous improvement of the instruments and the study of the phenomenon may shortly lead to the establishment of a novel mode of hygienic treatment which would permit an instantaneous cleaning of the skin of a person, simply by connecting the same to, or possibly, by merely placing the person in the vicinity of a source of intense electrical oscillations, this having the effect of throwing off, in a twinkle of the eye, dust or particles of any extraneous matter adhering to the body. Such a result brought about in a practicable manner would, without doubt, be of incalculable value in hygiene and would be an efficient and time-saving substitute for a water bath, and particularly appreciated by those whose contentment consists in undertaking more than they can accomplish.

High frequency impulses produce powerful inductive actions and in virtue of this feature they lend themselves in other ways to the uses of the electro-therapeutist. These inductive effects are either electrostatic or electrodynamic. The former diminish much more rapidly with the distance—with the square of the same—the latter are reduced simply in proportion to the distance. On the other hand, the former grow with the square of intensity of the source, while the latter increase in a simple proportion with the intensity. Both of these effects may be utilized for establishing a field of strong action extending through considerable space, as through a large hall, and such an arrangement might be suitable for use in hospitals or institutions of this kind, where it is desirable to treat a number of patients at the same time.

Fig. 6 illustrates the manner, as I have shown it originally, in which such a field of electrostatic action is established. In this diagram G is a generator of currents of very high frequency, C a condenser for counteracting the self-induction of the circuit which includes the primary P of an induction coil, the secondary S of which has two plates t t of large surface connected

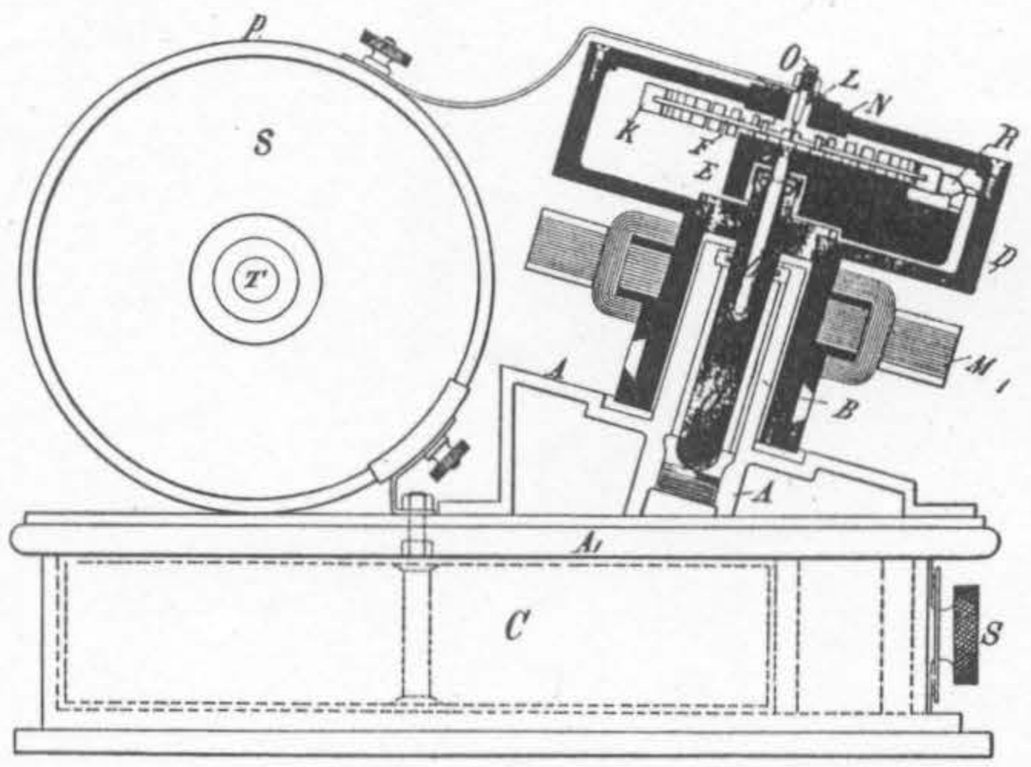


FIG. 9.

to its terminals. Well known adjustments being observed, a very strong action occurs chiefly in the space between the plates, and the body of a person is subjected to rapid variations of potential and surgings of current, which produce, even at a great distance, marked physiological effects. In my first experiments I used two metal plates as shown, but later I found it preferable to replace them by two large hollow spheres of brass covered with wax of a thickness of about two inches. The cables leading to the terminals of the secondary coil were similarly covered, so that any of them could be approached without danger of the insulation breaking down. In this manner the unpleasant shocks, to which the experimenter was exposed when using the plates, were prevented.

In Fig. 7 a plan for similarly utilizing the dynamic inductive effects of high frequency currents is illustrated. As the frequencies obtainable from an alternator are not as high as is desired, conversion by means of condensers is resorted to. The diagram will be understood at a glance from the foregoing description. It only need be stated that the primary p, through which the condensers are made to discharge, is formed by a thick stranded cable of low self-induction and resistance, and passes all around the hall. Any number of secondary coils s s s, each consisting generally of a single layer of rather thick wire, may be provided. I have found it practicable to use as many as one hundred, each being adjusted for a definite period and responding to a particular vibration passed through the primary. Such a plant I have had in use in my laboratory since 1892, and many times it has contributed to the pleasure of my visitors and also proved itself of practical utility. On a latter occasion I had the pleasure of entertaining some of the mem-

bers with experiments of this kind, and this opportunity I cannot let pass without expressing my thanks for the interest which was awakened in me by their visit, as well as for the generous acknowledgment of the courtesy by the Association. Since that time my apparatus has been very materially improved, and now I am able to create a field of such intense induction in the laboratory that a coil three feet in diameter, by careful adjustment, will deliver energy at the rate of one-quarter of a horse power, no matter where it is placed within the area inclosed by the primary loops. Long sparks, streamers and all other phenomena obtainable with induction coils are easily producible anywhere within the space, and such coils, though not connected to anything, may be utilized exactly as ordinary coils, and what is still more remarkable, they are more effective. For the past few years I have often been urged to show experiments in public, but, though I was desirous to comply with such requests, pressing work has so far made it impossible. These advances have been the result of slow but steady improvement in the details of the apparatus which I hope to be able to describe connectedly in the near future.

However remarkable the electrodynamic inductive effects, which I have mentioned, may appear, they may be still considerably intensified by concentrating the action upon a very small space. It is evident that since, as before stated, electromotive forces of many thousand volts are maintained between two points of a conducting bar or loop only a few inches long, electromotive forces of approximately the same magnitude will be set up in conductors situated near by. Indeed, I found that it was practicable in this manner to pass a discharge through a highly exhausted bulb, although the electromotive force required amounted to as much as ten or twenty thousand volts, and for a long time I followed up experiments in this direction with the object of producing light in a novel and more economical way. But the tests left no doubt that there was great energy consumption attendant to this mode of illumination, at least with the apparatus I had then at command, and, finding another method which promised a higher economy of transformation, my efforts turned in this new direction. Shortly afterward (some time in June, 1891,) Prof. J. J. Thomson described experiments which were evidently the outcome of long investigation, and in which he supplied much novel and interesting information, and this made me return with renewed zeal to my own experiments. Soon my efforts were centered upon producing in a small space the most intense inductive action, and by gradual improvement in the apparatus I obtained results of a surprising character. For instance, when the end of a heavy bar of iron was thrust within a loop powerfully energized, a few moments were sufficient to raise the bar to a high temperature. Even heavy lumps of other metals were heated as rapidly as though they were placed in a furnace. When a continuous band formed of a sheet of tin was thrust into the loop, the metal was fused instantly, the action being comparable to an explosion, and no wonder, for the frictional losses accumulated in it at the rate of possibly ten horse power. Masses of poorly conducting material behaved similarly, and when a highly exhausted bulb was pushed into the loop, the glass was heated in a few seconds nearly to the point of melting.

When I first observed these astonishing actions, I was interested to study their effects upon living tissues. As may be assumed, I proceeded with all the necessary caution, and well I might, for I had the evidence that in a turn of only a few inches in diameter an electromotive force of more than ten thousand volts was produced, and such high pressure would be more than sufficient to generate destructive currents in the tissue. This appeared all the more certain as bodies of comparatively poor conductivity were rapidly heated and even partially destroyed. One may imagine my astonishment when I found that I could thrust my hand or any other part of the body within the loop and hold it there with impunity. More than on one occasion, impelled by a desire to make some novel and useful observation, I have willingly or unconsciously performed an experiment connected with some risk, this being scarcely avoidable in laboratory experience, but I have always believed, and do so now, that I have never undertaken anything in which, according to my own estimation, the chances of being injured were so great as when I placed my head within the space in which such terribly destructive forces were at work. Yet I have done so, and repeatedly, and have felt nothing. But I am firmly convinced that there is great danger attending such an experiment, and some one going just a step farther than I have gone may be instantly destroyed. For, conditions may exist similar to those observable with a vacuum bulb. It may be placed in the field of the loop, however intensely energized, and so long as no path for the current is formed, it will remain cool and consume practically no energy. But the moment the first feeble current passes, most of the energy of the oscillations rushes to the place of consumption. If by any action whatever, a conducting path were formed within the living tissue or bones of the head, it would result in the instant destruction of these and death of the foolhardy experimenter. Such a method of killing, if it were rendered practicable, would be absolutely painless. Now, why is it that in a space in which such violent turmoil is going on living tissue remains uninjured? One might say the currents cannot pass because of the great self-induction offered by the large conducting mass. But this it cannot be, because a mass of metal offers a still higher self-induction and is heated just the same. One might argue the tissues offer too great a resistance. But this again cannot be the reason, for all evidence shows that the tissues conduct well enough, and besides, bodies of approximately the same resistance are raised to a high temperature. One might attribute the apparent harmlessness of the oscillations to the high specific heat of the tissue, but even a rough quantitative estimate from experiments with other bodies shows that this view is untenable. The only plausible explanation I have so far found is that the tissues are condensers. This only can account for the absence of injurious action. But it is remarkable that, as soon as a heterogeneous circuit is constituted, as by taking in the hands a bar of metal and forming a closed loop in this manner, the passage of the currents through the arms is felt, and other physiological effects are distinctly noted. The strongest action is, of course, secured when the exciting loop makes only one turn, unless the connections take up a considerable portion of the total length of the circuit, in which case the experimenter should settle upon the least number of turns by carefully estimating what he loses by increasing the number of turns, and what he gains by utilizing thus a greater proportion of the total length of the circuit. It should be borne in mind that, when the exciting coil has a considerable number of turns and is of some length, the effects of electrostatic induction may preponderate, as there may exist a very great difference of potential—a hundred thousand volts or more—between the first and last turn. However, these latter effects are always present even when a single turn is employed.

When a person is placed within such a loop, any pieces of metal, though of small bulk, are perceptibly warmed. Without doubt they would be also heated—particularly if they were of iron—when embedded in living tissue, and this suggests the possibility of surgical treatment by this method. It might be possible to sterilize wounds, or to locate, or even to extract metallic objects, or to perform other operations of this kind within the sphere of the surgeon's duties in this novel manner.

Most of the results enumerated, and many others still more remarkable, are made possible only by utilizing the discharges of a condenser. It is probable that but a very few—even among those who are working in these identical fields—fully appreciate what a wonderful instrument such a condenser is in reality. Let me convey an idea to this effect. One may take a condenser, small enough to go in one's vest pocket, and by skilfully using it he may create an electrical pressure vastly in excess—a hundred times greater if necessary—than any producible by the largest static machine ever constructed. Or, he may take the same condenser and, using it in a different way, he may obtain from it currents against which those of the most powerful welding machine are utterly insignificant. Those who are imbued with popular notions as to the pressures of static machines and currents obtainable with a commercial transformer, will be astonished at this statement—yet the truth of it is easy to see. Such results are obtainable, and easily, because the condenser can discharge the stored energy in an inconceivably short time. Nothing like this property is known in physical science. A compressed spring, or a storage battery, or any other form of device capable of storing energy, cannot do this; if they could, things undreamt of at present might be accomplished by their means. The nearest approach to a charged condenser is a high explosive, as dynamite. But even the most violent explosion of such a compound bears no comparison with the discharge or explosion of a condenser. For, while the pressures which are produced in the detonation of a chem-

ical compound are measured in tens of tons per square inch, those which may be caused by condenser discharges may amount to thousands of tons per square inch, and if a chemical could be made which would explode as quickly as a condenser can be discharged under conditions which are realizable—an ounce of it would quite certainly be sufficient to render useless the largest battleship.

That important realizations would follow from the use of an instrument possessing such ideal properties I have been convinced since long ago, but I also recognized early that great difficulties would have to be overcome before it could replace less perfect implements now used in the arts for the manifold transformations of electrical energy. These difficulties were many. The condensers themselves, as usually manufactured, were inefficient, the conductors wasteful, the best insulation inadequate, and the conditions for the most efficient conversion were hard to adjust and to maintain. One difficulty, however, which was more serious than the others, and to which I called attention when I first described this system of energy transformation, was found in the devices necessarily used for controlling the charges and discharges of the condenser. They were wanting in efficiency and reliability and threatened to prove a decided drawback, greatly restricting the use of the system and depriving it of many valuable features. For a number of years I have tried to master this difficulty. During this time a great number of such devices were experimented upon. Many of them promised well at first, only to prove inadequate in the end. Reluctantly, I came back upon an idea on which I had worked long before. It was to replace the ordinary brushes and commutator segments by fluid contacts. I had encountered difficulties then, but the intervening years in the laboratory were not spent in vain, and I made headway. First it was necessary to provide for a circulation of the fluid, but forcing it through by a pump proved itself impractical. Then the happy idea presented itself to make the pumping device an integral part of the circuit interrupter, inclosing both in a receptacle to prevent oxydation. Next some simple ways of maintaining the circulation, as by rotating a body of mercury, presented themselves. Then I learned how to reduce the wear and losses which still existed. I fear that these statements, indicating how much effort was spent in these seemingly insignificant details will not convey a high idea of my ability, but I confess that my patience was taxed to the utmost. Finally, though, I had the satisfaction of producing devices which are simple and reliable in their operation, which require practically no attention and which are capable of effecting a transformation of considerable amounts of energy with fair economy. It is not the best that can be done, by any means, but it is satisfactory, and I feel that the hardest task is done.

The physician will now be able to obtain an instrument suitable to fulfil many requirements. He will be able to use it in electro-therapeutic treatment in most of the ways enumerated. He will have the facility of providing himself with coils such as he may desire to have for any particular purpose, which will give him any current or any pressure he may wish to obtain. Such coils will consist of but a few turns of wire, and the expense of preparing them will be quite insignificant. The instrument will also enable him to generate Röntgen rays of much greater power than obtainable with ordinary apparatus. A tube must still be furnished by the manufacturers which will not deteriorate and which will allow to concentrate larger amounts of energy upon the electrodes. When this is done, nothing will stand in the way of an extensive and efficient application of this beautiful discovery which must ultimately prove itself of the highest value, not only at the hands of the surgeon, but also of the electro-therapist and, what is most important, of the bacteriologist.

To give a general idea of an instrument in which many of the latter improvements are embodied, I would refer to Fig. 9, which illustrates the chief parts of the same in side elevation and partially in vertical cross-section. The arrangement of the parts is the same as in the form of instrument exhibited on former occasions, only the exciting coil with the vibrating interrupter is replaced by one of the improved circuit breakers to which reference has been made.

This device comprises a casting A with a protruding sleeve B, which in a bushing supports a freely rotatable shaft a. The latter carries an armature within a stationary field magnet M and on the top, a hollow iron pulley D, which contains the break proper. Within the shaft a, and concentrically with the same, is placed a smaller shaft b, likewise freely movable on ball-bearings and supporting a weight E. This weight being on one side and the shafts a and b inclined to the vertical, the weight remains stationary as the pulley is rotated. Fastened to the weight E is a device R in the form of a scoop with very thin walls, narrow on the end nearer to the pulley and wider on the other end. A small quantity of mercury being placed in the pulley and the latter rotated against the narrow end of the scoop, a portion of the fluid is taken up and thrown in a thin and wide stream towards the centre of the pulley. The top of the latter is hermetically closed by an iron washer, as shown, this washer supporting on a steel rod L a disk F of the same metal provided with a number of thin contact blades K. The rod L is insulated by washers N from the pulley, and for the convenience of filling in the mercury a small screw o is provided. The bolt L forming one terminal of the circuit breaker is connected by a copper strip to the primary p. The other end of the primary coil leads to one of the terminals of the condenser C, contained in a compartment of a box A, another compartment of the same being reserved for switch S and terminals of the instrument. The other terminal of the condenser is connected to the casting A and through it to pulley D. When the pulley is rotated, the contact blades K are brought rapidly in and out of contact with the stream of mercury, thus closing and opening the circuit in quick succession. With such a device it is easy to obtain ten thousand makes and breaks per second and even more. The secondary s is made of two separate coils and so arranged that it can be slipped out, and a metal strip in its middle connects it to the primary coil. This is done to prevent the secondary from breaking down when one of the terminals is overloaded, as it often happens in working Röntgen bulbs. This form of coil will withstand a very much greater difference of potential than coils as ordinarily constructed.

The motor has both field and armature built of plates, so that it can be used on alternating as well as direct current supply circuits, and the shafts are as nearly as possible vertical, so as to require the least care in oiling. Thus, the only thing which really requires some attention is the commutator of the motor, but where alternating currents are always available, this source of possible trouble is easily done away with.

The circuit connections of the instrument have been already shown and the mode of operation explained in periodicals. The usual manner of connecting is illustrated in Fig. 8, in which A_2 A_2 are the terminals of the supply circuit, L, a self-induction coil for raising the pressure, which is connected in series with condenser C and primary P P. The remaining letters designate the parts correspondingly marked in Fig. 9 and will be understood with reference to the latter.

Vol. XXVI. NEW YORK, NOVEMBER 17, 1898. No. 550.

Mr. Tesla and the Czar.

THE personality of Mr. Tesla is one of the most fascinating in the field of modern invention, and his work is such as to command the interest of both the lay and the scientific public whenever he chooses to give details of his investigations and researches. If he had never done more than develop the theory and practice of the multiphase system, his life would have been useful above the ordinary; and even should it happen that none of his other ideas ever get into practical shape, his discoveries in electricity must always be regarded as important. We cannot number ourselves among those who, like the distinguished scientists, Profs. Brackett and Dolbear, quoted in our columns this week, are impatient with his tendency to let imagination outrun achievement and who virtually class him as a humbug. Mr. Tesla fools himself, if he fools anybody, when he launches forth

into the dazzling theories and speculations associated with his name. That he should desire to benefit the human race in ways now unknown, and should avow out loud belief in his capacity to do so, is surely not discreditable, any more than it is unworthy in the head of his own poetic Slavic race to propose the disarmament of the world. Granted that there will still be wars, and granted that all these wonderful visions of new arts in peace do not fructify without the work of a score of later geniuses, why find fault either with the Czar or with Mr. Tesla? Their aims appear wholly noble, their thoughts are beautiful, and if they fail, as they probably will in some material and vital respects, the world is certainly none the worse off for what they actually accomplish.

Just of late Mr. Tesla has been giving publicity to some of his newest work, and it is peculiarly interesting. We should have been glad, personally, to see him finish up some of the many other things that have occupied his energies these ten years past, but none of which now claim any place. For example, his "oscillator," or combination of generator and steam engine, which was to wipe out all other methods of power generation and reduce vastly the cost of power, by steam and electric economies. The very name is now bestowed by Mr. Tesla on another piece of apparatus, and though illustrated in detail and brought before the Chicago Electrical Congress in 1893, the "oscillator" of the original brand is, for aught the public knows, in the scrap heap. Yet it was a lovely invention, of infinite possibilities. We can only regret its neglect and oblivion, but if Mr. Tesla has other things more appealing to his mind for the present, that is his own business.

Of late also Mr. Tesla has brought forward another plan of power generation and transmission. At one period he expressed his belief in ability to disturb the earth's charge and thus send currents through the earth. That does not appear to be so feasible or attractive now as the idea of using the upper strata of the air which he says have a very superior conductivity. He would tether up aloft balloons in those strata and deliver to them large quantities of current at such high potential that it would travel economically across the space without wires, say from Niagara Falls to Paris. By this facile distribution of water power, coal and steam would become unnecessary to industry. The new plan may explain why Mr. Tesla has abandoned his old steam oscillator. It is earnestly to be hoped that this novel idea will prove workable. Balloons were a dismal failure in our late war, but that is no criterion, and Mr. Tesla may have some superior gas for inflation and sustentation purposes. It will be remembered that Mr. Marconi has already telegraphed from balloon to balloon, without wires, a distance of over twenty miles, thus proving in advance the tenability of Mr. Tesla's proposition.

The tremendous hold that war has taken upon the public mind is shown by the fact that even a genius of Mr. Tesla's independence is compelled to invention in that field. A patent issued to him last week intimates that he believes that torpedos and torpedo boats which were so utterly useless and unmanageable in the late conflict with Spain can be made more valuable if controlled entirely from shore, by a Navy Board, and without any crew. Last spring the ability to explode floating torpedos under ships from a distance without any wires was brilliantly demonstrated at Madison Square Garden several times a day for a month. Taking that idea, Mr. Tesla has applied the same principle to the electro-mechanical steering of torpedos, just as it is now done with several types, but, of course, in his case, without the intervening wires from shore. He is very sanguine that this will stop war, and we pray heartily that it may. The article or patent digest we print in this issue on the subject suggests improvements of his on existing apparatus that may render it, in spite of its great delicacy, able to evade jarring and jolting, the perils of the open sea, the defensive network crinolines around the ships, the concussions of great guns, and the intentional explosion of defenses placed in its way thus to derange and negative its operation. During the late war, apparatus far less sensitive than coherers was rendered useless by the firing of the heavy artillery on the ships, and it must be a preternaturally tough coherer that would escape the same fate. So also it must be a very difficult problem for which Mr. Tesla cannot suggest half a dozen diagrammatic solutions.

While all these curious things are "in the air," so to speak, it is a distinct pleasure to be able to print, as we do in this issue, Mr. Tesla's able and thoughtful paper read before the Buffalo meeting of the American Electro-Therapeutic Association. It compensates for the disappointment experienced from his unfinished lecture two years ago before the New York Academy of Sciences, which has never found its way into print, but of which the opening passages indicated the covering of the same ground. We trust that the data given by Mr. Tesla may stimulate our medical friends to greater employment of electricity. It is unfortunately true that disastrous results from injudicious use by some of them of Prof. Röntgen's great discovery of the X-ray have made medical men fight shy of handling electricity themselves lately, and we do not know whether Mr. Tesla's experiments will altogether reassure them, so striking and farreaching are they. But the saving of human life is a sacred thing. Every means and instrumentality must be tried by the surgeon and the physician, and it is devoutly to be hoped that having stopped the slaughter due to war Mr. Tesla will revert at some time to this brilliant paper and give the doctors apparatus that will help prevent the slaughter due to accident and disease.

It is not our desire to pose as apologists or publicists for Mr. Tesla. He needs no assistance of that kind; and so long as he commands freely whole pages of the Sunday papers, for which Mr. Wanamaker pays gladly his thousands of dollars, the technical and scientific journals have, indeed, little to do with the matter. All we wish to say is that it is not fair to condemn, as so many do, Mr. Tesla as visionary and impractical. No man has finished his work till he is dead, and even then there are long, long centuries in which his ideas can prove themselves true. The visionaries are thus often, in the end, the most sordid of realists—something Mr. Tesla will never be.

NEWS & NOTES

Tesla's Electrical Control of Moving Vessels or Vehicles from a Distance.

IN view of the public interest of late in anything which has a warlike appearance or apparatus tending to render war less probable by making it more horrible and destructive, and in view also of numerous recent disasters at sea, the current descriptions in the daily papers of a new invention of Mr. Tesla and reported interviews with him have been received with widely differing comments. In Mr. Tesla's own words, the invention consists of a complete and practicable solution of the problem of controlling from a given point the operation of the propelling engines, the steering apparatus and other mechanism carried by a moving object, such as boat or floating vessel, whereby the movement and the course of such a vessel may be directed and controlled from a distance, and any device carried by the same brought into action at any desired time. The system is based on the use, upon the object to be exploded or steered, of a Branly coherer and Marconi agitator of novel form, toward which impulses are sent from a Hertzian radiator. It will be remembered that this is what was done in a small but very successful way at the Electrical Exhibition in Madison Square Garden last May, when miniature floating torpedos fastened on a board floating under the bottom of model men-of-war were thus blown up daily, without wires, by means of the same "wireless telegraph" methods, from a distance of not less than 50 or 60 feet. Mr. Tesla's application is dated in July. It was one of the intentions at the exhibition to place all the receiving apparatus on the boat in the water; but for obvious reason pertinent to the locality it was found desirable to run the boat connections to a temporary shelf at the top edge of the tank and rest the cohering apparatus there; so that the floating mines or torpedos could be renewed frequently and also to prevent the boat from floating about, as one or two people were hurt by flying pieces when the explosions took place too near the sides. Another object was to prevent the continuous destruction of the coherers, being delicate and expensive apparatus then not readily obtainable. Mr. Tesla in his scheme embodies the idea of placing the coherer on the floating torpedo, and proposes that the impulses taken up by the coherer shall also operate steering magnets, as in other dirigible torpedos, such as the Sims-Edison, but without the wires to shore. This method he elaborates with wonted ingenuity, although he does not include the firing of artillery, which was also done last May at the exhibition, and of course might be done with equal facility on a floating ship, without wires from the shore; or on a submerged fort or an uninhabited monitor at a harbor entrance. His patent is limited merely, it would appear, to devices or mechanism for steering, and does not claim either the discharge of explosives or selective signaling, or other features of that kind.

Referring to Fig. 1, A designates any type of vessel or vehicle which is capable of being propelled and directed, such as a boat, a balloon, or a carriage. It may be designed to carry in a suitable compartment B objects of any kind, according to the nature

of the uses to which it is to be applied. The vessel—in this instance a boat—is provided with suitable propelling machinery, which is shown as comprising a screw propeller C, secured to the shaft of an electromagnetic motor D, which derives its power from storage batteries E E E E. In addition to the propelling engine or motor the boat carries also a small steering motor F, the shaft of which is extended beyond its bearings and provided with a worm which meshes with a toothed wheel G. This latter is fixed to a sleeve b, freely movable on a vertical rod H, and is rotated in one or the other direction, according to the direction of rotation of the motor F.

The sleeve b on rod H is in gear, through the cog-wheels H′ and H″, with a spindle G, mounted in vertical bearings at the stem of the boat and carrying the rudder F′.

The apparatus by means of which the operation of both the

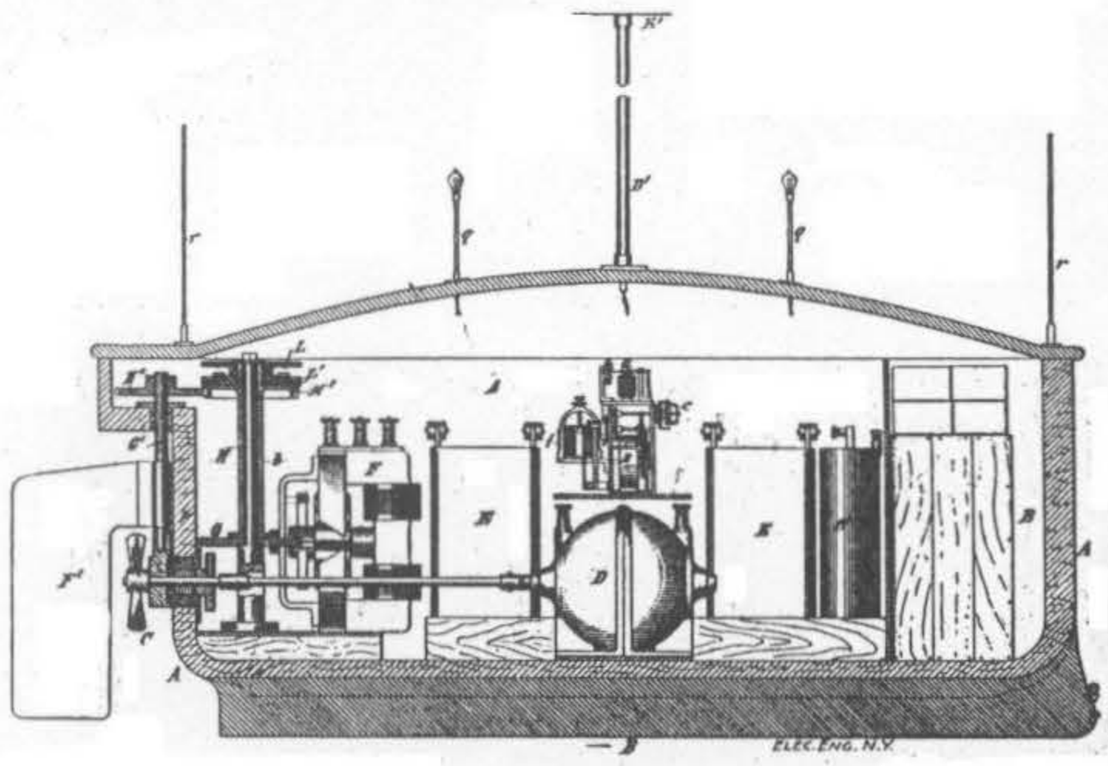

FIG. 1.

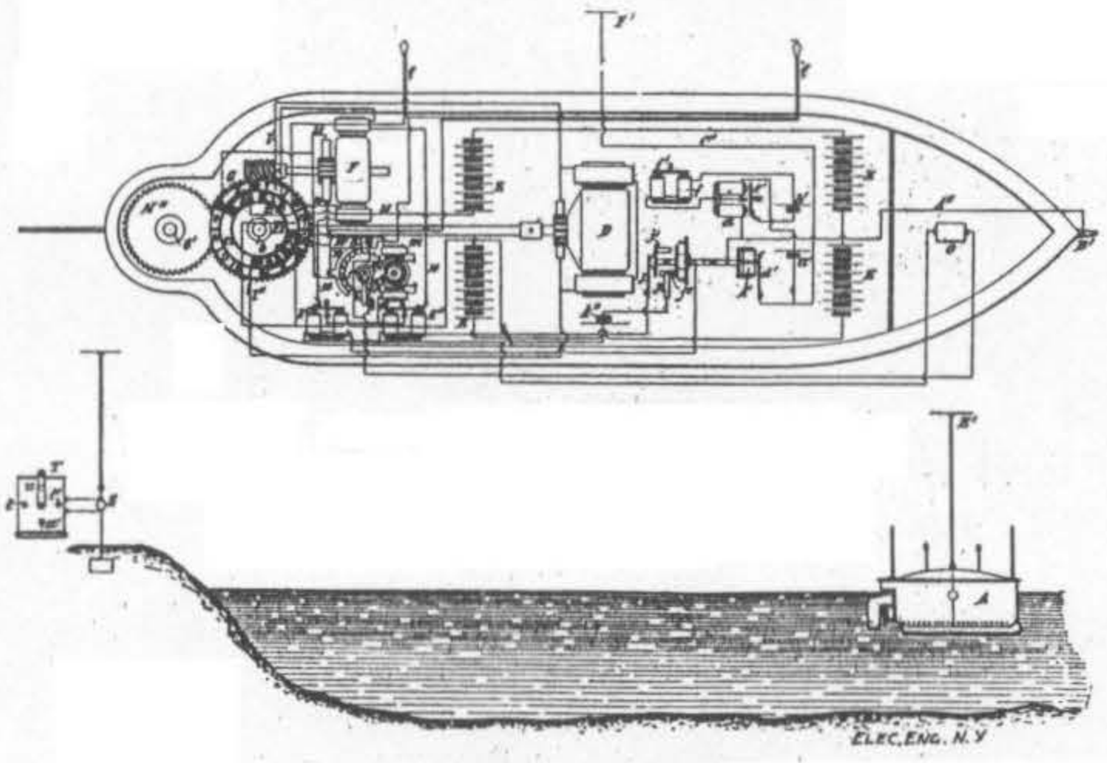
propelling and steering mechanisms is controlled involves a receiving circuit, adjusted and rendered sensitive to the influence of waves or impulses emanating from a remote source, the adjustment being so that the period of oscillation of the circuit is either the same as that of the source or a harmonic thereof.

The receiving circuit proper (diagrammatically shown in Fig. 2) comprises a terminal E′, conductor C′, a sensitive device A′, and a conductor A″, leading to the ground conveniently through a connection to the metal keel B′ of the vessel. The terminal E′ should present a large conducting surface and should be supported as high as practicable on a standard D′, which is shown as broken in Fig. 1; but such provisions are not always necessary. It is important to insulate very well the conductor C′ in whatever manner it be supported.

The circuit or path just referred to forms also a part of a local circuit, which latter includes a relay magnet a and a battery a′, the electromotive force of which is, as before explained, so determined that although the dielectric layers in the sensitive device A′ are subjected to a great strain, yet normally they withstand the strain and no appreciable current flows through the local circuit; but when an electrical disturbance reaches the circuit the dielectric films are broken down, the resistance of the device A′ is suddenly and greatly diminished, and a current traverses the relay magnet A.

The particular sensitive device employed consists of a metal cylinder, with insulating heads, through which passes a central metallic rod. A small quantity of grains of conducting material, such as an oxidized metal, is placed in the cylinder. A metallic strip, secured to an insulated post, bears against the side of the cylinder, connecting it with one part of the circuit. The central rod is connected to the frame of the instrument and so to the other part of the circuit. This instrument, which is similar in construction to the ordinary Branly coherer, differs from it only in the method used for restoring the particles to their original position after each impulse. Mr. Tesla uses for this purpose a spring device operated by the armature of an electromagnet. This is said to overcome all serious defects caused by the unequal size.



To do away with the defects in the sensitive device, Mr. Tesla makes the particles by a special tool, insuring their equality in size, weight and shape, and they are then uniformly oxidixed by placing them for a given time in an acid solution. This secures equal conductivity of their surfaces and stops their further deterioration, thus preventing a change in the character of the gas in the space in which they are enclosed. He prefers not to rarefy the atmosphere within the sensitive device, as this has the effect of rendering the former less constant in regard to its dielectric properties, but merely secures an airtight inclosure of the particles and rigorous absence of moisture, which is fatal to satisfactory working.

The normal position of the cylinder c is vertical, and when turned in the manner described, the grains in it are simply shifted from one end to the other; but inasmuch as they always fall through the same space and are subjected to the same agitation they are brought after each operation of the relay to precisely the same electrical condition and offer the same resistance to the flow of the battery current until another impulse from afar reaches the receiving current.

Referring again to Fig. 2, K′ K″ are two relay magnets conveniently placed in the rear of the propelling engine. One terminal of a battery k″ is connected to one end of each of the relay coils, the opposite terminal to the brush J′, and the opposite ends of the relay coils to the brush J and to the frame of the instrument, respectively. As a consequence of this arrangement either the relay K′ or K″ will be energized as the brush J′ bears upon the plate j′ or j″, respectively, or both relays will be inactive while the brush J′ bears upon an insulating space between the plates j′ and j″. While one relay, as K′, is energized, its armature closes a circuit through the motor F, which is rotated in a direction to throw the rudder to port. On the other hand, when relay K″ is active another circuit through the motor F is closed, which reverses its direction of rotation and shifts the rudder to starboard. These circuits, however, are at the same time utilized for other obvious purposes.

Mr. Tesla informs a "Herald" reporter that using his special apparatus for the production of electrical waves and impulses, he will operate from his laboratory in New York a model which he will exhibit at the Paris Exposition in 1900; from which it may be inferred that he does not expect immediate practical utilization of the idea beyond that with which the New York public has already been made familiar by the electrical exhibition of last May.

The reporters who have been allowed to enter the laboratory state that Mr. Tesla has there a model roughly outlined of a torpedo boat on stocks, the keel of copper plate, with rudder and propeller in the usual positions, and showing two small incandescent lamps on standards. With this he illustrates the operation of the steering gear and of the lights by means of the

FIGS. 2 AND 3.

apparatus for projecting and receiving the electrical waves or impulses. No details are given by them of the mechanism.

Discussing the subject Prof. C. F. Brackett, of Princeton University, says: "The shortest, most correct and most complete criticism which I can make in reference to this bold boast is that what is new about it is useless, while that which is useful had all been discovered by other scientists long before Tesla made this startling announcement. You will find the whole theory which he has applied in any up-to-date text book. What Tesla has done is simply to make theoretical application, which would prove to be absolutely ridiculous in application of inventions

which had already been discovered. There is nothing new about this. The theory is perfect, but the application absurd. So throughout Tesla's whole elaborate scheme, the theory is not at fault, although there is nothing original about it, but the circumstances under which its application would be necessitated are such that the only result would be failure. Do you suppose that in the din of battle it would be possible to put into execution those minute and carefully adjusted mechanical experiments, all of which are presupposed by his theory, which require the quiet of an uninterrupted laboratory to work successfully? Or do you think that the enemy would co-operate with the attack and place their vessels in exactly the correct position to be hit or that they would remain stationary while the torpedo boat approached? His theory would have to assume an affirmative answer in order to be a success, and moreover the torpedo boat would have to be seen from the base of operations in order to direct it. It would be discovered by the doomed vessel long before it reached its destination, and would be exploded on the spot, so how great an advance is this on the present mode of warfare?"

Prof. A. E. Dolbear, of Tufts College, Massachusetts, says: "This last so-called invention of Nikola Tesla's is a very pretentious affair, and it is so incredible that the story is not to be believed until the work is actually done. If Tesla said all that the 'Herald' quotes him as saying, then his whole scheme and his manner of working is unintelligible to me. He even says that 'this power can be exerted at any distance by an agency of so delicate, so impalpable a quality, that I feel I am justified in predicting that the time will come when it can be called into action by the mere exercise of the human will.'

"That is getting a little outside of science, but you will notice that Tesla himself is only predicting that this will come true. There has been no accomplishment. He proposes to do great things, but he does not tell how he is going to do them, and he hasn't done them himself yet.

"The announcement is most amazing, and, coming as it does from Tesla, scientists are all the more chary about accepting it. During the last six years he has made so many startling announcements and has performed so few of his promises that he is getting to be like the man who called 'Wolf! wolf!' until no one listened to him. Mr. Tesla has failed so often before that there is no call to believe these things until he really does them. Meantime, we are all waiting with much patience and without solicitude. We will believe them when they are done."

A FEW particulars of Mr. Nikola Tesla's new method of electric power transmission are given in the current uumber of the *Electrical Review*. From the article it appears that the invention consists in transmitting electrical power without the employment of metallic line conductors, by taking advantage of the conductivity of the rarefied air existing in the upper regions

NO. 1516, VOL. 59]

of the earth's atmosphere. In order to make this practicable, special apparatus has been devised for the production and conversion of excessively high electrical pressure. Heretofore, it has been possible, by means of the apparatus at command, to produce only moderate electrical pressures, and even these, with considerable risks and difficulties. Mr. Tesla, however, claims that he has devised means whereby he is enabled to generate, with safety and ease, electrical pressures measured by hundreds of thousands, and even by millions of volts. He has also, during his investigations with such apparatus, discovered certain highly important and useful facts, which are said to render practicable his new system of transmitting electrical energy. Among these are the following: first, that with electrical pressures of the magnitude and character which he has been able to produce, the ordinary atmosphere becomes, in a measure, capable of serving as a true conductor for the transmission of the current; second, that the conductivity of the air increases so materially with the increase of electrical pressure and the degree of exhaustion, that it becomes possible to transmit, through even moderately rarefied strata of the atmosphere, electrical energy up to practically any amount and to any distance.

Tesla Talks

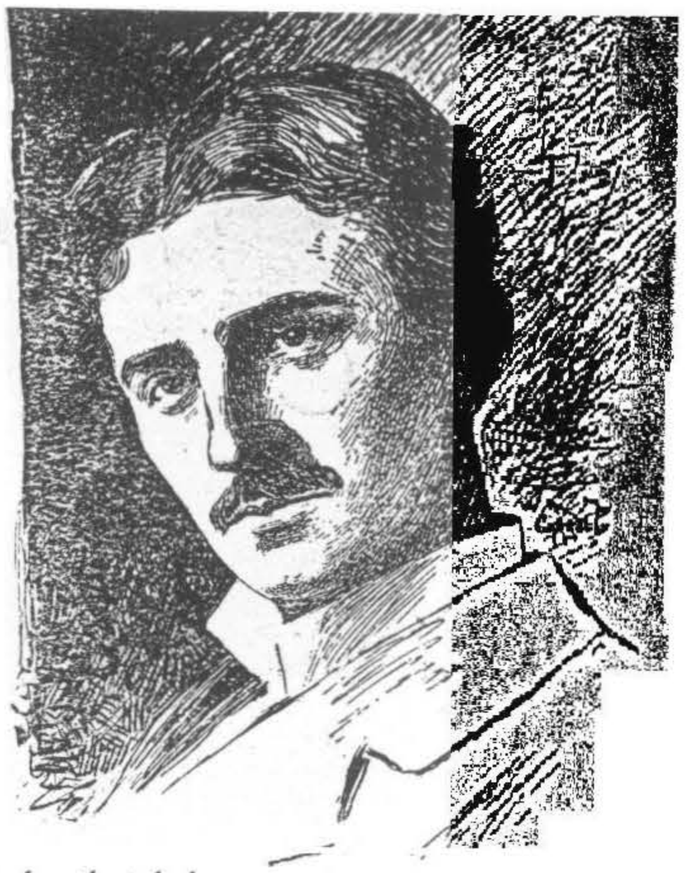
And Confirms His Astounding Story.

A TALL, spare man entered from the side door. He had a keen face—the dome of the head seeming to overbalance the sensitive chin.

This was the man who jounced the reading world out of its usual apathy several days ago by declaring that war would be abolished—the means being an invention of his, by which a torpedo or boat could be controlled from shore, although entirely cut off from ordinary means of communication—the governing impulses to be sent through the air.

"You must excuse me," he said, with a pleasant foreign accent, "but I cannot be interviewed. There is so m' :h put down that I do not say, and the subject is of too great importance to be treated lightly."

"But, Mr. Tesla, am I to understand that your invention remains to be perfected, or is now ready for operation?"



"It is now!" he answered, eagerly. "Within three days can be made ready a launch, torpedo boat, or what you will. There are four—five—men in the world who could apply these principles—not more—but they, by taking a piece here and something there, now that I have disclosed my idea, could utilize the invention at once. I do not care to make it quite so strong for publication, as every new idea arouses antagonism, and many people may call me fanatic, for that statement, but it is true."

"Could not a man-of-war have your sending apparatus on board, and thereby defeat the object of the people on shore, who send out the torpedo-boat?"

"No, they cannot thwart me. If they send signals they do it blind—as if shooting in the dark. Were there no protection but that, I should be safe, but I have a protection beyond that. It is an arrangement whereby the apparatus will recognize no signal but my own. If they attempt to thwart me they only hasten their own destruction, and, more than this, should they by any chance destroy the boat—what harm? Send out another four—ten—why not?"

"Would it not be difficult to hit a man-of-war at a distance of, say, twenty miles? It would be a good target close at hand, but a slight divergence caused by an ocean current, a draft of wind or any one of a number of things might cause your torpedo-boat to miss her mark."

"Great accuracy is not of necessity. A boat loaded with five hundred pounds of gun-cotton would shake a vessel sorely by exploding within five hundred yards of her—think, then, of exploding five hundred tons! The size of my vessel is not limited. Why, it would raise a wave four hundred feet high—sufficient to sink any ship afloat, more surely a man-of-war; they are all top-heavy."

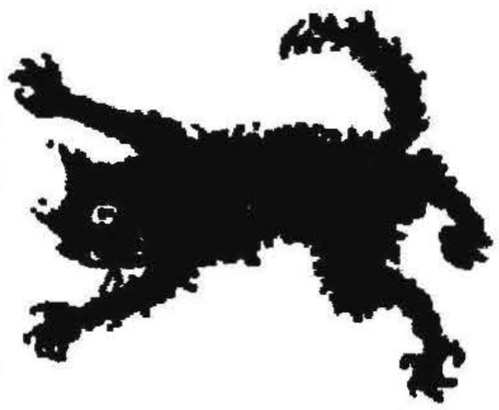
"Then you think that this invention is a practical thing at the present time?"

"Yes, sir. It is so. I think, also, that it is the greatest discovery of the age. There is a something artistic—an appeal to the imagination in it that the telephone, phonograph and other fine inventions lack. Think of the abolishment of war! And the means of doing it—by a vessel which I can control merely by a touch on an instrument not connected with it in any way. No wire—nothing! More than that, I do not have to touch the instrument."

"Now there's something, Mr. Tesla, that brings us to the psychological part of it. The papers quoted you as saying that you——

"Could control the apparatus by an effort of will," broke in the inventor. "There it was they perverted my meaning. Now listen—I can stand two metres away from that instrument, and by a mere stiffening of my muscles cause it to send a signal. It is so delicate in its adjustment that the disturbance of the electrical equilibrium caused by my muscular action affects it. Inasmuch as Sir William Crookes, that distinguished scientist and my good friend, has not hesitated to state openly his belief in telepathy, it is a reasonable flight of fancy for me to say that my machine—so sensitive—may be affected by the human will. But that is all it is—merely a pleasant speculation, founded on logical grounds. I have no evidence to support it, but I have a perfect right to state it—understand me—as a possibility—no more."

"But is not an apparatus of such extreme delicacy little suited to the rough-and-ready usages of warfare?"



"No—that is provided for. True, it would take experts to handle it, but they could do it. It is a great invention. Had I nothing else to show for a life-work, this would put the laurels of everlasting fame on my head. The people at the Patent Office were astonished that so simple and reasonable an idea had not occurred to someone before. I am sick with working on it; but it is complete. It is strange, but when I have an inspiration, always it seems to me as if my mother were near me—at my bedside—during my work—all the time. She was an inventor. She invented a weaving machine, attending to all details herself. Yes, and many things of more importance. My father was a mathematician and linguist. He was a man of note in both studies, but from my mother comes the inventive faculty, and now, though she is dead, when the pressure of thought of some new idea is on me, I feel her presence. But, concerning the invention. It is my idea to have a submerged vessel, having two rods sticking above water, or two puffs of smoke coming out, whereby to steer it; then it would be safe from the projectiles of the enemy.

"My device can also be used to propel lifeboats—Oh! of course, for any kind of boat. It is a thing of the present time and a thing that will work a revolution of the politics of the whole world. At first the smaller nations may have a desire to bully in their new-found strength, but that will adjust itself—and now, as I am very busy——

"Just one moment—What is your nationality, Mr. Tesla?"

"I am a Servian—not from the Kingdom of Servia, but from the outskirts—near Montenegro, And now I must say good-morning."

H. W. Phillips.

Mr. Tesla's Application of Hertz-Wave Transmission.

Exercising their well-developed ability to make a startling piece of news of a very ordinary event, the daily papers have taken up Mr. Nikola Tesla's recent patent, No. 613,809, issued November 8, 1898, and made of it "the greatest marvel of the age." The facts, as set forth in the patent cited, are in brief as follows: Hitherto the only practical means of controlling the movements of a vessel, such as a torpedo or a torpedo boat, at a distance has been the use of a cable, the disadvantages of which are obvious. The plan proposed by the inventor is to provide any such craft with a coherer connected between the hull and an elevated terminal and to so arrange the propelling and steering mechanism, which is motor-driven with storage-battery supply, that it can be controlled by various relays and auxiliary devices actuated through the agency of the Hertz waves.

A single coherer is used, the inventor preferring this to a plurality of coherers respectively syntonized to respond to waves of different frequency, although he states that he has "demonstrated the practicability of providing a great number of such receiving circuits—50 or 100 or more—each of which may be called up or brought into action when desired, without the others being interfered with." This coherer possesses some elements of novelty designed to yield a more uniform de-cohering action. It consists of a metal cylinder with insulating ends and a metal rod passing lengthwise through it. The cylinder normally stands with its axis vertical, and the de-cohering action consists of inverting it, throwing the granules or particles, which, according to the illustration, occupy about one-fifth of its length, from one end to the other. The patent also describes these granules as "manufactured by a special tool, insuring their equality in size, weight and shape, and uniformly oxidized by placing them for a given time in an acid solution of pre-determined strength. This secures equal conductivity of their surfaces and stops their further deterioration, thus preventing a change in the character of the gas in the space in which they are enclosed. I prefer not to rarefy the atmosphere within the sensitive device, as this has an effect of rendering the former less constant in regard to its dielectric properties, but merely secure a water-tight enclosure of the particles and rigorous absence of moisture, which is fatal to satisfactory working."

The auxiliary devices consist of ordinary relays, actuating a simple step-by-step escapement wheel, which in turn rotates brushes and commutators, affecting the various internal circuits of the boat. These differ in no essential respect from the rosettes or circuit controllers of synchronous printing-telegraph instruments, and many other means of accomplishing the same results by a different arrangement of details could, of course, be devised. There is apparently nothing broadly new in this part of the invention. The claims upon it, however, are very broad, the first claim reading as follows: "The improvement in the art of controlling the movements and operation of a vessel or vehicle herein described, which consists in producing waves or disturbances, which are conveyed to the vessel by the natural media, actuating thereby suitable apparatus on the vessel and effecting the control of the propelling engine, the steering and other mechanism by the operation of the said apparatus, as set forth." It is doubtful if this claim would withstand litigation in case of infringement, if it ever became possible to make such a system operative, as it is simply the use of the coherer as a relay for actuating a step-by-step mechanism, instead of a simple sounder. It is obvious that, unless Mr. Tesla has made revolutionary improvements in Hertz-wave apparatus which have not yet been disclosed, the coherer and auxiliary apparatus working therewith are altogether too delicate for the service proposed.

Mr. Tesla is quoted by the daily press in this connection as follows:

"War will cease to be possible when all the world knows that the most feeble of the nations can supply itself immediately with a weapon which will render its coast secure and its ports impregnable to the assaults of the united armadas of the world. Battleships will cease to be built, and the mightiest armorclads and the most tremendous artillery afloat will be of no more use than so much scrap iron. And this irresistible power can be exerted at any distance by an agency of so delicate, so impalpable a quality that I feel that I am justified in predicting that the time will come, incredible as it may seem, when it can be called into action by the mere exercise of the human will.

"My imagination fairly reels when I attempt to contemplate its countless possibilities. Already I hear the knell of the battleship and the monster gun. Their day has passed with the advent of a new and irresistible power, which gives to all nations an absolute power of defense against any attack.

"England has until now boasted of her mastery of the seas, but her superiority has vanished and she is now no stronger than the weakest of the maritime nations, so far as her offensive power is concerned. England, who is now so diligently preparing for war, will awake to this unwelcome discovery to-morrow and will be utterly confounded; and France, against whom her armaments have been reported to be preparing, will rejoice in the discovery that she possesses an all-powerful weapon of defense.

* * * * * *

"But I have no desire that my fame should rest on the invention of a merely destructive device, no matter how terrible. I prefer to be remembered as the inventor who succeeded in abolishing war. That will be my highest pride. But there are many peaceful uses to which my invention can be put, conspicuously that of rescuing the shipwrecked.

"It will be perfectly feasible to equip our life-saving stations with life cars, or life boats, directed and controlled from the shore, which will approach stranded vessels and bring off the passengers and crews without risking the lives of the brave fellows who are now forced to fight their way to the rescue through the raging surf. It may also be used for the propulsion of pilot boats, for carrying letters or provisions or instruments to inaccessible regions, for killing whales and for many other commercial or scientific purposes.

"In order to give a practical illustration of this it is my intention to exhibit a model of a torpedo boat at the Paris Exposition and direct all its movements from my office in New York." * * *

It is probable that the movements will be directed by messages sent via the transatlantic cables; otherwise we would advise the use of the torpedo boat and its directing mechanism for trans-oceanic telegraphy.

Tesla's Latest Claim.

Following is a verbatim statement from Nikola Tesla, in his application for a patent which last week was issued to him:

The problem, for which the invention forming the subject of the present application affords a complete and practicable solution, is that of controlling from a given point the operation of the propelling engines, the steering apparatus and other mechanism carried by a moving object, such as a boat, or any floating vessel, whereby the movements and course of such body or vessel may be directed and controlled from a distance, and any device carried by the same, brought into action at any desired time.

So far as I am aware, the only attempts to solve this problem, which have heretofore met with any measure of success, have been made in connection with a certain class of vessels, the machinery of which was governed by electric currents conveyed to the controlling apparatus through a flexible conductor. But this system is subject to such obvious limitations as are imposed by the length, weight and strength of the conductor which can be practically used, by the difficulty of maintaining with safety a high speed of the vessel or changing the direction of movement of the same with the desired rapidity, by the necessity for effecting the control from a point which is practically fixed, and by many well understood drawbacks inseparably connected with such a system.

The plan which I have perfected involves none of these objections, for I am enabled by the use of my invention to employ any means of propulsion, to impart to the moving body or vessel the highest possible speed, to control the operation of its machinery and to direct its movements from either a fixed point or from a body moving and changing its direction, however rapidly, and to maintain this control over great distances, without any artificial connections between the vessel and the apparatus governing its movements, and without such restrictions as these must necessarily impose.

In a broad sense, then, my invention differs from all of those systems which provide for the control of the mechanism carried by a moving object and governing its motion, in that I require no intermediate wires, cables or other form of electrical or mechanical connection with the object, save the natural media in space. I accomplish, nevertheless, similar results, and in a much more practicable manner, by producing waves, impulses or radiations, which are received through the earth, water or atmosphere by suitable apparatus on the moving body and cause the desired actions, so long as the body remains within the active region or effective range of such currents, waves, impulses or radiations.

The many and difficult requirements of the object here contemplated, involving peculiar means for transmitting to a considerable distance an influence capable of causing, in a positive and reliable manner, these actions, necessitated the designing of devices and apparatus of a novel kind in order to utilize to the best advantage various facts or results which, either through my own investigations or those of others, have been rendered practically available.

As to the part of my invention which involves the production of suitable waves or radiations and the conveying of the same to a remote receiving apparatus capable of being operated or controlled by their influence, it may be carried out in various ways which are at the present time more or less understood. For example, I may pass through a conducting path, preferably enclosing a large area, a rapidly varying current and by electro-magnetic induction of the same, affect a circuit carried by the moving body. In this case the action at a given distance will be the stronger the larger the area enclosed by the conductor and the greater the rate of change of the current. If the latter were generated in the ordinary ways, the rate of change, and consequently the distance at which the action would be practically available for the present purpose, would be very small; but by adopting such means as I have devised, that is, either by passing through the conducting path currents of a specially designed high-frequency alternator, or better still, those of a strongly charged condenser, a very high rate of change may be obtained, and the effective range of the influence thus extended over a vast area, and by carefully adjusting the circuit on the moving body so as to be in exact electro-magnetic synchronism with the primary disturbances, this influence may be utilized at great distances.

Another way to carry out my invention is to direct the currents or discharges of a high-frequency machine or condenser through a circuit, one terminal of which is connected directly or inductively with the ground and the other to a body, preferably of large surface and at an elevation. In this case if the circuit on the moving body be similarly arranged or connected, differences of potential on the terminals of the circuit, either by conduction or electrostatic induction, are produced, and the same object is attained. Again, to secure the best action, the receiving circuit should be adjusted so as to be in electro-mangnetic synchronism with the primary source as before, but in this instance it will be understood by those skilled in the art that, if the number of vibrations per unit of time be the same, the circuit should now have a length of conductor only one half of that used in the former case.

(*To be Continued.*)

Tesla's Latest Claim.

NUMBER II.

In last week's issue appeared the first installment of a verbatim statement from Nikola Tesla in his application for a patent. After a detailed recital of the proposed method and device, he says: What I claim is—

1. The improvement in the art of controlling the movements and operation of a vessel or vehicle herein described, which consists in producing waves or disturbances which are conveyed to the vessel by the natural media, actuating thereby suitable apparatus on the vessel and effecting the control of the propelling engine, the steering and other mechanism by the operation of the said apparatus, as set forth.

2. The improvement in the art of controlling the movements and operation of a vessel or vehicle, herein described, which consists in establishing a region of waves or disturbances, and actuating, by their influence exerted at a distance, the devices on such vessel or vehicle, which control the propelling, steering and other mechanism thereon, as set forth.

3. The improvement in the art of controlling the movements and operation of a vessel or vehicle, herein described, which consists in establishing a region of electrical waves or disturbances, and actuating, by their influence exerted at a distance, the devices on said vessel or vehicle, which control the propelling, steering and other mechanism thereon, as set forth.

4. The improvement in the art of controlling the movements and operation of a vessel or vehicle, herein described, which consists in providing on the vessel a circuit controlling the propelling, steering and other mechanism, adjusting or rendering such circuit sensitive to waves or disturbances of a definite character, establishing a region of such waves or disturbances, and rendering by their means the controlling circuit active or inactive, as set forth.

5. The combination with a source of electrical waves or disturbances of a moving vessel or vehicle, and mechanism thereon for propelling, steering or operating the same, and a controlling apparatus adapted to be actuated by the influence of the said waves or disturbances at a distance from the source, as set forth.

6. The combination with a source of electrical waves or disturbances of a moving vessel or vehicle, mechanism for propelling, steering or operating the same, a circuit and means therein for controlling said mechanism and means for rendering said circuit active or inactive through the influence of the said waves or disturbances exerted at a distance from the source, as set forth.

7. The combination with a source of electrical waves or disturbances and means for starting and stopping the same of a vessel or vehicle, propelling and steering mechanism carried thereby, a circuit containing or connected with means for controlling the operation of said mechanism and adjusted or rendered sensitive to the waves or disturbances of the source, as set forth.

8. The combination with a source of electrical waves or disturbances and means for starting and stopping the operation of the same, of a vessel or vehicle, propelling and steering mechanism carried thereby, local circuits controlling said mechanisms, a circuit sensitive to the waves or disturbances of the source and means therein adapted to control the said local circuits, as and for the purpose set forth.

9. The sensitive device herein described comprising in construction a receptacle containing a material such as particles of oxidized metal forming a part of the circuit, and means for turning the same end for end when the material has been rendered sensitive by the passage through it of an electric discharge, as set forth.

10. The sensitive device herein described, comprising in combination a receptacle containing a material such as particles of oxidized metal forming a part of an electric circuit, an electro-magnet in said circuit and devices controlled thereby for turning the receptacle end for end when said magnet is energized, as set forth.

11. The sensitive device herein described, comprising in combination a receptacle containing a material such as particles of oxidized metal forming part of an electric circuit, a motor for rotating the receptacle, an electro-magnet in circuit with the material and an escapement controlled by said magnet and adapted to permit a half revolution of the receptacle when the said magnet is energized, as set forth.

12. The combination with a movable body or vehicle, of a propelling motor, a steering motor and electrical contacts carried by a moving portion of the steering mechanism, and adapted in certain positions of the latter to interrupt the circuit of the propelling motor, a local circuit and means connected therewith for controlling the steering motor, and a circuit controlling the local circuit and means for rendering said controlling circuit sensitive to the influence of electric waves or disturbances exerted at a distance from their source, as set forth.

13. The combination with the steering motor, a local circuit for directing current through the same in opposite directions, a controlling circuit rendered sensitive to the influence of electric waves or disturbances exerted at a distance from their source, a motor in circuit with the steering motor, but adapted to run always in the same direction, and a local circuit or circuits controlled by said motor, as set forth.

NEW YORK, SATURDAY, NOVEMBER 19, 1898.

FACT AND FANCY.

Mr. Nikola Tesla, of New York, has invented what is known in naval science as a dirigible torpedo, that is to say, a torpedo which, instead of being self-driven and self-steering, like the Whitehead and the Howell, now in use in our navy, is driven and steered by an operator on shore, who controls the torpedo through electrical connections. Of the latter kind are the Sims-Edison, the Brennan, and the Victoria.

The Sims-Edison torpedo is driven by an electric motor carried within the shell of the torpedo, and it is steered by exciting certain magnets which control the steering gear. Current for operating the motor and magnets is supplied through a flexible cable which is wound upon a reel carried within the shell of the torpedo, and has one end connected to the shore. As the torpedo travels through the water, the cable unwinds. The torpedo is maintained at the proper depth by attaching it to a canoe-shaped float. To enable the operator to follow the course of the torpedo, two small flagstaffs are carried at each end of the float, and by keeping his eye on these, the operator is supposed to be able to steer the deadly weapon unerringly on its course. By night two colored lights are carried at the ends of the flagstaffs, and are hooded in such a way that, while they are visible to the operator, they are invisible to the enemy.

The Victoria, an Australian invention, differs from the last-mentioned in being entirely submergible below the water and in using compressed air as its motive power. When first started, it hauls a cable after it, unwinding it off a reel on shore, and the first part of its course is covered at moderate speed. When the operator has guided it to within striking distance of the enemy, a current is sent through the cable, which releases the reel on the torpedo and allows its cable to unwind. At the same time the current starts the air engines at full speed, and the final dash for the ship is made. The Brennan is another torpedo of the dirigible type, which received considerable attention as the result of its being taken up by the British Admiralty and subjected to exhaustive experiments. Like all the torpedoes of the dirigible type, however, it has proved to be only moderately successful, and, in common with them, is not regarded with much favor by naval authorities, the Whitehead automobile being par excellence the torpedo of the present day.

The most characteristic feature in Mr. Tesla's torpedo as distinguished from the others of the dirigible class is that, whereas they use a connecting cable for transmitting the controlling power to the torpedo, he makes use of the Hertzian waves, dispensing with the cable. This method of transmission is more popularly known under the name of "wireless telegraphy," and as such attracted considerable public attention during the recent experiments by the British Post Office with the apparatus designed by the young Italian, Marconi. On another page we reproduce some of the drawings accompanying the patent which has recently been granted to Mr. Tesla, and these, together with the descriptive matter, will render this interesting device clear to our readers.

Regarding the merits of the invention and its practical value, it is altogether too early to make any predictions. The abolition of the connecting cables is, of course, greatly to be desired, and the Tesla torpedo will, presumably, be rid of the liability to accident due to several thousand yards of cable trailing in the water. On the other hand, since the propelling current can no longer be transmitted from the shore, it becomes necessary to provide batteries within the torpedo itself, thereby adding again the weight that was saved by abolishing the cable.

It is true the range of the torpedo is enlarged (according to the inventor, indefinitely); but as the Sims-Edison has an extreme range of two miles, at which distance it would be extremely difficult to follow the motion of the two small flagstaffs above referred to, we fail to see what advantages would ensue from being able to drive and control the torpedo at any greater distance.

Except so far as it dispenses with the cables, it is not evident what advantages the Tesla torpedo possesses over others of the dirigible type, and unless it proves far more effective in actual test than they have done, it cannot be considered as even a formidable weapon.

Unfortunately for its reception by the thinking public, Mr. Tesla's improvement has been introduced to the world with some of the most extravagant rhapsodies that ever threw discredit upon an untried invention. Under the "scare head" title "Tesla declares he will abolish war," one of the leading New York journals quotes Mr. Tesla as saying in an interview: "War will cease to be possible when all the world knows to-morrow that the most feeble of the nations can supply itself immediately with a weapon which will render its coast secure and its ports impregnable to the assaults of the united armadas of the world. Battleships will cease to be built, and the mightiest armorclads and the most tremendous artillery afloat will be of no more use than so much scrap iron. And this irresistible power can be exerted at any distance by an agency of so delicate, so impalpable, a quality that I feel that I am justified in predicting that the time will come, incredible as it may seem, when it can be called into action by the mere exercise of the human will."

Having thus oratorically blotted out the navies of the world, the interviewed descends to particulars, and the reader, whose faith in battleships and cruisers is thus so rudely assailed, is relieved to learn that the mighty agent of this naval cataclysm is no more nor less than our time-honored friend the torpedo (that ever verdant topic of the universal destructionalist); in new war paint and snorting strange and new defiance, it is true, but still—"a torpedo." Unlike its prosaic forbears, however, this prodigy is not content with smiting anything in the way of a warship that may be in sight; for so keen is it on the scent that it could strike, we are told, a vessel that lay at Southampton, England, while the operator was snugly ensconced in the forts at Sandy Hook.

"Mr. Tesla told me," says the reporter, "that some months had elapsed since he had fully developed his device, for which he has applied for a patent. When it was learned that Admiral Cervera was bottled up at Santiago, it was his intention to apply his mechanism to several launches and similar small craft loaded with high explosives and annihilate the fleet at anchor. Admiral Cervera, however, came out and met his fate under the guns of the American fleet before the necessary arrangements could be made. Then Mr. Tesla planned a raid on the Spanish vessels in Havana Harbor, only to be thwarted by the proclamation of the suspension of hostilities."

In view of these facts we can well believe the inventor when, according to the journal in question, he says of his dirigible torpedo:

"My imagination fairly reels when I attempt to contemplate its countless possibilities. Already I hear the knell of the battleship and the monster gun! . . . England is now no stronger than the weakest of the maritime nations. . . . She will be utterly confounded, . . . and France will rejoice."

Now all this extravaganza may or may not express the true state of the "reeling imagination" above referred to. We prefer, charitably, to hope it does not; but the question to be asked in all seriousness is, What possible good can be done either to the inventor himself or to the great cause of science, which he is presumably desirous to promote, by confusing the minds of the public by such unscientific exaggerations as we have quoted above?

The facts of Mr. Tesla's invention are creditable enough in themselves. Their practical value will be demonstrated, we presume, in due course under the fierce searchlight of a test by naval experts. Until that time it would be better to allow the navies of the world to enjoy to the full that short spell of life which yet remains to them.

NIKOLA TESLA'S LATEST INVENTION.

We have recently been informed by the public press in flamboyant rhetoric that Nikola Tesla has devised a boat which is destined to revolutionize the art of warfare. Apart from its value as an excellent subject for sensational newspaper articles, Mr. Tesla's invention presents certain aspects which are, perhaps, not uninteresting from a scientific point of view. We have therefore produced herewith diagrams of this vessel, from which it will be seen that, ingenious as the mechanism employed may be, no very decided advantage is presented over the dirigible torpedo.

Of the annexed diagrams, Fig. 1 is a plan view of Tesla's boat, presenting a general view of the apparatus employed, Fig. 2 is a sectional view of the Tesla system, and Fig. 3 is a longitudinal section of the boat showing the mechanism in side elevation.

Tesla claims that, in a broad sense, his invention differs from all other systems of controlling boats, in so far as he uses no intermediate wires, cables, or other form of electrical or mechanical connection with the object, save the natural media in space.

The boat itself is provided with a propelling mechanism comprising a screw propeller, *C*, secured to the shaft of an electric motor, *D*, driven by the storage battery, *E*. The vessel is steered by a rudder controlled by a steering motor, *F*. The apparatus by means of which the operation of both the propelling and steering is controlled, involves the use of a receiving circuit adjusted and rendered sensitive to the influence of the electrical waves or impulses emanating from a distant source, the adjustment being such that the oscillations of the circuit and of the source of disturbance shall occur in electromagnetic synchronism.

The receiving circuit consists of a terminal, *E'*, a conductor, an electric controller similar to that used in "wireless" telegraphy, and means by which the current may be led to the ground through the medium of the vessel's keel. The circuit in question forms part of a local circuit, in which are included a relay magnet, *a*, and a battery, *a'*, the electromotive force of which is so determined that although the dielectric layers in the electric controller are subjected to great tension, yet normally they withstand the strain, and no appreciable current flows through the circuit. When, however, an electric impulse reaches the dielectric layers, they are broken down, thus suddenly diminishing the resistance and permitting a current to pass through the relay magnet. The particular controller employed need not be described here, but is shown in side elevation over the motor, *D*, in Fig. 3. The relay magnet, *a*, is used to control the operation of the propelling engine and of the steering apparatus.

Placed in the circuit of the electric controller is a commutator, by means of which the direction of the current may be changed in order to influence one of the two relay-magnets, *K'* or *K''*, placed in the circuit of the battery, *k''*. While one relay, *K'*, for example, is in operation, its armature closes a circuit passing through the motor, *F*, in order to cause the rudder to be swung to port. The other relay, *K''*, causes the motor to throw the rudder to starboard. The steering apparatus, as shown in Figs. 1 and 3, consists, in addition to the steering motor, *F*, of a toothed wheel, *G*, engaged by a worm on the shaft of the motor, *F*. The wheel, *G*, controls the rudder, *F'*, through the medium of a sleeve, *b*, a toothed wheel, *H''*, and rod, *G'*. A fixed vertical rod, *H*, is mounted within the sleeve, *b*, and carries an insulating disk, *L*, to the under surface of which brushes are secured. The sleeve, *b*, surrounding the rod, *H*, and turned by the motor, *F*, carries a disk, *L'*, upon the upper face of which are secured two concentric circles of conducting contact plates interspersed with insulated plates. In certain positions of the disk, *L'*, the brushes are in electric connection with the contact plates. Conductors connect the contact plates with the terminals of the propelling motor, *D*; and the poles of the battery, *E*, are so connected with two of the brushes that when the rudder is in straight position or turned to either side, the current is conveyed through these two brushes and through the contact plates to the propelling motor, *D*. The steering motor is similarly driven by current taken from the battery, *E*, and conducted to two brushes of the plate, *L*. The motor, *F*, according to Mr. Tesla, may always be caused to rotate in one direction whatever may be the position of the rudder; and may be caused to rotate in either direction whenever the rudder is inclined less than 45° from the center position.

In addition to this mechanism the vessel carries a small auxiliary motor, *m* (Fig. 1), connected in series with the armature of the steering motor. By means of this auxiliary motor, lights on the ends of the standards, *q*, may be flashed in order to indicate the course of the vessel to the operator at night.

In Fig. 2, illustrating diagrammatically the operation of the system, *S* indicates any source of electrical wave energy controlled by a switch located in a box, *T*. The handle of the switch is movable in one direction only, and stops on four points, *t*, *t'*, *u*, *u'*, so that as the handle passes from stop to stop, oscillations are produced during a very short interval. Tesla places the handle of the switch so that when arrested on the points, *t t'*, the boat is deflected respectively to the left or to the right from its course. The normal positions of the handle are *u u'*. The impulses sent forth from *S* are, according to Tesla, received by the terminal, *E'*, transmitted to the commutator, *j*, to influence one of the relays, *K' K''*, and to cause the motor, *F*, to act on the brushes to turn the rudder in whichever direction it may please the operator. The motor of the rudder causes the second set of brushes to act on the propelling motor to drive the vessel.

Whether, as Mr. Tesla claims, his apparatus, by reason of its certain and unlimited destructiveness, will tend to bring about and maintain permanent peace, is a question discussed elsewhere.

TESLA'S DIRIGIBLE BOAT.

Transmission of Power Through the Air Without Wires.

BY PROF. JOHN TROWBRIDGE.

Mr. Tesla has recently patented a method of transmitting power through the air without the use of wires. This method consists in producing a very great difference of potential between a high point in the atmosphere, reached by a wire connected to a balloon, and a distant point on a balloon, which in turn is connected through a stepdown transformer with the earth. A stepup transformer produces the high potential at the sending station, or at the first balloon, and the difference of potential thus created produces a current of conduction through the rarefied air to the second balloon and thence through the stepdown transformer to earth. Mr. Tesla relies upon the good conductivity of rarefied air to high electromotive force.

Some recent experiments I have made with high electromotive force are interesting in regard to the suggestion of Mr. Tesla, and are in continuation of those I described in the SCIENTIFIC AMERICAN for January 15, 1898. At that time my apparatus was capable of producing one million two hundred thousand volts. It now can produce three million.

Up to the point of one million and a half volts, the length of the electrical discharge in air appears to be closely proportional to the electromotive force. When this voltage is exceeded, the length of the spark no longer increases in proportion to this force, for instance, and electromotive force of approximately three million volts produces a spark of about seven feet in length, when it should excite one at least ten feet long. The reason of this diminution is readily seen when the operation of my apparatus is examined in the dark.

From both terminals and from the conductors to those terminals there is a luminous brush discharge to the walls and floor of the room. The main portion of the discharge is, so to speak, shunted through the air, which breaks down with facility at such high voltages. The high electromotive force exerts a similar action to that of diminished air pressure.

In the case of rarefied air, one sees the luminous area of discharge on the positive terminal extend farther and farther from the point of the terminal, thus indicating that there is an increased flow through the rarefied air. In ordinary atmospheric air the same increase of electrical conductivity takes place under the action of great electromotive force. When discharges produced by one million volts or more are excited between terminals six feet apart, in tubes filled with water, the tubes are speedily burst, and when the phenomenon is carefully examined, it is perceived that the disruptive sparks occur on the surface of the water inside the tubes which vaporize the water and thus lead to an explosion. The layer of air conducts more readily than the water. The same phenomenon can be shown by interposing a conductor made of plumbago and infusorial earth, making a resistance of about 10,000 ohms between the terminals of the apparatus. A spark passes over the surface of such a conductor through the air, if the length of such a conductor does not exceed ten or twelve inches.

I found also that the spark preferred to jump through five centimeters of air to passing through a thousand ohms of a copper sulphate solution. Thus the air evidently breaks down with increasing readiness when the electromotive force is increased beyond a certain limit.

One of the most striking experiments in this connection can be performed by coating a board with a thin layer of plumbago, which is polished upon the surface in such a manner as to make a resistance of about 1,000 ohms between broad terminal bands of copper. When a discharge under a difference of potential of 1,000,000 volts passes between the terminal bands, the entire surface of the conductor becomes luminous.

When my new apparatus was first set up, the coated surfaces of the Leyden jars were not more than a foot from the floor. On account of the great loss due to electrostatic induction, I determined to have the entire apparatus lifted three feet from the floor. A certain portion of the loss was thus obviated, but when discharge takes place, sparks an inch long can be drawn from the neighboring brick walls, and the entire room seems to be filled with brush discharges.

I believe, therefore, that beyond one million volts, the length of the spark is no longer proportional to the voltage, and that this departure from proportionality is due to the initial resistance of the neighboring air becoming less and less. In order to get the full effect of the voltage of my machine, I believe that it should be placed thirty or forty feet above the earth and at a distance from neighboring masses. The apparent length of lightning discharges at low altitudes is therefore no criterion of the voltage which produces these discharges; for there must be great leakage, which necessitates an excess of electromotive force to produce the discharge. On the other hand, the discharges in higher regions of the atmosphere are much lengthened on account of the increased conductivity of the medium.

In view of the experiments which I have described, I am led to believe that ordinary atmospheric air under very high voltage acts like a fairly good conductor, and I can conceive of such a high electromotive force that the initial resistance of air might not be more than the resistance of metals. The loss of electrical energy in producing difference of potential of three million volts at a distance of ten feet from the terminals of my machine is very great, and in employing such high voltages Mr. Tesla could only obviate great loss by lifting his entire generating apparatus far above the surface of the earth.

TESLA AND HIS WORK.

His Efforts in Various Fields of Investigation Described by Himself.

TO THE EDITOR OF THE SUN—*Sir:* Had it not been for other urgent duties, I would before this have acknowledged your highly appreciative editorial of Nov. 13. Such earnest comments and the frequent evidences of the highest appreciation of my labors by men who are the recognized leaders of this day in scientific speculation, discovery and invention are a powerful stimulus, and I am thankful for them. There is nothing that gives me so much strength and courage as the feeling that those who are competent to judge have faith in me.

Permit me on this occasion to make a few statements which will define my position in the various fields of investigation you have touched upon.

I cannot but gratefully acknowledge my indebtedness to earlier workers, as Dr. Hertz and Dr. Lodge, in my efforts to produce a practical and economical lighting system on the lines which I first disclosed in a lecture at Columbia College in 1891. There exists a popular error in regard to this light, inasmuch as it is believed that it can be obtained without generation of heat. The enthusiasm of Dr. Lodge is probably responsible for this error, which I have pointed out early by showing the impossibility of reaching a high vibration without going through the lower or fundamental tones. On purely theoretical grounds such a result is thinkable, but it would imply a device for starting the vibrations of unattainable qualities, inasmuch as it would have to be entirely devoid of inertia and other properties of matter. Though I have conceptions in this regard, I dismiss for the present this proposition as being impossible. We cannot produce light without heat, but we can surely produce a more efficient light than that obtained in the incandescent lamp, which, though a beautiful invention, is sadly lacking in the feature of efficiency. As the first step toward this realization I found it necessary to invent some method for transforming economically the ordinary currents as furnished from the lighting circuits into electrical vibrations of great rapidity. This was a difficult problem and it was only recently that I was able to announce its practical and thoroughly satisfactory solution. But this was not the only requirement in a system of this kind. It was necessary also to increase the intensity of the light, which at first was very feeble. In this direction, too, I met with complete success, so that at present I am producing a thoroughly serviceable and economical light of any desired intensity. I do not mean to say that this system will revolutionize those in use at present, which have resulted from the co-operation of many able men—I am only sure that it will have its fields of usefulness.

As to the idea of rendering the energy of the sun available for industrial purposes, it fascinated me early, but I must admit it was only long after I discovered the rotating magnetic field that it took a firm hold upon my mind. In assailing the problem I found two possible ways of solving it. Either power was to be developed on the spot by converting the energy of the sun's radiations or the energy of vast reservoirs was to be transmitted economically to any distance. Though there were other possible sources of economical power, only the two solutions mentioned offer the ideal feature of power being obtained without any consumption of material. After long thought I finally arrived at two solutions, but on the first of these, namely, that referring to the development of power in any locality from the sun's radiations, I cannot dwell at present. The system of power transmission without wires, in the form in which I have described it recently, originated in this manner. Starting from the two facts that the earth was a conductor insulated in space and that a body cannot be charged without causing an equivalent displacement of electricity in the earth, I undertook to construct a machine suited for creating as large a displacement as possible of the earth's electricity.

This machine was simply to charge and discharge in rapid succession a body insulated in space, thus altering periodically the amount of electricity in the earth, and consequently the pressure all over its surface. It was nothing but what in mechanics is a pump, forcing water from a large reservoir into a small one and back again. Primarily I contemplated only the sending of messages to great distances in this manner, and I described the scheme in detail, pointing out on that occasion the importance of ascertaining certain electrical conditions of the earth. The attractive feature of this plan was that the intensity of the signals should diminish very little with the distance, and, in fact, should not diminish at all, if it were not for certain losses occurring, chiefly in the atmosphere. As all my previous ideas, this one, too, received the treatment of Marsyas, but it forms, nevertheless, the basis of what is now known as "wireless telegraphy." This statement will bear rigorous examination, but it is not made with the intent of detracting from the merit of others. On the contrary, it is with great pleasure that I acknowledge the early work of Dr. Lodge, the brilliant experiments of Marconi, and of a later experimenter in this line, Dr. Slaby of Berlin. Now, this idea I extended to a system of power transmission, and I submitted it to Helmholtz on the occasion of his visit to this country. He unhesitatingly said that power could certainly be transmitted in this manner, but he doubted that I could ever produce an apparatus capable of creating the high pressures of a number of millions of volts, which were required to attack the problem with any chance of success, and that I could overcome the difficulties of insulation. Impossible as this problem seemed at first, I was fortunate to master it in a comparatively short time, and it was in perfecting this apparatus that I came to a turning point in the development of this idea. I, namely, at once observed that the air, which is a perfect insulator for currents produced by ordinary apparatus, was easily traversed by currents furnished by my improved machine, giving a tension of something like two and a half million volts. A further investigation in this direction led to another valuable fact, namely, that the conductivity of the air for these currents increased very rapidly with its degree of rarefaction, and at once the transmission of energy through the upper strata of the air, which, without such results as I have obtained, would be nothing more than a dream, became easily realizable. This appears all the more certain, as I found it quite practicable to transmit, under conditions such as exist in heights well explored, electrical energy in large amounts. I have thus overcome all the chief obstacles which originally stood in the way, and the success of my system now rests merely on engineering skill.

Referring to my latest invention, I wish to bring but a point which has been overlooked. I arrived, as has been stated, at the idea through entirely abstract speculations on the human organism, which I conceived to be a self-propelling machine, the motions of which are governed by impressions received through the eye. Endeavoring to construct a mechanical model resembling in its essential, material features the human body, I was led to combine a controlling device, or organ sensitive to certain waves, with a body provided with propelling and directing mechanism, and the rest naturally followed. Originally the idea interested me only from the scientific point of view, but soon I saw that I had made a departure which sooner or later must produce a profound change in things and conditions presently existing. I hope this change will be for the good only, for, if it were otherwise, I wish that I had never made the invention. The future may or may not bear out my present convictions, but I cannot refrain from saying that it is difficult for me to see at present how with such a principle brought to great perfection, as it undoubtedly will be in the course of time, guns can maintain themselves as weapons. We shall be able, by availing ourselves of this advance, to send a projectile at much greater distance, it will not be limited in any way by weight or amount of explosive charge, we shall be able to submerge it at command, to arrest it in its flight, and call it back, and to send it out again and explode it at will, and, more than this, it will never make a miss, since all chance in this regard, if hitting the object of attack were at all required, is eliminated. But the chief feature of such a weapon is still to be told, namely, it may be made to respond only to a certain note or tune, it may be endowed with selective power. Directly such an arm is produced, it becomes almost impossible to meet it with a corresponding development. It is in this feature, perhaps, more than in its power of destruction, that its tendency to arrest the development of arms and to stop warfare will reside. With renewed thanks, I remain, very truly, yours,

NEW YORK, Nov. 19, 1898. N. TESLA.

A Letter From Mr. Tesla.

NEW YORK, NOV. 18, 1898.
46 and 48 East Houston St.

TO THE EDITOR OF ELECTRICAL REVIEW—*Dear Sir:*

Under enclosure I forward a copy of a letter which is self-explanatory. If you consider it a justice to me to insert it in your next issue, kindly do so.

Yours very truly,
N. TESLA.

"THE ELECTRICAL ENGINEER" ASKED TO EXPLAIN.

NEW YORK, NOV. 18, 1898.
46 and 48 East Houston St.

EDITOR OF THE ELECTRICAL ENGINEER—*Sir:*

By publishing in your columns of November 17 my recent contribution to the Electro-Therapeutic Society, you have finally succeeded—after many vain attempts made during a number of years—in causing me a serious injury. It has cost me great pains to write that paper, and I have expected to see it appear among other dignified contributions of its kind, and, I confess, the wound is deep. But you will have no opportunity for inflicting a similar one, as I propose to take better care of my papers in the future. In what manner you have secured this one in advance of other electrical periodicals, who had an equal right to the same, rests with the secretary of the society to explain.

Your editorial comment would not concern me in the least, were it not my duty to take note of it. On more than one occasion you have offended me, but in my qualities both as Christian and philosopher, I have always forgiven you and have only pitied you for your errors. This time, though, your offense is graver than the previous ones, for you have dared to cast a shadow on my honor.

No doubt you must have in your possession, from the illustrious men whom you quote, tangible proofs in support of your statement reflecting on my honesty. Being a bearer of high honors from a number of American universities, it is my duty, in view of the slur thus cast upon them, to exact from you that, in your next issue, you produce these, together with this letter which, in justice to myself, I am forwarding to other electrical journals. In the absence of such proofs, which would put me in the position to seek redress elsewhere, I require that, together with the preceding, you publish instead a complete and humble apology for your insulting remark which reflects on me as well as on those who honor me.

On this condition I will again forgive you, but I would advise you to limit yourself in your future attacks to statements for which you are not liable to be punished by law.

N. TESLA.

TRANSMISSION OF POWER THROUGH THE AIR WITHOUT WIRES.

BY PROF. JOHN TROWBRIDGE IN THE "SCIENTIFIC AMERICAN."

Mr. Tesla has recently patented a method of transmitting power through the air without the use of wires. This method consists in producing a very great difference of potential between a high point in the atmosphere, reached by a wire connected to a balloon, and a distant point on a balloon, which in turn is connected through a step-down transformer with the earth. A step-up transformer produces the high potential at the sending station, or at the first balloon, and the difference of potential thus created produces a current of conduction through the rarefied air to the second balloon, and thence through the step-down transformer to earth. Mr. Tesla relies upon the good conductivity of rarefied air to high electro-motive force.

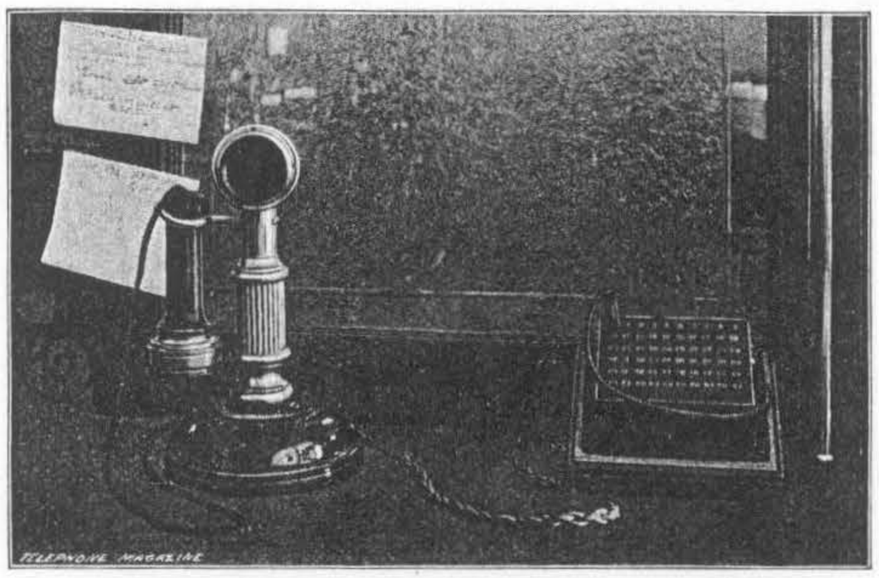

FIG. 1.—SIXTY-POINT STROMBERG-CARLSON TELEPHONE PLUG BOX.

Some recent experiments I have made with high electro-motive force are interesting in regard to the suggestion of Mr. Tesla, and are in continuation of those I described in the *Scientific American* for January 15, 1898. At that time my apparatus was capable of producing 1,200,000 volts. It can now produce 3,000,000.

Up to the point of 1,500,000 volts the length of the electrical discharge in air appears to be closely proportional to the electro-motive force. When this voltage is exceeded, the length of the spark no longer increases in proportion to this force, for instance, and electro-motive force of, approximately, 3,000,000 volts produces a spark of about seven feet in length, when it should excite one at least 10 feet long. The reason of this diminution is readily seen when the operation of my apparatus is examined in the dark.

From both terminals, and from the conductors to those terminals, there is a luminous brush discharge to the walls and floor of the room. The main portion of the discharge is, so to speak, shunted through the air, which breaks down with facility at such high voltages. The high electro-motive force exerts a similar action to that of diminished air pressure.

In the case of rarefied air, one sees the luminous area of discharge on the positive terminal extend farther and farther from the point of the terminal, thus indicating that there is an increased flow through the rarefied air. In ordinary atmospheric air the same increase of electrical conductivity takes place under the action of great electro-motive force. When discharges produced by 1,000,000 volts or more are excited between terminals six feet apart, in tubes filled with water, the tubes are speedily burst, and when the phenomenon is carefully examined, it is perceived that the disruptive sparks occur on the surface of the water inside the tubes, which vaporize the water and thus lead to an explosion. The layer of air conducts more readily than the water. The same phenomenon can be shown by interposing a conductor made of plumbago and infusorial earth, making a resistance of about 10,000 ohms between the terminals of the apparatus. A spark passes over the surface of such a conductor through the air, if the length of such a conductor does not exceed 10 or 12 inches.

I found also that the spark preferred to jump through five centimeters of air to passing through 1,000 ohms of a copper sulphate solution. Thus the air evidently breaks down with increasing readiness when the electro-motive force is increased beyond a certain limit.

One of the most striking experiments in this connection can be performed by coating a board with a thin layer of plumbago, which is polished upon the surface in such a manner as to make a resistance of about 1,000 ohms between broad terminal bands of copper. When a discharge under a difference of potential of 1,000,000 volts passes between the terminal bands, the entire surface of the conductor becomes luminous.

When my new apparatus was first set up, the coated surfaces of the Leyden jars were not more than a foot from the floor. On account of the great loss due to electrostatic induction, I determined to have the entire apparatus lifted three feet from the floor. A certain portion of the loss was thus obviated, but when discharge takes place, sparks an inch long can be drawn from the neighboring brick walls, and the entire room seems to be filled with brush discharges.

I believe, therefore, that beyond 1,000,000 volts, the length of the spark is no longer proportional to the voltage, and that this departure from proportionality is due to the initial resistance of the neighboring air becoming less and less. In order to get the full effect of the voltage of my machine, I believe that it should be placed 30 or 40 feet above the earth and at a distance from neighboring masses. The apparent length of lightning discharges at low altitudes is therefore no criterion of the voltage which produces these discharges; for there must be great leakage, which necessitates an excess of electro motive force to produce the discharge. On the other hand, the discharges in higher regions of the atmosphere are much lengthened on account of the increased conductivity of the medium.

In view of the experiments which I have described, I am led to believe that ordinary atmospheric air under very high voltage acts like a fairly good conductor, and I can conceive of such a high electro motive force that the initial resistance of air might not be more than the resistance of metals. The loss of electrical energy in producing difference of potential of 3,000,000 volts at a distance of 10 feet from the terminals of my machine is very great, and in employing such high voltages Mr. Tesla could only obviate great loss by lifting his entire generating apparatus far above the surface of the earth.

THE EARTH AND ITS ATMOSPHERE.

A CRITICISM AND ITS ANSWER.

AN INQUIRY.

To the Editor of Electrical Review:

In your issue of November 2, in an article dated New York, October 29, and entitled "Tesla's Aerial Power Transmission," T. J. M. says: "What, then, should be the effect of the earth rotating at its enormous speed *under the friction of the atmosphere*—a globe billions of times the surface of the archaic electric machine?"

If I am not mistaken, there is no "friction of the atmosphere" *with the earth*. The atmosphere moves with the earth. Did it not, we should be swept from its surface by the enormous velocity of our motion through the atmosphere.

There is no friction at the "*upper*" surface of the atmosphere, for there is absolutely nothing to cause friction.

It seems to me that T. J. M. must seek another explanation of the source of electricity that causes the electrical phenomena of the atmosphere.

S. R. M.

Ithaca, N. Y., November 4.

THE ANSWER.

To the Editor of Electrical Review:

If "S. R. M." had read discriminatingly he would have understood differently. As a whole, the earth and its atmosphere move together, or at least the text-books teach the student to consider the fact settled. But there are great disturbances constantly happening in the air and over vast areas and which can have tremendous effects capable of giving astonishing electrical manifestations, and in the upper strata electrical excitement of a most intense character would not, if manifested, cause any surprise to the modern thinker. What is a storm, if it be not a condition attended by the friction of the lower strata upon the earth's surface, and probably of the lower strata against the higher strata of air? Yet the storm may be, and often is, raging furiously over an area of a million square miles or more.

In the absence of the right sort of data, namely, observations and records of what is going on away up in our atmosphere, no one can say what is the primary cause of these great areas of high and low pressure.

Many days one can look up and observe several strata of clouds, each layer moving in an independent direction, proving the existence of stratum-friction, the clouds being merely the finger-boards or pointers, and having no relation to or bearing upon the fact of independently moving layers of air and the friction necessarily occurring.

And what is the cause of the steadily moving trade-winds in different parts of the world? Why is it that in a given locality the most destructive wind-storms always blow in the same direction? Text-books to the contrary, it is by no means demonstrated that there is no friction between the earth and its atmosphere. It is quite easy to conceive the idea of some friction, and easy to understand how the differential "winds" thus caused can take all sorts of directions. And a very little of that kind of disturbance could generate stupendous amounts of electricity. And it is quite as easy to believe—indeed, it would seem necessary to believe—that there are in the atmosphere movements just like the ocean tides, since air is as subject as water to the laws of gravitation.

Mr. Tesla to His Friends.

New York, Nov. 18, 1898.
46 and 48 East Houston St.

Editor of The Electrical Engineer, 120 Liberty St., New York City.

Sir—By publishing in your columns of Nov. 17 my recent contribution to the Electro-Therapeutic Society you have finally succeeded—after many vain attempts made during a number of years—in causing me a serious injury. It has cost me great pains to write that paper, and I have expected to see it appear among other dignified contributions of its kind, and, I confess, the wound is deep. But you will have no opportunity for inflicting a similar one, as I propose to take better care of my papers in the future. In what manner you have secured this one in advance of other electrical periodicals who had an equal right to the same, rests with the secretary of the society to explain.

Your editorial comment would not concern me in the least, were it not my duty to take note of it. On more than one occasion you have offended me, but in my qualities both as Christian and philosopher I have always forgiven you and only pitied you for your errors. This time, though, your offence is graver than the previous ones, for you have dared to cast a shadow on my honor.

No doubt you must have in your possession, from the illustrious men whom you quote, tangible proofs in support of your statement reflecting on my honesty. Being a bearer of great honors from a number of American universities, it is my duty, in view of the slur thus cast upon them, to exact from you that in your next issue you produce these, together with this letter, which in justice to myself, I am forwarding to other electrical journals. In the absence of such proofs, which would put me in the position to seek redress elsewhere, I require that, together with the preceding, you publish instead a complete and humble apology for your insulting remark which reflects on me as well as on those who honor me.

On this condition I will again forgive you; but I would advise you to limit yourself in your future attacks to statements for which you are not liable to be punished by law.

N. TESLA.

His Friends to Mr. Tesla.

ONE of the foremost electrical inventors of this country, whose name is known around the world, has been kind enough to say that The Electrical Engineer made Mr. Tesla. This is an attribution that we naturally put aside, for it is a man's own work that makes or unmakes him, but we do plead guilty to the fact that for these ten years past we have done whatever mortals could do to bring Mr. Tesla forward and secure for him the recognition that was duly his. Not only in the columns of this and other journals, but in magazines and books we have striven with all the ability we possessed to explain Mr. Tesla's ideas. The record is before all men. If there is a line or a word in it that seeks to do Mr. Tesla "serious injury," we demand its production by him. The man, whoever he be, who says we have ever in word or deed or thought tried to do Mr. Tesla any sort of injury, lies.

Within the last year or two Mr. Tesla has, it seems to us, gone far beyond the possible in the ideas he has put forth, and he has to-day behind him a long trail of beautiful but unfinished inventions. By mild criticism and milder banter, not being able to lend Mr. Tesla the cordial support of earlier years of real achievement, we have only very lately endeavored to express our doubts and to urge him to the completion of some one of the many desirable or novel things promised. We believe this to be true friendship.

For example, take Mr. Tesla's latest and furthest enlargement of his newest idea, as presented by him in a signed letter in the New York "Sun," of Nov. 21, unfolding his plan to dispense with artillery of the present type. At this moment we have space only for the following passage:

"We shall be able, availing ourselves of this advance, TO SEND A PROJECTILE, at much greater distance, IT WILL NOT BE LIMITED IN ANY WAY BY WEIGHT or amount of explosive charge, we shall be able to submerge it at command, TO ARREST IT IN ITS FLIGHT AND CALL IT BACK, and to send it out again and explode it at will, and, more than this, IT WILL NEVER MAKE A MISS."

When we are expected, wide awake and in our sober senses, to accept in silence such an utterance as that quoted above or that which describes as "a possibility" the operation of a distant torpedo boat by the mere exercise of the will, we refuse point blank and we are willing to face the consequences. Our past admiration of Mr. Tesla's real, tangible work is on record, and stands; but we draw the line at such things as these. We are sorry Mr. Tesla feels it so keenly, but we cannot help it.

Now, as to the specific points raised in the above letter, which Mr. Tesla certainly would not have written had he been well advised. As to the manner in which we came to print Mr. Tesla's paper, the two letters herewith speak for themselves.

The American Electro-Therapeutic Association.
Dr. Charles R. Dickson, Ex-President.
296 Sherbourne St.
Toronto, Canada, Sept. 26, 1898.

T. Commerford Martin, Esq., 120 Liberty St., New York.

Dear Sir—I was quite surprised to hear on Saturday last from my friend, Dr. Robert Newman, of New York, that the editors of The Electrical Engineer had received no notices of the meeting of our association; I understood that the secretary had sent them. However, in case you might find space to say something of us, I have patched up an article drawn from various sources giving full particulars, which you can cut down to the desired dimensions. I fully appreciate all that you have done for the association in the past, or would not go to this trouble. I also send you a copy of the programme and of hand-book. In regard to latter, I am very sorry that the Buffalo committee had to retain for such a long time the electro of Mr. Tesla which you were so kind as to loan to them through Dr. Newman.

I have to thank you very sincerely for the loan of the electro, and hope that it reached you in good condition.

Wishing your esteemed journal continued and increasing success, very truly yours. CHARLES R. DICKSON.

The American Electro-Therapeutic Association.
Dr. Robert Newman, Chairman.
64 West 36th St.
New York City, Oct. 20, 1898.

Messrs. T. C. Martin and J. Wetzler.

Messrs. Editors—We have now the necessary vote for you publishing Tesla's paper in The Electrical Engineer, you lending us the cuts in proper size for our transactions.

The pages of our book are 7½ by 5 inches—if our secretary is not dilatory, you will receive the mss. and illustrations at once. Will call soon. Yours most truly, ROBERT NEWMAN.

These show our relations with a deserving association and our efforts to assist its work. We may add as a matter of fact, for which, if necessary, the proofs will be presented, that before printing the paper, we sent Dr. Newman to technical publishers, who refused to print the matter in book form because there was not, in their estimation, sufficient demand for it among scientific men. Failing this, we were undoubtedly glad to give it a place in our pages, as it struck us as good "copy."

We venture also to direct attention to the dates of the Dickson and Newman letters, one Sept. 26 and the other Oct. 20. The Tesla paper was read on Sept. 15 and appeared in our columns Nov. 17. Does this gap of over two months between reading and publication justify Mr. Tesla's insinuation that we took swift and mean advantage of him and of our contemporaries? Will anyone produce a letter to show that anyone of our contemporaries ever took the slightest interest in the Tesla paper or even asked for it? If such letters exist, now is the time to produce them. The paper was given to The Electrical Engineer because this journal takes a deep interest in the advance of electro-therapists and has a wide circulation among them, and according to universal custom, the paper once read became the property of the association to deal with as it chose. That, without any particular effort, we should have secured a "scoop"—to use the slang of journalism—is nothing to be ashamed of; we rather glory in it, for whatever it is worth.

It will be noted that we placed freely at the disposal of the association a portrait block of Mr. Tesla which we value highly. We were anxious, however, to do him honor in this way, and loaned the original. Since that time, we have loaned it, without charge, to Mr. Belford, of "Success," in whose November issue it appears by our courtesy; and we have within the past week placed it at the disposal of another publishing house. Perhaps these are the attempts to do him an injury about which Mr. Tesla has so unfortunately allowed himself to be persuaded.

Now as to the very depreciatory quotations from the distinguished scientists, Profs. Brackett and Dolbear. The passage from Prof. Brackett appeared in the New York "Herald" of Nov. 9. That from Prof. Dolbear appeared in the New York "Herald" of Nov. 10. They had not been contradicted or withdrawn when we called attention to them and objected to them. One of our electrical contemporaries last week quoted them both like ourselves, but said it was inclined to agree with Prof. Dolbear. We now beg to call Mr. Tesla's attention to the subjoined dispatches from both scientists, and would say that having already expressed dissent from the views of both Profs. Brackett and Dolbear, we do not see how it concerns us any further.

(Press Telegram.)

Princeton, N. J., Nov. 20, 1898.

T. C. Martin, Editor of The Electrical Engineer, New York.

Some of the language on pages 490 and 491 of The Electrical Engineer of Nov. 17, purporting to be quoted from me, is a fairly correct reproduction of what I said to a "Herald" reporter in reply to his question as to the probable practicability of Mr. Tesla's device for the abolishing war already presented in the "Herald," a copy of which he showed me.

In the language which you quote, there is much confusion and inaccuracy, due to the fact that the reporter took no notes of what I said, but trusted his memory.

No subject other than that proposed, viz.: Is the proposed plan practicable, was discussed. C. F. BRACKETT.

North Cambridge, Mass., Nov. 21.

The Electrical Engineer, New York.

Letter received this morning. The "Herald" report was substantially accurate. I will write more to you presently.

A. E. DOLBEAR.

"Greatest Discovery of the Age."

Mr. H. W. Phillips, in the "Criterion" of Nov. 19, has an illustrated interview with Mr. Tesla, whom he quotes as follows in regard to his use of the coherer as a relay for steering dirigible torpedoes: "I think that it is the greatest discovery of the age. There is something artistic—an appeal to the imagination—in it that the telephone, phonograph and other fine inventions lack." In reply to an inquiry as to his ability to operate the coherer by an effort of the will merely, Mr. Tesla said to Mr. Phillips: "I have no evidence to support it, but I have a perfect right to state it—understand me—as a possibility—no more." Mr. Tesla also remarked: "Had I nothing else to show for a lifework, this would put the laurels of everlasting fame on my head."

Rontgen Society.—The president of the Röntgen Society and Mrs. Mansell Moullin and the council entertained a large number of scientific gentlemen and their friends at a conversazione at the St. Martin's Town Hall on Monday night. While a most enjoyable programme by the London Concert Orchestra, with a couple of songs by Mr. Fitzroy Sheridan, and an excellent buffet supplied the wants of the inner man, those who wished that "this too solid flesh could melt" had no difficulty in gratifying their desire. In the main hall, which was filled with exhibits, Dr. Hedley presided over the London Hospital outfit, supplied by Isenthal, Potzler, and Co. A small portable dark-room was set up, and this cupboard was well patronised by those who wished to examine their friends skeletons or part of their own. Similar exhibitions were given in a large darkened room by Dr. Pepperdene, and Messrs. Webster, Watson Baker, Coldwell, Cox, and Dean. A number of patients in charge of nurses were similarly examined, under the supervision of Dr. Walsh, assisted by Mr. Fenton and Mr. Isenthal, a case of congenital clavicular malformation being especially easy to discern. Another patient lay on a stretcher in the main hall, and his bones could be distinctly seen by means of the fluoroscope, which consists of a fluorescent screen fitted with bellows like a camera, ending in an eyepiece bound in fur. This permits the exclusion of all extraneous light, and these appliances are very useful in simple cases, as the room need not be darkened during the examination of the patient. The phenomena of the Geissler tubes by Messrs. Corser, Gerard Smith, and Vesey, and the "white magic" by Prof. Silvanus P. Thompson, F.R.S., who demonstrated the

action of the Tesla oscillator upon vacuum tubes destitute of electrodes, drew such a large audience that it was almost impossible to get near. Mr. Harry W. Cox showed a large induction coil with his new type of contact-breaker. The coil required about six amperes and twelve volts when giving a 19in. spark. Mr. Isenthal had an apparatus fitted with double bulbs. These tubes consist of a very large bulb, about double the size hitherto used. The tube is continued vertically, then another bulb, about a quarter of the size, and a small sideward branch with another anode in it, is added. The advantage claimed for this arrangement is that a continuous supply of X-rays is produced without the necessity of heating the bulb every now and then, and that the current required is very low. A large selection of X-ray photographs lined the room, and we should suggest that another time the tablets should bear more definite inscriptions. It is rather puzzling at first to come across a female skeleton, and to read: "Mr. A—— B——," this being presumably the name of the exhibitor, and not of the exhibit.

Teslaic Transmissions.—The best criticism we have seen of the enormous potentialities claimed by the daily Press, both here and in the States, for Tesla's latest development in electric works, is contained in the *Electrical World*. Our contemporary, in a leader headed "Boundless Space a 'Bus Bar," states that at least one of the American electrical journals has taken Mr. Nikola Tesla's patents more seriously than the inventor intended them. The idea proposed comprises nothing more nor less than a high-tension step-up transformer feeding into a vertical conductor with a terminal at such an elevation above the earth as to reach a strata of rarefied atmosphere which has a comparatively low electrical resistance, a similar step-down transformer to be connected at any desired point with the same conducting strata by means of any suitable device, such as that used by the illustrious Benjamin Franklin, or, preferably, as stated in the patent, by means of a balloon, the earth being utilised as a ground return. The fact is set forth that the atmosphere at 15lb. to the square inch, or other pressures common near the surface of this mundane sphere, is a good insulator, while at lower pressures, as is well known by manufacturers of 200-volt lamps, it becomes quite a fair conductor. By a rigid suppression of the reasoning faculties, and a little freedom of the imagination, fancy pictures a conductor poked up through the insulating sheath at Niagara, establishing an alternating difference of potential between the superincumbent ether and this ball of solid matter below protected by an atmospheric dielectric, which difference of potential can be tapped, so to speak, at any desired location, such as the large cities, or by express trains with electric locomotive towing balloon trolleys, making contact with an overhead conductor, from which they cannot readily slip off. The use of several great sources of natural power will, of course, necessitate generators of the same frequency running in synchronism with each other, as they are all, so to speak, connected across the same 'bus bars, and lacking the third 'bus bar, multiphase systems will go out of fashion. The system might, however, give other results more valuable than those of power transmission. With transmitting and receiving stations at Niagara Falls and New York City respectively, the State of New York would possibly be illuminated by a gigantic Geissler tube overhead that would turn night into day, put to shame the aurora borealis, and make the advocates of diffused illumination shout for joy. (The writer reserves all rights to the use of interplanetary space as a vacuum tube for lighting purposes.) Mr. Tesla should certainly be enjoined from putting his polished ball terminals too high, or a Crookes tube effect might be obtained, emitting a profusion of X-rays which would disclose altogether too much to anyone with fluorescent spectacles, and might make it necessary for mortals to carry leaden umbrellas to prevent the skin being burned from the tops of their heads.

Mr. Tesla's Paper Before the Electro-Therapeutic Society.

The recent publication in an electrical journal of a paper presented before the Electro-Therapeutic Society by Mr. Tesla on "High-Frequency Oscillations for Therapeutic Applications" has elicited the following letter from Mr. Tesla to the editor of the paper making the reprint, with the request that the letter be published in the columns of The Electrical World. The letter, which is self-explanatory, is as follows:

"By publishing in your columns of Nov. 17 my recent contribution to the Electro-Therapeutic Society, you have finally succeeded—after many vain attempts made during a number of years—in causing me a serious injury. It has cost me great pains to write that paper, and I have expected to see it appear among other dignified contributions of its kind, and, I confess, the wound is deep. But you will have no opportunity for inflicting a similar one, as I propose to take better care of my papers in the future. In what manner you have secured this one in advance of other electrical periodicals, who had an equal right to the same, rests with the secretary of the society to explain.

"Your editorial comment would not concern me in the least were it not my duty to take note of it. On more than one occasion you have offended me, but in my qualities both as Christian and philosopher I have always forgiven you and have only pitied you for your errors. This time, though, your offense is graver than the previous ones, for you have dared to cast a shadow on my honor.

"No doubt you must have in your possession, from the illustrious men whom you quote, tangible proofs in support of your statement reflecting on my honesty. Being a bearer of high honors from a number of American universities, it is my duty, in view of the slur thus cast upon them, to exact from you that in your next issue you produce these, together with this letter, which, in justice to myself, I am forwarding to other electrical journals. In the absence of such proofs, which would put me in the position to seek redress elsewhere, I require that, together with the preceding, you publish instead a complete and humble apology for your insulting remark, which reflects on me as well as on those who honor me.

"On this condition I will again forgive you, but I would advise you to limit yourself in your future attacks to statements for which you are not liable to be punished by law. N. Tesla.

"New York, Nov. 18, 1898, 46 and 48 East Houston Street."

SCIENCE AND SENSATIONALISM.

One of the most astonishing features in the development of modern journalism is the magnitude and successful audacity of the Sunday issues of the great daily papers, and among these there are none quite so successful in self-advertisement, with the unthinking half of the public at least, as those issues which are marked by the distinctive characteristics of yellow journalism.

Now, the yellow journal is nothing if it is not sensational, and in its quest for startling novelties to whet the palate of its readers, it invades every possible sphere of human life and interest and every branch of human knowledge. Science, which, one would have thought, would be severely let alone, is a favorite hunting ground of the reporter, and whole pages of the yellow journal seventh-day editions are loaded down with pseudo-scientific pabulum, upon which the Sunday reader is supposed to satisfy his hunger for scientific knowledge. The reporters for these journals are apparently sent out into the domains of science charged with a commission to magnify mole hills into mountains and use such facts as they may pick up as texts for exuberant essays, in which rhetoric gorges itself with superlatives and becomes positively tipsy with the fumes of its own wild imaginings.

Hence it is by the merest promptings of self-respect that the average man of science shuns the noisy notoriety of a Sunday paper "write-up," and reserves his announcements for the columns of the technical and scientific journals, or a lecture desk in the auditorium of the learned associations. The practice, the etiquette, we had almost said the ethics, of scientific research agree in rebuking the former and approving the latter method of making public announcement of results actually accomplished.

We shall not soon forget the extreme mortification exhibited in our presence on a recent occasion by a medical expert when he discovered, through our application to him for the true facts of the case, that the details of a difficult operation just performed by him had been published, with flattering encomiums and the inevitable inaccuracies, in a certain daily paper, thereby anticipating a paper on the subject that was to be duly presented in the columns of the medical journals.

This is the true professional spirit, and every departure from it tends in some degree to subvert the interest of science, and throw a stumbling block in the way of the honest seeker after knowledge.

We note with considerable regret that subsequently to his first extraordinary interviews, Mr. Tesla has seen fit to place himself at the service of those New York Sunday papers that are more or less notoriously sensational, with the result that the "annihilator" has taken on fresh terrors. It is now illumined by the flaming brush of the artist, and the public is diverted with realistic scenes in which the nine days' wonder is depicted as speeding, now above, now beneath the surface of a sea which is always propitiously calm, under a sky and in an atmosphere that are ever opportunely bright and clear, against a ship that is ever fortuitously within easy range, and always with the inevitable and unutterable result!

Judging from the comments of the scientific and technical press, we are not alone in our expressions of regret that any one of Mr. Tesla's undoubted ability should indulge in such obvious and questionable self-advertisement. That the author of the multiphase system of transmission should, at this late day, be flooding the press with rhetorical bombast that recalls the wildest days of the Keely motor mania is inconsistent and inexplicable to the last degree.

The facts of Mr. Tesla's invention are as few and simple as the fancies which have been woven around it are many and extravagant. The principles of the invention are not new, nor was Tesla even their original discoverer. While the present application of these principles is novel, there is nothing whatever in the device to warrant the sweeping claims which have been made in regard to its destructive powers. The connecting cable in the dirigible torpedo is only one of many insuperable obstacles to its success. Mr. Tesla has removed (or rather believes that he has) this one defect; let him now apply himself to mastering the others. Before he announces his ability to blot the navies of the world out of existence, let him answer a few pertinent questions, as follows:

If the torpedo must be seen to be controlled, and is scarcely visible at a distance of over a mile, even in a calm sea, how, in view of the great range, rapidity and accuracy of modern rifles, is the operator to keep within striking distance of the enemy? If the course of the torpedo can with difficulty be followed in calm weather, how will it be traced when the surface is disturbed even by a moderate sea, to say nothing of more boisterous water? Furthermore, what becomes of its accuracy in thick or foggy weather? The apparatus employed by Tesla is extremely sensitive to shock; how then will it fare amid the terrific concussion of a modern sea fight? If one of these weapons should be lost sight of in its course, does it not at once threaten friend and foe alike, and is not the operator himself in danger of being incontinently "hoist with his own petard"?

Lastly, and most pertinent question of all: What is to prevent the enemy from installing a transmitter on his own ship and himself sending out waves to act upon the receiver in the torpedo? We fail to find any provision made for this contingency, either in the patent or in any of the published interviews of the inventor. With a transmitter in the hands of the enemy the proper sequence of the motions of the torpedo could be destroyed, and the control of it prevented.

Tesla Demands an Apology.

Nikola Tesla has a grievance. He resents the imputation that he is a humbug, and proclaims himself a "Christian and philosopher," citing in support of this assertion the fact that numerous offenses against his dignity and personal wishes have been committed by those who have posed as his friends, but that in every case he has forgiven them freely. In further proof of his forbearance he declares his willingness to extend pardon for the last offense and restore the erring ones to favor, conditioned, however, upon the publication of a "complete and humble apology." Mr. Tesla has furnished the Western Electrician the following copy of a letter upon this subject which is self-explanatory:

To the Editor of the Electrical Engineer:

By publishing in your columns of November 17th my recent contribution to the Electro-therapeutic society you have finally succeeded—after many vain attempts made during a number of years—in causing me a serious injury. It has cost me great pains to write that paper and I have expected to see it appear among other dignified contributions of its kind, and, I confess, the wound is deep. But you will have no opportunity for inflicting a similar one, as I propose to take better care of my papers in the future. In what manner you have secured this one in advance of other electrical periodicals who had an equal right to the same rests with the secretary of the society to explain.

Your editorial comment would not concern me in the least were it not my duty to take note of it. On more than one occasion you have offended me, but in my qualities both as Christian and philosopher I have always forgiven you and have only pitied you for your errors. This time, though, your offense is graver than the previous ones, for you have dared to cast a shadow on my honor.

No doubt you must have in your possession, from the illustrious men whom you quote, tangible proofs in support of your statement reflecting on my honesty. Being a bearer of great honors from a number of American universities, it is my duty, in view of the slur thus cast upon them, to exact from you that in your next issue you produce these, together with this letter, which, in justice to myself, I am forwarding to other electrical journals. In the absence of such proofs, which would put me in the position to seek redress elsewhere, I require that, together with the preceding, you publish instead a complete and humble apology for your insulting remark, which reflects on me as well as on those who honor me.

On this condition I will again forgive you, but I would advise you to limit yourself in your future attacks to statements for which you are not liable to be punished by law.

New York, November 18, 1898. N. TESLA.

Transmission of Power Through the Air Without Wires.[1]

By Prof. John Trowbridge.

Mr. Tesla has recently patented a method of transmitting power through the air without the use of wires. This method consists in producing a very great difference of potential between a high point in the atmosphere, reached by a wire connected to a balloon, and a distant point on a balloon, which in turn is connected through a step-down transformer with the earth. A step-up transformer produces the high potential at the sending station, or at the first balloon, and the difference of potential thus created produces a current of conduction through the rarefied air to the second balloon and thence through the step-down transformer to earth. Mr. Tesla relies upon the good conductivity of rarefied air to high electromotive force.

Some recent experiments I have made with high electromotive force are interesting in regard to the suggestion of Mr. Tesla, and are in continuation of those I described in the Scientific American for January 15, 1898. At that time my apparatus was capable of producing 1,200,000 volts. It can now produce 3,000,000.

Up to the point of one million and a half volts, the length of the electrical discharge in air appears to be closely proportional to the electromotive force. When this voltage is exceeded, the length of the spark no longer increases in proportion to this force, for instance, and electromotive force of approximately 3,000,000 volts produces a spark of about seven feet in length, when it should excite one at least 10 feet long. The reason of this diminution is readily seen when the operation of my apparatus is examined in the dark.

From both terminals and from the conductors to those terminals there is a luminous brush discharge to the walls and floor of the room. The main portion of the discharge is, so to speak, shunted through the air, which breaks down with facility at such high voltages. The high electromotive force exerts a similar action to that of diminished air pressure.

In the case of rarefied air, one sees the luminous area of discharge on the positive terminal extend farther and farther from the point of the terminal, thus indicating that there is an increased flow through the rarefied air. In ordinary atmospheric air the same increase of electrical conductivity takes place under the action of great electromotive force. When discharges produced by 1,000,000 volts or more are excited between terminals six feet apart, in tubes filled with water, the tubes are speedily burst, and when the phenomenon is carefully examined, it is perceived that the disruptive sparks occur on the surface of the water inside the tubes, which vaporize the water and thus lead to an explosion. The layer of air conducts more readily than the water. The same phenomenon can be shown by interposing a conductor made of plumbago and infusorial earth, making a resistance of about 10,000 ohms between the terminals of the apparatus. A spark passes over the surface of such a conductor through the air, if the length of such a conductor does not exceed 10 or 12 inches.

I found also that the spark preferred to jump through five centimeters of air to passing through a thousand ohms of a copper-sulphate solution. Thus the air evidently breaks down with increasing readiness when the electromotive force is increased beyond a certain limit.

One of the most striking experiments in this connection can be performed by coating a board with a thin layer of plumbago, which is polished upon the surface in such a manner as to make a resistance of about 1,000 ohms between broad terminal bands of copper. When a discharge under a difference of potential of 1,000,000 volts passes between the terminal bands, the entire surface of the conductor becomes luminous.

When my new apparatus was first set up, the coated surfaces of the Leyden jars were not more than a foot from the floor. On account of the great loss due to electrostatic induction, I determined to have the entire apparatus lifted three feet from the floor. A certain portion of the loss was thus obviated, but when discharge takes place, sparks an inch long can be drawn from the neighboring brick walls, and the entire room seems to be filled with brush discharges.

I believe, therefore, that beyond 1,000,000 volts, the length of the spark is no longer proportional to the voltage, and that this departure from proportionality is due to the initial resistance of the neighboring air becoming less and less. In order to get the full effect of the voltage of my machine, I believe that it should be placed 30 or 40 feet above the earth and at a distance from neighboring masses. The apparent length of lightning discharges at low altitudes is therefore no criterion of the voltage which produces these discharges, for there must be great leakage, which necessitates an excess of electromotive force to produce the discharge. On the other hand, the discharges in higher regions of the atmosphere are much lengthened on account of the increased conductivity of the medium.

In view of the experiments which I have described, I am led to believe that ordinary atmospheric air under very high voltage acts like a fairly good conductor, and I can conceive of such a high electromotive force that the initial resistance of air might not be more than the resistance of metals. The loss of electrical energy in producing difference of potential of 3,000,000 volts at a distance of 10 feet from the terminals of my machine is very great, and in employing such high voltages Mr. Tesla could only obviate great loss by lifting his entire generating apparatus far above the surface of the earth.

1. From the Scientific American.

Tesla Describes His Investigations.

[From the New York Sun.]

I cannot but gratefully acknowledge my indebtedness to earlier workers, as Dr. Hertz and Dr. Lodge, in my efforts to produce a practical and economical lighting system on the lines which I first disclosed in a lecture at Columbia College in 1891. There exists a popular error in regard to this light, inasmuch as it is believed that it can be obtained without generation of heat. The enthusiasm of Dr. Lodge is probably responsible for this error, which I have pointed out early by showing the impossibility of reaching a high vibration without going through the lower or fundamental tones. On purely theoretical grounds such a result is thinkable, but it would imply a device for starting the vibrations of unattainable qualities, inasmuch as it would have to be entirely devoid of inertia and other properties of matter. Though I have conceptions in this regard, I dismiss for the present this proposition as being impossible. We cannot produce light without heat, but we can surely produce a more efficient light than that obtained in the incandescent lamp, which, though a beautiful invention, is sadly lacking in the feature of efficiency. As the first step toward this realization I found it necessary to invent some method for transforming economically the ordinary currents as furnished from the lighting circuits into electrical vibrations of great rapidity. This was a difficult problem, and it was only recently that I was able to announce its practical and thoroughly satisfactory solution. But this was not the only requirement in a system of this kind. It was necessary also to increase the intensity of the light, which at first was very feeble. In this direction, too, I met with complete success, so that at present I am producing a thoroughly serviceable and economical light of any desired intensity. I do not mean to say that this system will revolutionize those in use at present, which have resulted from the co-operation of many able men; I am only sure that it will have its fields of usefulness.

As to the idea of rendering the energy of the sun available for industrial purposes, it fascinated me early, but I must admit it was only long after I discovered the rotating magnetic field that it took a firm hold upon my mind. In assailing the problem I found two possible ways of solving it. Either power was to be developed on the spot by converting the energy of the sun's radiations or the energy of vast reservoirs was to be transmitted economically to any distance. Though there were other possible sources of economical power, only the two solutions mentioned offer the ideal feature of power being obtained without any consumption of material. After long thought I finally arrived at two solutions, but on the first of these, namely, that referring to the development of power in any locality from the sun's radiations, I cannot dwell at present. The system of power transmisson without wires, in the form in which I have described it recently, originated in this manner: Starting from the two facts that the earth was a conductor insulated in space and that a body cannot be charged without causing an equivalent displacement of electricity in the earth, I undertook to construct a machine suited for creating as large a displacement as possible of the earth's electricity.

This machine was simply to charge and discharge in rapid succession a body insulated in space, thus altering periodically the amount of electricity in the earth, and, consequently, the pressure all over its surface. It was nothing but what in mechanics is a pump, forcing water from a large reservoir into a small one and back again. Primarily, I contemplated only the sending of messages to great distances in this manner, and I described the scheme in detail, pointing out on that occasion the importance of ascertaining certain electrical conditions of the earth. The attractive feature of this plan was that the intensity of the signals should diminish very little with the distance, and, in fact, should not diminish at all, if it were not for certain losses occurring chiefly in the atmosphere. As all my previous ideas, this one, too, received the treatment of Marsyas, but it forms, nevertheless, the basis of what is now know as "wireless telegraphy." This statement will bear rigorous examination, but it is not made with the intent of detracting from the merit of others. On the contrary, it is with great pleasure that I acknowledge the early work of Dr. Lodge, the brilliant experiments of Marconi, and of a later experimenter in this line, Dr. Slaby of Berlin. Now, this idea I extended to a system of power transmission, and I submitted it to Helmholtz on the occasion of his visit to this country. He unhesitatingly said that power could certainly be transmitted in this manner, but he doubted that I could ever produce an apparatus capable of creating the high pressures of a number of millions of volts which were required to attack the problem with any chance of success, and that I could overcome the difficulties of insulation. Impossible as this problem seemed at first, I was fortunate to master it in a comparatively short time, and it was in perfecting this apparatus that I came to a turning point in the development of this idea. I, namely, at once observed that the air, which is a perfect insulator for currents produced by ordinary apparatus, was easily traversed by currents furnished by my improved machine, giving a tension of something like two and a half million volts. A further investigation in this direction led to another valuable fact, namely, that the conductivity of the air for these currents increased very rapidly with its degree of rarefaction, and at once the transmission of energy through the upper strata of the air, which, without such results as I have obtained, would be nothing more than a dream, became easily realizable. This appears all the more certain, as I found it quite practicable to transmit, under conditions such as exist in heights well explored, electrical energy in large amounts. I have thus overcome all the chief obstacles which originally stood in the way, and the success of my system now rests merely on engineering skill.

Referring to my latest invention, I wish to bring out a point which has been overlooked. I arrived, as has been stated, at the idea through entirely abstract speculations on the human organism, which I conceived to be a self-propelling machine, the motions of which are governed by impressions received through the eye. Endeavoring to construct a mechanical model resembling in its essential, material features the human body, I was led to combine a controlling device, or organ sensitive to certain waves, with a body provided with propelling and directing mechanism, and the rest naturally followed. Originally the idea interested me only from the scientific point of view, but I soon saw that I had made a departure which sooner or later must produce a profound change in things and conditions presently existing. I hope this change will be for the good only, for, if it were otherwise, I wish that I had never made the invention. The future may or may not bear out my present convictions, but I cannot refrain from saying that it is difficult for me to see at present how, with such a principle brought to great perfection, as it undoubtedly will be in the course of time, guns can maintain themselves as weapons. We shall be able, by availing ourselves of this advance, to send a projectile at much greater distance; it will not be limited in any way by weight or amount of explosive charge; we shall be able to submerge it at command, to arrest it in its flight, and call it back, and to send it out again and explode it at will, and, more than this, it will never make a miss, since all chance in this regard, if hitting the object of attack were at all required, is eliminated. But the chief feature of such a weapon is still to be told, namely, it may be made to respond only to a certain note or tune; it may be endowed with selective power. Directly such an arm is produced, it becomes almost impossible to meet it with a corresponding development. It is in this feature, perhaps, more than in its power of destruction, that its tendency to arrest the development of arms and to stop warfare will reside.

With renewed thanks, I remain, very truly yours,

N. TESLA.

New York, November 19, 1898.

Tesla and Job.

[From the Indianapolis Journal.]

When Job was asked, "Who hath divided a watercourse for the overflowing of waters, or a way for the lightning of thunder?" it is not recorded what answer was made; but if the same question were addressed to Nikola Tesla he would promptly reply, "I, Lord." And to the query, "Canst thou send lightnings, that they may go and say unto thee, 'Here we are?'" he would answer: "Yea, verily, that can I." But Job, it must be remembered, was a modest man.

An Inquiry about Tesla's Electrically Controlled Vessel.

TO THE EDITOR OF ELECTRICAL REVIEW:

I have read some of the newspaper effusions relative to Mr. Nikola Tesla's latest invention, and have noted the articles and your editorial in the issue dated the 16th instant of your valued paper. In connection therewith permit me to inquire: Has not a very serious and important consideration in the operation of Mr. Tesla's apparatus been overlooked? It occurred to me that, while the vessel is controlled primarily by means of a "coherer" which receives the "waves" from the "transmitter" on shore, this same "coherer" can also be influenced by "waves" set up and transmitted *from the vessel menaced*, and the movements of the Tesla craft made uncontrollable. The Tesla vessel would, when nearer the vessel attacked, be within a stronger field of the radiations from the latter vessel's transmitter than from the controlling transmitter on shore or elsewhere. It will be necessary for Mr. Tesla to devise some method of control that can not be counter-influenced by the enemy.

Yours truly,

N. G. WORTH.

Indianapolis, November 21.

AN ANALYSIS OF TESLA'S WORK.

SOME NON-TECHNICAL VIEWS AND A RESPONSE BY TESLA DESCRIBING HIS EFFORTS IN SEVERAL FIELDS OF WORK.

The articles published below are taken from the New York *Sun*, a journal that is conservatively and ably conducted in all its scientific discussions. We consider its editorial review of Tesla's efforts and ambitions the best that has appeared, and Tesla's letter that follows will be read with interest by every one acquainted with modern electrical work. It is the first communication of this kind ever sent to the lay press by Tesla, who has been the victim of probably more forged interviews and sensational articles appearing without authority than any other inventor.

The *Sun* editorial is as follows:

NIKOLA TESLA AND HIS QUEST.

[*From The Sun, New York, November 13, 1898*]

Nikola Tesla has just made public some facts about an invention intended to make war too terrible to be prosecuted, and thus to insure peace between nations. The war with Spain drew Mr. Tesla's mind aside for the time from the line of studies which has engaged him for years. Inspired and fired by patriotism, he has applied to a war engine some of the principles which he discovered in following his inquiries into new methods of applying energy to the purposes of peace.

The success or failure of Mr. Tesla's latest invention will not turn him away from the great project which has possessed his mind for years. This, as he puts it, is to harness the sun's power to do the work of mankind. He does not mean to catch the power of the sun's rays directly, but to utilize that enormous portion of their power which is expended upon the earth's surface in sucking from sea and lake waters which are afterward precipitated upon the higher parts of the land.

That there are waterfalls upon the earth which are capable of producing all the energy which mankind uses for power, heat and light is well known. The use of water-powers, however, is limited within narrow margins, partly because of the investment cost of instalment, but chiefly because the great waterfalls are remote from the seats of population and trade. Before Mr. Tesla began his researches there was no method known by which the power generated at a remote place could be transmitted to where it was wanted except at a loss of efficiency which was prohibitory. Since that time, by the use of currents of from 10,000 to 20,000 volts, it has become possible to send electric power successfully over wires for 35 miles or more, and one plant is now building to transmit power 85 miles.

But to utilize the great water-powers of the world, the transmittal of energy for a distance of from 50 to 100 miles is hardly more useful than a reach of eight or ten miles. Mr. Tesla designs to annihilate space. He would take the power of a Niagara, transform it into an electric current, and send this without appreciable loss to any place on earth where it was needed for use. Mr. Tesla has, accordingly, devised an electric oscillator which will receive the electric current from its source and give it an intensity which, as the inventor calculates, would enable a copper thread to carry 50,000 horse-power across the ocean. Mr. Tesla claims to have discovered, furthermore, that at an altitude easily reached by balloons the rarefied air has a conductivity equal to copper, while the denser layer of air below is a non-conductor. He proposes to suspend one pole of his electric circuit in the air at Niagara Falls and the other at Paris, and to forward his current through the upper air to France, whence it shall return through the earth when its active energy has been expended in work. He believes that he will be able to make this demonstration in 1900 as an exhibit at the coming world's fair at Paris, and to drive all the machinery at that exposition with the power from our great waterfall. The significance of his success would be that coal would become a convenience instead of a necessity, and water-power and electricity would replace coal and steam for the work of the world.

Another great quest which Mr. Tesla has been conducting side by side with this—and, in fact, leading along the same lines—is for the means of producing light from electricity without heat. It was well known when Tesla began his studies that a Crookes vacuum tube could be made to glow by passing through it currents of electricity at a high tension, but no electrician could evolve from these tubes more than a phosphorescent glow. To turn this into a white light which should shine like the face of the sun itself was the problem to be solved. All his investigations led Mr. Tesla to conclude that the thing which was needed was to be able to give to electrical currents voltages enormously beyond any which had ever been produced, and then to be able to handle and control the currents thus transformed. From this need grew his electrical oscillator, with which Mr. Tesla proposes to produce a current with an intensity of 800,000 volts, capable of transmission across the Atlantic. In Mr. Tesla's laboratory the vacuum tubes glow like sunshine, and their introduction for use is waiting only for a reduction of the cost of their light to a commercial basis, a reduction which he says is near at hand.

Since Mr. Tesla began investigating the possibilities of such high-tension currents as he produces by means of his oscillator he has made some startling announcements, such as that of his ability to use the whole earth as a conductor, and to telegraph to any part of its surface from any other part, sending messages jointly to many stations, or separately to each, at will. Perhaps because none of these late triumphs of Mr. Tesla's genius have yet been brought into practical use, there are many persons who declare that he is a visionary and impractical. It must be remembered that his discovery of the rotating electric field was of as great importance in its day as are his later discoveries now. That was announced in 1882, yet it was nearly 10 years before its value was fully recognized.

The personality of Nikola Tesla is as interesting as are the results of his scientific labors. His ways of work differ radically from the methods of those who study by experiment and elimination. Tesla seldom experiments, and when he does it is to prove a theory, not to form one. In 11 years, he says, only one of his experiments has failed. His processes are mental, and at times, he declares, his mind reaches out into fields so vast that he is afraid, and recalls it. He verifies his conclusions afterward by figures and experiments.

No other great scientific genius ever turned aside from his work to devise means for putting an end to war. Others have invented guns, armor, explosives and other accessories of war, but even in these cases the inventions were in a line with work in which the inventors were already engaged. Mr. Tesla's first design was to apply his method of control to such engines as automible torpedoes, and to use these to destroy the Spanish fleets, but as he went on, the broader idea came to him to make his war machine so irresistible as to render war itself improbable.

TESLA DESCRIBES HIS EFFORTS IN VARIOUS FIELDS OF WORK.

[*From The Sun, New York, November 21, 1898*]

TO THE EDITOR OF THE SUN—SIR: Had it not been for other urgent duties, I would before this have acknowledged your highly appreciative editorial of November 13. Such earnest comments and the frequent evidences of the highest appreciation of my labors by men who are the recognized leaders of this day in scientific speculation, discovery and invention are a powerful stimulus, and I am thankful for them. There is nothing that gives me so much strength and courage as the feeling that those who are competent to judge have faith in me.

Permit me on this occasion to make a few statements which will define my position in the various fields of investigation you have touched upon.

I can not but gratefully acknowledge my indebtedness to earlier workers, as Dr. Hertz and Dr. Lodge, in my efforts to produce a practical and economical lighting system on the lines which I first disclosed in a lecture at Columbia College in 1891. There exists a popular error in regard to this light, inasmuch as it is believed that it can be obtained without generation of heat. The enthusiasm of Dr. Lodge is probably responsible for this error, which I have pointed out early by showing the impossibility of reaching a high vibration without going through the lower or fundamental tones. On purely theoretical grounds such a result is thinkable, but it would imply a device for starting the vibrations of unattainable qualities, inasmuch as it would have to be entirely devoid of inertia and other properties of matter. Though I have conceptions in this regard, I dismiss for the present this proposition as being impossible. We can not produce light without heat, but we can surely produce a more efficient light than that obtained in the incandescent lamp, which, though a beautiful invention, is sadly lacking in the feature of efficiency. As the first step toward this realization, I found it necessary to invent some method for transforming economically the ordinary currents as furnished from the lighting circuits into electrical vibrations of great rapidity. This was a difficult problem, and it was only recently that I was able to announce its practical and thoroughly satisfactory solution. But this was not the only requirement in a system of this kind. It was necessary also to increase the intensity of the light, which at first was very feeble. In this direction, too, I met with complete success, so that at present I am producing a thoroughly serviceable and economical light of any desired intensity. I do not mean to say that this system will revolutionize those in use at present, which have resulted from the co operation of many able men. I am only sure that it will have its fields of usefulness.

As to the idea of rendering the energy of the sun available for industrial purposes, it fascinated me early, but I must admit it was only long after I discovered the rotating magnetic field that it took a firm hold upon my mind. In assailing the problem I found two possible ways of solving it. Either power was to be developed on the spot by converting the energy of the sun's radiations or the energy of vast reservoirs was to be transmitted economically to any distance. Though there were other possible sources of economical power, only the two solutions mentioned offer the ideal feature of power being obtained without any consumption of material. After long thought I finally arrived at two solutions, but on the first of these, namely, that referring to the development of power in any locality from the sun's radiations, I can not dwell at present. The system of power transmission without wires, in the form in which I have described it recently, originated in this manner. Starting from the two facts that the earth was a conductor insulated in space, and that a body can not be charged without causing an equivalent displacement of electricity in the earth, I undertook to construct a machine suited for creating as large a displacement as possible of the earth's electricity.

This machine was simply to charge and discharge in rapid succession a body insulated in space, thus altering periodically the amount of electricity in the earth, and consequently the

pressure all over its surface. It was nothing but what in mechanics is a pump, forcing water from a large reservoir into a small one and back again. Primarily I contemplated only the sending of messages to great distances in this manner, and I described the scheme in detail, pointing out on that occasion the importance of ascertaining certain electrical conditions of the earth. The attractive feature of this plan was that the intensity of the signals should diminish very little with the distance, and, in fact, should not diminish at all, if it were not for certain losses occurring, chiefly in the atmosphere. As all my previous ideas, this one, too, received the treatment of Marsyas, but it forms, nevertheless, the basis of what is now known as "wireless telegraphy." This statement will bear rigorous examination, but it is not made with the intent of detracting from the merit of others. On the contrary, it is with great pleasure that I acknowledge the early work of Dr. Lodge, the brilliant experiments of Marconi, and of a later experimenter in this line, Dr. Slaby, of Berlin Now, this idea I extended to a system of power transmission, and I submitted it to Helmholtz on the occasion of his visit to this country. He unhesitatingly said that power could certainly be transmitted in this manner, but he doubted that I could ever produce an apparatus capable of creating the high pressures of a number of millions of volts, which were required to attack the problem with any chance of success, and that I could overcome the difficulties of insulation. Impossible as this problem seemed at first, I was fortunate to master it in a comparatively short time, and it was in perfecting this apparatus that I came to a turning point in the development of this idea. I, namely, at once observed that the air, which is a perfect insulator for currents produced by ordinary apparatus, was easily traversed by currents furnished by my improved machine, giving a tension of something like 2,500,000 volts. A further investigation in this direction led to another valuable fact; namely, that the conductivity of the air for these currents increased very rapidly with its degree of rarefaction, and at once the transmission of energy through the upper strata of the air, which, without such results as I have obtained, would be nothing more than a dream, became easily realizable. This appears all the more certain, as I found it quite practicable to transmit, under conditions such as exist in heights well explored, electrical energy in large amounts. I have thus overcome all the chief obstacles which originally stood in the way, and the success of my system now rests merely on engineering skill.

Referring to my latest invention, I wish to bring out a point which has been overlooked. I arrived, as has been stated, at the idea through entirely abstract speculations on the human organism, which I conceived to be a self-propelling machine, the motions of which are governed by impressions received through the eye. Endeavoring to construct a mechanical model resembling in its essential, material features the human body, I was led to combine a controlling device, or organ sensitive to certain waves, with a body provided with propelling and directing mechanism, and the rest naturally followed. Originally the idea interested me only from the scientific point of view, but soon I saw that I had made a departure which sooner or later must produce a profound change in things and conditions presently existing. I hope this change will be for the good only, for, if it were otherwise, I wish that I had never made the invention The future may or may not bear out my present convictions, but I can not refrain from saying that it is difficult for me to see at present how, with such a principle brought to great perfection, as it undoubtedly will be in the course of time, guns can maintain themselves as weapons. We shall be able, by availing ourselves of this advance, to send a projectile at much greater distance, it will not be limited in any way by weight or amount of explosive charge, we shall be able to submerge it at command, to arrest it in its flight, and call it back, and to send it out again and explode it at will, and, more than this, it will never make a miss, since all chance in this regard, if hitting the object of attack were at all required, is eliminated. But the chief feature of such a weapon is still to be told; namely, it may be made to respond only to a certain note or tune, it may be endowed with selective power. Directly such an arm is produced, it becomes almost impossible to meet it with a corresponding development. It is in this feature, perhaps, more than in its power of destruction, that its tendency to arrest the development of arms and to stop warfare will reside. With renewed thanks, I remain,

Very truly, yours,

N. TESLA.

Tesla and His Critics.

We have received from Mr. Nikola Tesla, with a request that it be printed in our columns, a letter containing a personal attack on the editor of one of our electrical contemporaries. Owing to the personalities contained, which form the greater part of the letter, we regret that our editorial policy will not permit us to print the communication in full, and we will therefore only notice such parts as may be considered to have a journalistic or public bearing.

Mr. Tesla accuses our contemporary of having done him an injury by reprinting in its columns a paper read by him before a medical society; and of having cast a shadow on his honor and attacked his honesty in an editorial comment apropos of the said paper. Aside from their personal bearing, these charges involve the right of a journal to reprint matter that has passed out of the hands of a writer and become, through publication, the property of the

world at large; and the right to criticise, as a professional journal, public announcements of scientific discoveries pertaining to the profession which it represents.

As to the first charge, our contemporary in answer prints satisfactory evidence that the republication in its columns of the paper in question was authorized by the chairman of the medical society before which it was read. Even in the absence of such authorization, however, it is difficult to see what justification there can be for Mr. Tesla's statement: "By publishing in your columns of Nov. 17 my recent contribution to the Electro-Therapeutic Society, you have finally succeeded * * * in causing me a serious injury." The paper was presented before a national professional body, and, therefore, it is to be presumed, was maturely composed by its author with a knowledge that such presentation constituted publication to the world, and laid the statements contained open for comment or criticism from any source—not even excluding an electrical journal.

As to the second charge, a careful reading of the editorial upon which it is based leaves only the impression that the writer was actuated by a kindly motive in reminding Mr. Tesla of the many unfilled promises he has made to the public in recent years—promises of light without heat, a revolution by means of his "oscillator" in the generation of electrical energy, the transmission of electricity without wires, the destruction of fleets by means of an application of the coherer—to which list might have been added the expulsion of microbes by means of an electrification of the body and other announcements which, with those noted, have earned for Mr. Tesla the popular title of "The Wizard." Surely this constituted a legitimate subject for editorial comment by an electrical journal, and the manner in which the warning was conveyed—that Tesla had arrived at the stage when fulfillment of some of the many promises made had become vitally necessary to his reputation—was not such as to call for a violent attack on his critic.

The truth plainly stated is, that for several years Mr. Tesla has only escaped similar criticism in professional and scientific journals on account of the high esteem in which he is held personally, and through recollection of the magnificent boon he bestowed on the world by the invention early in his career of the polyphased system. The manner in which he has permitted himself to be exploited by the sensational newspaper press has been a source of pain to his friends, and has largely alienated from him the sympathy of the electrical profession. Moreover, his periodical promise of being on the point of accomplishing some wonder that would revolutionize electrical science has had an untoward effect on the electrical industry, for among laymen it has tended to produce the belief that at any moment one of Tesla's great discoveries may materialize and destroy all present investments.

SCIENTIFIC PROBLEMS, PROGRESS AND PROPHECY

Tesla's Latest Discovery.....Electrical Review

As civilization advances and our needs multiply, the demands on the toilers in the various departments of science constantly increase, and naturally the activity in the direction of providing new resources becomes more and more intense. But the severest burden is undoubtedly on the engineer, mechanic or inventor, whose task it is to produce motive power. The problem of providing economical power has ever taxed the inventive mind, and with the introduction of electricity a great stride in advance has been effected. But still, many limitations were encountered in the difficulties of efficiently transmitting the energy of great sources of power, which exist in abundance in Nature, to remote places of utilization. Here it is that Nikola Tesla did his first great work by discovering the rotating magnetic field, and applying it to a practical system of electric power transmission, now used in all parts of the world. As we were then, so now we are privileged to record another forward step, which, if successful on a large scale, will prove of astounding consequences, for it will open up unlimited resources of practically costless power. Tesla now proposes to transmit, without the use of any wires, through the natural media—the earth and the air—great amounts of power to distances of thousands of miles. This will appear a dream—a tale from the Arabian Nights. But the extraordinary discoveries Tesla has made during a number of years of incessant labor, make it evident that his work in this field has passed the stage of mere laboratory experiment, and is ready for a practical test on an industrial scale. The success of his efforts means that power from such sources as Niagara will become available in any part of the world regardless of distance.

Passing Comment

An Editorial Review of Current Events and Comtemporary Publications.

TESLA'S LINELESS POWER TRANSMISSION SYSTEM.

Nikola Tesla, to whose lines of research and invention the electrical world owes much, has secured patents on a novel system "of electric power transmission through natural media," and which, briefly described, consists in the generation of extremely high electromotive forces, even up into millions of volts, and the transmission of electrical energy from point to point thereby through the rarified atmosphere of the high altitudes. A description of the proposed system will be found in the *Electrical Review*, (N. Y.) for October 26th, together with a full page view of a Tesla oscillator, photographed in action, showing that the actual width of space traversed by the luminous streams issuing from a single terminal is over sixteen feet; that the area covered by the streamers is approximately two hundred square feet, and that the estimated effective electric pressure is two and one-half million volts. From the description, which is taken from the patent specifications, it appears that the generating and receiving stations do not differ from present practices in power transmission plants of today; but the novel features consist in the spirally wound coils of the raising and lowering transformers, and the conduction of the high potentials named to rarified strata of atmosphere as by balloons, a grounded return being used.

The times are not ripe for the acceptance of the views implied by the inventor. More than that, other ideas suggested and patented by him bear to a marked extent the imprint of day dreaming and unhealthful pandering "to the gallery" through the lurid columns of Sunday papers, and his once great name has suffered a possibly irreparable injury. Still, as stated, the engineering world owes much to his fertile brain, and its seeming degeneration can only excite pity and regret.

⚜ ⚜ ⚜

Science and Sensationalism

Mr. Tesla's recently announced invention (see PUBLIC OPINION, November 10) has given rise to considerable criticism of his work and methods, the New York *Electrical Engineer* being especially severe in its comments upon the extravagance of the inventor's claims. The issue of this journal for November 24 prints a letter from Mr. Tesla bitterly complaining of the treatment he has received. The *Engineer* replies:

Within the last year or two Mr. Tesla has, it seems to us, gone far beyond the possible in the ideas he has put forth, and he has to-day behind him a long trail of beautiful but unfinished inventions. By mild criticism and milder banter, not being able to lend Mr. Tesla the cordial support of earlier years of real achievement, we have only very lately endeavored to express our doubts and to urge him to the completion of some one of the many desirable or novel things promised. We believe this to be true friendship. For example, take Mr. Tesla's latest and furthest enlargement of his newest idea, as presented by him in a signed letter in the New York *Sun*, of November 21, unfolding his plan to dispense with artillery of the present type. At this moment we have space only for the following passage:

> We shall be able, availing ourselves of this advance, to send a projectile, at much greater distance, it will not be limited in any way by weight or amount of explosive charge, we shall be able to submerge it at command, to arrest it in its flight and call it back, and to send it out again and explode it at will, and, more than this, it will never make a miss.

When we are expected, wide awake and in our sober senses, to accept in silence such an utterance as that quoted above or that which describes as "a possibility" the operation of a distant torpedo boat by the mere exercise of the will, we refuse point blank and we are willing to face the consequences. Our past admiration of Mr. Tesla's real, tangible work is on record, and stands; but we draw the line at such things as these. We are sorry Mr. Tesla feels it so keenly, but we can not help it.

Scientific American, New York, November 26

We note with considerable regret that subsequently to his first extraordinary interviews, Mr. Tesla has seen fit to place himself at the service of those New York Sunday papers that are more or less notoriously sensational, with the result that the "annihilator" has taken on fresh terrors. It is now illumined by the flaming brush of the artist, and the public is diverted with realistic scenes in which the nine days' wonder is depicted as speeding, now above, now beneath the surface of a sea which is always propitiously calm, under a sky and in an atmosphere that are ever opportunely bright and clear, against a ship that is ever fortuitously within easy range, and always with the inevitable and unutterable result! Judging from the

comments of the scientific and technical press, we are not alone in our expressions of regret that any one of Mr. Tesla's undoubted ability should indulge in such obvious and questionable self-advertisement. That the author of the multiphase system of transmission should, at this late day, be flooding the press with rhetorical bombast that recalls the wildest days of the Keely motor mania is inconsistent and inexplicable to the last degree.

The facts of Mr. Tesla's invention are as few and simple as the fancies which have been woven around it are many and extravagant. The principles of the invention are not new, nor was Tesla even their original discoverer. While the present application of these principles is novel, there is nothing whatever in the device to warrant the sweeping claims which have been made in regard to its destructive powers. The connecting cable in the dirigible torpedo is only one of many insuperable obstacles to its success. Mr. Tesla has removed (or rather believes that he has) this one defect; let him now apply himself to mastering the others. Before he announces his ability to blot the navies of the world out of existence, let him answer a few pertinent questions, as follows:

If the torpedo must be seen to be controlled, and is scarcely visible at a distance of over a mile, even in a calm sea, how, in view of the great range, rapidity, and accuracy of modern rifles, is the operator to keep within striking distance of the enemy? If the course of the torpedo can with difficulty be followed in calm weather, how will it be traced when the surface is disturbed even by a moderate sea, to say nothing of more boisterous water? Furthermore, what becomes of its accuracy in thick or foggy weather? The apparatus employed by Tesla is extremely sensitive to shock; how then will it fare amid the terrific concussion of a modern sea fight? If one of these weapons should be lost sight of in its course, does it not at once threaten friend and foe alike, and is not the operator himself in danger of being incontinently "hoist by his own petard"? Lastly, and most pertinent question of all: What is to prevent the enemy from installing a transmitter on his own ship and himself sending out waves to act upon the receiver in the torpedo? We fail to find any provision made for this contingency, either in the patent or in any of the published interviews of the inventor. With a transmitter in the hands of the enemy the proper sequence of the motions of the torpedo could be destroyed, and the control of it prevented.

Tesla's Dirigible Boat.—Several American journals have now published extracts of Tesla's patent for the construction of a vessel which can be controlled from a distance without conducting wires. We have carefully read the accounts which have appeared, and, curiously, it is a fact that in each case the real innovation or invention is not described. In fact, the details published are obvious ones which would suggest themselves to the youngest electrician. The wireless system of telegraphy is used as a means of communication to the crewless vessel, and one receiver only is provided. This receiver works four different relays for steering and stopping and starting. These relays are comparatively simple, but not a word has yet been published as to how four differentiating signals are transmitted to the one receiver. Surely this must be disclosed in the patent; but why are the technical papers so lax in their extracting?

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *November 18.*

A Recent Patent of Nikola Tesla.—The daily papers within the past week, by means of startling headlines, announced that Mr. Nikola Tesla would make war so horrible that no nation would care to undertake it. The basis of the story rested on a patent issued to Mr. Tesla on November 8th. The facts, as set forth in the patent, are in brief as follows :—Hitherto the only practical means of controlling the movements of a vessel, such as a torpedo or torpedo boat, at a distance, has been by the use of a cable, the disadvantages of which are obvious. The plan proposed by the inventor is to provide any such craft with a coherer connected between the hull and an elevated terminal, and to so arrange the propelling and steering mechanism which is motor-driven with storage battery supply, that it can be controlled by various relays and auxiliary devices actuated through the agency of the Hertz waves. A single coherer is used. It possesses some elements of novelty designed to yield a more uniform decohering action. It consists of a metal cylinder, with insulating ends and a metal rod passing lengthwise through it. The cylinder normally stands with its axis vertical, and the decohering action consists in inverting it, throwing the particles, which occupy one-fifth of its length, from one end to the other. According to the patent, these granules are manufactured by a special tool, insuring their equality in size, weight and shape, and are uniformly oxidised. This secures equal conductivity of their surfaces, and stops their further deterioration, thus preventing a change in the character of the gas in the space in which they are enclosed. The auxiliary devices consist of ordinary relays, actuating a multiple step-by-step escapement wheel, which, in turn, rotates the brushes and commutators, affecting the various internal circuits of the boat.

ANSWER TO AN INQUIRY CONCERNING TESLA'S LATEST INVENTION.

In the ELECTRICAL REVIEW last week appeared an inquiry from Mr. N. G. Worth, of Indianapolis, relating to a probable defect in the electrically-controlled vessel recently patented by Nikola Tesla. Mr. Worth inquired if the ship or fort menaced could not set up a counter-influence by means of similar apparatus, which would be more powerful at a nearer radiation than that transmitted to the attacking vessel from the distant point where the original and controlling influence was created. A number of electrical experts and the inventor himself have been consulted on this point, in addition to a careful perusal by the writer of the technical description of the invention which appeared in full exclusively in this journal on November 9 and 16. The following passage from the patent, in which the italics are our own, is republished as bearing on this question:

"It will be obviously noted from the preceding that, whichever of these or similar contrivances be used, the sensitiveness and, what is often still more important, the reliability of operation are very materially increased by a close adjustment of periods of vibration of the transmitting and receiving circuits, and, although such adjustment is in many cases unnecessary for the successful carrying out of my invention [Tesla evidently refers here to the many uses of his invention in peace—ED.] I nevertheless make it a rule to bestow on this feature the greatest possible care, not only because of the above-mentioned advantages, which are secured by the observance of the most favorable conditions in this respect, but also, and chiefly, with the object of *preventing the receiving circuit from being affected by waves or disturbances emanating from sources not under the control of the operator*. The narrower the range of vibrations, which are still capable of perceptibly affecting the receiving circuit, the safer will the latter be against extraneous disturbances. To secure the best result it is necessary, as is well known to experts, to construct the receiving circuit, or that part of the same in which the vibration chiefly occurs, so that it will have the highest possible self-induction and, at the same time, the least possible resistance. *In this manner I have demonstrated the practicability of providing a great number of such receiving circuits—50 or 100 or more—each of which may be called up or brought into action whenever desired without the other being interfered with.*

The above statement answers part of the question to the point, for, if the sending and receiving circuits are skillfully adjusted, the enemy attacked would be practically powerless, as he could only by the barest chance strike the vibration to which the receiving circuit on the vessel would respond. It is difficult enough, even for the best expert, to make an exact adjustment of two such circuits, let alone the far more difficult problem which in this respect would confront the enemy attacked. Granted he had an apparatus on board capable of developing electrical waves of any pitch, still he would never be able to know which of the notes struck is affecting the circuit on the assailing vessel, since this effect would be only momentary and speedily counteracted by the sending apparatus which the operator guiding the vessel in its course is controlling.

But, quite apart from the above, let it be assumed that such adjustment of the sending and receiving circuits was not at all observed, and that no agents were known capable of affecting a sensitive device on the Tesla vessel, which agent, by its very nature, made it impossible for the enemy to ward off the attack. The latter supposition is manifestly untrue, since any radiation propagating in straight lines, as light or short Hertzian waves, may be used for operating the vessel, and such radiations may be screened off on the side towards the enemy, so that the latter could not affect the controlling device on the attacking vessel. Still, even in such an extreme case, it would seem to us that, while it might be easy to disturb the dot and dash signals in wireless telegraphy, it would be quite a different matter to prevent an operator from directing his vessel to wherever he desires, for *he* only would know precisely how the signals affect the mechanism, whereas the supposed opponent would have no knowledge whatever in this respect and could never tell whether, in working his apparatus, he is aiding or thwarting the efforts of his assailant. However, his signals would be of telling effect only after the assailing vessel had reached a point at which the signals from both the sources are of equal intensity. Now it would be quite easy, in our opinion, for the operator controlling the course of the vessel and the operation of the apparatus on board of the same, to direct it straight upon the enemy, put the machines at top speed, release the exploding mechanism and render all further signals inactive. Since the vessel can carry any amount of explosive, it would not be necessary to come very close to the enemy to insure his destruction.

How about the intensity of the signals? Can the signals from a man-of-war be made as strong as from a vessel especially fitted for this purpose? Would it be advisable to have such a powerful apparatus on board of a warship when the experts tell us that powerful electrical vibrations are apt to make large sparks fly about in any part of the structure, thus becoming liable to short-circuit the light mains and injure any of the important electrical apparatus on board, and, worst of all, inflame the stores of explosives? Would any commander undertake the responsibility of operating such a powerful apparatus on board of his ship under such conditions? And anyway, how is he to know to what kind of influence the controlling device on the assailing vessel is designed to respond? And granted he does, will he feel sure to start his apparatus going when there might be a vessel submerged in the neighborhood responsive to his signals and ready to ignite a great quantity of explosive, and to so annihilate his costly ship and living crew? How would he know that, by his own signals, he is not drawing upon his ship one of the vessels especially adapted for such purpose, thus bringing destruction upon himself through his very efforts to ward off the danger? Would he not expose himself to such liabilities, particularly at night? A great many more of such arguments might be made if they were needed, and all of this, it seems to us, has been overlooked in the various comments we have perused. It is well known that most of the naval engagements must of necessity take place near the coast. Now it is not difficult to employ on shore a sending apparatus, fixed or portable, of great power, against which any on board of a warship would be ineffective, and we ask again how could a commander of a fleet possibly venture to approach the coast within 10 or 15 miles when he would know that in so doing he is risking not one but all of his vessels?

Our inquirer is mistaken in the belief that the use of the coherer is indispensable in Tesla's invention. The inventor is very explicit on this point, as will be observed by perusing his text. To cite only one passage, he states:

"A great variety of electrical and other devices, more or less suitable for the purpose of detecting and utilizing feeble actions, are now well known to scientific men and artisans, and need not be all enumerated here. Confining myself merely to the electrical * * *"

Those who have criticized this important advance seem to confound a special means for carrying out the invention for the invention itself. The latter is not limited to any particular mode of signaling, and on this point Tesla expresses himself clearly, as may be seen from the following quotation:

"Finally, I may avail myself, in carrying out my invention, of electrical oscillations which do not follow any particular conducting path, but propagate in straight lines through space, of rays, waves, pulses, or disturbances of any kind, capable of bringing the mechanism of the moving body into action, from a distance and at the will of the operator, by their effect upon suitable controlling devices."

Signaling without wires, in some way or other, is very old—in fact, ancient—whereas Tesla, as we have before stated, has created an art entirely novel, for there never was such a thing as guiding the movements of a distant body and controlling all of its appliances without any artificial connection whatever.

It is, perhaps, astonishing that this epochal idea has not been evolved in times long past, for it would seem that it might have been carried into effect, without the use of any electrical means whatever, by some scientific men of old, like Archimedes. He must have known, for instance, that by striking a shrill note he could set into vibration a delicate reed or diaphragm at a distance of as much as two or three miles, and he might have known that the force so developed could be utilized, in many ways, to control the movements of a rudder or other device on a vessel, and that by such control the vessel could be guided upon the enemy's ship and the latter destroyed, as by ramming into it, or by causing, for example, a large quantity of inflammable fluid to flow on the water and then igniting the fluid through a contrivance actuated by the signal from a distance, far out of the reach of the enemy's weapons. When gunpowder was discovered, and when we gained knowledge of voltaic electricity, it became still more easy to carry out the idea. When the action of light on a selenium cell was observed, a simple means was offered for effecting the control at great distances. The observation that currents are propagated through the ground to considerable distances and that inductive effects take place between circuits widely apart, again enlarged the possibilities, until finally the science of electrical vibrations and synchronized circuits afforded the best means for carrying the idea into practice. These means, which are accessories in this invention, will, in all probability, multiply and be further improved as time goes on, and, with every advance in this direction, this new art will be brought to greater perfection.

To one who considers that for centuries past a large proportion of human effort has been spent in devising and producing the most efficient means for destroying an enemy, the tremendous importance of this new departure is instantly impressive. The weapon is no longer one dependent on the chance of hitting, nor one subject to the limitations of the modern projectile, nor one which can be rendered inoffensive by armor protection, however thick. The mere moral effect of a weapon of unlimited powers of destruction must be so great as to lead to a radical change in warfare, first on sea and next on land, but its success in the end can not help compelling the nations, for the sake of humanity, to stop the slaughtering of men and sacrifice of property.

The Genius of Destruction.

[*Translated from "L'Évenément."*]

Man is born a vandal. His instinctive joy, his first pleasure is to destroy. From the reminiscences of his primitive savagery, throughout the process of civilization, this barbarous atavism which incites him to destruction and strife adheres to him. War, apart from the sacred causes which arise from the right of legitimate defense, is often nothing else than a manifestation of this instinct. It seems that Man, in imitation of Nature, and even oftener than Nature, offers an example, wants to create cataclysms in obeyance to this fatal heredity. His very genius provokes or produces them; for, since it is a question of catastrophes, the ambition of his knowledge knows no limits, and, devoured by the spirit of Evil, he perfects his engines of disaster and ruin.

Thus Nikola Tesla, a learned American, a rival of the illustrious Edison, has just made a discovery which, when applied to the art of warfare on sea or land, is to furnish to the armies a power of destruction so formidable that one scarcely dares to contemplate its practical results. The secret of this discovery resides in the transmission of electrical energy to distances which, until now, nobody could surmise. By simple atmospheric conduction, and without any wire whatever, the current is to traverse thousands of kilometers, bring mourning and desolation and carry death, silently, invisibly, into the ranks of the enemy, who will not even be aware of the approach of the Camarde and able to defend himself against its unforeseen blow.

It is with such exploits that human wisdom taxes its ingenuity, and one still dares to praise the moral effect of philosophy.

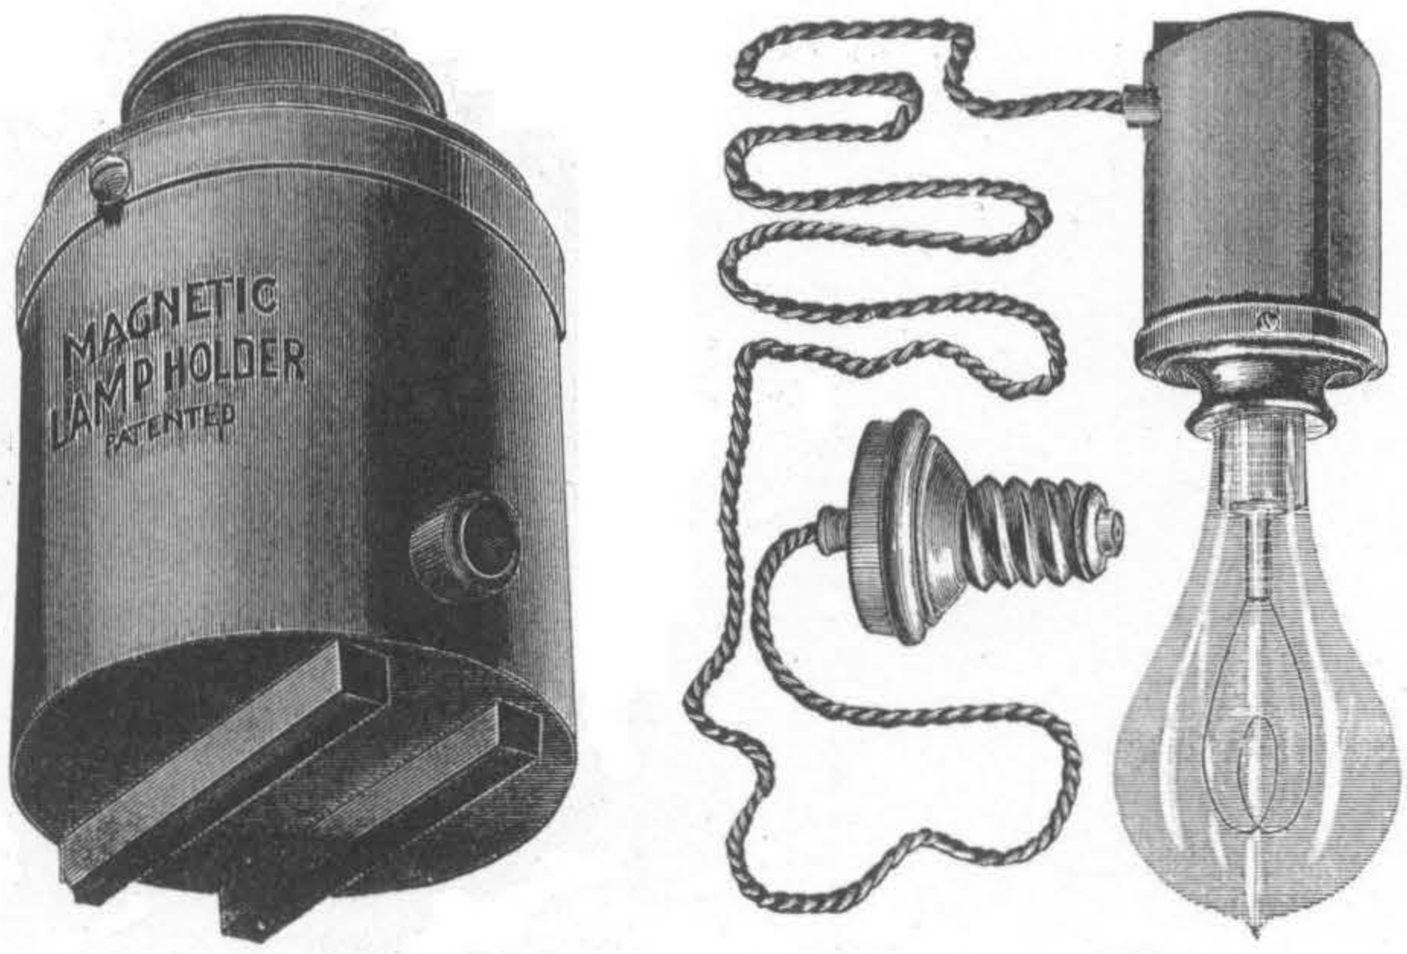
According to Nikola Tesla, the problem solved by him consists in producing and projecting currents of an enormous voltage heretofore unknown to electricians.

By means of this discovery an operator may, in the shelter of his laboratory, his person not exposed to the least danger, in perfect security blow up out at sea boats carrying explosives at incalculable distances and beyond the range of the most powerful guns.

A simple unarmored, unprotected vessel, having not even a cannon on board, but capable of great speed, may become the most terrible adversary of a whole fleet. A single operator in command of a flotilla of small boats, the evolutions of which are controlled by him with mathematic precision, may destroy the enemy's squadrons without having himself run any risk. In the same manner, and with as little danger, he may send into the enemy's port explosives which would produce a disaster similar to an earthquake.

In order to cause the credit to be given to such prophecies to be appreciated, the learned Yankee has constructed a small model of a boat which performs all the evolutions of his prescription. It is terrible in its precision. An electric motor placed at a distance, in another room, controls all its movements automatically and in a reliable manner. And in this way an electrician on board of a flagship seeming quite inoffensive may, with a simplicity which would eclipse the knowledge of the most profound strategists, direct against the enemy small vessels intended to spread death around themselves—death which nobody suspects, which calls unawares and from afar, with the prophetic surprise of a cataclysm prepared by man.

This is terrible, and causes one to shudder when contemplating this power of destruction brought to the height of its terror.



We must not be incredulous, however. Nikola Tesla proposes to instruct the most intellectual and skeptical people on earth. He intends to exhibit at the exposition in 1900 a torpedo of his invention. He will himself direct its movements from New York, without a conducting wire, by simple electric transmission through the high regions of the atmosphere.

And when we have been entertained what will be the result for humanity, thus threatened with the worst catastrophes, at the mercy of an infernal operator endowed with fiendish, almost diabolical power?

The man who could make this discovery knows how to reassure us in this regard. Like all inventors of destructive machines, he claims that his instrument will make the governments which are inclined to create international conflagrations hesitate. The power of destruction of which he disposes is, he says, so unlimited and its employment in war would endow an army with such an instrument of victory, that no country being concerned about the lives of human beings would dare to assume before civilization, before history, the terrible responsibility of a scientific war. On this account Nikola Tesla claims a right to be called a benefactor of humanity.

Posterity will, perhaps, accord him this claim, as well as to others who have, like him, perfected the art of destroying in bulk and at wholesale, dreaming of such numbers of deaths that nobody would want to boast the tragic glory of ever having caused them.

The genius of destruction would seem to have, then, two aims. It creates evil, but mostly good. Through its help the abolition of wars may no longer be a utopia of generous dreamers, an empty dream of enlightened, altruistic thinkers who have compassion with their fellowmen. A blessed era will open up to the people, whose quarrels will be settled in view of the terror of the cataclysms promised by science, views radiant with peace, which has at last conquered over centuries of barbarism, and there will be definite harmony in the entirely pacified universe!

FIGS. 1 AND 2.—A MAGNETIC INCANDESCENT LAMP HOLDER.

What contradictions of conception is the human mind subject to? At the moment when, thanks to the magnanimous initiative of Czar Nicholas II, the problem of universal disarmament is attracting the attention, the solicitude, of the diplomats of all nations, an inventor, a physicist of the New World, promises us the end of the barbarous international duels by the tragical horror of the work of Death, by an unheard-of improvement in the processes of destruction.

Will the universal peace result, then, from the excess of evil, or from the moral philosophy which springs out of modern civilization? Who can predict it to a certainty?

What does it matter, after all, whether we owe it to the former or the latter, if only some day this sublime utopian dream, this dawn of new times announced by the prophets of humanity, will realize, perhaps, at the beginning of the century which is about to be born. MARCEL HUART.

Paris, November 12.

Tesla's Views on his Critic.—The *Electrical Engineer* of New York in a recent issue printed the full text of a lecture by Mr. Nikola Tesla before the American Electro-Therapeutic Association. This course, and their leader on the subject, has drawn forth the following letter from this noted inventor: "Sir,—By publishing in your columns of Nov. 17 my recent contribution to the Electro-Therapeutic Society you have finally succeeded—after many vain attemp made during a number of years—in causing me a serious injury. It has cost me great pains to write that paper, and I have expected to see it appear among other dignified contributions of its kind, and I confess the wound is deep. But you will have no opportunity for inflicting a similar one, as I propose to take better care of my papers in the future. In what manner you have secured this one in advance of other electrical periodicals who had an equal right to the same, rests with the secretary of the society to explain. Your editorial comment would not concern me in the least were it not my duty to take note of it. On more than one occasion you have offended me, but in my qualities both as Christian and philospher I have always forgiven you, and have only pitied you for your errors. This time, though, your offence is graver than the previous ones, for you have dared to cast a shadow on my honour. No doubt you must have in your possession, from the illustrious men whom you quote, tangible proofs in support of your statement reflecting on my honesty. Being a bearer of great honours from a number of American universities, it is my duty, in view of the slur thus cast upon them, to exact from you that in your next issue you produce these, together with this letter, which, in justice to myself, I am forwarding to other electrical journals. In the absence of such proofs, which would put me in the position to seek redress elsewhere, I require that, together with the preceding, you publish instead a complete and humble apology for your insulting remark, which reflects on me as well as those who honour me. On this condition I will again forgive you, but I would advise you to limit yourself in your future attacks to statements for which you are not liable to be punished by law.—N. TESLA." Our contemporary's leader in question does not, in our opinion, warrant the tone of Mr. Tesla's letter, and the justification both for publishing the lecture and for criticising Mr. Tesla's statements in the American Sunday papers are ample.

NOTES.

More Tesla Marvels.—The *New York Herald* of November 13th contains a sensational article on Tesla's recent inventions in wireless transmission of power. The article is full of inaccuracies evolved from the unscientific imagination of the reporter. Here are some of the gems :— Speaking of Tesla's new generator, it is said : "With a machine creating a pressure of millions of volts, Tesla lashes the vast ocean of electricity of the earth into a cyclonic storm. Instantly the waves spread in all directions through the universe of matter." By this we are led to believe that Tesla transmits power by means of electric waves. This may, as a matter of fact, be true, but, nevertheless, Tesla expressly repudiates this mode of transmission in his specification. A description, with an illustration, is given of Tesla's new torpedo boat, which, however, appears to be merely controlled from the shore by Tesla currents. The motive power is an old-fashioned battery of accumulators on board. Moreover, the controlling is not done by the new Tesla currents, but by a species of Marconi telegraphy. At least, there is a coherer on board the boat, and this is affected by electric waves sent by an oscillator "which may be tucked away in one's pocket like a cigarette case." Since the generator of Tesla's high pressure air-piercing currents contains 50 miles of wires, it is not very suitable for carrying in the pocket. On turning a little crank, the generator gives forth two waves at each half-turn. "The effect of these is like that of the vibrations produced by the voice in a telephone. On the vessel to be controlled is a broken electric circuit, loose metallic particles of a metallic oxide being at the point of separation." By means of the coherer, which is evidently what the reporter is describing, electric circuits are closed on board the torpedo boat, which control the rudder and the battery which furnishes the motive power. We imagine Tesla is not the first to propose the application of electric wave telegraphy to control the movements of an electric torpedo boat.

"The Greatest Discovery of the Age."

When England set her navy afloat upon the sea,
She had no anticipation of my great discovery,
For 'tis I, the only I, that have made her ships but scrap.
Any nation now may whip her, e'en the smallest on the map,
By "the greatest discovery of the age."

For the blowing up of navies will now be only fun.
An exertion of my will or thought and, lo! the thing is done!
I've combined a wireless telegraph and torpedo dirigible
In so evident a fashion, some say not patentable,
My "greatest discovery of the age."

I care not if the whole shebang was generally known,
I'll be very much *offended* if 'tis not *now* my own.
I'm a Christian and philosopher, as I have truly said;
The laurels of undying fame are resting on my head
For "the greatest discovery of the age."

And when I *am* offended, my forgiveness is complete
When I get a full apology, with humbleness replete.
I've put a stop to wars, but do not rest my claim
On such a simple act as that for everlasting fame.
My super-extra glory rests upon the arts of peace,
I'm in for killing whales and sich and getting at their grease
By my "greatest discovery of the age."

I'm so struck on this my latest that my brain it fairly reels,
And my head it gets to spinning as if 'twere hung on wheels.
I had an oscillator once, a tuneful dynamo,
A revolution 'twas to make, by vibrating to and fro.
'Twas a very great discovery of the age.

But it died ere it was born and resteth as a myth,
And its name now means some coils I experimented with
As another great invention of the age.

To shake the charge of mother earth, another scheme of mine
Beats thunderstorms and earthquakes, all along the line.
But wait till 1900. O, won't the people talk,
When I blow up stuff at Paris, when I think so at New York,
By my "greatest discovery of the age!"

I've labored with high frequency to publish and proclaim
That I own some great discoveries, connected with my name;
By high-potential discourse I've tried to bring to light
That there weren't any others who contributed a mite
To such very great discoveries of the age.

But the shade of Cabanellas, and of many others too,
Are upsetting my endeavors, and proving my hoodoo.
I content myself in this, that the papers of the day
Will print my schemes sensational and boom me by the way
As "the greatest discovery of the age."

Electricity's Mystery.

[From Collier's Weekly.]

Mr. Tesla's announcement that he is prepared to destroy a ship by means of electricity, yet not by means of wires, has been received with cheerful incredulity. It is a bountiful Providence which has enabled man to ridicule what he does not understand. Ridicule has been the prelude of every great invention. It has crooned at its cradle. But though it came to jeer, again and again it has remained to stare. That is as it should be. The beginning of truth is amazement. But in this case, as in all others, the proof of the pudding is in the eating. The value of Mr. Tesla's process remains to be shown. Just at present it is a mystery. Yet, so also is electricity. No marvel which electricity has worked is as marvelous as electricity itself. To call it a mystery, though, is a misuse of language. Correctly speaking, there is no such thing; but there is ignorance, and it is in a manner both delightful and flattering to general self-esteem that the one is confused with the other. In the chartless morrow which the future has in charge it is not extravagant to assume that ignorance will evaporate, knowledge become exact, that electricity will yield its secret, and perhaps for those who then live fathom the recesses of the sky. From a servant it may develop into a confidant; it may tell of its wanderings, of its conception, of its sudden avatars and all that it has seen. But this is conjecture. The point is, that in manipulating it, with a wire or without, there is a difference in degree rather than in kind.

Treatment of Inventors.

[From the Mansfield, O., News.]

Tesla, the electrician, whose promises excel his performances, has been having a few words with the editor of an electrical journal and has come out second best. If he thus fares with one of the brethren in his own line troublous times are ahead for him if he tackles the laymen of the press, who are ever ready to give the glad hand to an inventor who invents, but who are rather merciless on those long on talk and short on deeds, whether they be inventors or politicians.

Tesla's Fears.

[From the Anaconda, Mont., Standard.]

Tesla has satisfied himself and is trying to satisfy others that he has discovered a principle, the application of which "must produce a profound change in things and conditions presently existing." Tesla's only fear is that his invention will be used by men for evil purposes—that, like the invention of gunpowder, it will not be an unmixed good to the world. But it is a comfort to him to know that, for one thing, it will abolish war.

Tesla's Romances.

[From the Minneapolis Times.]

Tesla has administered a severe scolding to the editor of an electrical journal, who intimated that Mr. Tesla might find it profitable to give his imagination a rest and finish up some of the wonderful things he has set out to do. In these days of scientific miracles it isn't safe to be skeptical, but some of those announcements of Tesla's read as if they might have been inspired by the product of the poppy in the pipe.

NOTES.

Tesla and his Critics.—Our contemporary the *Electrical Engineer* (N.Y.) has given offence to Mr. Tesla by an article entitled "Mr. Tesla and the Czar." The connection between these two famous personages is not at first sight apparent, but it appears that both are Slavs, and Tesla's new scheme for aerial power transmission strikes our contemporary as belonging to the same class as the Disarmament scheme of the Czar. The aims of both Tesla and the Czar, says our contemporary, "appear wholly noble, their thoughts are beautiful, and if they fail, as they probably will in some material and vital respects, the world is certainly none the worse off for what they actually accomplish." Though the article is not wholly unappreciative of the good work which Tesla has accomplished, it twits Tesla with the number of his unfinished inventions, and unnecessarily perhaps emphasises the assertion that Profs. Brackett and Dolbear have virtually classed him as a humbug. Tesla has written in reply that by this last straw our contemporary has strained his Christianity and philosophy to the breaking point, demands proofs of the animadversions of the distinguished professors, which he says reflect on his honour and honesty, and through him upon a number of American Universities, who have conferred great honours upon him. The *Electrical Engineer* replies by pointing out the support that it has given to Mr. Tesla and his inventions since the beginning of his career, and professes that its mild criticism and mild banter was a sign of true friendship. We confess that we don't think that there was anything much in what our contemporary said, but the way in which it was put might be expected to give offence to a man of Tesla's poetic sensibility.

Tesla and His Complaints.—Our contemporary the *American Electrician* sums up the points at issue between Mr. Nikola Tesla and another American journal in the following concise terms: "The truth plainly stated is, that for several years Mr. Tesla has only escaped similar criticism in professional and scientific journals on account of the high esteem in which he is held personally, and through recollection of the magnificent boon he bestowed on the world by the invention early in his career of the polyphased system. The manner in which he has permitted himself to be exploited by the sensational newspaper Press has been a source of pain to his friends, and has largely alienated from him the sympathy of the electrical profession. Moreover, his periodical promise of being on the point of accomplishing some wonder that would revolutionise electrical science has had an untoward effect on the electrical industry, for among laymen it has tended to produce the belief that at any moment one of Tesla's great discoveries may materialise and destroy all present investments."

Tesla Polyphase Patents Declared Invalid in Germany.

The Reichsgericht of Germany has confirmed the decision of the lower courts declaring the Tesla polyphase motor patents invalid. The court reviewing the case, holds that the patents are void owing to their not having been worked according to the requirements of the German patent law. The court goes on to say, however, that even if the patent had been sustained on that ground, it would have been, nevertheless, invalidated owing to the fact that the invention was not adequately described in the German patent specification, whereas the American patent specification is clear. It is understood that the Helios Co., of Cologne, who control the Tesla patents in Germany, will no longer contest the suits which it has brought against several parties in Germany.

TELEGRAPHING WITHOUT WIRES.

TESLA'S LATEST INVENTION.

C. D. Wood, in the "Yale Scientific Monthly."

For many years there was but one man to whom our country could look for its advancement in electricity. Thomas A. Edison was the undisputed leader, and his word was law in the world of applied electricity. In the past few years there has been another man to step to the front, and through his skill and persistent mastering of difficulties he has obtained a similar or even higher position in the world of science.

Nicola Tesla is not an American by birth, but as his name implies, was born in Austria. Thinking that an opening was in store for him in this country, he made it his home, and to it he has contributed the results of his discoveries. Tesla's career has been one of difficulty. On two different occasions his laboratory has been on fire, and several important models were destroyed, on which he was still working.

For the past year the young inventor has been studying the problem of conveying electric currents without visible conductors. He has proved the theory concerning the ability of waves of ether to carry electricity, and has brought it to a practical test by making luminous, without the aid of wire, cylinders suspended in the middle of a room. He now claims that it is possible, without the aid of other media than the earth and the atmosphere in a certain state to transmit large quantities of electricity an indefinite distance. The transmission of such currents for long distances would open up a field of electrical engineering the extent of which would be hard to conceive. It is well known that air, when enclosed in a vessel, can be so rarified as to destroy its insulating properties, and become a fair conductor. If the so-called electrical pressure at a certain point is sufficient, and that point be elevated so as to obtain the proper rarefaction, the electrical energy at the point can be conveyed to an indefinite distance.

Tesla has invented a machine (if it may be called that) by which, without danger to the human body, he can produce an electrical pressure to the amount of 2,500,000 volts. As the conductivity of the air increases directly as the pressure, the more current produced, the greater is the efficiency of the air to carry the particular current.

Tesla's generating apparatus or transformer, as he calls it, consists of a secondary coil, built up as usual around an iron core and wound with a large number of convolutions. This coil is surrounded by another, having wire of heavier diameter, but wound with fewer convolutions. This comprises the primary or low-tension coil, and is electrically connected to the secondary, in order that there may be no difference of potential. The length of the secondary coil is now to be considered. That the greatest possible electrical pressure may be obtained, the length of coil should be equal to one-quarter of the wa length of the electrical disturbance in the circuit.

The current in this case may be supposed to travel 182,000 miles per second; there a frequency of 925 per second would maintain 925 stationary waves; hence, each wave should be 200 miles long. Tesla proposes that his coil shall be 50 miles in length. The current coming from the terminal connected with the earth traverses the transformer, and is led by an ordinary conductor to an elevated station. This elevated terminal is generally a rounded surface suspended at a height which insures the rarefaction of the air necessary to conduct that particular current. If the potential is high enough and the surrounding conditions of the country favorable, the air will offer less resistance than an ordinary copper conductor. If there were mountains in the vicinity, the elevated terminals would have to be placed upon them, for a large portion of the electricity would otherwise escape to the higher ground.

Situated at an equal elevation at the receiving station, we have a terminal similar to the one just described, and connected with the receiving transformer. The machi resembles the first transformer, except that the coils are in a reversed position. The inner coil with the greater number of convolutions acts as a primary, and the low tension coil takes the part of the secondary. Another conductor completes the circuit by carrying the current to the earth. In the circuit of the transformer lamps, motors or any other machines for the utilization of current are placed. Such is the practical application of the new theory. These elevated terminals might be suspended from balloons, or placed upon high promonitories, provided the elevation is sufficient.

This scheme of transmitting electricity appeals to the business man as well as to the scientist, for he can readily see what large incomes could be realized with comparatively moderate expense. If the Kings County Electric Power Company of Long Island, which is now the largest electrical concern in the United States, could utilize the power of Niagara by this new method, they could do away with their several power houses and cut down their expenses one-half. This invention has not been the product of a small amount of work, but the outcome of long series of experiments and careful study on the part of the inventor. Tesla is purely a man of science. His connection with Edison was severed because he did not believe in a scientific life for the money that was to be found therein. He believed in giving his inventions to the world with unrestricted freedom, differing from his older partner, who was the business man, as well as the inventor.

Telegraphing Without Line Wires*—I.

BY WILLIAM BISSING.

It will be seen from the patents hereinafter cited that the present subject is not new. It has occupied the attention of inventors for at least fifty years; and, indeed, if we include signaling by flashlight or by sound, it will be found that for thousands of years man has been endeavoring to communicate to distant points without the intervention of artificial connecting media. It would, however, go beyond the limits of this article to mention all the experiments and applications of the various forms of signaling by light and other natural agents that have been tried for so many years. In view of the renewed interest in the subject that has been aroused by recent experiments of English and Continental physicists, who have used electrical methods for accomplishing the above result, and in view of the close relationship which exists in this country between the work of the theoretical scientist and the work of the practical inventor, it may be of interest to give a review of the electrical development of the patented art bearing on this form of signaling.

The electrical methods which have been used to transmit intelligence without intervening wires may be broadly divided into three distinct classes, i. e., conduction methods, in which battery currents are used and in which the earth serves as a conductor; methods in which the transmission is effected by induction, and electrical wave methods. Induction methods may be again subdivided into two classes, to wit: Electromagnetic and electrostatic methods.

CONDUCTION METHODS.

About the earliest patent in which the earth is used as a conductor to effect transmission is the English patent to Lindsay, No. 1242, of 1854. This patent contains all the essentials which enter into this means of telegraphing, and is open to all the objections that accompany this system. In it, as shown in Fig. 1, the patentee telegraphs across an intervening water course by using on one side of the water a battery, *B*, connected to two plates which are placed a considerable distance apart in the stream or lake. On the opposite side of the water course are placed two corresponding plates connected by wires which include a galvanometer and another battery. The patentee states that "the distance between the two plates on one side of the water course is greater than the distance across the water or to the plates of the opposite battery. Suitable keys, *K*, may be placed in the circuits. On closing the key in one circuit the electric current will pass into the water at *C*, through the wire or wires which are on the opposite side of the water, and re-cross at *F*; or, more correctly speaking, the electric current divides between the two courses in an inverse ratio to their resistances, so that a portion of it takes the circuitous course." It will, of course, be evident that the distance between the plates of one circuit may be diminished, if at the same time the e. m. f. of the battery connected to these plates be increased.

In the conduction system we are dealing with two plates buried in a conducting medium and kept at a suitable difference of potential. We may imagine the current distributed through the medium along certain stream lines, a fall of potential resulting along the different lines of flow. If the two ends of a receiving circuit be grounded at two points between which there is a sufficient difference of potential, enough current will be shunted through this circuit to actuate a recorder. An analogous case is afforded by the laboratory experiment, in which the lines of flow of the current from a battery are determined, when its poles are placed in contact with a sheet of tin foil. One end of a circuit which includes a galvanometer and a battery is touched to the sheet of foil, and the other end moved until a position is found for which the galvanometer gives no deflection. The former end of the circuit is then kept in its original fixed position on the tin foil, and the latter end moved until another point is found for which the galvanometer deflection is zero and so on. These points are then plotted and enough pairs of points found to locate the equipotential curves, which are normal to the lines of flow. It will be seen therefore that in the conduction system, the receiver might have its terminals so located that no current from the transmitter will be shunted through it and that the best position for the terminals of the receiving circuit is in a stream line of maximum intensity and at right angles to the equipotential curves. It will also be desirable to curve the end plates of the receiving circuit to fit the equipotential curves at the points where they are buried in the earth so that all the points of each plate may be at the same potential. This will avoid local circuits in the plates. Usually such curvature will be unnecessary, since the plates are small and the stream lines are straight at the points where the receiving terminals are located, and plane plates may consequently be substituted.

The objections to this method of transmission are many and obvious. Nowadays, when, in all large cities, currents from railway circuits and lighting systems are constantly leaking to earth, great disturbances of the instruments used in this system must be expected. Secrecy is impossible, since anyone may ground his instrument, and thus receive the signals intended for another. Only a small portion of the current generated by the battery will pass through the receiving instrument. This instrument must, therefore, be quite sensitive, which in turn may render it subject to the disturbances above referred to. The battery current, moreover, is short circuited by street-car rails, gas pipes and water pipes, so that very little current will reach the recorder.

It is interesting to notice, however, that this particular method has been many times revived, even as late as 1894, when it appeared in "Cosmos," Paris, March 3, 1894, republished by the "Electrical Review," Vol. 24, p. 193, which described some experiments by the Abbé L. Michel, in which telephones were used as receiving

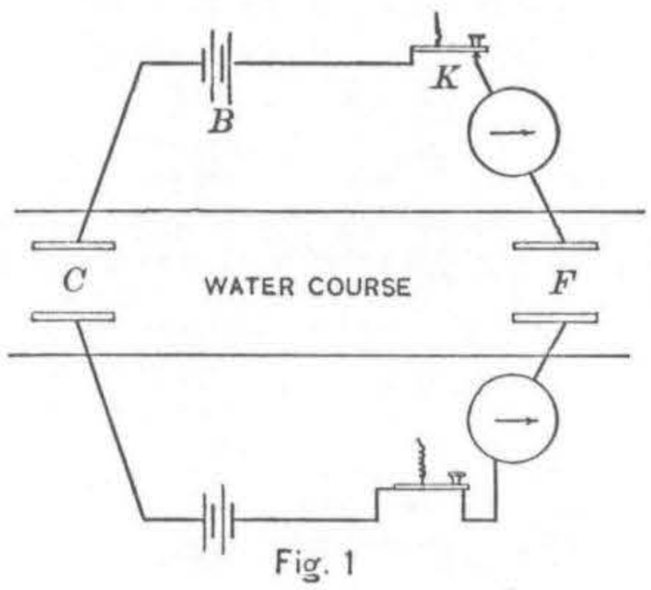


Fig. 1

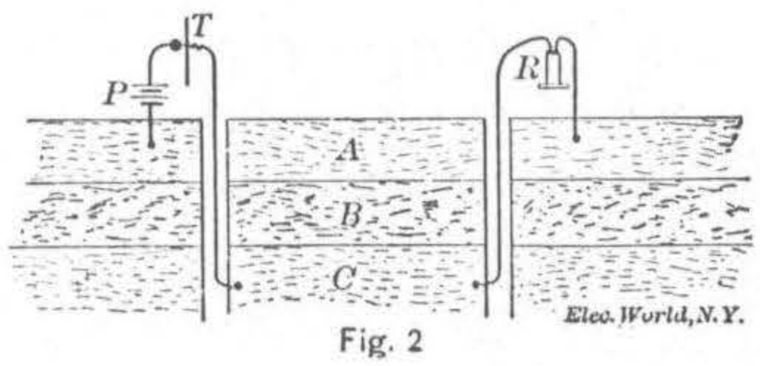

Fig. 2

and transmitting instruments. See Fig. 2. Five accumulators *P* were used in the transmitter circuit, and with the receiver *R* placed in a building about 3000 feet away, telegraphic dispatches were heard quite distinctly. In these experiments two distinct paths may be arranged for the electric current, according to the position of the plates in each circuit. If a plate is placed at the bottom of a well at *C*, and the other plate of the same circuit is placed in the surface soil *A*, and if there is an intervening layer *B* of high resistance soil between the transmitter plates, the plates of the receiving instrument *R* being similarly located, then the path of the current will be from one plate of the transmitter through the surface soil to the corresponding plate of the receiver, then through the receiving instrument and back by the bottom layer of earth. The intervening high resistance stratum will prevent short circuiting of each instrument. The other method would be to locate the plates of each instrument a suitable distance apart, but all of them in the surface soil, which is substantially the method of the English patent to Lindsay.

Between the dates of Lindsay's invention and the "Cosmos" article a number of patents have been taken out, all based on the principle of the resistances of branched circuits. Among them may be enumerated the following: In Great Britain—Haworth, No. 843, of 1862, and No. 2682, of 1863; Smith, No. 8159, of 1887;

*The classification adopted in this article has been followed by the patented art in its development, and is also that which has been used by Prof. S. P. Thompson in a review of the literature of the subject in the "Journal of the Society of Arts," London, April 1, 1898.

Stevenson, No. 5498, of 1892; Smith et al., No. 10,706, of 1892; and in the United States the following: Ader, No. 377,879, February 14, 1888; Blake, No. 526,609, September 25, 1894.

The Smith patents show a means of communicating from the shore to a lighthouse on an island by the use of submerged plates, one pair being connected to a receiving instrument in the lighthouse, and another pair arranged to include the former pair between them, the latter pair being connected by wires to a transmitting battery and key on the shore. In the last cited patent to Smith step-down transformers are used to energize the plates located in the signaling circuit. These, of course, generate heavy currents, so that an appreciable part of them may flow through the receiving instrument in the lighthouse. It is evident that devices of the last-named character can transmit signals through a short distance only without intervening wires. The advantages that result from their use are due to the ability of dispensing with shore connections for the cables on rocky coasts where lighthouses are usually situated. In heavy gales the ordinary cable is often torn from its bed and communication between the shore and the lighthouse is interrupted. By burying one of the plates of a conduction system in the ocean sufficiently below the surface of the water to avoid the disturbing action of the waves on the signals, and its neighbor in a well on the lighthouse shore, the necessity of bringing a cable end on land is avoided, and a fairly satisfactory means of communication is established.

An application of this method to ship signaling seems to offer a chance of success, owing to the short distance between the ship and the signal transmitting circuit. In this connection the following

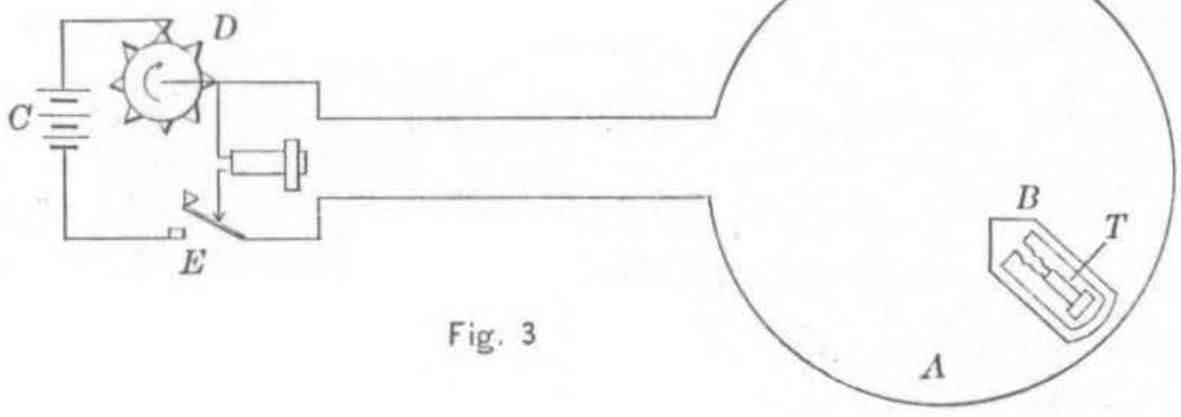

Fig. 3

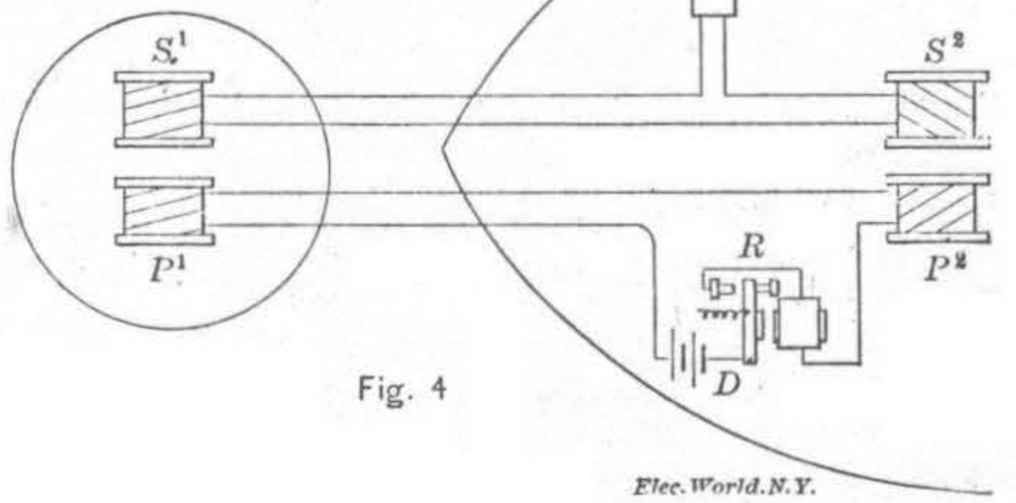

Fig. 4

patents may be cited, which illustrate a means of avoiding collisions of ships with each other, or of preventing them from running ashore: In Germany, Somzee, No. 44,101, of 1888; in Great Britain, Stevenson, No. 5498, of 1892, and in the United States, Blake, No. 526,609, September 25, 1894.

In Somzee's invention each ship carries a pair of plates submerged in the water, one at the bow, the other at the stern, the plates being connected by wires which include a signal-receiving instrument, such as a telephone or galvanometer. Shoals may be indicated by suitably energized stationary plates, the current from which is diverted into the receiving circuit on the ship whenever the vessel approaches shallow water. A similar method is used in the Stevenson and Blake patents. The conduction system of transmission is fully explained by Rathenau in a report to the General Electric Society in the "Elektrotechnische Zeitschrift," for November 8, 1894, in which it was suggested that a telephone receiver be used to receive the signals. The metallic diaphragm of the telephone was to be replaced by a light tongue, which should be tuned to respond to the predetermined rate of vibration of the transmitting circuit. This rate was to be imposed upon the circuit by a suitable tuning fork operating a circuit breaker. The investigator stated that communication had been effected over a distance of 3 miles.

INDUCTION METHODS.

These methods have already been classified into electromagnetic and electrostatic systems. The difference between them is largely one of degree, inasmuch as in each both kinds of induction may play a part, although usually the effect of one preponderates over that of the other. The intimate relationship which exists between the two methods is explained by the modern theories of inductive action. Maxwell's theory assumes that an e. m. f. which acts upon a dielectric produces an electric displacement, and that the change in electric displacement is an electric current called the displacement current. This displacement current in dielectrics is accompanied by magnetic force. It originates a field of magnetic lines of induction which surround it just as a wire carrying a current is surrounded by lines of force. The converse propositions whereby displacement currents are created by the change in the intensity of a magnetic field readily follow from the original assumption.

According to the J. J. Thomson theory, both kinds of induction are produced by electrostatic tubes of force, called by him Faraday tubes, some of them open and some closed, which are distributed through the ether. Each open tube which starts from a positive charge of electricity terminates on an equal and opposite negative charge. This gives rise to the ordinary phenomenon of electrostatic induction. The phenomena of the electromagnetic field are due to the motion of the Faraday tubes, or to changes in their position or shape; if, for example, a moving tube cuts a closed conductor, a current is induced in it.

The differences in the two methods above referred to result from the relative importance of the induction coil and the condenser in the particular circuit under consideration. In electromagnetic induction methods the magnetic field of the circuit supplied by the induction coil is the important element, in the so-called electrostatic system the effects are due to the condenser which gives rise to the electrostatic field of force.

The term electrostatic induction, which has been freely used, seems to be a misnomer when applied to phenomena which are due to electricity in motion. The appearance and disappearance of the induction tubes which accompany the charge and discharge of a condenser give rise to the induced current, and the effect is not one of electrostatics but of electrokinetics. It would be more accurate therefore, to apply the term capacity or condenser methods to the class called electrostatic induction, and the phrase mutual-induction system to the electromagnetic-induction methods. The older terms have been retained for convenience.

ELECTROMAGNETIC INDUCTION METHODS.

About 1893 Mr. W. H. Preece gave a renewed impetus to the electromagnetic induction class by some experiments performed in England, in which the inductive method was exhaustively tried. In previous experiments by the same investigator in which buried plates were connected to two parallel wires a considerable distance apart, the effects were attributed largely to earth conduction, and it was necessary to prove that the action in the later trials was electromagnetic in its nature. This was unquestionably true in some of the experiments, but there is still some doubt as to the nature of the action in all the tests. One method was to use insulated copper wires in quarter-mile squares laid on a level plain, a quarter of a mile apart. Alternating currents were sent through the transmitting circuit, and these, when interrupted by means of a telegraph key, gave Morse signals which were received in suitable telephones. The data are given in full in the Proceedings of the Electrical Congress at the World's Fair for 1893, published by the American Institute of Electrical Engineers.

The electromagnetic induction method has been the subject of a number of patents, attention being called to the following: In the United States—Phelps, No. 307,984, Nov. 11, 1884; 312,506, Feb. 17, 1885; Woods, No. 373,915, Nov. 29, 1887; Ader, No. 377,879, Feb.

14, 1888. In England—Evershed, No. 10,161, of 1892; Sennett, No. 13,415, of 1892, and Evershed, No. 18,312, of 1896. In Germany the patent to Somzee above cited.

The patents to Phelps and to Woods furnish applications of the method of transmitting signals to or from a moving railway train. A coil of wire, including in its circuit a transmitting key and a receiving instrument, is located on the car so that the coil may pass in close proximity to a telegraph wire strung upon poles or on the roadbed. These devices necessitate the presence of a telegraph operator upon the car, and inasmuch as it is an easy matter to dispatch telegrams at the nearest stopping point which may be written out on the train, it will readily be seen why this system has not gone into extensive use.

The English patents to Evershed and to Sennett above cited disclose methods of signaling from the shore to lightships or other vessels approaching the shore. An inductive circuit is arranged with a coil A, see Fig. 3, located in the ocean in a horizontal plane, the coil being supported, if desired, by suitable buoys so as to bring the magnetic field produced by the coil near the surface of the water below the vessel B which sails over it. The signaling circuit may be produced by an alternating-current dynamo, or by means of a battery C and revolving contact wheel D, which rapidly interrupts the battery current. A telegraph key E is used, by means of which signals of short and long duration are given according to the Morse or other code. The receiving instrument may be a telephone receiver T or an electromagnet acting on a reed of metal tuned to correspond in pitch to the frequency of the secondary currents. A call bell may be rung by means of a local battery in the circuit of a relay, the relay consisting of a tuning fork designed to respond to the timed impulses of the transmitting circuit.

In the German patent to Somzee, which has been discussed above, a modification is used which adopts the principle of the Hughes induction balance. See Fig. 4. In this method the balance is formed by two circuits, each including a pair of coils, one circuit being completed through a battery D, and automatic circuit breaker R, and the other through a bell. One pair of coils $P^2 S^2$ is placed upon the ship, the other pair $P^1 S^1$ is located upon a float which is dragged by the ship. The inductive effect of P^2 on S^2 is normally balanced by that of P^1 on S^1. When the vessel approaches a shoal, which should be marked by means of a large metal buoy, the balance of the currents is destroyed by the metal of the buoy and the bell rings. The method employed by Somzee has been used by Huskisson in patent No. 542,732, July 16, 1895, for the automatic firing of mines located in a harbor. The induction balance is connected to the mine, and when the ship passes over it the current balance being destroyed by the inductive action of the metal of the ship, the mine is fired.

In the methods which have just been described the effects are due to mutual induction. The current flowing through the signaling circuit creates a magnetic field of force, the lines of which penetrate the receiving circuit. Any change in the intensity of the current produces a corresponding change of the field, and this gives rise to an induced current in the receiving circuit, whose e. m. f. is measured by the rate of decrease of magnetic induction through it. This gives the equation

$$E = - M \frac{di}{dt}$$

in which E is the induced e. m. f. at any instant, M is the coefficient of mutual induction of the two circuits, and i is the current in the inducing circuit at any instant.

If, as in some of the cases discussed above, we have an alternate current flowing through the primary circuit whose equation is

$$i = I \sin a$$

in which I is the maximum value of the primary current, we have for the value of the induced e. m. f.:

$$E = M I \cos a \frac{da}{dt}.$$

The effective secondary induced e. m. f. is therefore:

$$E' = 2 \pi f M I'$$

in which I' is the effective primary current, f is the frequency of the primary current wave, and M is the coefficient of mutual induction.

It follows from this equation that in order to make this method of signaling as sensitive as possible we must use large currents of high frequency in the signaling circuit, as many turns of wire as possible in both circuits and increase the permeability of the intervening medium by introducing magnetic materials therein.

(To be Continued.)

Telegraphing Without Line Wires—II.

By William Bissing.

ELECTROSTATIC INDUCTION METHODS.

The electrostatic system may be said to represent an intermediate stage in the development of the art of telegraphing without line wires. Some of the difficulties which are met and overcome in this method of signaling, e. g., the dampening effect of intervening obstacles, occur in the modern or Hertzian wave method. In some of the patents that used electrostatic induction for their effects electrical waves occur, but, as will appear more fully below, the wave effect is lost or inconsiderable. Some of the electrostatic methods have been used, a number of years ago, in railroad signaling, examples of which are furnished by the following patents: Smith, 247,127, September 13, 1881; Phelps, 334,188, January 12, 1886; Edison et al, 486,634, November 22, 1892.

The patent to Smith was the first to describe a means of signaling by induction to a moving railway train. The metallic roof of the car which should be insulated is connected to a wire which leads to one terminal of a telephone receiver, the other terminal of the receiver being grounded through the wheels and rails. A telegraph line is strung along the track in closer proximity to the car than is customary for Morse signaling. On telephoning over the line from a station on the road the car roof is affected inductively, and a current is produced in the receiver on the car, the line and the roof forming the two plates of a condenser. An advantage of this method of transmitting signals is that the line wire along the track may be used for telegraphing according to the ordinary Morse system, without disturbing the telephonic signals. The current induced in the car circuit in this patent is probably due to both electromagnetic and electrostatic induction.

In the patent to Edison, et al, No. 486,634, see Fig. 5, a pair of suitably insulated plates *aa* are placed upon the car roof, and a wire *1* connects them to one terminal of the secondary of an induction coil *E*, the other terminal of which is connected to the telephone *F*, from which a wire *2* runs to ground at the car wheel. The primary of the induction coil is connected through a switch *e* to an electromagnetic circuit breaker *I* and battery *H*. Sparking at the circuit breaker is prevented by the condenser *K*. A switch *G* normally short-circuits the secondary of *E*. A similar apparatus is placed at the sending station. In receiving signals the switch *e* is opened, and *G* is left in its short-circuiting position. The signal will then be received at *F*, the telephone taking the place of the Morse sounder. In sending signals *e* is closed and *G* depressed at intervals to produce dots and dashes according to the length of depression of the key, a series of impulses which produces a rattle in the telephone receiver being sent to line each time the key is closed. The system used in this patent resembles that used by Edison in patent No. 465,971, which will be described below. Both patents were applied for in the same year, viz., 1885.
