Mr. Tesla also described a very interesting phenomenon which he illustrated by an experiment. By means of this new apparatus, he is able to produce an alternating current in which the E. M. F. of the impulses in one direction preponderates over that of those in the other, so that there is produced the effect of a direct current. In fact, he expressed the hope that these currents would be capable of application in many instances, serving as direct currents. The principle involved in this preponderat-

ing E. M. F. he explains in this way: Suppose a conductor is moved into the magnetic field and then suddenly withdrawn. If the current is not retarded, then the work performed will be a mere fractional one; but if the current is retarded, then the magnetic field acts as a spring. Imagine that the motion of the conductor is arrested by the current generated, and that at the instant when it stops to move into the field, there is still the maximum current flowing in the conductor; then this current will, according to Lenz's law, drive the conductor out of the field again, and if the conductor has no resistance, then it would leave the field with the velocity it entered it. Now it is clear that if, instead of simply depending on the current to drive the conductor out of the field, the mechanically applied force is so timed that it helps the conductor to get out of the field, then it might leave the field with higher velocity than it entered it, and thus one impulse is made to preponderate in E. M. F. over the other.

With a current of this nature, Mr. Tesla energized magnets strongly, and performed many interesting experiments bearing out the fact that one of the current impulses preponderates. Among them was one in which he attached to his oscillator a ring magnet with a small air gap between the poles. This magnet was oscillated up and down 80 times a second. A copper disk, when inserted within the air gap of the ring magnet, was brought into rapid rotation. Mr. Tesla remarked that this experiment also seemed to demonstrate that the lines of flow of current through a metallic mass are disturbed by the presence of a magnet in a manner quite independently of the so-called Hall effect. He showed also a very interesting method of making a connection with the oscillating magnet. This was accomplished by attaching to the magnet small insulated steel rods, and connecting to these rods the ends of the energizing coil. As the magnet was vibrated, stationary nodes were produced in the steel rods, and at these points the terminals of a direct current source were attached. Mr. Tesla also pointed out that one of the uses of currents, such as those produced in his apparatus, would be to select any given one of a number of devices connected to the same circuit by picking out the vibration by resonance. There is indeed little doubt that with Mr. Tesla's devices, harmonic and synchronous telegraphy will receive a fresh impetus, and vast possibilities are again opened up.

Mr. Tesla was very much elated over his latest achievements, and said that he hoped that in the hands of practical, as well as scientific men, the devices described by him would yield important results. He laid special stress on the facility now afforded for investigating the effect of mechanical vibration in all directions, and also showed that he had observed a number of facts in connection with iron cores.

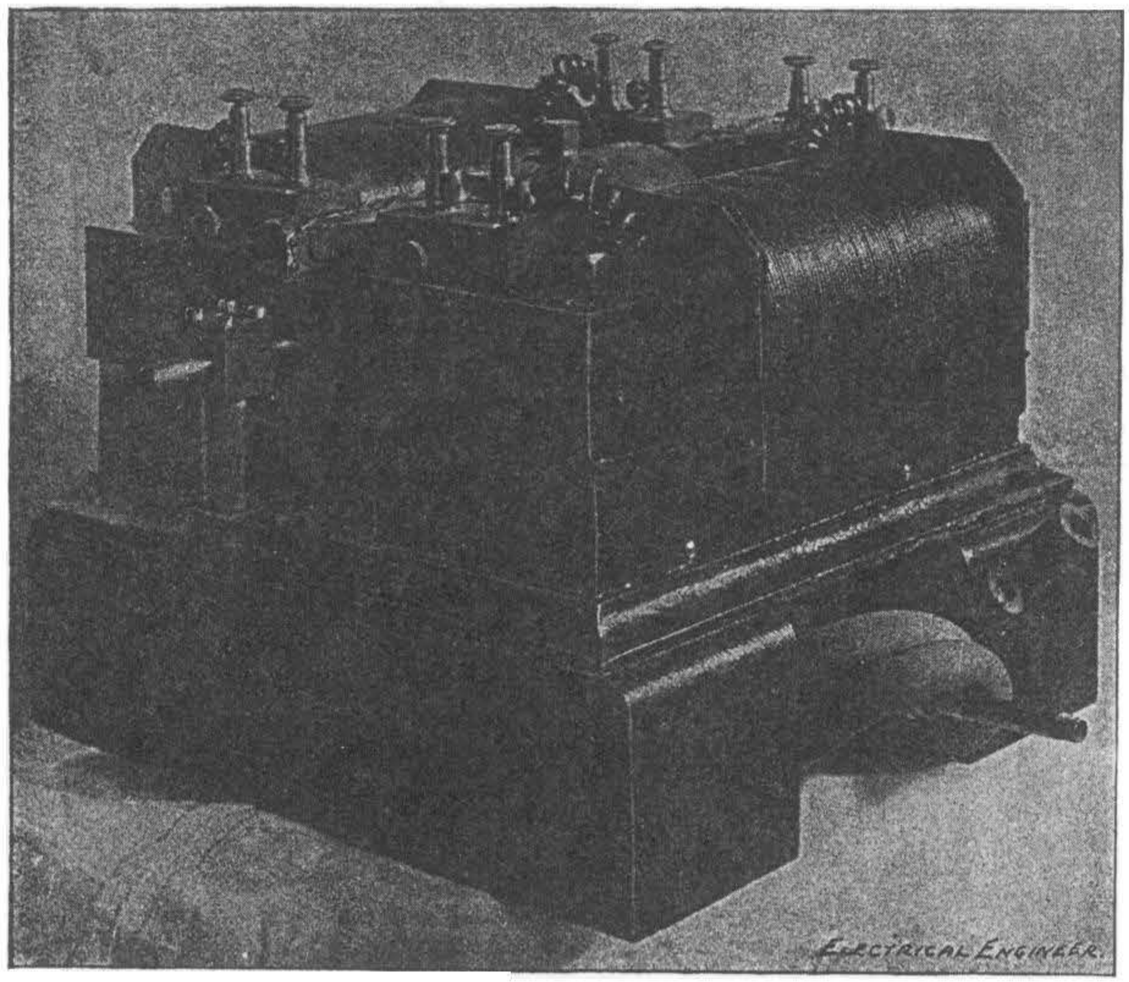

FIG. 1.

The engraving, Fig. 1, shows, in perspective, one of the forms of apparatus used by Mr. Tesla in his earlier investigations in this field of work, and its interior construction is made plain by the sectional view shown in Fig. 2. It will be noted that the piston P is fitted into the hollow of a cylinder C which is provided with channel ports O O, and I, extending all around the inside surface. In this particular apparatus there are two channels O O

for the outlet of the working fluid and one, I, for the inlet. The piston P is provided with two slots s s′ at a carefully determined distance, one from the other. The tubes T T which are screwed into the holes drilled into the piston, establish communication between the slots s s′ and chambers on each side of the piston, each of these chambers connecting with the slot which is remote from it. The piston P is screwed tightly on a shaft A which passes through fitting boxes at the end of the cylinder C. The boxes project to a carefully determined distance into the hollow of the cylinder C, thus determining the length of the stroke.

Surrounding the whole is a jacket J. This jacket acts chiefly to diminish the sound produced by the oscillator and as a jacket when

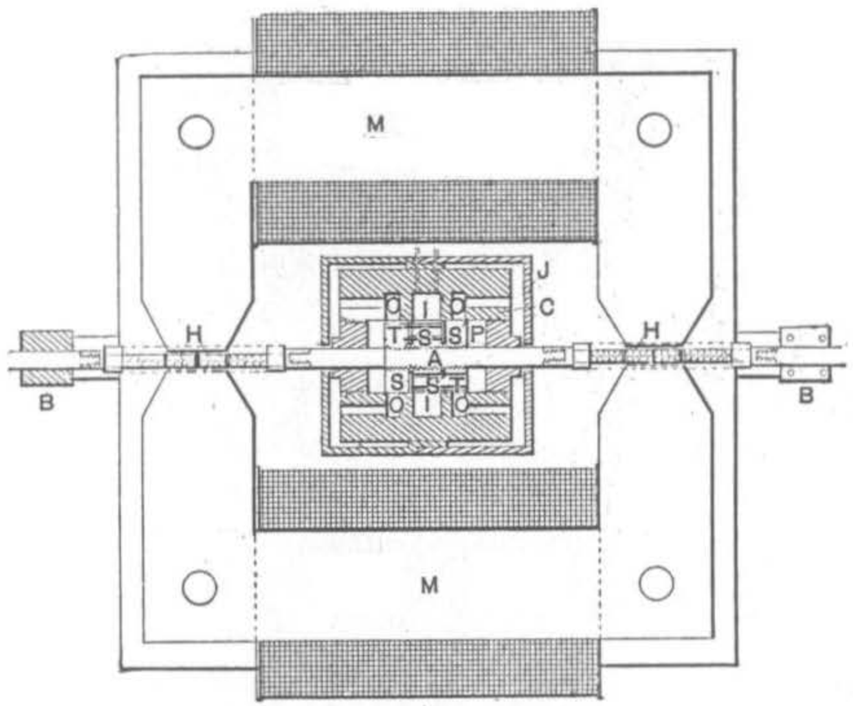

FIG. 2.

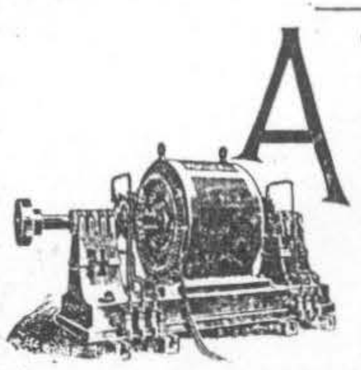
the oscillator is driven by steam, in which case a somewhat different arrangement of the magnets is employed. The apparatus here illustrated was intended for demonstration purposes, air being used as most convenient for this purpose.

A magnetic frame M. M. is fastened so as to closely surround the oscillator and is provided with energizing coils which establish two strong magnetic fields on opposite sides. The magnetic frame is made up of thin sheet iron. In the intensely concentrated field thus produced, there are arranged two pair of coils H H supported in metallic frames which are screwed on the shaft A of

the piston and have additional bearings in the boxes B B on each side. The whole is mounted on a metallic base resting on two wooden blocks.



The operation of the device is as follows: The working fluid being admitted through an inlet pipe to the slot I and the piston being supposed to be in the position indicated, it is sufficient, though not necessary, to give a gentle tap on one of the shaft ends protruding from the boxes B. Assume that the motion imparted be such as to move the piston to the left (when looking at the diagram) then the air rushes through the slot s′ and tube T into the chamber to the left. The pressure now drives the piston towards the right and owing to its inertia, it overshoots the position of equilibrium and allows the air to rush through the slot s and tube T into the chamber to the right, while the communication to the left hand chamber is cut off, the air of the latter chamber escaping through the outlet O on the left. On the return stroke a similar operation takes place on the right hand side. This oscillation is maintained continuously and the apparatus performs vibrations from a scarcely perceptible quiver amounting to more than $\frac{1}{10}$ of an inch, up to the vibrations of a little over $\frac{3}{8}$ of an inch, according to the air pressure and load. It is indeed interesting to see how an incandescent lamp is kept burning with the apparatus showing a scarcely perceptible quiver.

To perfect the mechanical part of the apparatus so that oscillations are maintained economically was one thing, and Mr. Tesla hinted in his lecture at the great difficulties he had first encountered to accomplish this. But to produce oscillations which would be of constant period was another task of no mean proportions. As already pointed out, Mr. Tesla obtains the constancy of period in three distinct ways. Thus, he provides properly calculated chambers, as in the case illustrated, in the oscillator itself; or he associates with the oscillator an air spring of constant resilience. But the most interesting of all, perhaps, is the maintenance of the constancy of oscillation by the reaction of the electromagnetic part of the combination. Mr. Tesla winds his coils, by preference, for high tension and associates with them a condenser, making the natural period of the combination fairly approximating to the average period at which the piston would oscillate without any particular provision being made for the constancy of period under varying pressure and load. As the piston with the coils is perfectly free to move, it is extremely susceptible to the influence of the natural vibra-

tion set up in the circuits of the coils H H. The mechanical efficiency of the apparatus is very high owing to the fact that friction is reduced to a minimum and the weights which are moved are small; the output of the oscillator is therefore a very large one.

Theoretically considered, when the various advantages which Mr. Tesla holds out are examined, it is surprising, considering the simplicity of the arrangement, that nothing was done in this direction before. No doubt many inventors, at one time or other, have entertained the idea of generating currents by attaching a coil or a magnetic core to the piston of a steam engine, or generating currents by the vibrations of a tuning fork, or similar devices, but the disadvantages of such arrangements from an engineering standpoint must be obvious. Mr. Tesla, however, in the introductory remarks of his lecture, pointed out how by a series of conclusions he was driven to take up this new line of work by the necessity of producing currents of constant period and as a result of his endeavors to maintain electrical oscillation in the most simple and economical manner.

Multiphase Motors and the Transmission of Power

A QUESTION so important as the long distance transmission of power had been apparently overlooked in the preparations for the recent International Electrical Congress, as no papers on this subject appeared in the programme, and this fact excited more or less comment. When it was understood that the matter would come up for consideration in the section of Pure Practice, over which Prof. E. J. Houston presided, it was evident that the discussion would be followed with great interest, and that the attendance in Section B during that time would be very large. The idea, it is stated, originated with Dr. Louis Duncan, of Johns Hopkins University, who has always taken an active interest in this question, and is regarded as one of the leading exponents of the transmission of power by alternating currents in this country.

On Thursday forenoon the chairman of Section B accordingly called upon Dr. Duncan to open the discussion, and as many points of great value and interest were brought out it is given below in more detail than the brief synopsis which appeared in the report of the proceedings of the congress in the last issue of The Electrical World.

Dr. Louis Duncan.

Dr. Duncan first explained why the discussion had arisen; it was found that there were no papers on the list of those to be read before the congress which touched upon the subject, and as a great many men, who had a large amount of practical experience, and who probably knew a great deal more about multiphase systems than any one in this country were present at the congress, it was desirable, if possible, to get hold of their knowledge and experience.

Dr. Duncan then briefly described the theory of the multiphase motor, and showed that the distribution of E. M. F. was such as to give a higher efficiency than is possible in direct current machines. Taking the case of two independent alternating currents with a difference of phase of 90 degrees, one is at zero when the other is at maximum, and if these are led around the magnets of a four-pole dynamo it is evident that a maximum E. M. F. is induced in each wire when it is placed in the best possible position in the field of natural strength. There is, then, a distribution of electrical force in the conductors about the armature, such that the highest electrical force is obtained exactly where it is desired. The distribution is such that the current is obtained exactly where we want it, and for that reason the conditions are better than in a continuous current machine. It has been found in the first place in working up the problem that the electrical efficiency of such a motor is a very simple expression, equal to the angular velocity of the armature divided by the angular velocity of the field. Such a motor would start up just like a continuous current motor, and would have an efficiency greater than a continuous current motor, provided there were no lagging of the current. The starting of the motors is the most serious question which has to be dealt with; if we have a motor where the drop of potential is 10 per cent. or something like that, and if the machine when starting has a current of many times the normal current, the whole distribution is disarranged. It is just as if a continuous current motor were started with the brushes shifted almost 90 degrees from the neutral point of the commutator: The question is, How is it possible to get rid of this trouble? The first thing to do would be to decrease the self-induction; this has been done by the Stanley company by placing short-circuited coils near the armature coils; but this is done at the expense of a good deal of space which could otherwise be filled with iron, and it is questionable whether it would not be just as well to utilize that space by putting more iron into it. Another way is to increase the armature resistance of the motor. There has been a great deal of trouble with multiphase motors, and one of the reasons for it is this: Suppose that a wave is applied that is not a sine curve, but is a positive and fundamental wave, a number of upper harmonics; suppose we have the E. M. F. together with the same harmonics, then the efficiency of the motor would be greatly reduced. If the motor were revolving at 900 revolutions and the field at 1,000 the electrical efficiency would be 90 per cent., but if more waves are there, say, the third or fifth harmonics, then the efficiency is greatly decreased. It is a very difficult thing to experiment on these armature currents because any ordinary means for obtaining the curve will not work. Another piece of machinery which Dr. Duncan considered of great importance, and which he hoped would be discussed, was the rotary transformer. He illustrated by diagrams upon the board the theory of operation of such a machine, and pointed out some of the inherent difficulties. He called attention to the fact that all the current does not pass through the armature, and that this is a very important point, because the question comes up as to how much energy can be transformed with one of these machines. Another question which he hoped would be discussed was that, with a given machine, say, of 100 h. p., can more energy be transformed with a three-phase than with a two-phase machine; and, if so, in what proportion. He closed his discussion by remarking that he hoped that those present who had practical experience in this line would not hesitate to speak, and that the discussion would be simple and straightforward.

Mr. C. F. Scott called attention to the Tesla polyphase system which constitutes a part of the exhibit of the Westinghouse Electric and Manufacturing Company in Electricity Building. The purpose of the exhibit is to show a complete working system for generating, transmitting and distributing power on a large commercial scale. The system includes:

I. A prime mover. II. A generating dynamo. III. Raising converters and transmission line and reducing converters. IV. Motors and rotary transformers for general power and electrical service.

The prime mover in general practice is water power, but in the present plant a 500-h. p. two-phase Tesla motor of the rotary field type serves as prime mover. The current for this motor is received from one of the 750-kw. two-phase Westinghouse generators of the lighting plant in Machinery Hall. The number of alternations is 7,200, and the pressure is reduced from 2,000 volts to 200 volts before being delivered to the motor. The current is delivered to the rotating element of the motor through brushes resting on four collecting rings. The winding is a drum winding laid in small slots in the surface. The stationary element of the motor is of laminated iron set in an outside casting. Large copper rods are run through holes in the iron plates near the inner surface, and are suitably connected at the ends. Resistances are put in circuit with this winding for starting the motor, and when speed is attained these resistances are short-circuited, leaving this winding completely closed on itself.

This motor drives a 500-h. p. two-phase alternating current generator. This machine is of the ordinary type of railway generator. There is a field of six poles which is excited by a small direct current machine driven by a 5-h. p. two-phase Tesla motor of the rotary field type. The exciter in general practice would be driven by a water-wheel. The large generator delivers from four collecting rings two currents differing in phase 90 degrees. The number of alternations is about 4,000 per minute, or 33⅓ periods per second at a potential of 300 volts on each circuit. The machine is also provided with a direct current commutator connected with the same winding, delivering current at 500 volts. This commutator would not be used when the machine is intended as an alternating current generator only. The current from this machine is delivered to a marble switchboard, where it is regulated and connected with the various transmission circuits, as desired. This board will afford facilities for connecting various circuits with any one of the several generators which may be placed in a large generating station. The current from the switchboard is received by alternating current converters or transformers by which the potential is raised in the present plant to 1,200 volts. In practice, the transformation would be to a much higher voltage, depending upon the distance of transmission. The transmission circuit conveys the current to the receiving station, where it is reduced by transformers to electromotive forces appropriate to the machines to be supplied. The current passes through a marble switchboard in which there are suitable provisions for operating the various machines in the receiving station.

The largest machine in this station is a 500-h. p. two-phase Tesla motor and rotary transformer. This machine is similar in general construction to the generator above described. The alternating current at 360 volts is passed into four collecting rings on the armature. Special connections of the field circuit are made for starting the machine, and when the motor has attained full speed a switch is turned giving the final connections and running the machine as a self-exciting synchronous motor, which maintains the exact speed of the generator by which it is driven except in cases of extreme overload. The armature of this machine is provided with a double pulley with belts driving a Worthington pump and a 40-light Westinghouse alternating current arc-light dynamo. The armature is supplied with a direct current commutator connected with the same winding which receives the alternating current, and delivers direct current at a potential of 500 volts. This current is utilized for operating two 30-h. p. street railway motors mounted upon a standard Dorner & Dutton truck, and also a 60-h. p. direct current motor mounted upon an Ingersoll-Sergeant air compressor. The direct current also supplies a series of direct current constant potential arc lamps. The current from the switchboard is also carried directly to a 60-h. p. two-phase motor and rotary transformer, which receives the current at 30 volts and delivers direct current at 50 volts adapted to electrolytic work, charging of storage batteries, and is at present used for operating the large Schuckert search light in an adjoining space. The current from the switchboard also operates a 60-h. p. two-phase Tesla motor of the synchronous type, which is adapted for any kind of constant speed work. In the present exhibit it is direct coupled to a 45-kw. slow-speed alternator of the constant potential type used for incandescent lighting. Current from the switchboard is also directly utilized for supplying incandescent lamps. Mr. Scott then called attention to the excellent mechanical design of the machines and the necessity of such work to insure success and economy in the practical operation of a plant. He described briefly the construction of the machines, and showed their fitness for the work for which they were designed. Attention was also called to the simplicity and solidity of the whole system and to its great flexibility. Mention was made of the successful installation and operation of a lighting plant for over 100 h. p. using 10,000 volts over a 28-mile circuit in southern California is an initial step which covers a distance greater than is required in a majority of the cases in which power transmission is proposed.

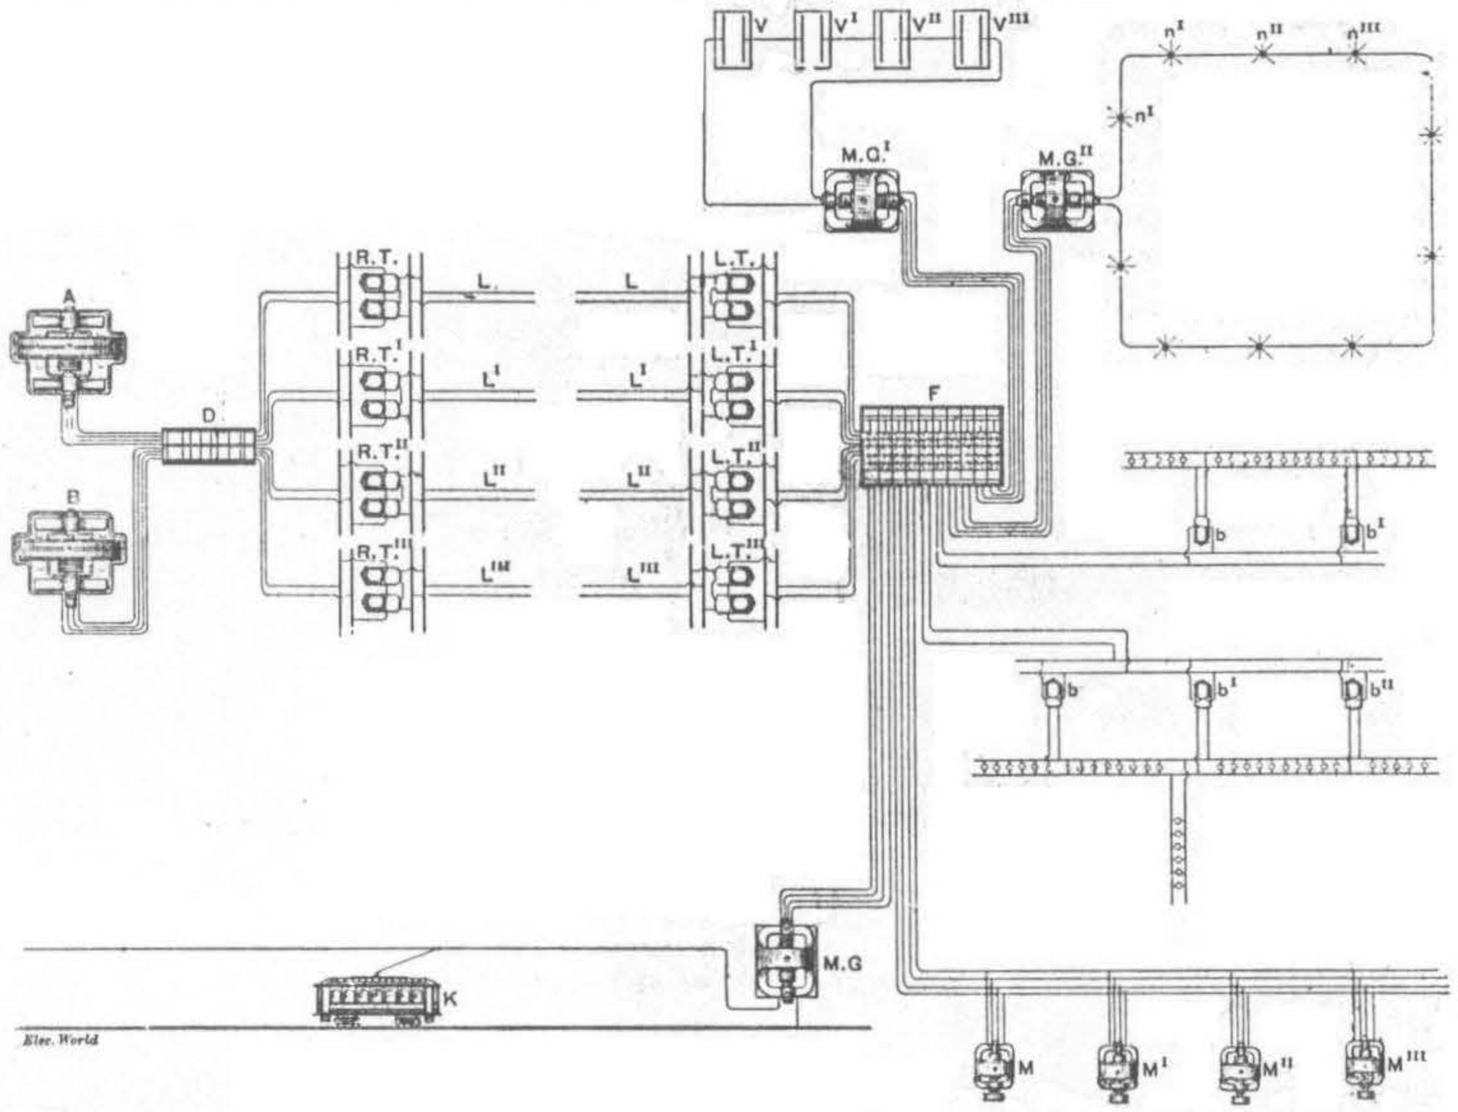


DIAGRAM OF MULTIPHASE OR TESLA SYSTEM OF TRANSMISSION AND DISTRIBUTION.

Mr. W. F. C. Hasson, of San Francisco, was then

called upon to continue the discussion. He stated that, as consulting engineer, he represented a variety of companies in California who desired to transmit power electrically to the aggregate amount of some 40,000 h. p. over distances ranging from 10 to 44 miles. Notwithstanding the fact that Mr. Scott had referred to the successful transmission of power for lighting purposes at San Antonio over 28 miles, the transmission of power electrically over long distances in California was a failure. Over a year ago the first contract for a definite transmission of power was closed, and to-day the superintendent of the mine in which the installation was made in eastern California is looking at his burned-out field coils after the generator has been in operation for less than thirteen days. The whole system just described is logical, and very beautiful on paper, but it does not establish the commercial success of long distance transmission of power. The machinery must be so built that it will not run for hours or days, but for weeks and months. Installations of this kind are almost invariably in places which are distant from railways, and where repairs are impossible, and the machinery must be of such a kind that it will be practically impossible for accidents to happen. Mr. Hasson stated that he believed in the transmission of power, and had been an apostle of it for some time in California, but that he was obliged to definitely state that as far as California was concerned the results had been failures, at least from the standpoint of the investor. Some months ago he was called upon to decide upon certain plans for the transmission of 3,000 h. p. for 20 miles; mose elaborate and beautiful descriptions of methods arriving at the results were placed before him, but not a single working drawing of any kind.

Dr. Louis Bell then took up the subject and first expressed satisfaction that a previous speaker had referred to the two-phase system as a polyphase system, because he thought that all which applies to the two-phase system applies in varying degrees to all other numbers of phases. He stated that there are in general three methods which are usually proposed for power transmission—that of the direct current, which Prof. Crocker had been championing in his paper before the Congress; that of single-phase currents and that of polyphase currents. In regard to the first, it could only be said that in this country, at least, it had not been altogether a success; the great difficulty seems to be that when the current increases to any considerable extent difficulties are at once to be met with. As for alternating currents, the reason why they are preferable is that they can be utilized in so many different ways. So long as the direct current had a monopoly of all motor service there was no choice, but at the present day that is changed; the single-phase system is now applicable to motor service, though not as well as the polyphase system, nor is it as well adapted to the operation of the rotary transformer, which is destined to play an important part in the future transmission by polyphase currents. The single-phase motor in its present state of development can be considered as nothing else than a rather poor polyphase motor; it starts on the polyphase principle, but with the objection that the rotary field established is not a circular rotary field but an elliptical one, and, consequently, gives less efficiency in the motor. Coming finally to the polyphase systems, they may be divided into two classes, those having two wires per phase or independent circuits, and those having non-independent circuits. A two-phase system with three wires is somewhat simpler than the two-phase independent circuit system; the three-phase system, operated on separate circuits, requires six wires, but with combined circuits requires only three wires—as few as are required by any polyphase system. Furthermore, in all the polyphase non-independent circuits polyphase systems save copper, as over the direct current, the simple alternating and the polyphase system with separate circuits, and this saving varies in degree from 12 or 13 per cent. in the two-phase to 25 per cent. in the three-phase. Another important feature of the three-phase dependent circuit system is that there is less self-induction and capacity on the line than in single or two-phase systems. For the installation of lights the difference between a dependent circuit system with three wires and an independent circuit system with at least four wires is very little because it is necessary to split the cur cuits in any case, but in most cases three wires are more convenient than four. The great objection which has been raised against the polyphase system with dependent circuits is that it does not regulate well, but this criticism is ill founded, as we know from experiments. In the first place it is quite possible to arrange such a system so that the difference between the different branches of the circuit will be almost unnoticeable. The means of doing this are simple, and therefore it is well to state as the result of positive experiments that without any complicated means of compensation whatever it is possible to obtain closely concordant voltages in all branches of polyphase system.

In regard to polyphase motors, there is no very wide difference in principle or in operation between two, three, four, or *m* phase motors or in their action on dependent or independent circuits. When such motors are properly designed there is no doubt that they are decidedly superior to any direct current machine, and that is one of the strong reasons for using the polyphase systems.

Dr. Bell stated that he had been experimenting with motors of this type for a long time, and that he had never yet succeeded, even under the most adverse conditions, in burning out a single machine in any way whatever, a record which could hardly have been made with any kind of a direct current motor. If overloaded they will stop, and not burn out for a pretty long period; they start quite well, as well as any ordinary direct current motor; and in regard to the current required, they start just about as a shunt motor does. It is possible to run a polyphase motor at a widely varying range of speed (say, from 1-10th speed up to full speed), keeping a practically constant torque. Dr. Bell, in closing, defended the polyphase machine against the accusation of a large lagging current.

Prof. S. P. Thompson, first speaking for M. Thury, briefly described the transmission plant at Genoa, where a direct curernt of 1,200 volts was employed and no difficulties were experienced. Another interesting continuous current plant is that operating between Biberist and Rondchatel, a distance of about 20 miles. Forty amperes of current at 3,500 volts are there transmitted. At Genoa eight dynamos, all joined in series, each running at nominally about 1,000 volts, supply generators. These are all samples of practical installations for which M. Thury makes himself responsible.

In speaking for himself, Prof. Thompson first touched upon the continuous current problem, stating that many continuous current machines of high voltage had been successfully operated, and citing cases as illustrations. Coming to the question of alternating current work, he caled particular attention to the installation at Rome, where the source of power was a waterfall some fourteen miles distant. He had studied the polyphase transmission at Frankfort, where there were eight or ten different systems on exhibition, from all the great firms in the world; he did not believe that there was any best system, but that each one was best for its own purposes. He did not care to prophesy, but would give his personal opinion as to what would be the general system in use ten years from date. He did not like the complication of three-phase transformers, and three-phase switchboards and other apparatus, although he did like three-phase and two-phase alternating current dynamos and motors. The system recently described by a previous speaker was very beautiful, but he did not like its complications. In the future he thought that all the applications of polyphase work would be abandoned, and that engineers would return to simple alternating current motors; in other words, that the simple alternating current will be the one thing which ten years hence will be found to be effective for all long distance transmission.

Mr. C. P. Steinmetz remarked that out of justice he would be obliged to take the part of the continuous current; the largest amount of power distributed in the United States to-day is distributed by continuous currents; this shows that the continuous current is not dead yet, and the many references to rotary transformers showed that even the advocates of the polyphase systems still consider that they cannot get along without the old continuous current. With regard to the polyphase and single-phase systems, it makes little difference how many phases there are, because any system of polyphase currents can be transformed into any other system of polyphase currents by using two transformers only; furthermore the motors of the different polyphase systems are essentially the same. Mr. Steinmetz thought that the system of the future would be the single-phase system. There would be no longer any trouble with self-induction or capacity, for proper appliances would eliminate their effects entirely.

Prof. George Forbes stated that he was informed that there had been an organized conspiracy among the American engineers, led by no less a man than Dr. Louis Duncan, to draw out the foreign engineers on the subject of transmission of power and multiphase motors; he did not think that this referred to him, as he has ceased to look upon himself as a foreign engineer. Prof. Forbes then proceeded to outline the methods which had been adopted for the great transmission plant at Niagara Falls. The subject had been investigated most thoroughly by himself and others connected with the enterprise, in order that the best system might be selected. The first step taken was the decision that there should be central stations established at Niagara Falls to transmit power to places at greater or less distances away, as opposed to the proposition of locating all the mills directly at the Falls. It was decided that the whole of the transmission should be done by means of electricity. In 1890 a number of plans were invited from different engineers and engineering firms as to the best means of utilizing the large power of the Falls, and these plans were submitted to an engineering congress, which met in London at the beginning of 1891. Prof. Forbes in his report at that time, stated that he regarded the best means to be that of transmission by means of alternating currents of electricity; that the two-phase system should be employed with two separate circuits of high voltage; that transformers should be used for reducing the pressure down to a safe limit; that in the mills and works synchronizing alternating current motors should be used in some cases, and in others two-phase motors should be employed, and that in cases where direct current was necessary alternating motors should be used to drive continuous current machines. During the three years since that time hardly a change has been made in the system proposed.

After the congress referred to had closed, bids were asked from all the greatest firms in the world. The greatest difficulty was experienced in nearly every case by those who proposed to use continuous currents, and in every case the cost was largely in excess of that of the alternating system. Another thing which had been decided upon was to use the same system for both short and long transmission. The advantages, however, in the use of high potentials for short distances are the same as for long, and it was found that the amount of copper which would be neccessary to transmit 50,000 h. p. at a potential of 1,000 volts over even a short distance would almost completely fill a subway large enough for a man to walk through, and the cost would, of course, be prohibitive.

Prof. Forbes hardly agreed with Prof. Thompson that the multiphase motors would disappear from general use, and that single-phase motors with a multiphase means of starting would be more universally adopted; this he regarded as only one of the possibilities of the applicable to almost every class of work.

For continuous work, such as will be found in mills, the synchronous motor would be employed in the Niagara plant, but in all ordinary workshop practice where it is necessary to stop, start and reverse continually, the multiphase motor would be employed. One reason why the two-phase independent circuit transmission was chosen for the Niagara plant was that it was likely to take care of all developments which would be made for the next few years in alternating current apparatus; even if single-phase machines alone should be used the single-phase currents can be developed more cheaply by a two-phase machine than by the ordinary single-phase generator. This was appreciated as early as 1879, when Mr. Gramme built his first alternating current dynamo with two phases, having eight poles, a revolving field and a fixed armature. The water of the Niagara River, as is well known, is taken off one mile above the Falls by a large canal, which has been built; it is then taken by tunnels into the wheel pits and sent down on penstocks to the depth of 140 feet to the turbines below. These turbines have been designed by a firm of Geneva, of world-wide reputation, and have been constructed by the I. P. Morris, of Philadelphia, and will be delivered shortly. The water, after passing through the turbines, is carried down through the tunnels, which have been built to the river below the falls. On the top of the turbines is a vertical shaft coming to the surface of the ground, and rotating at 250 revolutions per minute, which enables the large dynamos to be directly connected to the shaft without gearing. Prof. Forbes then took up the question of whether step-up transformers should be used or dynamos generating a current of very high potential. He estimated that, with a loss of 3 per cent. in the transformers in the 5,000-h. p. units, $3,000 per year would be saved per unit. With stationary armatures it was as easy to build a dynamo for very high potentials, as it was a transformer itself. Overhead lines, subways or conduits were the three means by which the current could be transmitted, and it was a very serious question as to which should be used. The subway was obviously the most satisfactory, but the pole line was the cheapest. It had been decided that the work would be done either by bare overhead conductors or by bare wires carried in a subway. The transmission of power to considerable distances from Niagara Falls would confront the company in the immediate future, and it was possible that electricity would be used to propel the canal boats on the Erie Canal, in which case a line of several hundred miles in length would be required; at any rate the transmission of power to Buffalo was a possibility of the near future; the expense of a subway over such distances would be of course, very large. Experiments would be carried out with the pole system to determine its real merits. In the meantime a subway had been started which would carry conductors from the power station at least as far as the Pittsburgh Reduction Works, about half a mile distant.

Prof. H. A. Rowland did not agree with Prof. Forbes that dynamos of very high potential could be constructed without much difficulty. He was inclined to favor the use of step-up transformers. The small loss would not be of much consequence where the source of energy was a water power of such capacity. The difficulties that would be encountered in the construction of a dynamo of 10,000 to 20,000 volts would be very great. He did not know of any such in the world, and did not believe that it was practicable to build one. In the case of the transformer it was built in sections, so that there might not be more than 1,000 volts difference of potential between any adjacent wires. Then again, as the potential increases, the amount of coper which can be got into the groove in the armature becomes less and less. The matter of frequency was also

an important point, and the lower limit has never been thoroughly investigated. The first effect of reducing the frequency is to diminish the poles in the dynamo, and if we go down far enough it is necessary to slow up the machine until we have a dynamo running at a small speed, and its output is not what is desired. Again, if in a multiphase system the two sides are not perfectly balanced with a very low frequency, a tremor occurs which may produce a very great vibration of the machine, and this applies to both dynamos and motors. Further, the decrease of frequency necessitates increasing the size of the transformers in a ratio something like five to one. If it is desired to have motors running at 1,000 revolutions per minute the limit of the number of periods is somewhere about 20.

Dr. Louis Bell then considered some further points in addition to the remarks he had already made. He assured Dr. Duncan that the effects of the wave shape on the operation of single or polyphase motors was an experimental fact, but that in practice the effect on the efficiency was not likely to be great with well designed machines. In regard to the regulation of interconnected circuit polyphase systems, he had found it quite easy to satisfactorily regulate the triphase inter-dependent circuit system. It was much the same question that had arisen when the three-wire direct current system had been introduced, and the same objections were made against it. As to rotary transformers, he was not as hopeful as Prof. Forbes that any more simple form of commutator would come into general use in the near future. The rotary transformer has an efficiency from 90 to 95 or 96 per cent., and is a thoroughly reliable and comparatively simple piece of apparatus. He favored the use of step-up transformers rather than dynamos of very high potential on the ground that there was no experimental knowledge in the latter case; for extremely large machines he thought, however, that they might be built for very high voltages. In considering the line two important factors were the inductance and the frequency. As regards the inductance, the triphase or polyphase interconnected systems, for the same energy transmitted at the same voltages, give a lower induction on the line. With the triphase interconnected system the inductance is a little less than .6 of what it is on the single-phase or independent circuit multiphase system. As to frequency, the upper practical limit would probably be somewhat less than the frequency now ordinarily used, that is, 125 to 130 cycles. The lower limit would be determined in the ordinary distribution plant by the necessities of incandescent lighting; below 30 periods, or, in fact, below 33 periods, incandescent lamps do not work well. Arc lamps with the best soft cored carbons work fairly well at 45 to 50 cycles. The practical limit, then, is probably from 30 to 35 cycles. The keeping up of an overhead line is a most serious problem. The subway is, on the other hand, in most cases absolutely prohibitive from a commercial point of view. He thought that in most of the overhead work bare overhead wires must be employed, and, if they were dangerous, that people must learn to keep away from them. The limit of distance to which power could be transmitted practically depends almost entirely upon the conditions. Given the price of coal high enough power can be transmitted to almost any distance. It is absolutely necessary, however, not to economize in the matter of insulation.

Dr. Louis Duncan, in closing the discussion, stated that the tendency of most of the foreign engineers and those of the American speakers wha had had no practical experience was in the direction of the single-phase system; but that those among the Americans who had had considerable experience, and had seen the advantages of the multiphase system, were in favor of it; certainly the multiphase system at present was the only practical system for general distribution. The question of frequency was one of vast importance. If it is intended to do arc or incandescent lighting, then 50 periods per second must be used; if lower periods are used, the lag of the current is greatly increased.

Western Electrician.

EVERY SATURDAY.

Vol. XIII. CHICAGO, SEPTEMBER 9, 1893. No. 11

Electricity at the World's Fair.

Aside from several distinguished members of the congress who remained to see the exposition, two notable figures attracted attention in the electricity building last week—Thomas A. Edison and Nikola Tesla. Mr. Edison paid several visits to the building, strictly in the capacity of a spectator, and greatly enjoyed his inspection of the exhibits. Mr. Tesla gave a number of experiments before invited guests and the general public. On Tuesday afternoon he repeated, at the agricultural assembly hall, the substance of his lecture on "Mechanical and Electrical Oscillators," which was delivered before the members of the congress on the preceding Friday. On this occasion he had for an audience von Helmholtz and a number of other scientists who had been unable to attend the first lecture. On Tuesday evening Mr. Telsa repeated his beautiful and interesting high tension and high frequency experiments in the dark pavilion of the Westinghouse company in electricity building before a number of foreign engineers, including W. H. Preece, H. D. Wilkinson, MM. Mascart and de la Touanne, Dr. Lobach, F. W. Tischendoerfer and others. He also instructed and entertained other parties of visitors at intervals during the week at the same place by similar demonstrations. In conversation with a representative of the WESTERN ELECTRICIAN, however, Mr. Telsa said that he considered his researches into oscillatory phenomena, and the results that he had already obtained in that direction, his greatest work, and that he hoped to continue his investigations until he could present the world a system of mechanical and electrical vibration of commercial utility.

The German historical exhibit of electrical apparatus which is illustrated on this page can be found in the central portion of the eastern gallery of the electricity building, and the collection, which has only lately been opened to the public, will well repay a visit, as it is alike instructive to the student and interesting to the casual visitor. Here are shown devices which are claimed to substantiate the assertion that three of the great applications of electricity —the electric telegraph, the electric speaking telephone and long-distance power transmission—were first made in Germany. The articles shown were contributed largely by Siemens & Halske, of Berlin, although a number were obtained from the Imperial German Postoffice Department and other sources. The central feature of the display, at the back of the exhibit, is a bust of Werner von Siemens, the great German electrician, of heroic size, conspicuously placed under a large canopy. To the right, on a pedestal, is a life-sized bust of Sömmerring, for whom is claimed the honor of inventing the electric telegraph. On the left is a bust of Philip Reis, who is undoubtedly entitled to the distinction of having invented the first electric speaking telephone, crude though it undoubtedly was, the date being 1861. On either side of these busts are bas-relief heads of Gauss and Weber, all of the sculptured figures being outlined against a background of dark crimson cloth, which conceals the side of the building. On this background is also arranged a series of framed photographs showing the primary and secondary stations of the three-phase installation used in the Lauffen-Frankfort power transmission experiment, with pictures of the line construction and of the work accomplished by this electrically transmitted power at the Frankfort electrical exposition. One of the oil insulators used is also shown. It will be remembered that the Germans succeeded in transmitting 300 horse power over 100 miles at a pressure

of 30,000 volts, and of this achievement they are naturally not a little proud. Arranged in front of the busts are a number of interesting relics. An effort was made to secure the apparatus used by Sömmerring in his first experiments with the galvanic telegraph, some eighty years ago, but without success, as the descendents of the noted physicist, who reside in Frankfort, would not consent to the removal of the instruments to America, even temporarily. Models of the Reis telephone instruments are shown, however. One of the most interesting features of the collection is the electro-magnetic telegraphic apparatus of Gauss and Weber, which was devised about 1833. It is big and clumsy, and the signals were recorded by means of a reading telescope and a mirror. A piece of the wire used in the first telegraph line in Goettingen in the year mentioned is shown, with printed copies of some interesting letters written at that time to the mayor of the town by Prof. Weber. Appropriately placed near the central bust is the first machine built in Germany on the dynamo-electric principle. It was invented by Werner von Siemens, and brought out in 1866. This interesting exhibit has but one armature winding. It is carefully preserved. Among the other Siemens & Halske appliances is the first dynamo with a von Hefner-Alteneck drum armature, which dates from 1872, and a Gramme ring machine produced between '75 and '80. The latter was a commercial machine, with commutator and brushes that do not differ greatly from the type of to-day. Another machine that excites attention is an old flat ring dynamo, with an armature that also serves as a commutator by placing the brushes on the outside winding, as is done in the large Siemens & Halske generator in machinery hall. The Siemens & Halske display also includes the oldest unipolar dynamo, an old electric drill, an interesting collection of historical lamps, including the first differential arc lamp of von Hefner-Alteneck and the standard amyl-acetate lamp, and many measuring instruments, among which is a selenium photometer made by Werner von Siemens in 1877. The first electric locomotive built by Siemens & Halske, which was produced in 1879, is accorded a prominent position in the middle of the space, and it appears curious and antiquated when compared with the electric railway motors of the present day. In the northern portion of the space are many old instruments that are worthy of inspection. These include a number of the telegraphic appliances used by Siemens in the '40's, the original machine for pressing gutta percha for insulation, old resistance boxes, galvanometers and the like.

A number of the gallery exhibitors in the electricity building have united in issuing a neat little souvenir for presentation to visitors. This memento consists of a booklet containing a portrait of Chief Barrett and views of the exhibits of the Ansonia Electric company, W. R. Brixey, Bates Manufacturing company, Commercial Cable company, North American Phonograph company, Edison Manufacturing company, Caldwell electric cloth cutter, Electrical Engraving company, Electric Appliance company, Electric Heat Alarm company, Eureka Tempered Copper company, Chas. F. Hall, Gamewell Fire Alarm & Telegraph company, McNeil-Tinder Electric company, Newman Clock & Manufacturing company, Reliance Gauge company, Weston Electrical Instrument company and others. The idea of this souvenir originated with George B. Clark, who displayed much energy in pushing the plan to completion.

Luther Stieringer, the designer of the electric fountains at the World's Fair, left for New York on Saturday. The evidence of Mr. Stieringer's second visit to the fair since the opening can be seen in the greatly improved operation of the fountains, which are now taking their rightful position among the great popular attractions on the grounds. Mr. Stieringer hopes to return before the close of the fair to inspect the exposition as a spectator.

Of the four exhibit spaces in electricity building occupied by the Westinghouse Electric & Manufacturing company, the two most prominent, which are located in the nave of the building, are shown in Figs 2 and 3. This company has about 15,000 square feet of space in this building in addition to its great alternating incandescent plant in machinery hall. In the exhibit particular attention is paid to the transmission of power by the Tesla polyphase system. The space illustrated in Fig. 2 is that in the northern portion of the building. It contains the beautiful Westinghouse golden pavilion and also the Tesla generating station, although the machinery of the latter is not shown in the picture. The current is carried from this section by an overhead pole line, shown in Fig 2, to a receiving station, Fig. 3, where it is utilized for various purposes. A very complete account of this system is given in Mr. Scott's paper, which is presented on page 126 of this issue, and it is therefore unnecessary to dwell further on it here. The exhibit of street railway apparatus is principally contained in the space illustrated in Fig. 3. It includes one 270 horse power multipolar generator directly connected to a Westinghouse compound engine; one 400 horse power multipolar generator of the belt-driven type; several Westinghouse street railway motors—single reduction—of 20, 25 and 30 horse power capacity; one Brownell 20 foot car equipped with two 30 horse power Westinghouse motors—single reduction—series multiple controller, etc.; one Stephenson 16 foot car equipped with two 30 horse power Westinghouse motors—single reduction—series multiple controller, etc. There is also a complete line of switches, ammeters, voltmeters, automatic circuit breakers, lightning arresters, switchboard fittings and connections and motor details illustrating construction. In addition the Westinghouse company exhibits a Lamokin car in the transportation building. This car is 18 feet long and is equipped with two 30 horse power single reduction motors and a series multiple controller. The company also shows a Laclede car similarly equipped on the exhibition tracks near the terminal station. The cars in electricity building are placed over a pit, so that visitors can inspect the motors and connections from beneath. The company also makes a large exhibit of arc and incandescent lighting apparatus and of general electrical supplies. Included in this list may be mentioned standard Westinghouse alternators of various sizes, including a field casting of a 450 kilowatt belt-driven alternator, showing the Westinghouse method of casting laminated poles into cast iron frame; standard Westinghouse converters and transformers; special converters equipped with non-arcing metal lightning arresters; direct current motors and generators of the horizontal type; direct current generators and motors of the "letter" type; direct current generators of the multipolar type; direct current motors of the Manchester type; alternating current arc light dynamos; Shallenberger alternating current meters, complete and in operation, also parts illustrating construction; Wurts non-arcing metal lightning arresters for alternating current circuits, in operation; lightning arresters of various types for direct current circuits; switches for alternating and direct current work; ammeters and voltmeters for direct and alternating currents. One of the most interesting sections of the display is B 1, in the southeastern portion of the building. Here, in addition to Shallenberger meters and Wurts non-arcing metal lightning arresters, is the personal exhibit of Nikola Tesla and the dark room in which the Tesla experiments are shown. Some of the early motors designed by Mr. Tesla are shown, and also the parts of a small machine built in an attempt to produce a self-exciting alternator. The head of Columbus, occupying the large wall space at the south end of the building, together with the decorative scrolls and letters, and which is made up of Sawyer-Man stopper incandescent lamps lighted by current from the circuits of the Exposition company, which are supplied by the Westinghouse central station plant in machinery hall, completes the display in electricity building.

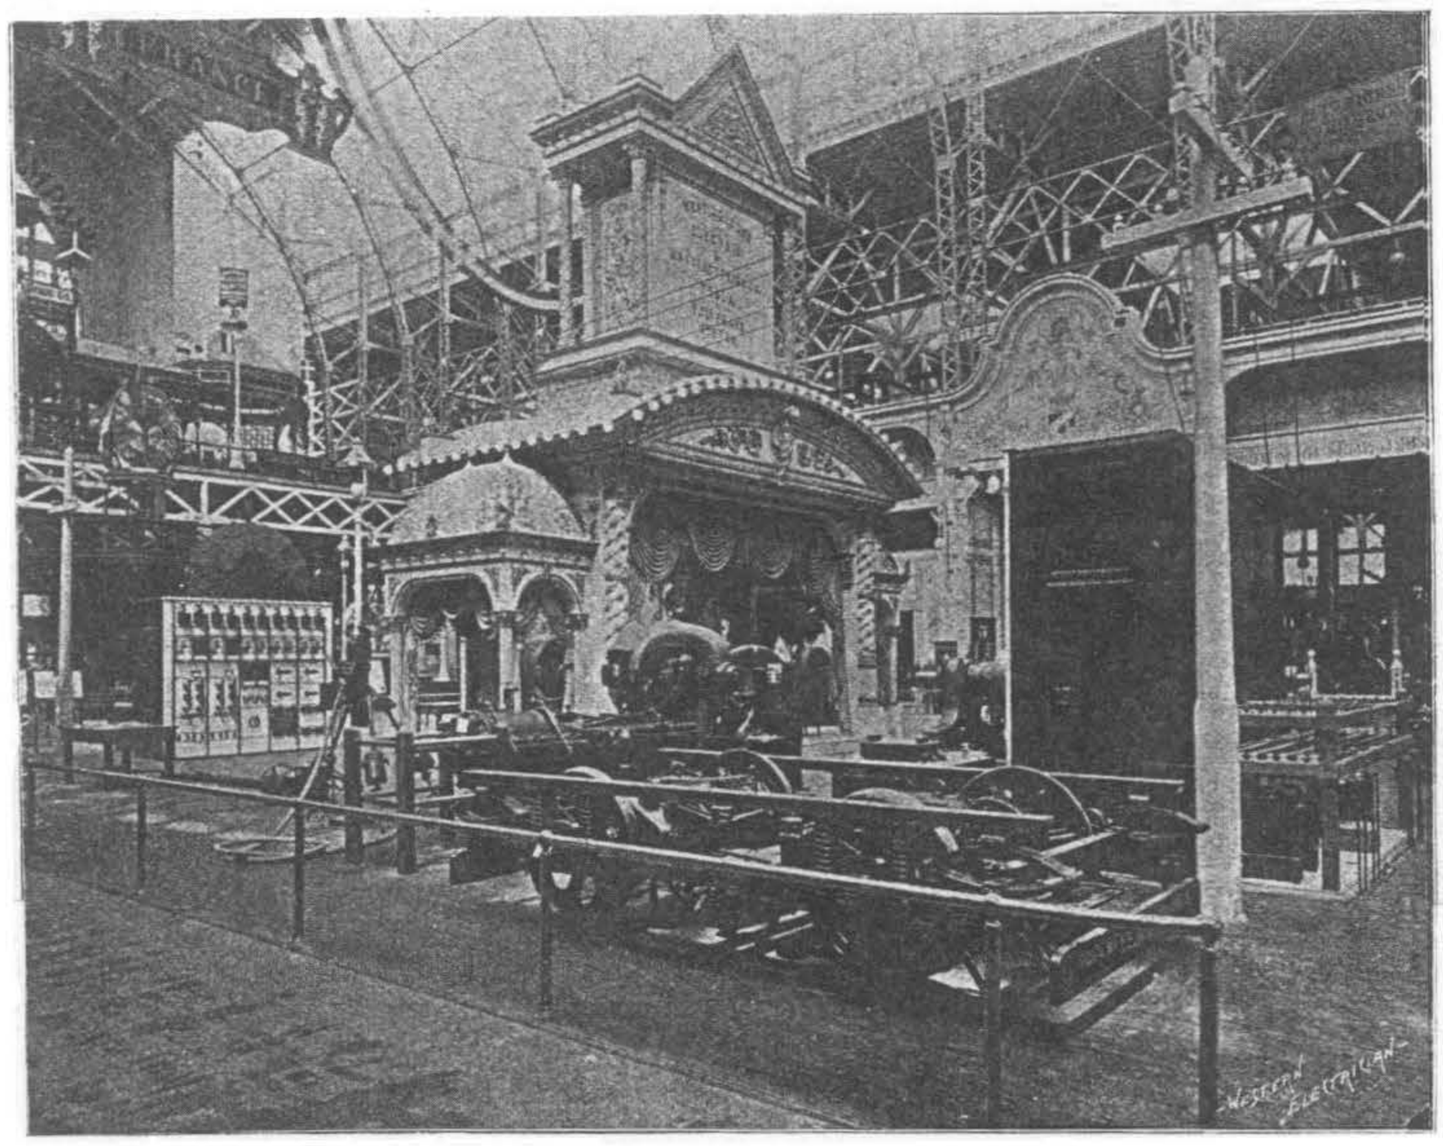

FIG. 2. ELECTRICITY AT THE WORLD'S FAIR.—EXHIBIT OF THE WESTINGHOUSE COMPANY, ELECTRICITY BUILDING.

The *Street Railway Gazette* has issued in pamphlet form its "Directory of Street Railway Exhibits at the World's Fair." The compilation has been carefully made and should be of great assistance to all particularly interested in the appliances used in street railway work.

The Turin jubilee pole for arc lamps, which was illustrated in the WESTERN ELECTRICIAN of April 22d last, has at last arrived on the World's Fair grounds. It has been erected in the General Electric company's space in the electricity building, near the tower of light, instead of in the rear of the administration building, as was originally, intended.

The General Electric company's five-foot projector, which is claimed to equal the largest Schuckert searchlight on the manufactures building in power, has been erected on the colonnade between the machinery and agricultural buildings. This huge lamp stands about 10 feet 6 inches high to the upper side of the ventilator on the top of the drum, and the total weight is about 5,500 pounds. The reflecting lens mirror used in this projector is 60 inches in diameter. It is a concave spherical mirror of the Mangin type, and was manufactured especially for this projector in Paris. It is a fine specimen of optical work, 3¼ inches thick at the edges and 1 1-16 inch thick at the center, weighing about 700 pounds. This mirror is mounted at one end of the big drum, the other end of which is furnished with a door consisting of a metal rim in which are fixed a number of plate-glass strips 5-16 inch thick by 6 inches wide. Inside this drum, and sliding upon ways arranged on the bottom, is placed the arc lamp, which is entirely automatic in its action, is 6 feet high, and weighs about 400 pounds. The upper or positive carbon is 1¼ inches in diameter and 22½ inches long, with a 5-16 inch core of soft carbon running from end to end through its center. The lower or negative carbon is 1¼ inches in diameter, 15 inches long, and also has a core of soft carbon running through it. In addition, its outer surface is heavily coated with copper. The positive carbon is set a little in front of the negative, and thus almost all the intense light of the incandescent crater is cast upon the reflector. The maximum current at which this lamp operates is 200 amperes, and at this current the lamp is calculated to have a luminous intensity of about 90,000 to 100,000 candles, which is multiplied many times by the mirror. Ventilators at the top and sides allow a constant current of air to pass through the drum and dissipate the heat generated by the arc lamp; and they are so arranged that no light can escape through them. All the connections for adjusting the positions of the carbons and the lamp are brought through the drum to the outside, and are arranged in close proximity to one another at one side, so that all may be manipulated by the operator

without moving from his position. The drum is supported by trunnions in bearings at the top of a Y-shaped fork, set in a base-plate, and the whole is supported on a system of friction wheels, forming a turntable resting upon the top of a massive pedestal, supporting the whole structure. The drum, fork and base plate may be rotated horizontally on the turntable either by hand or by gearing provided for this purpose. The drum may also be raised or lowered in a vertical plane.

The thirty-ton electric locomotive exhibited by the General Electric company on the tracks near the terminal station is now operated at 11 A. M. and 3 and 8 P. M. daily.

R. H. Pierce, the electrical engineer of the exposition, and L. S. Boggs, the assistant engineer for electrical power, have prepared a table showing the number, distribution and capacity of the electric motors in the service plant at the World's Fair. This table, which gives an excellent idea of the extended use of electrically transmitted power at Jackson Park, is given below:

MOTORS IN USE AT THE WORLD'S FAIR.

As will be seen, 315 motors, with an aggregate capacity of 2,348 3/4 horse power, are connected with the exposition circuits. This does not include the large number of motors in electricity building for which the exhibitors themselves supply current from machinery hall, and which are not operated by the Exposition company. The following is a list of the names of the different varieties of motors operated on exposition circuits: Eddy, Crocker-Wheeler Edison, Thomson-Houston, Diehl, Lundell, Jenney, Westinghouse, Perret, Sprague, Sperry, Card, Ford & Washburn, Keystone, Dunderdale, Eickemeyer, C. & C., Holtzer-Cabot, Western Electric, Kester, Wagner, Detroit, Mather, Emerson, Mayo, Waddell-Entz, Brush, Simpson.

Additional details in relation to the elevated electric railway plant at the World's Fair are always interesting, and so no apology is necessary for supplementing the general articles on the road that have appeared in this journal by further particulars. Electrical engineers will find the sectional drawing of the 1500 kilowatt generator in the power house, Fig. 4, of particular interest. The machine has twelve poles, is compound wound, and is carefully insulated from the ground. The air space between the faces of the poles and the face of the armature is 7-16 of an inch. The armature is built up of sheet iron punchings set around a spider shrunk on the hub. The outer face of the spider is slotted as are the inner faces of the armature punchings, so that they dove tail together. Each circle of sheet iron is carefully insulated from the preceding one, except at one point, and this results in giving to the armature a spiral construction. Not less than 17,200 pieces of sheet iron, weighing 25 tons, were used to build up the nine sheet iron sections, separated from each other by eight brass open rings, resembling spoked wheels, which serve for ventilating purposes. Two four ton cast iron washers held together by bolts, complete the material composing the armature core. The winding of the armature consists of copper strips 3 1/4 inches wide by 1/4 inch thick, two turns to the coil. These are carefully insulated from each other by mica, and each couple is inserted in one of the 348 slots in the laminated armature body each of which is itself lined with a mica tube. The strips are held in place by means of a wooden wedge. The side connections are then riveted and soldered to the strips and are brought down to the massive copper commutator. There are twelve brushes, which are manipulated by means of a hand wheel actuating a gearing concealed beneath the floor of the power house. The switchboard, Fig. 5, is made of enameled slate framed in mahogany, and is a striking feature in the installation. It is composed of five panels, one for each machine, each panel containing all the instruments necessary for the control of the machine to which it belongs, *i. e.*, triple pole switches, shunt rheostats, ammeters, automatic circuit breakers, lightning arresters, lightning switches, etc. The circuit breakers are of the new design of the General Electric company, and are provided with automatic resetting devices which close them electrically. With this electrical reset, all or any desired number of circuit breakers in the station can be reset at once. The generators are adjusted so to run in perfect harmony as exactly to divide the load in proportion to their relative capacities—a nice problem with generators of such varied sizes and types. The transportation service is effected by trains running at four minute intervals, each train consisting of a motor car and three trailers; the trains weighing 63 tons each, seating 280 people and the cars being of the same length as those generally used on elevated roads—about forty-five feet from end to end. The weight of these trains, as compared with a train drawn in the usual way by a locomotive, shows a saving of about 20 tons dead weight. The motor cars are equipped with four General Electric motors of the single reduction four pole type, one on each axle. These machines, one of which is shown in Fig. 6, are the most powerful railway motors yet constructed, developing 133 horse power each. They are geared for a speed of 30 miles an hour. Current is taken from the conductor rails by means of a sliding shoe contact, Fig. 7. The motors are controlled by a series parallel controller of special type, operated by an ingenious compressed air mechanism. The motors are connected up in a novel way. When the car is started the four motors are in series, then two in series and two short-circuited then, the four in series of two pairs of motors each in multiple, then two in multiple and two short-circuited and finally all in multiple. By this method the trains are started smoothly and without jerk, and the speed is imperceptibly increased. Air is furnished to the controller and to the air brakes, which are fitted to each train, by an air compressor pump, similar to that used on locomotives, but operated by an electric motor.

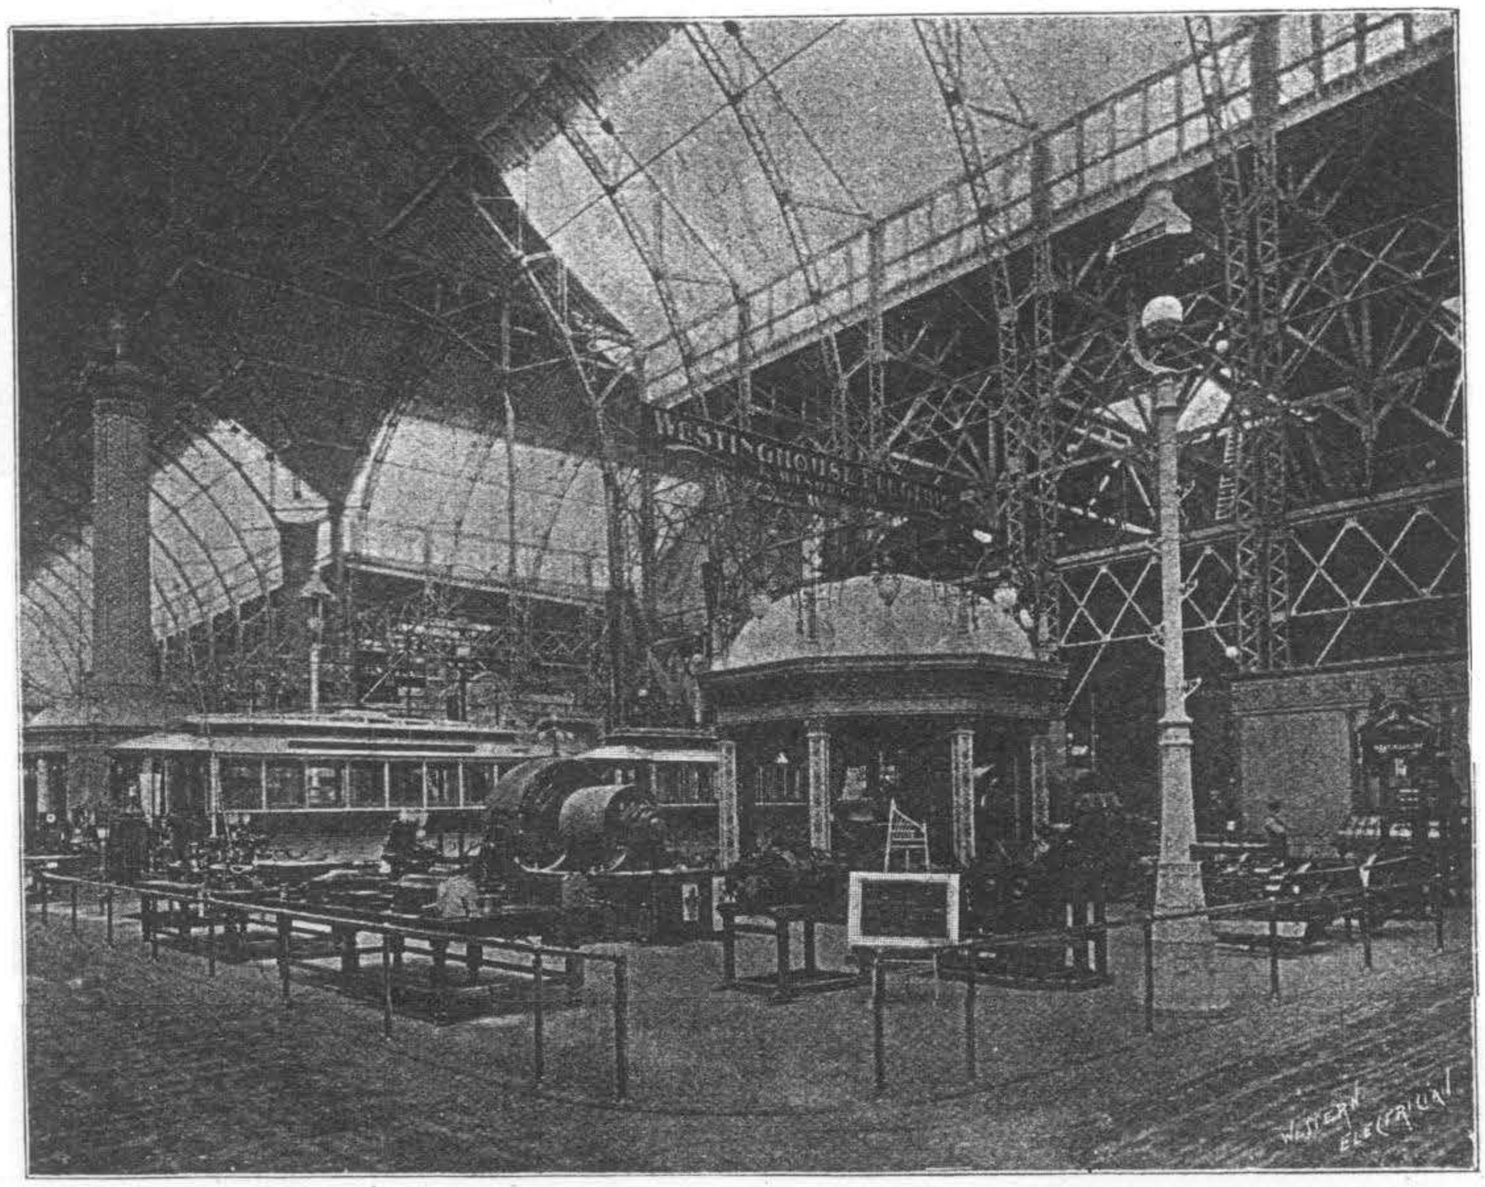

FIG. 3. ELECTRICITY AT THE WORLD'S FAIR.—EXHIBIT OF THE WESTINGHOUSE COMPANY, ELECTRICITY BUILDING.

Exhibit of Tesla's Polyphase System at the World's Fair.[1]

By C. F. Scott.

An exhibition of power transmission at the World's Fair which is of exceptional interest, is the Tesla polyphase system which constitutes a part of the exhibit of the Westinghouse Electric & Manufacturing company in electricity building. The exhibit includes generators, motors, transformers and other apparatus of various sizes and types. The system itself is not new in its general plan. There are but few features of novelty in the electrical system which have not been the subjects of publications or patents. The purpose of the exhibit is not so much to bring out what is novel in electrical invention as it is to give a complete exhibit of commercial machinery constituting the elements of a power system on a large scale. The exhibit will attract practical electrical engineers rather than those who are interested only in electrical inventions.

The purpose of the exhibit is therefore to show a complete working system for generating, transmitting and distributing power on a large commercial scale. The system includes:

1. A prime mover.
2. A generating dynamo.
3. Raising converters and transmission line and reducing converters.
4. Motors and rotary transformers for general power and electrical service.

The prime mover in general practice is water power, but in the present plant a 500-horse power two-phase Tesla motor of the rotary field type serves as prime mover. The current for this motor is received from one of the 750 kilowatt, two-phase Westinghouse generators of the lighting plant in machinery hall. The number of alternations is 7 200, and the pressure is reduced from 2,000 to 200 volts before being delivered to the motor. The current is delivered to the rotating element of the motor through brushes resting on four collecting rings. The winding is a drum winding laid in small slots in the surface. The stationary element of the motor is of laminated iron, set in an outside casting. Large copper rods are run through holes in the iron plates near the inner surface, and are suitably connected at the ends. Resistances are put in circuit with this winding for starting the motor, and when speed is attained, these resistances are short circuited, leaving this winding completely closed on itself.

This motor drives a 500 horse power two-phase alternating current generator. This machine is of the ordinary type of railway generator. There is a field of six poles which is excited by a small direct current machine driven by a 5 horse power two-phase Tesla motor of the rotary field type. The exciter in general practice would be driven by a water wheel. The large generator delivers from four collecting rings two currents differing in phase ninety degrees. The number of alternations is about 4000 per minute, or 33 1-3 periods per second at a potential of 360 volts on each circuit. The machine is also provided with a direct current commutator connected with the same winding, delivering current at 500 volts. This commutator would not be used when the machine is intended as an alternating current generator only. The current from this machine is delivered to a marble switch-board where it is regulated and connected with the various transmission circuits, as desired. This board will afford facilities for connecting various circuits with any one of the several generators which may be placed in a large generating station. The current from the switch-board is received by alternate current convertors or transformers, by which the potential is raised in the present plant to 1200 volts. In practice, the transformation would be to a much higher voltage, depending upon the distance of transmission. The transmission circuit conveys the current to the receiving station, where it is reduced by transformers to electromotive forces appropriate to the machines to be supplied. The current passes throngh a marble switch-board in which there are suitable provisions for operating the various machines in the receiving station.

The largest machine in this station is a 500 horse-power

1. Read before the World's Electrical Congress, August 24, 1893.

two-phase Tesla motor and rotary transformer. This machine is similar in general construction to the generator described. The alternating current at 360 volts is passed into four collecting rings on the armature. Special connections of the field circuit are made for starting the machine, and when the motor has attained full speed, a switch is turned giving the final connections and running the machine at a self-exciting synchronous motor,

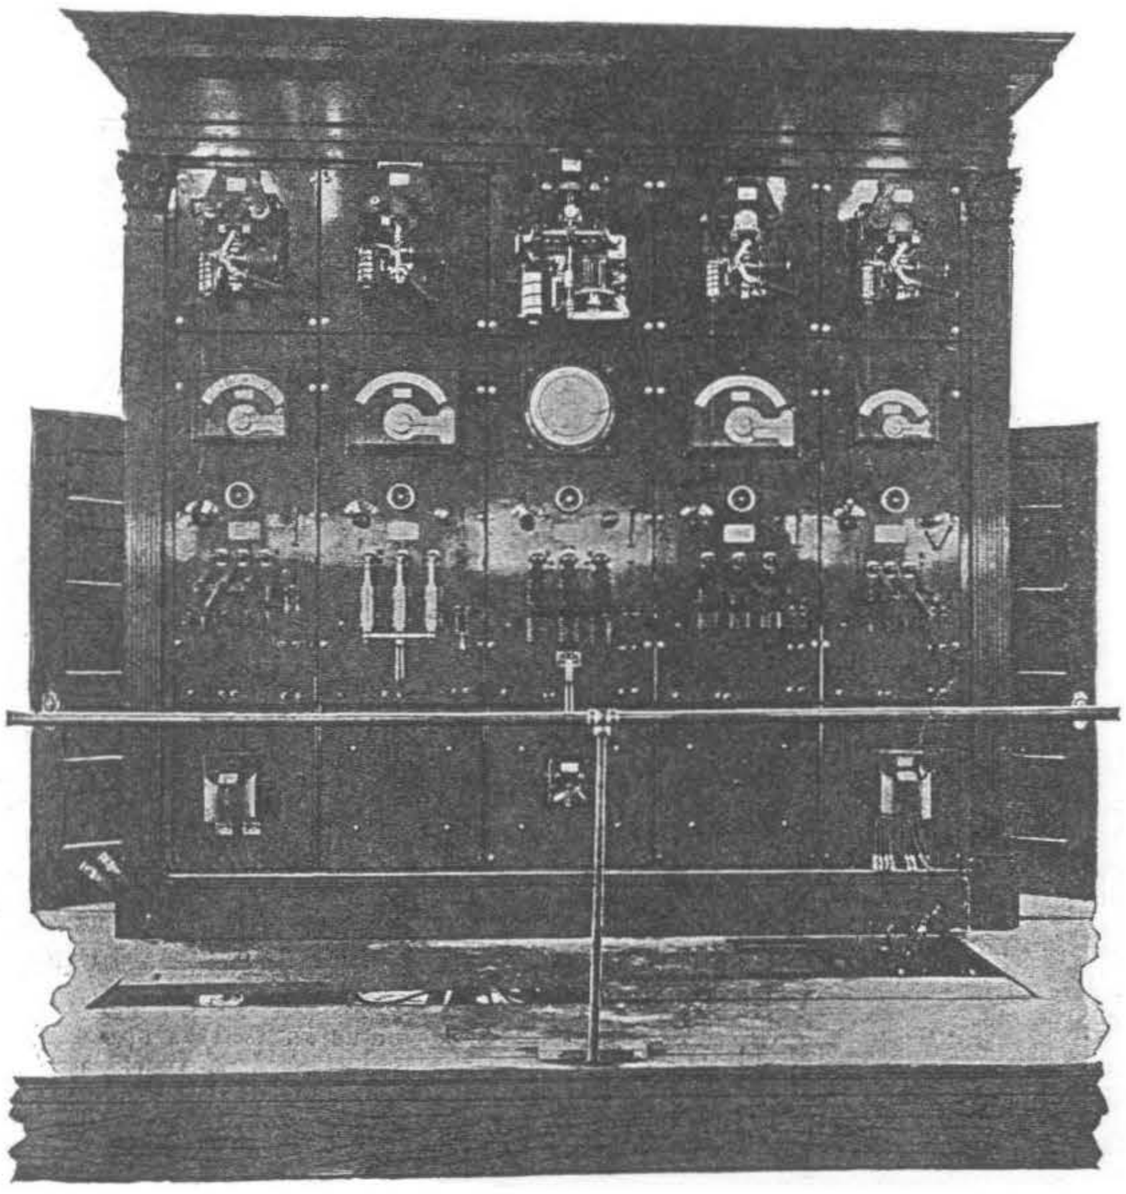

FIG. 5. ELECTRICITY AT THE WORLD'S FAIR.—SWITCHBOARD, INTRAMUAL POWER STATION.

which maintains the exact speed of the generator by which it is driven, except in cases of extreme overload. The armature of this machine is provided with a double pulley with belts driving a Worthington pump and a 40-light Westinghouse alternating current arc light dynamo. The armature is supplied with a direct current commutator connected with the same winding which receives the alternating current, and delivers direct current at a potential of 500 volts. This current is utilized for operating two 30 horse power street railway motors mounted upon a standard Dorner & Dutton truck, and also a 60 horse power direct current motor mounted upon an Ingersoll-Sergeant air compressor. This direct current also supplies a series of direct current constant potential arc lamps. The current from the switchboard is also carried directly to a 60 horse power two phase motor and rotary transformer, which receives the current at 36 volts and delivers direct current at 50 volts adapted to electrolytic work, charging of storage batteries, and is at present used for operating the large Schuckert search light in an adjoining space. The current from the switchboard also operates a 60 horse power two-phase Tesla motor of the synchronous type, which is adapted for any kind of constant speed work. In the present exhibit, it is direct coupled to a 45 kilowatt slow speed alternator of the constant potential type used for incandescent lighting. Current from the switchboard is also directly utilized for supplying incandescent lamps.

It is commonly recognized that the mechanical design and workmanship upon electrical apparatus has fully as important a bearing upon its successful operation as the electrical design. In fact, in actual experience it is found that electrical enterprises which have failed or have been unsuccessful have been deficient usually in mechanical rather in electrical elements. It is, therefore, of especial importance to note the mechanical features of a new system, and to observe whether simplicity and strength and durability are insured. Visitors to the present exhibit are struck with the general similarity in construction of the machines employed for widely different electrical purposes. The general form and construction of the large Tesla motor of the rotating field type, the alternate current generator, the alternate current motors, the rotary transformers, the alternating current arc machine and the constant potential alternator have an appearance of general similarity.

The main castings are two in number. The lower one contains half of the field magnets and the bearings for the armature shaft. This simple form insures rigid bearings for the armature. The upper casting contains the remaining field magnets. The field magnets are made of laminated soft steel plates of high permeability, which are cast into the yoke of the machine. The armature is built up of thin disks of soft steel with grooves in the surface for receiving the windings. The armatures are drum wound with, in general, large conductors placed in special heavy insulating tubes through the slots. This construction affords excellent insulation and protection of the wires, and the strains upon the wires, which in case of sudden heavy loads or short circuits may be very great, are transmitted directly to the iron core without chance for slipping or abrasion. In general, no band wires are required. The winding and connection of the armature of the multipolar machines for delivering direct current are such that there are always two and only two parts of the winding in multiple. This insures electrical symmetry, which prevents the improper distribution of current in the armature conductors, which would result if there were a greater number of armature circuits in multiple and the armature should get slightly out of center from excessive wear in the bearings, or other cause.

Attention is called to these points of simplicity and solidity of construction because they are so vital to the success of electrical working, and because the general improvement which is constantly being made in the mechanical development of electrical apparatus has been fully utilized in the design of this system. It is much to the credit of the system, and confidence in its success is assured, for the very reason that it uses and makes but slight modification in types of machines which have been worked out in practice in other lines of service.

This system possesses characteristics which adapt it to a wide field of service, as it combines the requisites for transmitting power over long distances and for transforming it into suitable forms for distribution and application to a wide range of uses. The employment of the alternate current transformer permits the use of low potential machines securing greater cheapness, efficiency and a higher factor of safety than is possible with high potential machines. By the use of alternating current the difficulties in construction and operation, which are inherent to commutators, are avoided on generators and motors. The low pressure of the machine is readily transformed to potentials adapted to great distances. The alternating current supplies two-phase motors of either the rotary field non-synchronous type or of the synchronous type, and the rotary transformer transforms alternating into direct current. The work of this machine is equivalent to that of an alternating current motor driving a direct current generator. The two armatures, however, have been combined in one and placed in one field, and not only is the second machine eliminated but the output of the single machine is greater than that of the two machines together, and the efficiency is increased and the commutation of a greater current is readily effected. The alternating current circuit can supply, therefore, constant potential direct current at any voltage, and is available for all kinds of work in which direct current is necessary or is preferable to alternating current. Incandescent lighting may be supplied from the alternating current circuits, and arc lamps may be supplied by direct current from the rotary transformer or from arc machines driven by synchronous motors.

It should be noted that the idea of complication may result from the grouping of several applications of the system with the transmission system proper. The transmission system proper ends with the switchboard and rotary transformer in the receiving station. Other apparatus would be located where it may be required for use, distributed over a city or through mills and mines.

The alternating and direct current at various potentials for these various lines of service are secured from one generator and one transmission line. This is of practical

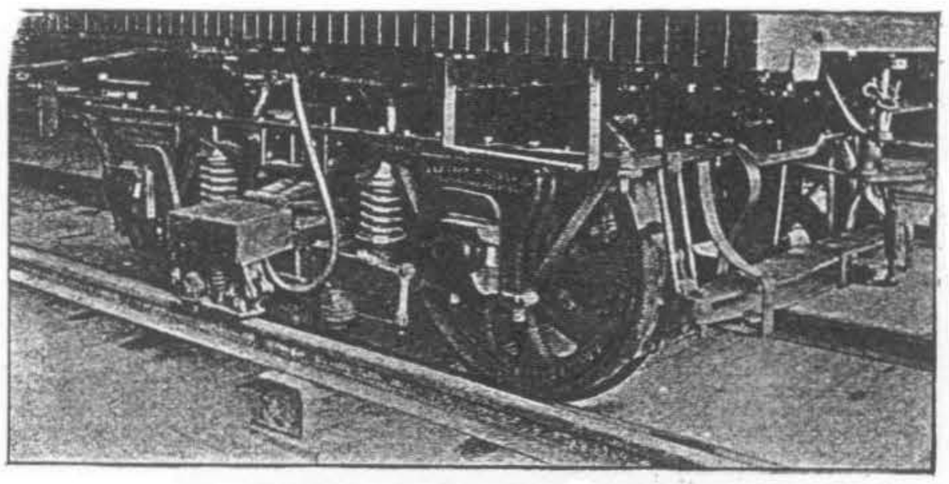

FIG. 7. ELECTRICITY AT THE WORLD'S FAIR.—TROLLEY SHOE, INTRAMURAL RAILWAY.

importance, both in small plants where it would be impracticable to install different generators and circuits for different kinds of service, and also in large plants where there are numerous generators. In such plants similarity and interchangeability of machines and circuits is of great economy and value in practical service.

Electrical inventors have done their part well in discovering the principles and laws which form the basis for a complete electrical system. Designers and mechanics have taken up these inventions and have developed them and constructed apparatus for practical working which is now presented to the electrical engineer for adaptation to the various demands for the transmission and distribution of power. He may take up the work with full assurance, as plants are already in operation which place beyond question the practicability not only of general distribution and service, but also of transmission over long distances and at high potentials, The successful installation and operation of a lighting plant for over 100 horse power using 10,000 volts over a 28-mile circuit in southern California is an initial step which covers a distance greater than is required in a majority of the cases in which power transmission is proposed.

This exhibit of the Tesla polyphase system is the mechanical realization of one of the most unique and beautiful discoveries in electricity in recent years.

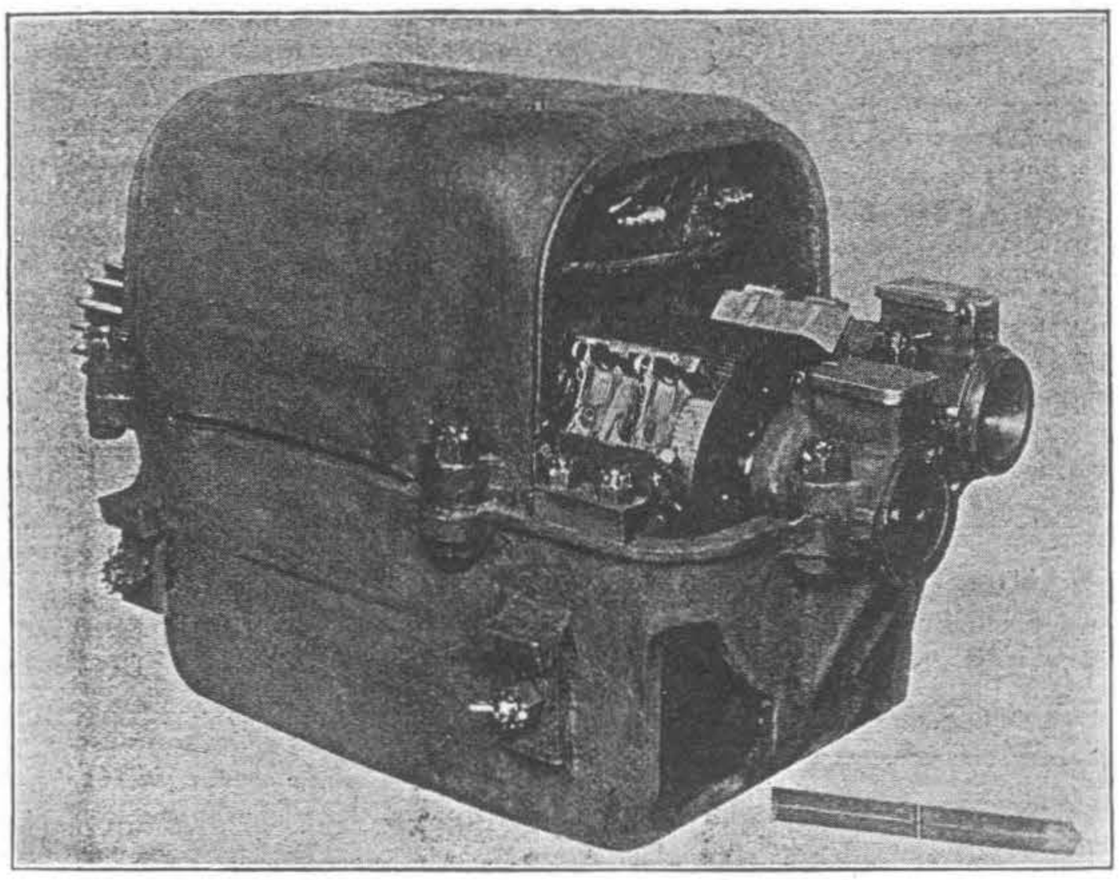

FIG. 6. ELECTRICITY AT THE WORLD'S FAIR.—133 HORSE POWER MOTOR USED ON INTRAMURAL RAILWAY.

WORLD'S FAIR NOTES.

Mr. Tesla is expected to return to Chicago the later part of this week and will then conduct in person some of the high frequency experiments which have made him so famous. The Westinghouse dark room will be used for the displays, but no definite time has yet been fixed.

The Hertz reflectors, which have been promised some time, are now shown in operation in the exhibit of Queen & Co. The reflectors are parabolic in form and when an oscilatory discharge of a high potential current takes place at the focus of one, the effect is reproduced at the focus of the other.

The Westinghouse company has placed a glass floor in one of the cars exhibited in the railway department so that the operation of the motor can be easily seen from above. The Columbus egg, which has proven such an attraction to the Westinghouse space, is now shown the first fifteen minutes of every hour from 3 until 10 p. m.

Visitors to the Electricity Building have found a new attraction in the Hoggson time stamp which has recently been placed in the exhibit of the E. S. Greeley Co. The stamp shows the date and time of day and the machine is electrically connected with a clock so as to change the time indicated every minute. On account of its many commercial uses the device is attracting considerable attention.

ALTERNATING CURRENTS OF HIGH POTENTIAL AND HIGH FREQUENCY, VIZ.: TESLA'S APPARATUS AND CURRENTS. "RAPIDLY ALTERNATING ELECTROSTATIC STRESSES."

It is characteristic of alternating currents, that their energy is manifested, not so much *in* the wire, as in the space surrounding it, and the greater the frequency and the potential, the more extensive do some of the phenomena outside of the wire become. In this space, energized by the alternating current traversing the wire, may be exhibited by the aid of proper devices arranged to capture and transform the electric energy, light, heat, mechanical motion and chemical action; lamps glow, metals fuse, motors are caused to spin, and chemicals to combine. And this space around the current conveying wire is not narrowed to minute fractions of an inch, but may be measured in yards. Here is a field of force within whose influence a patient may be readily brought. Such a field would be termed an alternating electrostatic field; it is most marked around the terminals of a secondary coil whose primary is conveying an alternating current. It is the same field as that associated with the spark discharges of electrostatic machines, and even in a lesser degree with our best constructed medical induction coils, as I have shown by glow lamp tests applied to them.

The electrostatic field was indeed familiar to all; but in a feeble and minor degree. In medicine it has been a prominent feature of administrations from the influence machine in both simple insulation of the patient, in the spark, and more particularly in my own method of the static induced or interrupted current, and has been in medical use in connection with that machine. But so far as relates to induction coils, little or no account has been taken of the electrostatic properties of the current. Our attention has been wholly occupied, as has been that of the electrical engineers, with the current in the wire, and not with properties of this current—the electrostatic field outside of it.

But in induction coils affording high frequency, high potential currents, for instance, from hand to hand, it must now be noted that we have to deal with two effects—1st. The effect of the direct passage of the current through the body, and: 2nd, the lateral, surging, wave impulses spreading out in every direction from the passing current. The former of these effects alone has hitherto claimed attention. That the latter effects now

claim attention alike in the industries and in medicine is due to the wonderful experiments of Nikola Tesla. We have, as he modestly says, the same apparatus, the induction coil, and the same phenomena, only the apparatus is operated differently, and the phenomena are presented in a different aspect. So different indeed is the aspect of the phenomena that the entire scientific world hails their presentation as a revelation.

Mr. Tesla's first publication was in the *Electrical World*, of Feb. 21, 1891, under the title of "Phenomena of Alternating Currents of very High Frequency." Referring to effects upon the human body he writes, "the discharge of even a very large coil cannot produce seriously injurious effects, whereas, if the same coil were operated with a current of lower frequency, though the E. M. F. would be much smaller, the discharge would be most certainly injurious." The writer's experiences tend to show that the higher the frequency the greater the amount of electrical energy which may be passed through the body without serious discomfort."

The Tesla Apparatus.—Mr. Tesla obtains the high frequency mechanically, and by the aid of a well known natural phenomenon—mechanically by a specially constructed dynamo machine giving a frequency of about 10,000 per second, and naturally, by aid of the intensely rapid alternating or oscillating discharge of Leyden jars or condensers. The latter carry the frequency up to anywhere from 500,000 to 1,500,000 alternations per second. Low frequency may, however, be employed when the condensers are in the secondary circuit.

How important an element the Leyden jar may be in increasing frequency both in the electrostatic phenomena of the influence machine already in medical use, and in the Tesla apparatus, may be judged of from a calculation of Dr. Oliver J. Lodge that a common pint Leyden jar discharged through an ordinary discharging rod will possess a rate of oscillation equal to about ten million per second.

Mr. Tesla's high potential is due to the frequency and to "step up" transformation by coils. It consists practically of a high frequency dynamo whose current enters a primary wire, a secondary wire within whose circuit is included a condenser and discharging rods, and again a coil to which a part of the secondary wire acts as a primary.

The Tesla effects, as they are now frequently termed, are obtained:

a. By direct connection with both terminals.

b. In the space intervening between the terminals, or in the space about either one singly.

Using the apparatus above described with alternating current dynamos of low or high frequency, Tesla obtains remarkable effects. Among them may be noted:

a. The brush discharge.

With two cotton covered wires arranged parallel and near to one another, the wires are strongly illuminated by streams of flame, spreading from one to the other. The brush led from a circle of wire, 30 centimetres in diameter, to a small brass sphere, is formed into a beautiful cone of light, or again, concentrated upon small, thin wires, greatly intensifies the light.

With two circles of wire, respectively 30 and 80 centimetres in diameter, a continuous circular luminous sheet is produced.

An increase of the molecular or atomic vibration changes the color of the discharges from purplish to white.

In these experiments, the molecules of air about the terminals are intensely agitated, and give rise to the light.

b. Rotation of a motor connected to one terminal wire only of the coil.

c. Illumination of exhausted bulbs or lamps containing a refractory substance sealed within them, and when attached only to one terminal of the coil, the molecular bombardment within the bulb incandescenses the refractory substance, and emits light. Such substances are fused, disintegrated and dissipated by the intense electric bombardment.

Buttons of carbon, diamond, pumice-stone and carborundum were used. To protect the leading-in wire from the effects of the bombardment, a screen aluminium tube may be used, which acts electrostatically by reason of its conductivity, and also mechanically; the screen, becoming charged, economizes the energy supplied to the bulb by not taking it up after it is once charged. Again, the same exhausted bulbs are illuminated without the aid of a leading-in wire, the energy required being transmitted through the glass.

d. To excite vacuum tubes throughout the whole extent of a room, lighting up the tube wherever it is held in space, and at a distance from the conductor, the intense electrostatic field is set up by converting the oscillatory current of a condenser to a higher potential. Such a field Mr. Tesla establishes between two sheets of metal several yards in area and several yards apart. A vacuum tube held within the space between the metal sheets, glows intensely.

It becomes an interesting question to determine to what extent high potential, high frequency currents may be of value in medicine. The shock from the secondary coils above described are very light and can be taken without inconvenience. This to many has seemed remarkable on account of the very high voltage. Much speculation has been indulged in as to why these currents do not produce great muscular contraction, and great pain, and dangerous results. It has been suggested that the rapidity of the alternations is too great to excite the nerves, or again, that the current thus generated does not penetrate the conductor, but traverses only its surface. An explanation would seem to me to be that the current strength of what seems to be a killing current is comparatively small, since it is reduced enormously by each "step up" transformation. But other explanations are advanced.

In the immunity from pain and muscular contraction observed by D'Arsonval with a low frequency and a current strength of 5 amperes, another explanation must be sought for, and this is the comparatively gradual rise and fall of potential characteristic of the sinusoidal current, and physiologically vastly different in its effects from the impulsive rush of the condenser currents of Tesla and myself. D'Arsonval's high rate of frequency is obtained from an alternator and from induction coils, and condensers.

Whatever effects are to be obtained from Tesla currents must be obtained:

a. By the direct passage of the current through the person.

b. By this means, and by taking into account the lateral electrostatic surgings outward from this direct current.

c. By interposing the patient within the rapidly alternating electrostatic stresses constituting the field between the terminals, and yet not in contact with them.

Electro-dynamic induction effects need not probably be taken into account.

The extended physiological effects of the Tesla currents have yet to be investigated, since no apparatus has been available to

physicians or physiologists, but judging from the powerful effects upon human beings of the currents of electrostatic machines whose output is more feeble in total energy, even if equal in potential, these currents seem to me to promise most interesting and most fruitful results.

We can in our imagination picture a future group of patients pursuing any agreeable occupation, reading, conversing, playing games, and so on, in a room whose two opposite walls are of metal connected to the two terminals of a Tesla apparatus, and thus submitted to a furious molecular bombardment in the intervening space. We can imagine the surprise of the new comers, as they see the vacuum tubes carried in their hands burst into a glow of light when they are brought within the influence of the magical and invisible stream. We know that their temperatures would be raised by the bombardment, and we cannot help believing, though awaiting the proof, that profound alterations in their nutritional processes would be produced, whose influence would be far reaching in the cure of disease, particularly of the functional type.

We present to our readers on page 68 of this issue a brief sketch of Mr. Tesla's latest achievements. Figures are not given, because the apparatus has not reached that state of mechanical perfection at which it is expected, sooner or later, to arrive. Sufficient to say, however, that with one of his oscillators and generators, each weighing but a few pounds, he has brought to bursting a 50 candle-power standard incandescent lamp. He has furnished us with a means of obtaining great outputs with almost minimum masses of metal. The oscillators have a promising future before them, and we await with interest their development.

THE MECHANICAL AND ELECTRICAL OSCILLATORS OF NIKOLA TESLA.

"Obedience,
Bane of all genius, virtue, freedom, truth,
Makes slaves of men and of the human frame
A mechanized automaton."—*Shelley.*

Thus has it been with nearly all projectors. Pioneers into the unknown have felt their power when they saw the unlimited stretch before them.

A great man upon being asked how he managed to accomplish more than others, replied, "I just do a little bit more than anybody else has done."

It has been said that a genius is one who takes infinite pains, and that he is born, not made. These statements hardly seem to reconcile themselves to each other, unless it be, the power of intense concentration and of almost limitless energy is a divine gift.

Incidents amount to nothing unless they are recognized and appreciated. The humming tea-kettle with its latent power was the vision on the wall to him who first recognized its importance. The frog legs of Galvani was but an accepted hint to those who laid the foundation of our grand and growing science. As in the life of man, where his advent is a bright spot in his history, so these pioneer discoveries were the beacons which showed the way to higher and more useful things.

We are almost tempted to change the words of the wise and worldly Solomon, who said, "There is nothing new under the sun," to, "There is nothing old under the sun." All fields present vast possibilities in their cultivation. The fruits to be obtained from these rich and generous soils are only to be procured by those who work to gather them.

Launched as we are into the realms of imaginative science, we cannot help but realize that it is the severely practical which, in the end, advances us most. Progress, strong and steady progress, having the inertia of a master mind, is full of possibilities. He who is free, untrammeled and backed with a store of the essentials that have gone before; he who lives in a world of his own and has a strong mind in a strong body, is bound to produce that which will startle plodders in the beaten paths well worn by those, the multitude gone before.

Few are they who can say: "I am as free as Nature's first made man."

He then who profits by the experience of others and follows his own line of thought approaches a certain state of freedom; but it is merely comparative.

"On their own merits modest men are dumb."

Some men have said that while Nikola Tesla has produced wonderful results, he has given the world but little of practical value. Those who have been careless enough to make this statement have evidently not realized that of which they spoke. Was the voltaic pile the dynamo of to-day? Was the æolipile the steam engine of the present? A little reflection will show us that Mr. Tesla is a pioneer; but above all, that he is essentially a practical and efficient economist. He has eagerly and unceasingly searched for radical defects in existing machines. He has patiently sought for losses in efficiencies, which, to the ordinary experimenter, were considered a matter of course. His work during the last few years, as the public has imagined, was in the line of effects due to currents of high frequencies, and a method of transmitting intelligence by means of electrical waves to almost limitless distances on the earth. And the public have been right; but little did they imagine what this man had in store for them.

A few sceptics may raise their eye-brows and say, "What does all this amount to?" These few may be quickly silenced by showing to them results. Could anyone ask for more? But to those who are impatiently waiting and who have a sincere belief, based upon previous experiences, that "the mountain will not bring forth a mouse, but that out of it a greater mountain shall spring forth," I will say: Listen to a simple tale which we will call "The History of an Invention."

On Friday evening, August 25, Nikola Tesla startled the assembled scientists at the World's Fair with what he chose to call his mechanical and electrical oscillators. None knew what he was going to see when he read the title of this lecture. None knew of the possibilities which would be presented by this radical departure in the twin sciences, steam and electrical engineering. And here is the way in which this last child of Mr. Tesla's brain was conceived.

While Mr. Tesla was working on his motor he realized the need for absolute synchronism, and this we will call Necessity No. 1.

In his extensive and varied work in high frequency currents, he obtained exceedingly small efficiencies, due to the fact that the north and south poles of his magnets were, in many cases, as close as one-sixteenth of an inch apart, and the wires which wrapped them were one-thirty-second of an inch in diameter. Magnify these conditions and the practical electrician will readily see how the efficiency will be reduced to a minimum. This led Mr. Tesla to think that the remedy for this defect would be the discarding of iron, thus making his armature entirely of copper; and to this we will give the name, Necessity No. 2.

His thoughts were not alone on electrical engineering. The losses from the furnace to the dynamo stood out in bold relief in the intricacies of his thoughts.

One of the most useful devices to mankind is the crank, that means of changing a reciprocating motion to a motion of revolution. But in that change, oh what a loss is there! That ponderous thing—the flywheel of the steam engine—melted into thin air over 50 per cent. of the power from the piston. We have a maximum resistance, practically an infinite resistance, at two points, each co-incident with the axis of the piston head, and this resistance diminishes until we obtain two points which have a minimum resistance, and in this passage from the infinitely great to the almost infinitely small we recognize our loss.

In our mammoth engines it requires special buildings to construct the separate parts, and then think of the huge masses of metal—necessary evils to the heretofore existing steam engines. Advances have been made, it is true, and a 12 per cent. loss due to belting has been saved by the direct coupled dynamos. But before the advent of the oscillator few attempts were made to reduce this sinful waste from the piston to the flywheel, and this we will call Necessity No. 3.

Here then are three great necessities, and if we may believe the old adage, we should expect great children from these great mothers; nor have we any cause to be disappointed.

Although Mr. Tesla's mechanical and electrical oscillators are not, as yet, practically perfect, the theories stand and they are obviously reasonable and correct.

We first will deal with the mechanical oscillator. We shall see how this device does away completely with those accessories called the flywheels, regulators and governors. We shall see how the ponderous pile of metal to be moved may be reduced to one-fortieth its original bulk, and still have its efficiency maintained.

The mechanical oscillator briefly described may be pictured by imagining an exceedingly short stroke piston, and port valves which extend completely around the cylinder. The oscillations of this short stroke piston may be varied in frequency by the resistance encountered. In practice these oscillations need not be more than from 40 to about 90 per second, and since the length of the movement of the piston is slight, its lineal velocity is hardly more, if equal, to that of an ordinary Corliss engine. Here though is where the beauty of the oscillator is apparent. It is perfectly regular in its movements.

To give a better idea of its method of motion we can compare it to a swinging pendulum which, though we may increase its velocity at any point of its swing, its time of oscillation is not varied a thousandth of a second, provided, of course, that nothing but gravity and the uniform surrounding medium, the air, affects it. This is exactly the case with the oscillator; if it is resisted at any point of its path, or if the steam pressure is varied, it makes no difference in the time of its "swing," and we thus have an oscillator which may be made absolutely synchronous with other oscillators, by the addition or subtraction of definite weights. Necessity number one is thus filled.

It will be seen also that necessity number three is here done away with, for our motion is simply a reciprocating one, and we need no conversion to a motion of revolution. Instead of having a generator whose armature revolves, we have one which accommodates itself to this reciprocating motion, and whose armature or field magnets, as the case may be, oscillates in a straight line. Some, perhaps, will say that this is nothing new. Nothing new is claimed for it; it is simply an improvement—an improvement which accommodated itself to the existing conditions required by the mechanical oscillator.

Let us take, for instance, the case where the armature is directly and rigidly connected with the oscillating piston. A simple form of the field magnets would be represented by two iron tubes placed concentrically—the inside diameter of one twice the outside diameter of the other—and imagine both these tubes to have such thick walls that the inside tube becomes practically a rod, the outside tube having the same thickness. Let the farther end of these two tubes be covered by a mass of iron, and immediately underneath this covering, around the inside tube, be wrapped the field magnet coils. Upon the passage of a current an intense field will be produced, and backwards and forwards in this field, near the other extremity of the two tubes, does a simple coil of wire oscillate with a clearance of but a hundredth of an inch on each side. This coil of wire is the armature, whose axis is co-incident with the axis of the mechanical oscillator. Thus we see flywheel and governor are thrown aside; a simple efficient steam engine is produced and hardly a simpler dynamo could be conceived. Delicate and absolutely accurate mechanical construction is not so necesssary as in the case of other machinery of its kind. No larger tool than a six inch lathe is necessary to turn out a 100 horse-power oscillator. Owing to its small size the losses due to heating large masses of iron are entirely done away with.

Here we have two new devices constructed on sound scientific principles. It rests with the mechanical engineer to perfect the minor details of the mechanical construction of the mechanical oscillator, and with the electrical engineer to give the finishing touches to the electrical oscillator. There is a great future before them.

Who shall they or he be?

It needs no vivid imagination to hear the answering echo of this question as it resounds in the minds of the true lovers of Nature and Progress; for who can possibly know more about this great improvement in steam and electrical construction than he, the father, who has given life to and tended these oscillators with most intense solicitude through the progress of the invention? And although the most prominent quality which all have observed in Nikola Tesla is his true modesty, his apostles should be allowed to place his name alongside of those of Franklin, Faraday and Henry. JULIAN A. MOSES.

Mr. Tesla's Lecture at the Congress.

Mr. Tesla has succeeded in constructing a new, and what seems to be a perfect, mechanism for producing electrical oscillations of a constant period, independent of the driving force, of frictional losses, and the load. At his lecture on "Mechanical and Electrical Oscillators," at Chicago, he mentioned, among other things, that he was able, by this new apparatus, to produce an alternating current in which the E.M.F. of the impulses in one direction preponderates over that of those in the other, so that there is produced the effect of a direct current. In fact, he expressed the hope that these currents would be capable of application in many instances, serving as direct currents. The New York *Electrical Engineer* describes the machine, but only very scantily. The principle involved in this preponderating E.M.F. is explained by Mr. Tesla as follows: suppose a conductor is moved into the magnetic field and then suddenly withdrawn; if the current is not retarded, then the work performed will be a mere fractional one, but, if the current is retarded, then the magnetic field acts as a spring. Imagine that the motion of the conductor is arrested by the current generated, and, at the instant when it stops, there is still the maximum current flowing in the conductor; then this current will, according to Lenz's law, drive the conductor out of the field again, and, if the conductor had no resistance, then it would leave the field with the velocity at which it entered it. Now, it is clear that if, instead of simply depending on the current to drive the conductor out of the field, a mechanically applied force is so timed that it helps the conductor to get out of the field, then it might leave the field with a higher velocity than that at which it entered it, and thus one impulse is made to preponderate in E.M.F. over the other. With a current of this nature Mr. Tesla energised magnets strongly and performed many interesting experiments, bearing out the fact that one of the current impulses preponderates. We hope to see more of Mr. Tesla's apparatus when he next honours us by bringing it to England.

Western Electrician.

EVERY SATURDAY.

Vol. XIII. CHICAGO, OCTOBER 7, 1893. No. 15

Electricity at the World's Fair.

Awards formed the principal topic of discussion among the electrical exhibitors at the World's Fair last week. The exclusive publication of the list in the WESTERN ELECTRICIAN excited much interest, and the paper was in great demand. The comments were many and varied. Some exhibitors were jubilant; others were angry and disgusted, while not a few professed indifference, with the remark, "What do the awards amount to, anyway?" It was noticeable, however, that all seemed eager to secure the diplomas and medals before the list was posted. Many, also, were puzzled by the fact that several awards, in a number of cases, were given on one class of apparatus. This is explained by the fact that the judges did not consider the comparative merits of exhibits in making awards. They examined each exhibit entered for an award separately, and if, in their judgment, the article or group was found to be worthy of commendation an award was given it, the specific points of excellence being detailed in the diploma. It thus happened that on the commoner sorts of apparatus, such as arc lamps, for instance, a number of awards were given on the same class of exhibits, although the exact language of the awards, specifying the points of excellence, will not be alike on any two diplomas. In effect, the judges, by making an award, say that the exhibit, while perhaps not better than another, is excellent, and as such entitled to recommendation to the public. No effort was made to single out the best exhibit in each class for a solitary award. By bearing this distinction in mind a better understanding of the work of the judges will be had.

Some of the awards were based on tests and some were not, according to circumstances. The awards on storage batteries, incandescent lamps, insulated wires for electric lighting, standard cells and some of the transformers, however, were not included in the list published last week because tests on them were not completed. Some of these were announced later in the week, but it will be some time before the list is entirely complete. There were 183 awards in the list of September 26th, and it is expected that the total will reach 210. In the list published last week the General Electric company's award numbered 18, for "alternating current dynamos for series arc lighting," should have been omitted, and under the head of Germany "Gemelzen, Nuremburg," should read "C. Schmelzer, Nuremberg." Otherwise the list is correct—a gratifying result when consideration is taken of the haste that Prof. W. E. Anderson was obliged to make in preparing it, owing to the pressure of other duties. Additional awards have been announced as follows:

United States.

American Battery company, Chicago.—Storage batteries.

General Electric company, New York.—(30) Incandescent lights used in the decoration of rooms and other structures.

Elisha Gray, Highland Park, Ill.—The telautograph.

Westinghouse Electric & Manufacturing company, Pittsburg.—(13) High tension experimental apparatus.

Germany.

Gas Motoren Fabrik Deutz, Cologne.—Gas motor directly connected to dynamo.

Charles Pollak, Frankfort.—Storage batteries.

The judges authorize the statement that the Allgemeine Elektricitaets Gesellschaft of Berlin received no award because its exhibit was *hors concours*, owing to the fact that Herr Rathenau, the managing director of the company, was a member of the committee of electrical judges. For a similar reason no award was given to the "Transactions of the American Institute of Electrical Engineers," the secretary of the Institute being a judge and many of the other judges being members of the Institute.

The illustration presented on this page gives an excellent idea of a portion of the Westinghouse incandescent lighting plant in machinery hall. The features of thi

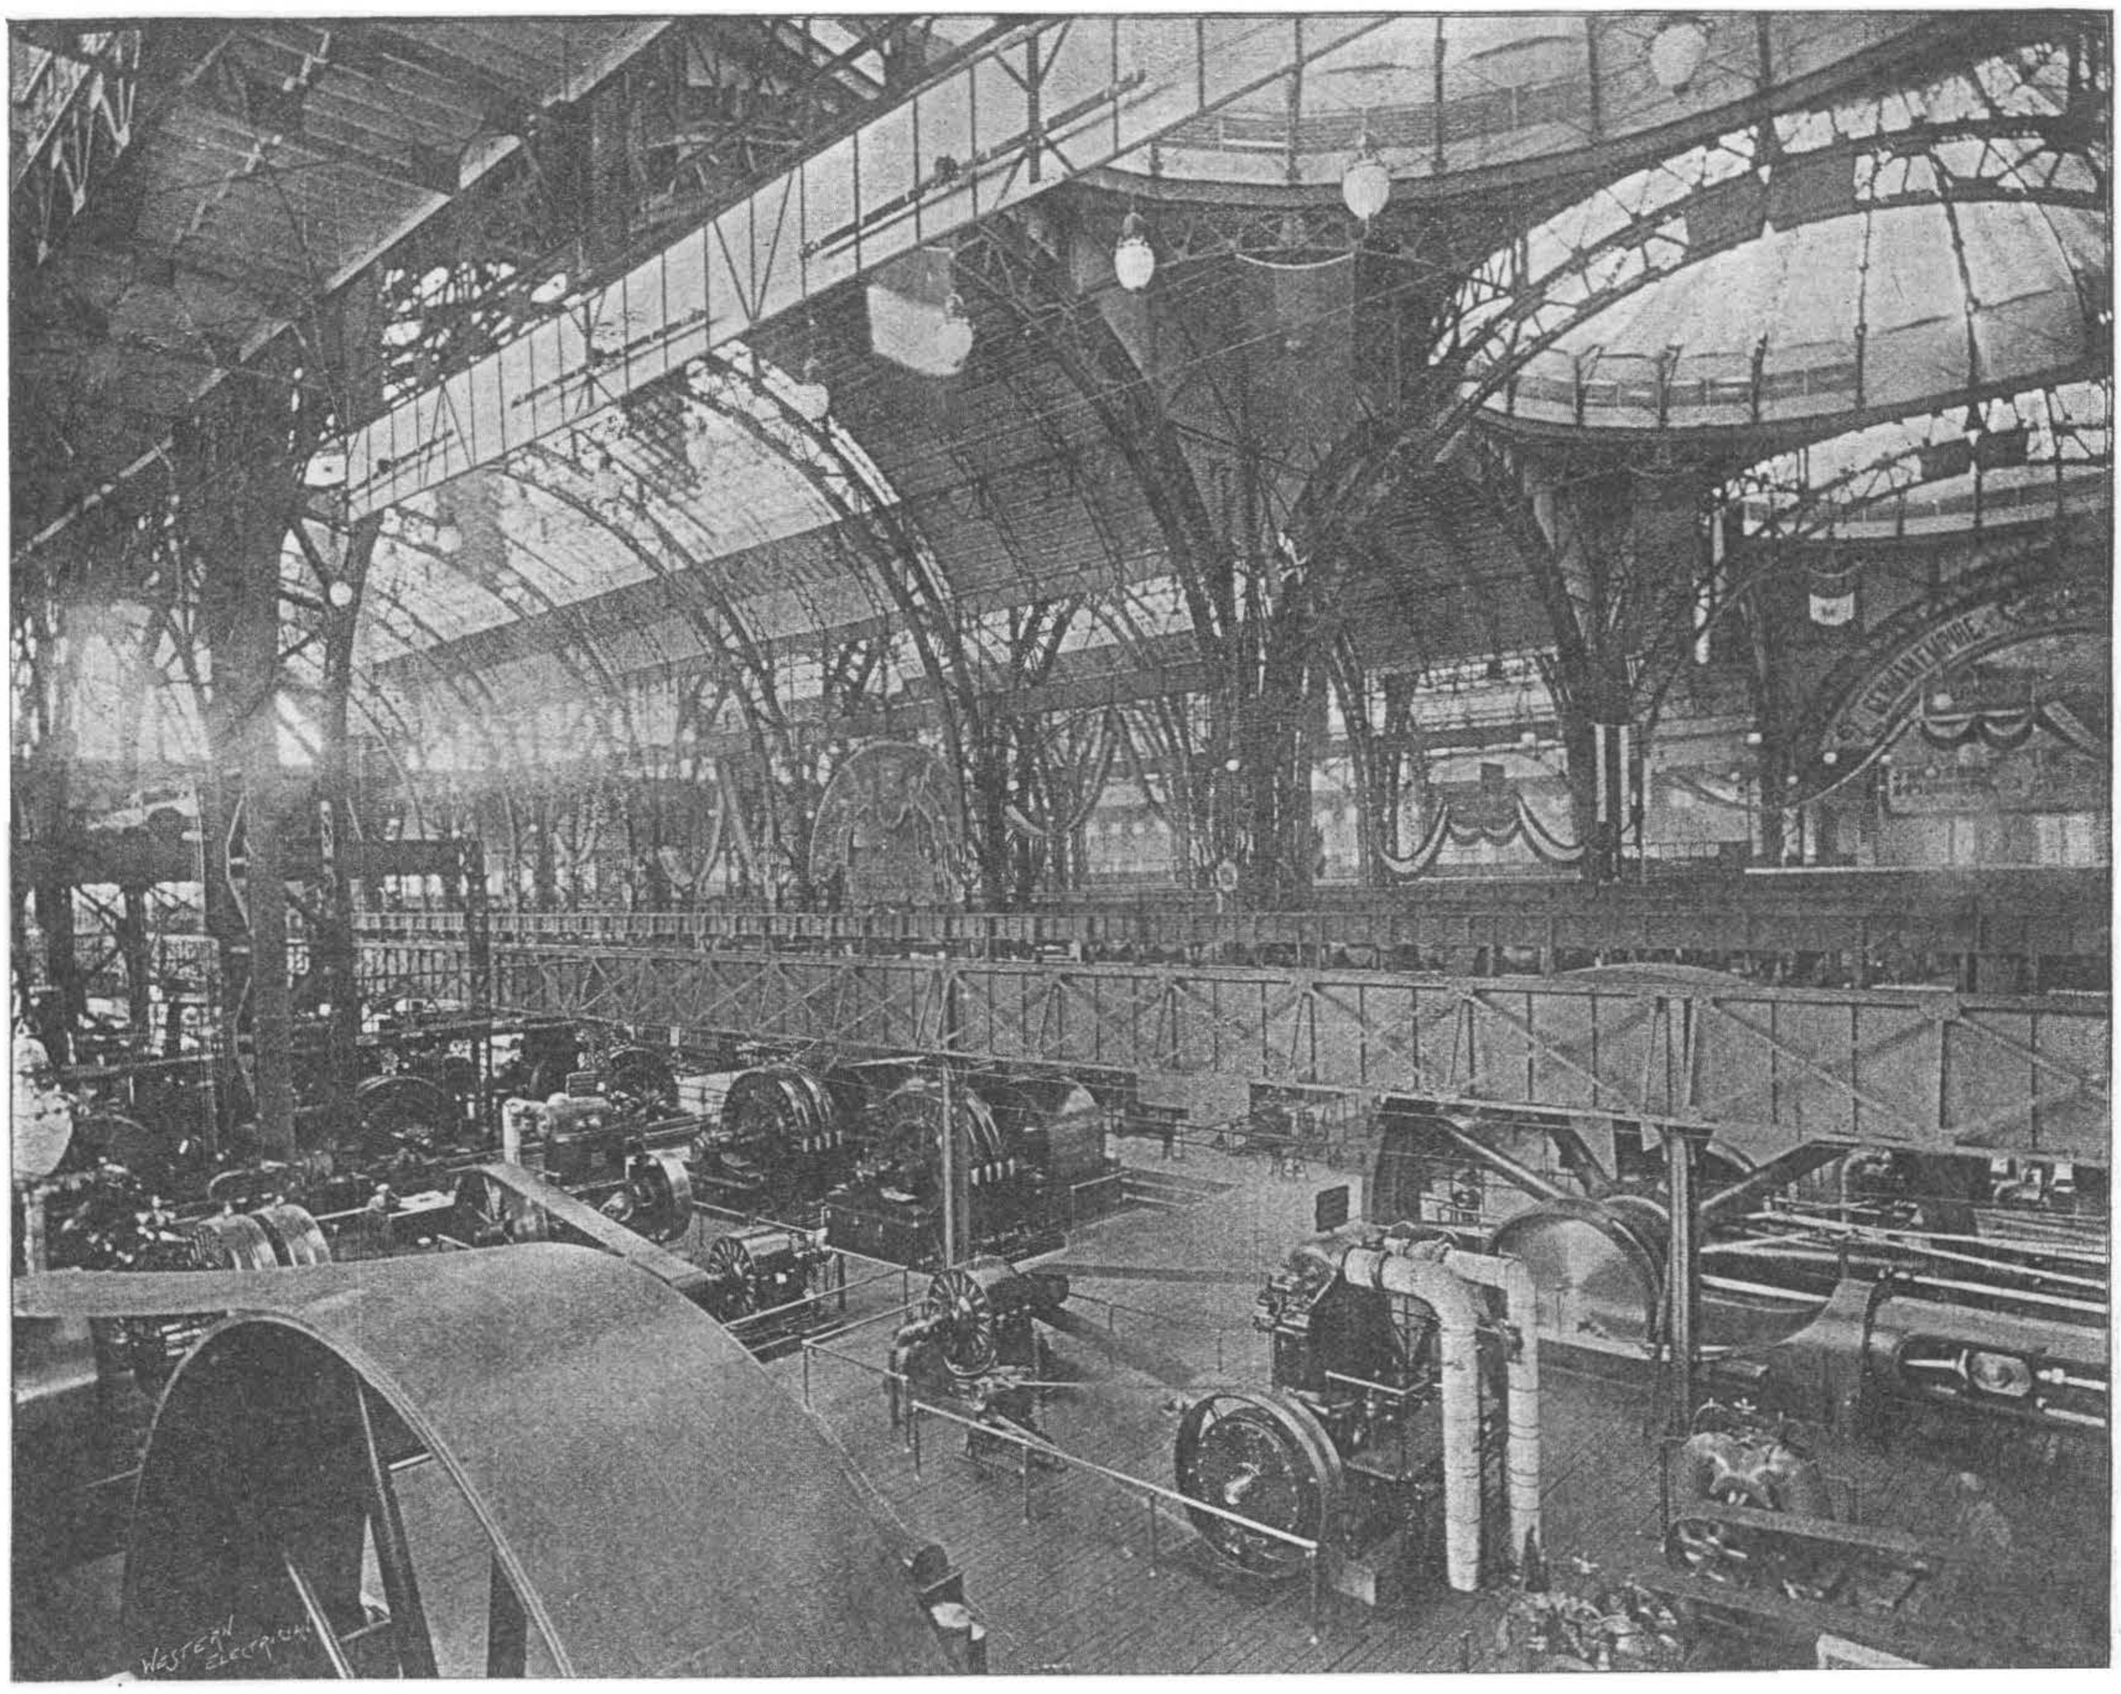

FIG. I. ELECTRICITY AT THE WORLD'S FAIR.—WESTINGHOUSE INCANDESCENT LIGHTING PLANT, MACHINERY HALL.

large and interesting installation have been before described in this journal. The picture was taken from the second gallery of the Westinghouse switchboard. The two 10,000 light alternators belt-driven by the Allis 2,000 horse power engine are shown and also a general view of the plant. The fly-wheel shown prominently in the foreground is that of the Fraser & Chalmers 1,000 horse power engine. Fig. 2 shows the row of four directly connected Westinghouse engines and alternators. It is interesting for comparison with the belt-connected sets.

On a recent busy Saturday the Elektron company carried 3,111 persons in its electric elevator in electricity building.

The incandescent lamp test is proceeding satisfactorily. The General Electric company of London has submitted a number of 16 candle power, 100 volt lamps for alternating current, and these are being tested with the others. Several 32 candle power lamps are also being tested.

Among the floats to appear in the parade on Chicago day is one which will be furnished jointly by the General Electric company and the Chicago Edison company. The float will be 38 feet long, 28 feet high and 9 feet wide. The design chosen is that of an immense dragon made of papier mache. Not a sign of the latter material will be seen, for every spot on the dragon will be covered by miniature incandescent lamps, of which over 1,000 will be

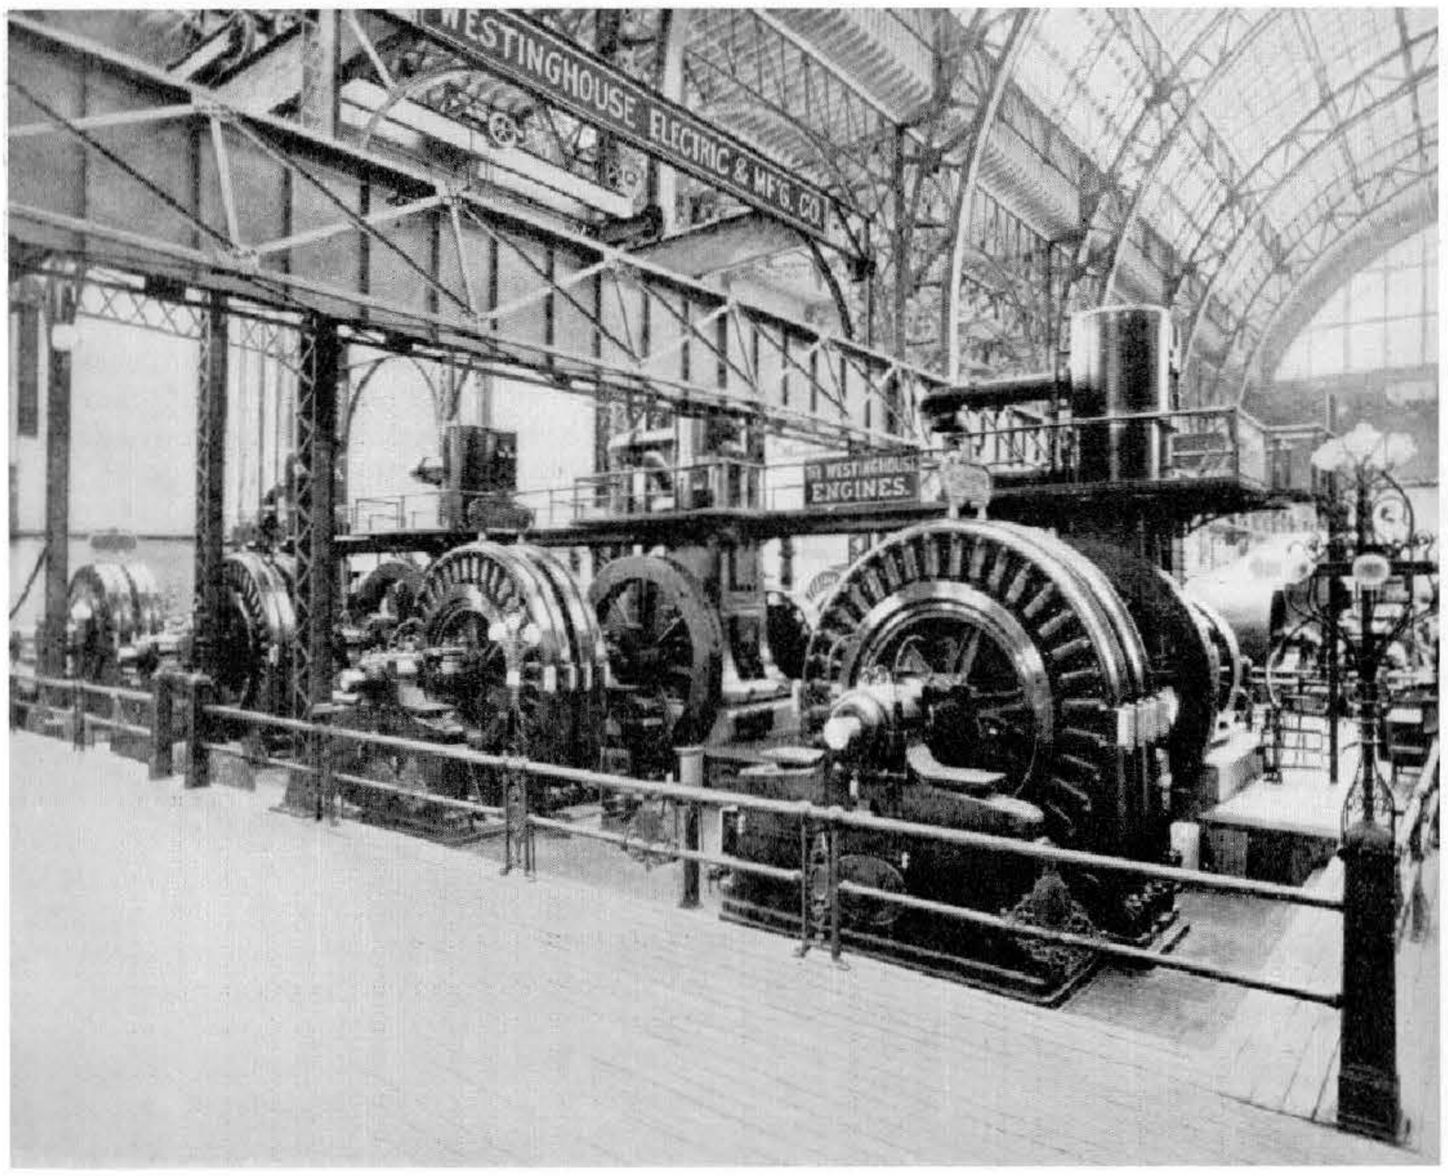

FIG. 2. ELECTRICITY AT THE WORLD'S FAIR.—WESTINGHOUSE ENGINE-DYNAMOS, MACHINERY HALL.

used. Beneath the truck a directly connected marine lighting set of 15 kilowatts capacity and wound for 80 volts will be placed, out of the sight of the spectator. By a switching arrangement the color of the dragon will be changed at intervals from green to red. The flaming breath and steaming nostrils will be supplied in a simple manner. The exhaust steam will be conducted through the throat and nostrils of the gleaming papier mache dragon. Dazzling lights will extend along the wings to the tips, which will be twenty-eight feet above the truck. Eight horses will draw this flaming creature, with its blazing red eyes and its chameleon-like hide. Immediately in front of the horses will be another truck, on which will stand the genius of electricity in the form of a woman. She will hold a fairy wand in her hand, at the tip of which will be placed a brilliant white light, supplied by a current from the dragon behind. The cost of the float will be more than $2 000.

Fig. 3 shows the exhibit of the firm of Schuckert & Co., of Nuremberg, Germany. The display is located in the northeastern portion of electricity building, on the ground floor, and is devoted mainly to marine work and search-lights. Three projectors are exhibited, the largest, which is prominently shown in the illustration, being erected on a platform in the front of the exhibit space and seven feet above the floor. This search-light is operated every evening and has a mirror diameter of 90 centimeters. It has double dispersing lenses and is the largest type used in the German and other navies. Two projectors of this size and character are installed on the cruiser Kaiserin Augusta, which attracted much attention at the naval review in New York harbor last spring. The movement of the drum is accompanied by two motors in the base of the projector, which are controlled from a wall governor, which, on shipboard, can be located at any point desired. The lamp consumes 120 amperes of current, the potential at the carbons being 55 volts. Current is supplied from the adjacent Westinghouse exhibit. This projector is provided with a jalousie signaling apparatus consisting of an iron screen in front of the lenses which can be rapidly opened and closed and by which messages can be telegraphed through the atmosphere by dots and dashes of light. Back of the large elevated search-light are two others, each having a mirror diameter of 60 centimeters. The one on the north side of the space is intended for naval use, while the other, shown at the right in the picture, is intended for fortifications. Between the two smaller search-lights is an ingenious electric signaling device for naval use, designed as a means of communication between the commanding officer on the bridge and the engine room. By moving the handle of the instrument until a corresponding pointer rests on that portion of the dial marked with the order desired to be given, the officer causes a similar movement on the dial of a duplicate instrument in the engine room. The instrument is made double, so that the engineer can signal back the order, which is repeated on a second dial, thus preventing mistakes. An engine-dynamo for use on shipboard is shown in the center of the exhibit space. The combination is compact and strong and is said to have high efficiency. The engine runs at 450 revolutions per minute, and the dynamo has a capacity of 170 amperes at 70 volts. The latter has four poles and a Gramme armature. Two copper brushes set at an angle of 90° on the commutator are used. The machine is designed with the idea of supplying current for either search-lights or incandescent lamps. It is used to a considerable extent in the German navy. On a table is shown the horizontal arc lamp used for projectors, with a differential magnet for establishing the arc and a feeding magnet. A number of measuring instruments are shown, including a recording wattmeter and Hummel ammeters and voltmeters. The improved Pilsen arc lamp is exhibited in several forms, some of the fixtures, as shown by the illustration, being highly ornamental. About the walls of the booth are a number of photographs of central stations equipped by Schuckert & Co., as well as large diagrams showing the useful angles of light of the Mangin and Schuckert mirrors for search-lights, greatly to the advantage of the latter. An interesting automatic cut-out switch and a display of electrolytic zinc complete the exhibits. The latter display includes a plate of zinc four feet long and two feet wide produced by the Dieffenbach-Kittler electrolytic process at zinc mines in Westphalia. Granulated zinc is also shown. Both are produced directly from the ore. A display of carbons made by C. Schmelzer, of Nuremberg, is also made in this space.

In addition to the exhibit in electricity building Schuckert & Co. have four large search-lights on the roof of the manufactures building, supply the arc lights in the German government building and show drawings of electric lighting stations in the German engineering exhibit in transportation building. In machinery hall there is a Deutz gas engine directly connected to a Schuckert dynamo, which supplies current for arc and incandescent lamps.

The Washburn & Moen Manufacturing company has three exhibits at the World's Fair—a general exhibit in manufactures building, a display of wire ropes, etc., in the mines building, and an exhibit of electrical wires and cables in electricity building. The first and last named are illustrated in Figs. 4 and 5. In the general display copper wire is shown in all stages, including ore, ingots, rods and all sizes of wire down to the finest that can be drawn, half the thickness of a human hair. This exhibit also includes piano wire, iron and steel wires, watch and clock springs, chains, tacks, nails, spikes, bale ties, bicycle spokes and many other kinds of hardware. Indeed it is asserted that there is hardly a house in the United States that does not include in its furnishings and fittings some article made by this company, which employs nearly 6,000 men in good times and possesses the oldest wire factory in the country. The electrical exhibit, Fig. 5, can be found near the center of the eastern gallery of electricity building. It consists of a large central show-case, apparatus for testing the "salamander" fire-proof wire and samples of all kinds of wire for electrical purposes. An interesting feature is a section of the largest insulated cable ever made, having a cross-section of copper of 2,500,000 circular mils. Feeders for electric railway lines having an area of 500,000 circular mils are also shown. An order for 145 miles of this feeder cable for the Brooklyn City Railway company has just been completed by the Washburn & Moen company. Smaller sizes of feeder cables are also shown and all sizes of weather-proof wire, ranging from No. 0000 to No. 20, rubber covered and both taped and braided. Magnet wires, both round and flat, are displayed. It is claimed that copper of a higher conductivity than any other is used for this wire. A complete exhibit of "salamander" insulated fire-proof wire, "salamander" lamp cord and "salamander" switch-board wire is made. A remarkable test of the fire-proof qualities of this insulation is shown. A sample is put in circuit with a piece of lead-covered cable at the testing table before alluded to. A current of 150 amperes from accumulators is then passed through the wires until the insulation and lead covering of the other wire are melted. The "salamander" wire is then taken out uninjured. A similar test is made with underwriters' wire and "salamander," heating the wire to a red heat and destroying the insulation on the underwriters' wire without affecting the fire-proof wire. The exhibit also comprises lead-encased cables, office and annunciator wire, hard drawn trolley wire, iron signal strand wire for electric railways, coils of tinned copper wire and rubber covered wire arranged in seven pyramids. The large central case contains a pyramid of "salamander" lamp cord in different colors, samples of all sizes of wire, bare and insulated, and coils of hard drawn and annealed copper wire, one of which is 35 miles long. A curiousity is a copper rod drawn from No. 0 size to No. 40, presenting the appearance of a metal whip. The electrical exhibit is a comprehensive and instructive one and is well worth a visit. Herbert Smith is in charge of all the exhibits of the Washburn & Moen company, while C. T. Snedekor has supervision of the display in electricity building.

The Action of the Eye.*

NIKOLA TESLA.

It can be taken as a fact, which the theory of the action of the eye implies, that for each external impression, that is, for each image produced on the retina, the ends of the visual nerves concerned in the conveyance of the impression to the mind must be under a peculiar stress or in a vibratory state. It now does not seem improbable that, when by the power of thought an image is evoked, a distant reflex action, no matter how weak, is exerted upon certain ends of the visual nerves, and, therefore, upon the retina. Will it ever be within human power to analyze the condition of the retina when disturbed by thought or reflex action, by the help of some optical or other means of such sensitiveness that a clear idea of its state might be gained at any time? If this were possible, then the problem of reading one's thoughts with precision, like the characters of an open book, might be much easier to solve than many problems belonging to the domain of positive physical science, in the solution of which many if not the majority of scientific men implicitly believe. Helmholtz has shown that the fundi of the eyes are themselves luminous, and he was able to *see*, in total darkness, the movement of his arm by the light of his own eyes. This is one of the most remarkable experiments recorded in the history of science, and probably only a few men could satisfactorily repeat it, for it is very likely that the luminosity of the eyes is associated with uncommon activity of the brain and great imaginative power. It is fluorescence of brain action, as it were.

Another fact having a bearing on this subject which has probably been noted by many, since it is stated in popular expressions, but which I cannot recollect to have found chronicled as a positive result of observation, is that at times, when a sudden idea or image presents itself to the intellect, there is a distinct and sometimes painful sensation of luminosity produced in the eye, observable even in broad daylight.

Two facts about the eye must forcibly impress the mind of the physicist, notwithstanding he may think or say that it is an imperfect optical instrument, forgetting that the very conception of that which is perfect, or seems so to him, has been gained through this same instrument. First, the eye is, as far as our positive knowledge goes, the only organ which is *directly* affected by that subtile medium which, as science teaches us, must fill all space; secondly, it is the most sensitive of our organs, incomparably more sensitive to external impressions than any other.

This divine organ of sight, this indispensable instrument for thought and all intellectual enjoyment, which lays open to us the marvels of this universe, through which we have acquired what knowledge we possess, and which prompts us to and controls all our physical and mental activity—by what is it affected? By light! What is light?

It is beyond the scope of my lecture to dwell upon the subject of light in general, my object being merely to bring presently to your notice a certain class of light effects and a number of phenomena observed in pursuing the study of these effects. But to be consistent in my remarks it is necessary to state that according to the idea now accepted by the majority of scientific men as a positive result of theoretical and experimental investigation, the various forms of manifestation of energy which were generally designated as "electric," or more precisely "electro-magnetic," are energy manifestations of the same nature as those of radiant heat and light. Therefore the phenomena of light and heat, and others besides these, may be called electrical phenomena. Thus electrical science has become the mother science of all, and its study has become all-important. The day when we shall know exactly what "electricity" is, will chronicle an event probably greater and more important than any other recorded in the history of the human race.

* Extract from paper on the "Action of the Eye," read before Franklin Institute.

The Action of the Eye.—It can be taken as a fact, which the theory of the action of the eye implies, that for each external impression, that is, for each image produced on the retina, the ends of the visual nerves concerned in the conveyance of the impression to the mind must be under a peculiar stress or in a vibratory state. It now does not seem improbable that, when by the power of thought an image is evoked, a distant reflex action, no matter how weak, is exerted upon certain ends of the visual nerves, and, therefore, upon the retina. Will it ever be within human power to analyze the condition of the retina when disturbed by thought or reflex action, by the help of some optical or other means of such sensitiveness that a clear idea of its state might be gained at any time? If this were possible, then the problem of reading one's thoughts with precision, like the characters of an open book, might be much easier to solve than many problems belonging to the domain of positive physical science, in the solution of which many, if not the majority, of scientific men implicitly believe. Helmholtz has shown that the fundi of the eyes are themselves luminous, and he was able to *see*, in total darkness, the movement of his arm by the light of his own eyes. This is one of the most remarkable experiments recorded in the history of science, and probably only a few men could satisfactorily repeat it, for it is very likely that the luminosity of the eyes is associated with uncommon activity of the brain and great imaginative power. It is fluorescence of brain-action, as it were.—*Nikola Tesla, in Scientific American, New York.*

Nikola Tesla's Lecture.

Mr. Tesla's lecture on "Mechanical and Electrical Oscillators" was delivered in Assembly Hall at the southwest corner of the Agricultural Building at the World's Fair grounds on Friday evening as announced in the program. Every member of the congress with one or two exceptions was present and the greatest interest was manifested in the experiments that were shown.

It was twelve minutes after eight when Prof. Elisha Gray introduced Mr. Tesla to the audience in the following words: "I came down here to-night for the purpose of introducing to you a gentleman whose name needs no introduction as it is a household word with all electricians, but I wanted to do him the compliment of coming here as the official head of the World's International Congress of Electricians and to extend to him the compliment of an introduction for them as well as for myself. This compliment loses none of its force when I tell you that I have another official duty to perform to-night and it will be necessary for me to leave immediately, but if I should follow my inclinations I should stay, for no one wants to hear and see these experiments more than myself. I have the honor, ladies and gentlemen, of introducing to you Nikola Tesla. I wish to add one word, inasmuch as I have to leave; I am going to ask Dr. T. C. Mendenhall to do the honors for the rest of the evening."

Immediately the hearty applause subsided Mr. Tesla said: "Ladies and Gentlemen: We are told in a delightful anecdote how, many years ago, when science was still in its infancy, a man to whom the world is largely indebted for the discovery of a great truth was meditating in his garden when the idea came to him, and how on that occasion he was carried away by his enthusiasm. Be that an actual fact or not it is certain that the search for truth through the centuries that have elapsed has exercised an immense power on the imagination of man. It seems as though we are actual witnesses of the researches and experiments made by the discoverers and inventors of ages gone by, and that we are almost in a condition to know how they felt at the moment of sublime inspiration.

"I am sure in this audience there are many who have felt this most exquisite pleasure and whose presence here will forever fix the recollection of this evening upon my mind To feel this pleasure is accorded to but few; however, I can say myself that I have felt it and am still under the impression of the pleasure which the accomplishment of a few insignificant thoughts that have come to me and the speculation on the possibilities of their future development have caused. In these results I am, inventor like, quite taken up, and I hardly dare hope to be able to develop them as I wish, but I feel that I must explore them; and again I have doubted my ability to present them satisfactorily. Yet I am sure of the practicability of investigations in this manner from the few results I have so far obtained.

"I can best tell you what I have attempted if I comply with the scientific duty and tell you exactly the history of these inventions. It was at a time when I was strenuously endeavoring to solve a question or two which was considered insolvable, first, Was it possible to operate a motor without sliding contact, and second; was it possible to develop constant currents in a certain direction? I found the solution to the one problem and produced dynamos without commutators and that success emboldened me to go ahead and apply whatever of knowledge and experience I possessed to the solution of the other problem.

"On the occasion of my first visit to this country I stepped into the exposition at Philadelphia and I saw there a very thick copper washer provided with handles that visitors would move within a magnetic field. That day it occured to me that when the plate was moved slowly in the field there was experienced resistance, and that when the plate was suddenly pressed in there was a rebound as though it struck against something solid. After returning from the exposition the thought occurred to me that if I took a conductor and moved it into the field and then rapidly withdrew it, Icould in this way obtain whatever of electro-motive force there was. In the first place I was impressed with the analogy of this device to the induction coil, in which the same process takes place. When we impart current to the primary circuit we put lines of force slowly into the field and when we break the current we take the force swiftly away. I began to think of a mechanism which would be capable of fulfilling these conditions.

"During my work with induction coils and motors which succeeded I became familiar with currents of high frequency, and then I clearly realized the problem before me. I convinced myself that in alternating distributions we must induce currents of more thad one phase and that we must have a better organization and a perfected mechanism capable of rendering the current into steady oscillations before we could obtain the desired results. Here then I was confronted with this difficulty. I constructed small machines of the ordinary type which enabled me to investigate, but when I endeavored to construct machines with a

greater number of alternations for higher frequency I found that I met insurmountable mechanical difficulties.

"And then the idea came up and I asked, how it would be if I took a very strong field and reciprocated very rapidly a conductor in that field, would I not have a similar machine and one which would not involve loss in the iron? And now I began to consider this matter very seriously and later I considered this question, knowing what has been done in the field of harmonic telegraphy and supposing that instead of the ordinary dynamo we take dynamos constructed like the pendulum of a clock and on a harmonic vibration principle, would we not then obtain alternating currents of a perfectly defined and absolutely constant period, which it is impossible to accomplish with an ordinary machine because it possesses so great inertia? And then again I thought like this, with such powerful machines there is a possibility of transmitting energy through the air and by means of this energy of transmitting messages. This, then, is one of the mainsprings which has driven me into this work."

Here by means of diagrams Mr. Tesla described the construction of the engine which he has invented for producing these absolutely constant oscillations and which is operated by compressed air under 100 pounds pressure and delivered at the rate of 40 cubic feet per minute. One of these engines having a diameter of about two inches and a half and of about that length operated a small motor and has a capacity of nearly one-half horse power. After this Mr. Tesla showed the operation of the lârger engine having a piston and plunger weighing 20 pounds which was oscillated at the rate of 78 times a second, and stated that 5,000 or 10,000 oscillations per second could be as readily produced. The next experiment was made by attaching a horse shoe magnet having a wire about two feet in length inserted through it to show the vibration to the plunger of the engine. The engine was then set in motion, a current communicated to the magnet through wires attached to the nodes of the magnet wire. A copper disc revolving on an axis was then introduced by Mr. Tesla between the poles of the magnet while the same was being oscillated by the engine. The result of the experiment was that the copper disc began slowly to revolve, thus disproving the theory that there is no electro-magnetic force at work in the disc and that the force was simply one produced by induction as has been believed universally heretofore.

Mr. Tesla next attempted to show an experiment with what might be called a three coil generator, but the apparatus had been damaged in some way and refused to work. The next experiment was one with a large engine similar to that last described, having attached to the plunger of the oscillator a core of iron which played through four field magnets excited with a current at 5,000 volts from the Westinghouse plant. A current was generated by the apparatus, and was used to run a small registering motor, thus proving that generators can be constructed on the ideas evolved by Mr. Tesla in accordance with these more recent experiments, and having an absolutely constant current. It should be added that one of the claims made by Tesla for these oscillators is that the period will not be varied after the machine is started, whether the pressure be 10 pounds or 100 pounds, and that the electrical currents produced from small units will oscillate just as as the pendulum oscillates, and be unaffected by the circuit load or any imaginable condition. The oscillators are so constructed that they can be adjusted so as to run with practically no noise, and with the entire absence of any pounding effect.

WESTINGHOUSE APPARATUS AND THE TESLA SYSTEM ADOPTED AT NIAGARA FALLS.

THE CATARACT CONSTRUCTION COMPANY, has finally, after a long and thorough investigation of all the means submitted for transmitting power at Niagara, awarded the contract to the Westinghouse Company who will employ the Tesla multiphase system. The introduction of multiphase currents was some time since determined upon, but after protracted examination the Cataract Company settled upon the two-phase plan, this being recognized as the most flexible and remunerative in commercial exploitation.

The contract primarily calls for three generators of 5,000 h. p. each with corresponding motors and accessories. The revolving fields of the generators will be constructed with inwardly projecting poles and will revolve in a horizontal plane, being mounted upon the vertical shafts of the turbines. The weight of the shafts, turbines and armatures is to be carried by the upward pressure of the water-columns producing the heads for the turbines. The E. M. F. generated will be 2,000 to 2,400 volts and will be increased by step-up transformers for long-distance transmission and lowered by reducing transformers for distribution. The motors will be the two-phase Tesla. The system adapts itself readily to the use of motor generators or rotary transformers so that it is possible to develop either single-phase alternating currents or continuous currents of any desired E. M. F. as may be required for the uses of individual customers. It is expected that a large amount of power will be employed for manufacturing purposes, arc and incandescent lighting, electrolytic work and power purposes generally. It is also understood that the company contemplates sending current at high electromotive forces to Buffalo and greater distances to be used for lighting and power purposes. The work upon the apparatus has already been begun and it will be installed at the earliest possible date.

This is a high tribute to the Westinghouse Company, and not less so to the merits of the multiphase system.

Trade Notes and Novelties

THE
Electrical Engineer.

Vol. XVI. NOVEMBER 8, 1893. No. 288.

THE TESLA ELECTRICAL OSCILLATOR.

OUR readers will recall our short résumé of Mr. Tesla's lecture before the International Electrical Congress in Chicago,[1] which gave in brief outline the results accomplished in the search for an apparatus which would enable the electrical engineer to obtain currents or electrical oscillations economically without engines with rotating parts. The subject was an entirely novel one and came rather unexpectedly, and perhaps the majority of technical men have not even yet fully realized the full scope and far reaching effects of Mr. Tesla's novel work. We believe, therefore, that many will be interested in additional details relating to this work, and it is with this object in view that we give here a description of one form of Mr. Tesla's apparatus which he used in the lecture above referred to. Mr. Tesla, at that time, in compliance with a generally expressed desire left one of his oscillators in his personal exhibit at Chicago, until the end of the Exposition, and also, for fully a week, allowed all of his lecture apparatus to remain in the annex to the Agricultural Building where the lecture was held, and where it was inspected by numerous interested visitors.

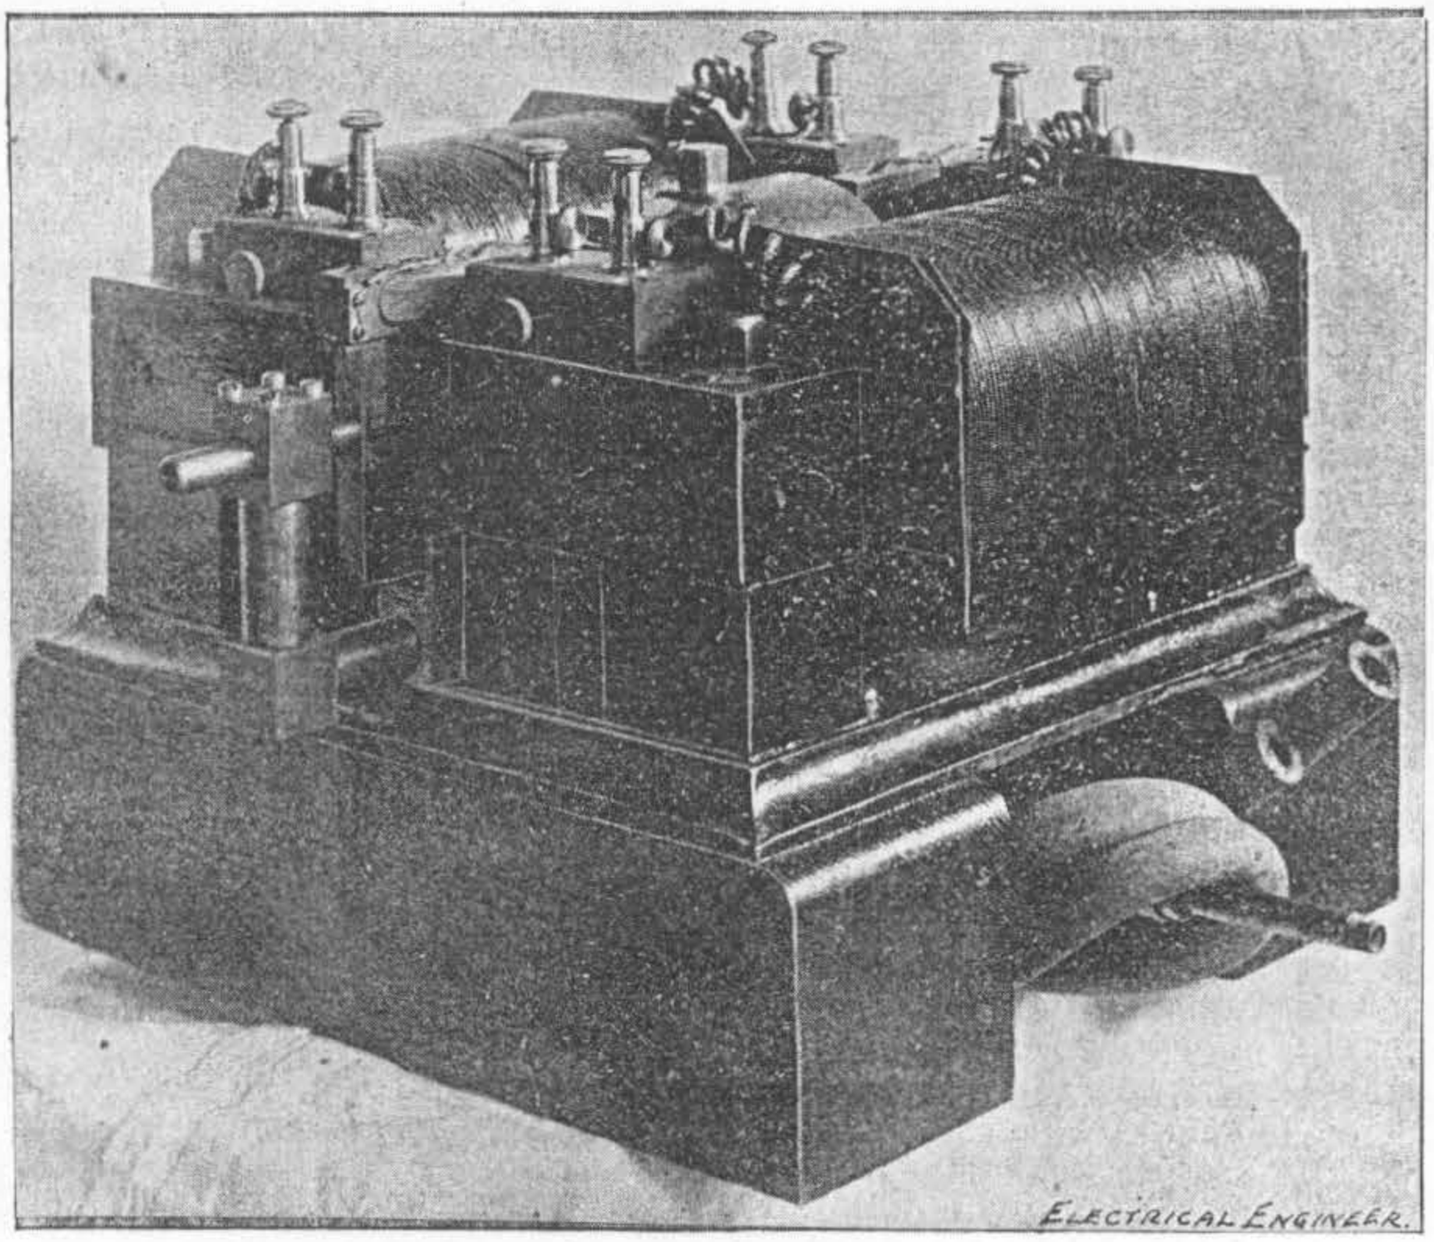

FIG. 1.—THE TESLA ELECTRICAL OSCILLATOR.

As we stated in our brief account, in these oscillators a freely movable piston, which is not connected to any rotating parts possessing inertia, as in ordinary engines, but which oscillates directly a coil or magnet and so generates electric current. Mr. Tesla pointed out in his lecture the great difficulty he had encountered in obtaining mechanical oscillation; he explained how he was guided first, in his earlier attempts, to imitate the process in a Leyden jar, in which electrical oscillations follow from an inadequate rate of supply, as compared with the rate of consumption. He exhibited a number of drawings showing apparatus in which he first employed compressed air passing through an opening, the section of which was properly calculated so that the rate at which the air was supplied was not sufficient to keep up a steady pressure; the latter would therefore suffer a sudden diminution upon a plunger being pushed to certain distance. By applying the simple laws of mechanical oscillation, determining, namely, the rigidity of the air spring and the weight of the movable parts, he was able to maintain oscillations ranging from small numbers to the most rapid mechanical vibration. He then devoted his energies to the perfection of the many varieties of apparatus of this kind with a special object of using steam as the working fluid, and getting the greatest mechanical and thermal efficiency out of the apparatus. Mr. Tesla was very sanguine in his expectations and from his remarks on that occasion we gathered that a vast field is opened up which will yield important practical results.

Our engraving Fig. 1 shows, in perspective, one of the forms of apparatus used by Mr. Tesla in his earlier investigations, and its interior construction is made plain by a sectional view shown in Fig. 2. It will be noted that the a piston P is fitted into the hollow of a cylinder C which is provided with channel ports O, O, and I, extending all around the inside surface. In this particular apparatus there are two channels O O for the outlet of the working fluid and one, I, for the inlet. The piston P is provided with two slots S S′ at a carefully determined distance, one from the other. The tubes T T which are screwed into the holes drilled into the piston establish communication between the slots S S′ and chambers on each side of the piston, each of these chambers connecting with the slot which is remote from it. The piston P is screwed tightly on a shaft A which passes through fitting boxes at the end of the cylinder C. The boxes project to a carefully determined distance into the hollow of the cylinder C, thus determining the length of the stroke.

Surrounding the whole is a jacket J. This jacket acts chiefly to diminish the sound produced by the oscillator and as a jacket when the oscillator is driven by steam, in which case a somewhat different arrangement of the mag-

2. See THE ELECTRICAL ENGINEER, Aug. 30, 1893.

nets is employed. The apparatus here illustrated was intended for demonstration purposes, air being used as most convenient for this purpose.

A magnetic frame M M is fastened so as to closely surround the oscillator and is provided with energizing coils which establish two strong magnetic fields on opposite sides. The magnetic frame is made up of thin sheet iron. In the intensely concentrated field thus produced, there are

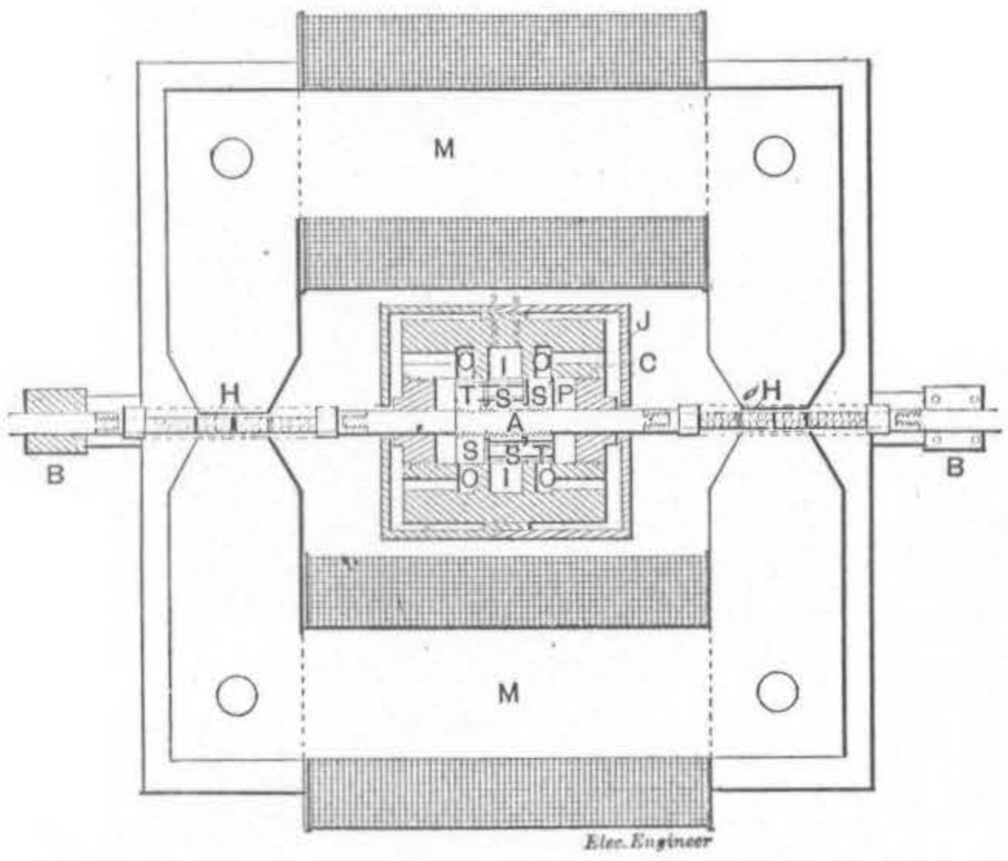

FIG. 2.—THE TESLA OSCILLATOR.—SECTIONAL VIEW.

arranged two pairs of coils H H supported in metallic frames which are screwed on the shaft A of the piston and have additional bearings in the boxes B B on each side. The whole is mounted on a metallic base resting on two wooden blocks.

The operation of the device is as follows: The working fluid being admitted through an inlet pipe to the slot I and the piston being supposed to be in the position indicated, it is sufficient, though not necessary, to give a gentle tap on one of the shaft ends protruding from the boxes B. Assuming that the motion imparted be such as to move the piston to the left (when looking at the diagram), then the air rushes through the slot s′ and tube T into the chamber to the left. The pressure now drives the piston towards the right and, owing to its inertia, it overshoots the position of equilibrium and allows the air to rush through the slot s and tube T into the chamber to the right, while the communication to the left hand chamber is cut off, the air of the latter chamber escaping through the outlet O on the left. On the return stroke a similar operation takes place on the right hand side. This oscillation is maintained continuously and the apparatus performs vibrations from a scarcely perceptible quiver amounting to no more than $\frac{1}{64}$ of an inch, to vibrations of a little over $\frac{3}{8}$ of an inch, according to the air pressure and load. It is indeed interesting to see how an incandescent lamp is kept burning with the apparatus showing a scarcely perceptible quiver.

To perfect the mechanical part of the apparatus so that oscillations are maintained economically was one thing, and Mr. Tesla hinted in his lecture at the great difficulties he had first encountered to accomplish this. But to produce oscillations which would be of constant period was another task of no mean proportions. As we pointed out, in the article before referred to, Mr. Tesla obtains the constancy of period in three distinct ways. Thus, he provides properly calculated chambers, as in the case illustrated, in the oscillator itself; or he associates with the oscillator an air spring of constant resilience. But the most interesting of all, perhaps, is the maintenance of the constancy of oscillation by the reaction of the electromagnetic part of the combination. Mr. Tesla winds his coils, by preference, for high tension and associates with it a condenser, making the natural period of the combination fairly approximating to the average period at which the piston would oscillate without any particular provision being made for the constancy of period under varying pressure and load. As the piston with the coils is perfectly free to move, it is extremely susceptible to the influence of the natural vibration set up in the circuits of the coils H H. The mechanical efficiency of the apparatus is very high owing to the fact that friction is reduced to a minimum and the weights which are moved are small; the output of the oscillator is therefor a very large one.

Theroretically considered, when the various advantages which Mr. Tesla holds out are examined, it is surprising, considering the simplicity of the arrangement, that nothing was done in this direction before. No doubt many inventors, at one time or other, have entertained the idea of generating currents by attaching a coil or a magnetic core to the piston of a steam engine, or generating currents by the vibrations of a tuning fork, or similar devices, but the disadvantages of such arrangements from an engineering standpoint must be obvious. Mr. Tesla, however, in the introductory remarks of his lecture, pointed out how by a series of conclusions he was driven to enter this line of work because of the necessity of producing currents of constant period and his endeavors to maintain electrical oscillation in the most simple and economical manner. A further development of this work will no doubt be watched with great interest.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed, and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

VOL. XVI. NEW YORK, NOVEMBER 8, 1893. No. 288.

THE LESSON OF THE INTRAMURAL.

THE best facilities for travel within the World's Fair grounds were those furnished by the Intramural elevated electric railway, winding around just inside the palings, from one end to the other, very much like a big "C" with a curl at each extremity. The line consisted of close upon 15,000 feet of double track and nearly 2,000 feet of single track. Trains ran ordinarily at 4 minute intervals and usually consisted of the motor car and three trailers, all four carrying passengers. All the cars were open, and all the seats were placed across the car, back to back, entrance being made by low doors which slid open or shut, all at the same time. The heaviest train loads were taken up or discharged with wonderful rapidity. As is well known, current was supplied to the motor cars by third rail.

The record of such a road as this is surely of interest to every large city in the country, and we are glad to be able to record the fact that the service was from first to last an enormous success. No fewer than 6,000,000 paying passengers were carried, and there was not a single accident. On Chicago day the total ran up to 125,000 passengers for the single day; and there were many other days when the figures reached 70,000 or 80,000. The service was smooth, regular and punctual, and the capacity of the road could easily have been increased had it proved necessary. The figures of operation are being carefully worked out, but they will show an economy beyond dispute. After such a brilliant demonstration, it is impossible for any man to declare that elevated electric roads will not work; and it is high time that such roads were availed of to relieve the congestion of passenger traffic that now prevails in every large American city, morning and evening and holidays all the year around. Moreover, it is high time that steam locomotives on elevated roads within city limits were arbitrarily ruled off the track. One could always sit in the Intramural cars and enjoy the fresh, free air without any stain to clothing or any soot or smoke flying in one's face; yet only a few yards away the open cars of the Illinois Central were crowded with passengers approaching or leaving the Fair, who were often harassed beyond endurance by the sulphurous, sooty clouds from the locomotives. The New York Elevated to-day is similarly a nuisance, chiefly, perhaps solely, on account of the smoke, soot, oil, ashes, drippings, etc., that it distributes lavishly all the way from the Battery to the Baseball grounds; and there is no longer any reason or any excuse for it. We watched personally the Intramural, day in and day out for six months together, riding sometimes half a dozen times in a single day, and never once did we see the slightest accident, trouble, confusion, or annoyance to any passenger. The motion of the cars was pleasant, and the motive power gave absolutely no sign of its presence. There were probably details to be improved, and that will be improved when new roads are equipped as they are soon to be; but the system as a whole is an unqualified success.

We could wish, as loyal New Yorkers, that this city or Brooklyn were the first to adopt the new method, but once again Chicago seems to be ahead, for news comes that the Northwestern Elevated Railroad Company has been formed, with a capital of $15,000,000, to operate such a road from Chicago out Evanston way. The directorate includes Mr. Frederick Sargent, recently the electrical and mechanical engineer of the Fair, and we understand that he will have a large share in the work of construction. Is New York never to have any of these modern conveniences and blessings that Chicago and Liverpool find within such easy reach?

THE TESLA ELECTRICAL OSCILLATOR.

ON another page we give a brief description of one form of Mr. Tesla's mechanico-electric oscillator, which formed part of his exhibit in Chicago. It would be hardly possible at this moment to foresee the ultimate effect which this latest work of Mr. Tesla will have upon the practical development of the electrical industry. Mr. Tesla is very sanguine, and if only part of his hopes are realized, its importance will not be long in making itself felt. The production of electrical currents in general with simpler apparatus than heretofore employed, and to all appearances with a more economical one, is certainly an achievement to be hailed by all who have the welfare of the industry at heart; while the maintenance of oscillations of constant period which may now be obtained by Mr. Tesla's apparatus in a positive manner, without the objectionable, older methods, is a result which scientific men certainly cannot fail to appreciate. We are now on the eve of witnessing the carrying out of some of Mr. Tesla's ideas on a grand scale in the work at Niagara—ideas advanced more than five years ago—and we have cause to feel certain that practical results will shortly come of this latest work. We are thus strengthened in our conviction, long since expressed, that practical results will also follow in the line of economical light production, now that Mr. Tesla has provided more perfect apparatus for the investigation of the phenomena which are associated with his name.

Western Electrician.

EVERY SATURDAY.

Vol. XIII. CHICAGO, NOVEMBER 11, 1893. No. 20

Electricity at the World's Fair.

A more marked change than that presented by the appearance of Jackson Park before and after October 31st would be difficult to imagine. The gala existence of the exposition came to an end with absolute abruptness, and the World's Fair is now in truth a "vanishing city." In common with all the other exhibitors, those in charge of the electrical machinery and appliances in machinery hall and electricity building are packing up and getting away as fast as possible, and many exhibits have already disappeared. The great central station plant in machinery hall is being rapidly dismantled. All arc lights except those used for patrol lighting have been cut out, and it is probable that this service, which will last until next spring, will be thrown on the block of Standard machines entirely. The Westinghouse company is supplying incandescent lighting to the administration, woman's and service buildings only, while all the power circuits except those supplied from one C. & C. generator will soon be cut out.

In all directions the electrical activity at the fair has ceased entirely or is only feebly existent. The electrical fountains were stopped in the middle of last week for lack of water and current; the searchlight apparatus has been removed from the roof of the manufactures building; the electric launches are not running, and the electricity building contains a confused mass of exhibits in various stages of packing and removal. On the intramural railway trains of two cars each, instead of four or five, are running, but at less frequent intervals and carrying but few passengers. The process of dismantling the plant in the intramural station has already been begun, and the 2,000 horse power generator is being taken apart for shipment to Brooklyn. The road is run by the Lake Erie upright engine, with plenty of power to spare. General Manager Baker furnishes the following interesting figures, showing the number of passengers carried on the intramural during the six months of the fair:

May	151,550
June	784 756
July	854,107
August	992,958
September	1,447,882
October	1,580.980
Total	5,812,233

The line complete is said to have cost between $800,000 and $1,000,000, and adding the anticipated proceeds of the sale of the material to the receipts from fares it is believed that the company will come out about even—a much better result than was anticipated early in the season.

Especial interest attached to the Fort Wayne plant in electricity building during the closing days of the fair by reason of the fact that it furnished current for the incandescent lamp test, which attracted much attention. Fig. 1 shows this plant as run during this period, with the members of the Fort Wayne Electric company's World's Fair staff grouped about the machines. The young men shown in the picture are E. A. Barnes, who had charge of the exhibit, E. H. Belden, W. Dudley, F. Dudley and O. Shepard. One of the far-famed Columbian Guards also lend his dignified presence to the scene. E. Waterman was connected with the exhibit, but is not shown in the illustration. Mr. Barnes left for Fort Wayne on Monday.

In the *Chicago Tribune's* excellent World's Fair souvenir edition of November 1st the following epitome of the results of the electrical display at the exposition was contributed by Chief Barrett:

I wish to comply with your request for a parting thought on the results attained in this department of the exposition. I wish to do so primarily because it is your request, as I recognize the fact that the newspapers of Chicago have been the most powerful forces at work in behalf of the fair. No other combined influences, or, indeed, all others,

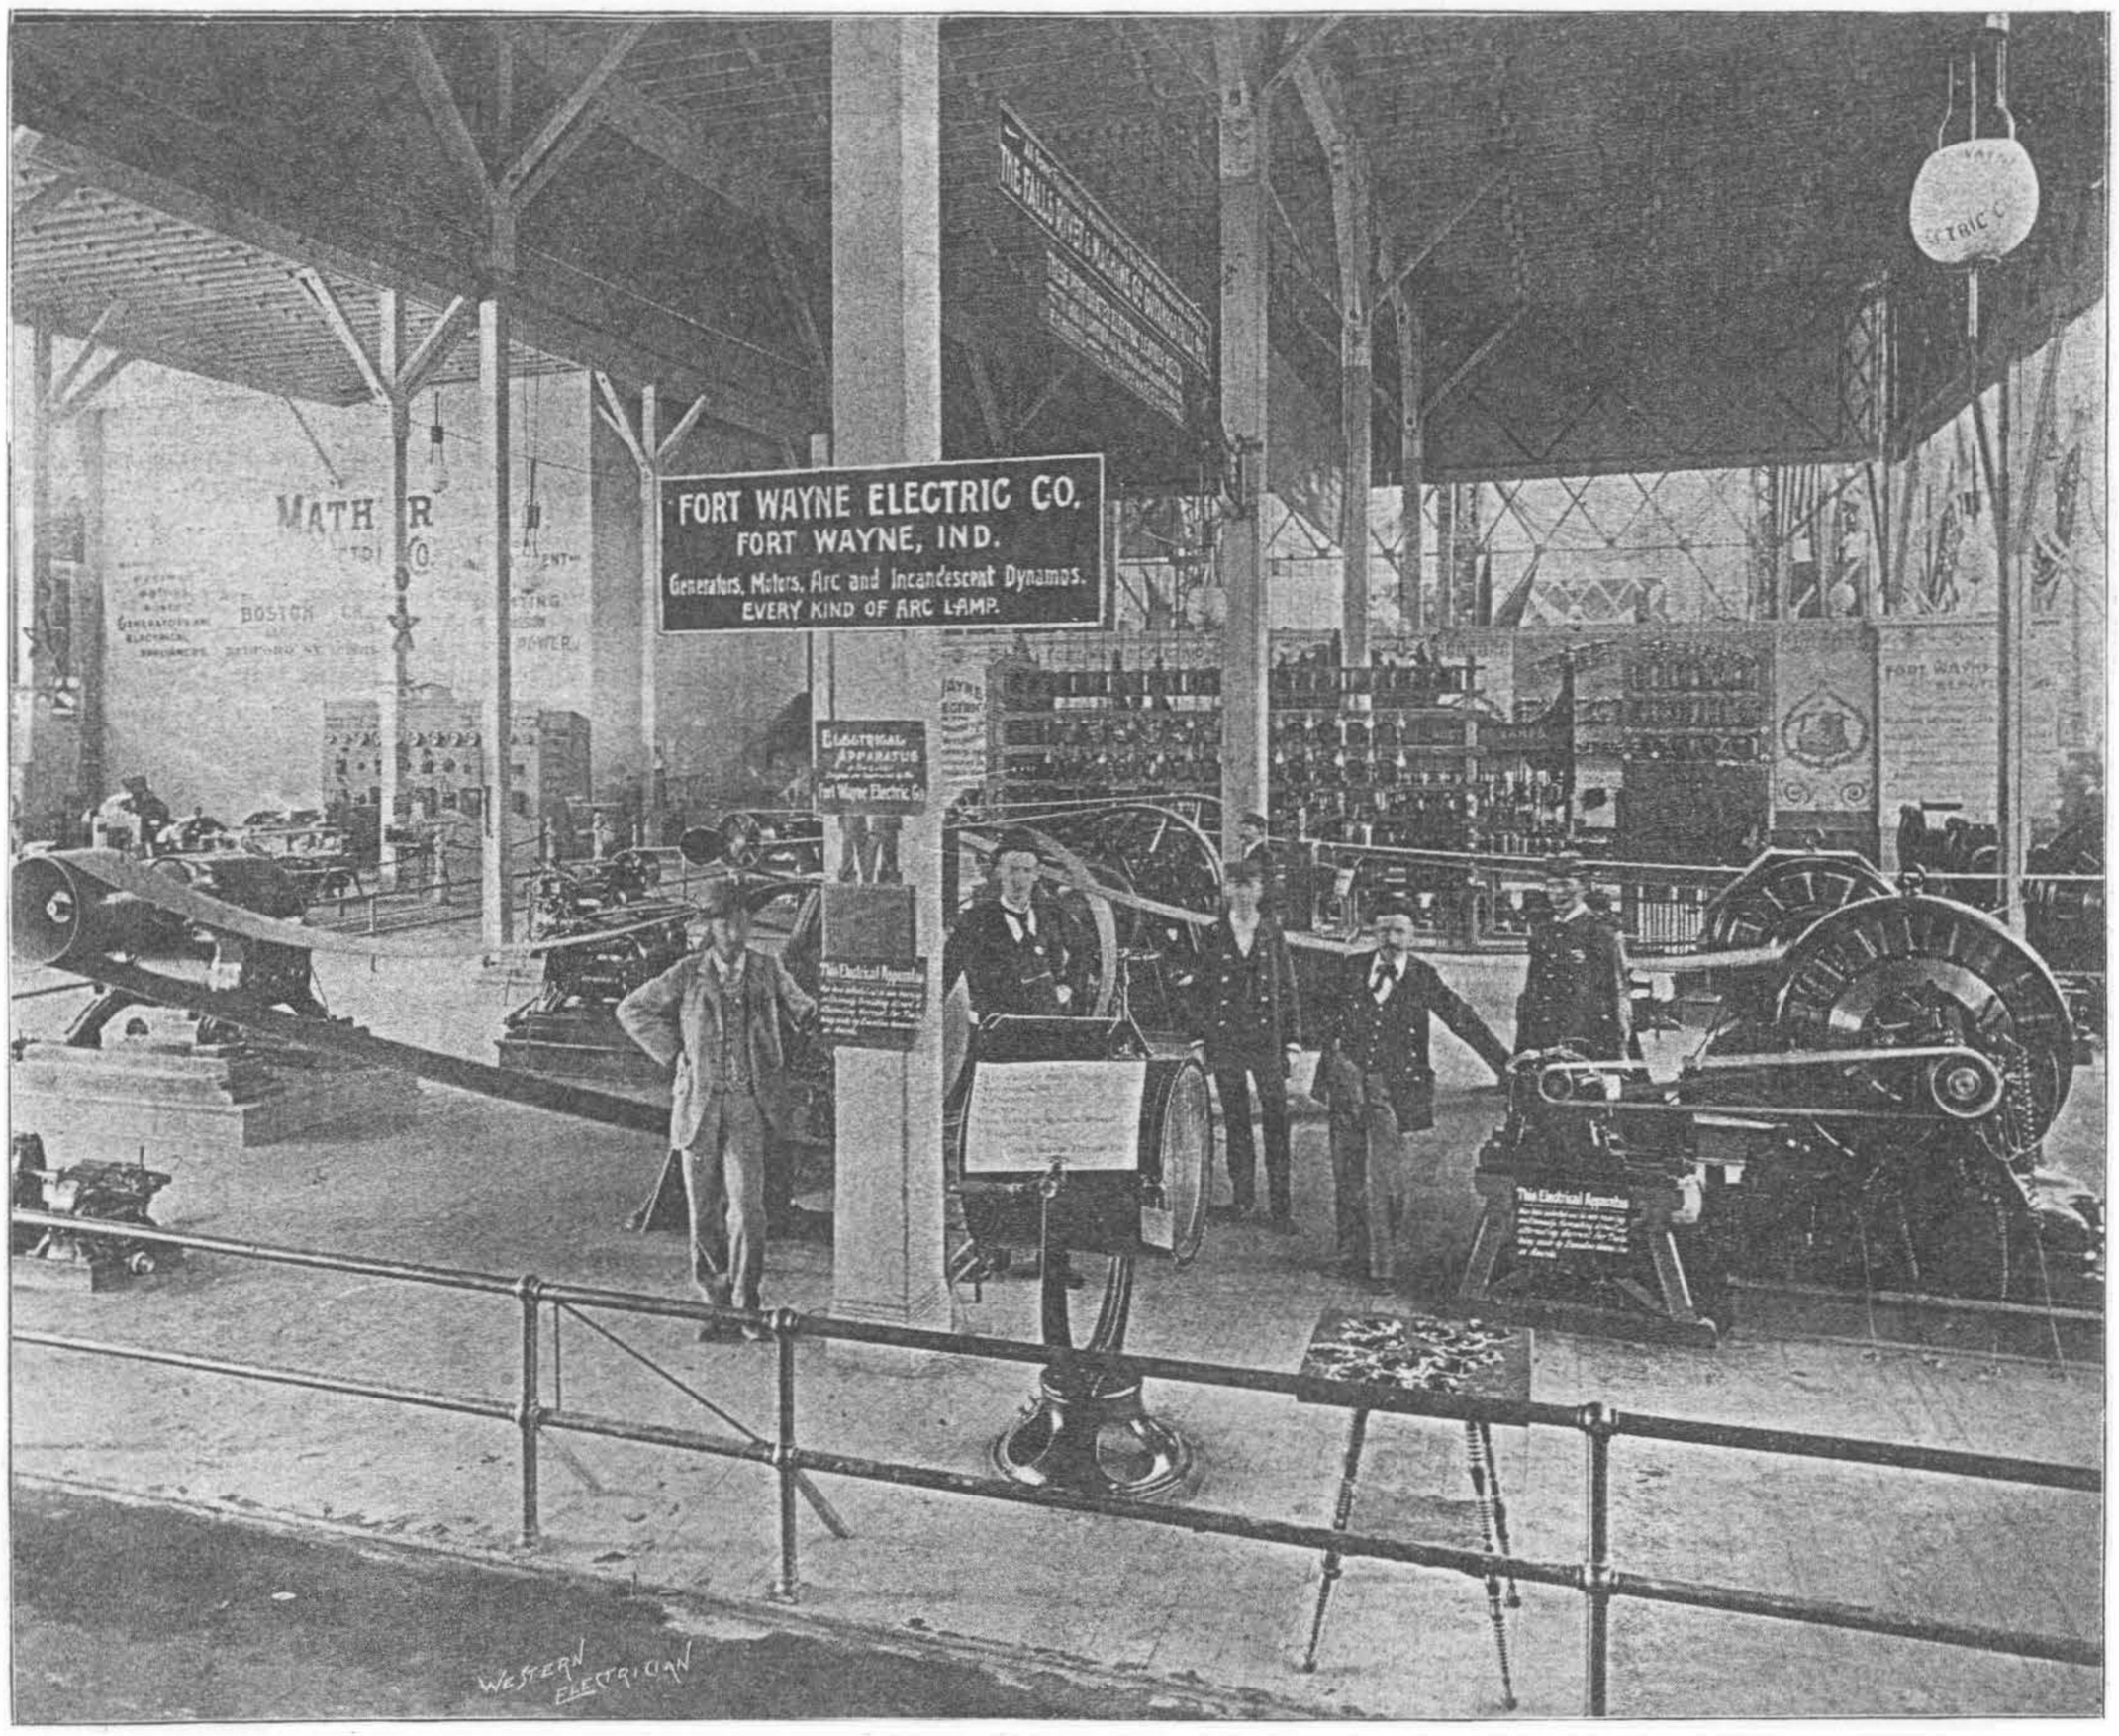

FIG. 1. ELECTRICITY AT THE WORLD'S FAIR.—EXHIBIT AND EXPOSITION STAFF OF THE FORT WAYNE ELECTRIC COMPANY, ELECTRICITY BUILDING.

have done so much to bring about whatever success has been achieved. They have been, as it were, guiding and protecting genii, or, like an approving or protecting conscience, they have held up our hands when we were right, and in a spirit of friendship have reproved us when their judgment was against us. While we may differ from the judgment passed by the Chicago papers many times, we nave never impugned their motives nor respected them the less because of those differences.

Speaking of the department, I desire to say that we have accomplished the highest aim which the well posted man could have set. We have not been the instrument for bringing out any great new principle, like the arc or incandescent light, telephone or dynamo. It seems that this is not an epoch of radical inventions. What we have done, though, is to demonstrate beyond question the commercial applicability of electricity in lines not heretofore mastered. The incandescent plant in service at the Fair is not alone the most extensive but the most economical—to the contractor—and the most efficient ever constructed, leaving out of consideration the perfection attained in decoration. Its chief merit, of course, apart from careful mechanical construction of the machinery, lies in the fact that it employs what is known as the alternating system of transmission, which means to the financier a saving of immense sums in copper and the further possibility of lighting territory at long distances from the source of supply of power.

One of the most powerful strides in electricity is in the adoption at the fair for the first time of very large units in machines and in their operation by what is known as the multiphase system of transmission. These large machines, especially those doing away with shafting and belting, by being directly coupled to their engines, open really a new epoch in the direction of economy and efficiency. Saving in friction, saving in the expenses of operation, and saving in first cost are among the advantages. Nearly all the large companies are going into this class of machine construction, and business competition will do the rest for perfection and progress.

Motors for power service have been demonstrated in greater variety than ever before. Beginning with the operation of the sawmills used in the period of construction, and ending with the tiny motors operated by exhibitors in an infinite variety of ways, we have some of the possibilities of the future.

The electric launches have demonstrated that this class of service is cheaper than by any other power. These boats have earned more money with less outlay in cost and maintenance than would have been possible with steam or any other power. Moreover, they are cleanly, rapid and in every way enjoyable.

Cooking by electricity and its application for domestic purposes is also henceforth commercial if it had not been before. It may not be uninteresting to the public to know that electric cooking and other domestic applications of the current have been commercial for a good while and that the lack of success hitherto in these directions has been due almost entirely to fights over patents.

I think these few words will indicate a train of thought for the intelligent reader to follow as an indication of the ends intended to be reached by me in the organization and execution of the work for this department.

Following Prof. Barrett's article the *Tribune* prints the following interesting personal gossip of the assistants in the office of the department:

Prof. Barrett's first assistant in the department, Dr. J. Allan Hornsby, has been in the work from its inception, having been appointed secretary of the department on the day that Prof. Barrett's commission was approved by the directors. Mr. Hornsby has done the actual work of the department under Prof. Barrett's direction, consulting with the chief on all matters at all times. Prof. Barrett's position as city electrician has made it impossible for him to give all his time to the work, hence the necessity to have a man with him in whom he had perfect confidence. John W. Blaisdell, general superintendent, is best known before the footlights, having been on the stage for some years and having become famous in theatrical work with the best actors of the day. He was for some years manager of Hooley's theater, and was with the best companies at all times. Mr. Blaisdell has had the thankless task of passing upon applications for passes for those in business with the department. W. W. Primm, engineer for the department, is a West Point man, and has been the brains of more than one large engineering project for which some famous engineer got the credit. He has been with Prof. Barrett for nearly two years, and is in no small degree to be credited with the success of the department. Willis Hawley, one of the assistants, came to the department from the active management of a large station at Urbana, O. He is an expert in every branch of the business, having secured his early training in the factory of the Western Electric company of this city. He can do anything from winding an armature to building a station from his own designs. George J. Henry is an inspector of electrical service. Largely to his efforts is due the magnificent fire protection of the building, which has in it concentrated power enough to burn a hole in Lake Michigan. Mr. Henry is also an expert amateur photographer, and has been taking the photographs for Prof. Barrett's report to the director-general. Orlando Shepard came to the department as Mr. Henry's co-laborer in the inspection department from one of Prof. Barrett's city lighting plants. Frank J. Sullivan and Stacey Butler are two young men through whose hands has passed every piece of apparatus exhibited in the building. They have kept all the records of the receipts of goods and have delivered every piece, not one case having been lost. They have relieved each other for night duty, one or the other being in service during the whole twenty-four hours of every day since the fair opened. Last but by no means of least importance in the department is the stenographer, George E. Moore. When the work of the office became too severe to be done by two young ladies Mr. Moore was employed in their stead. In closing it may be stated that Prof. Barrett's men have been paid salaries, as a rule, in excess of those paid in any other department. He has insisted on the best men he could find and has likewise insisted that they be paid for their services. One of the secrets of Prof. Barrett's success as an executive lies in the fact that every man in the department has specific duties to perform and is held to a strict personal account for their proper and prompt execution.

The exhibit of electrical and mechanical watchmen's clocks illustrated in Fig. 2 was made in the gallery of electricity building by the Newman Clock & Manufacturing company of Chicago. Mr. Newman was personally in charge, and succeeded in impressing the merits of his apparatus on many visitors.

FIG. 2. ELECTRICITY AT THE WORLD'S FAIR.—EXHIBIT OF THE NEWMAN CLOCK & MANUFACTURING COMPANY, ELECTRICITY BUILDING.

Portions of the personal exhibit of Nikola Tesla in electricity building, in connection with the Westinghouse display, are illustrated in Figs. 3 and 4. In the former is shown, on the right, a curious experiment with the alternating current. A current of 100 volts with 7,200 alternations was transformed to a potential of 15,000 volts and the frequency also greatly increased by a spark-gap and Leyden jars. A ∩-shaped bar of copper three-quarters of an inch in diameter was placed in the circuit thus created, and three lamps connected across at intervals, as shown in the illustration. When the current was turned on the lowest lamp burned about up to candle power, the next above burned dimly and the highest showed a slight red glow, demonstrating that the current took the path of high resistance through the lamps rather than the infinitely slight resistance of the copper bar, and that this seeming resistance of the thick copper decreased toward the top, allowing more and more of the current to pass through it instead of the lamp. This curious effect is explained by the theory that the extremely high frequency of the current set up local or eddy currents in the copper bar, and that this impedance was sufficient to divert the current through the small conducting medium and high resistance of the lamps. In approaching the top of the bar the impedance grew less and a greater proportion of the current passed through the mass of copper, lighting the lamps but feebly in consequence. With a direct or ordinary alternating current this apparent contradiction of the laws of electricity would not occur.

On the left in Fig. 3 are shown the transformers, circuit breaker and Leyden jars used in producing the high potentials and high frequencies used in the Tesla experiments in the Westinghouse "dark room." A 100 volt alternating current was first transformed to 100,000 volts by two 50,000 volt transformers in series. By the use of the wheel shaped circuit-breaker and Leyden jars shown on the table in the illustration the rate of alternation was multiplied many times and an additional transformer raised the pressure to about a million volts. This was the current used for the Tesla vacuum tube experiments.

The experimental apparatus used by Tesla in developing his polyphase system was shown on a table near the "dark room," and is represented in Fig. 4. Here are all sorts of fields and armatures for motors, and the whole made an extremely interesting collection. In the center was shown the "Columbus egg" of the Westinghouse company, embodying the principles of the Tesla system. In the rear of this table were shown small two and three-phase motors of the latest Tesla type. In the space illustrated the Shallenberger meter, Wurts non-arcing and "Keystone" lightning arresters were exploited on display boards.

Electrical men will find much of interest and importance in the following list of awards in group 69 (comprising motors and apparatus for the generation and transmission of power, hydraulic and pneumatic apparatus), department of machinery:

United States.

Abendroth & Root Manufacturing company, New York, N. Y.—Special riveted pipes; (2) sectional water tube boiler.
Aermotor company, Chicago, Ill.—Pneumatic pump.
Alexander Bros., Philadelphia, Pa.—Leather belting.
American Hoist & Derrick company, St. Paul, Minn.—Contractors' machinery.
American Leather Link Belt company, New York, N. Y.—Leather link belting.
American Well Works, Aurora, Ill.—Collection of pumping and well appliances.
Andrews, Johnson & Co., Chicago, Ill.—Fan engines.
Ashton Valve company, Boston Mass.—Pop safety valves.

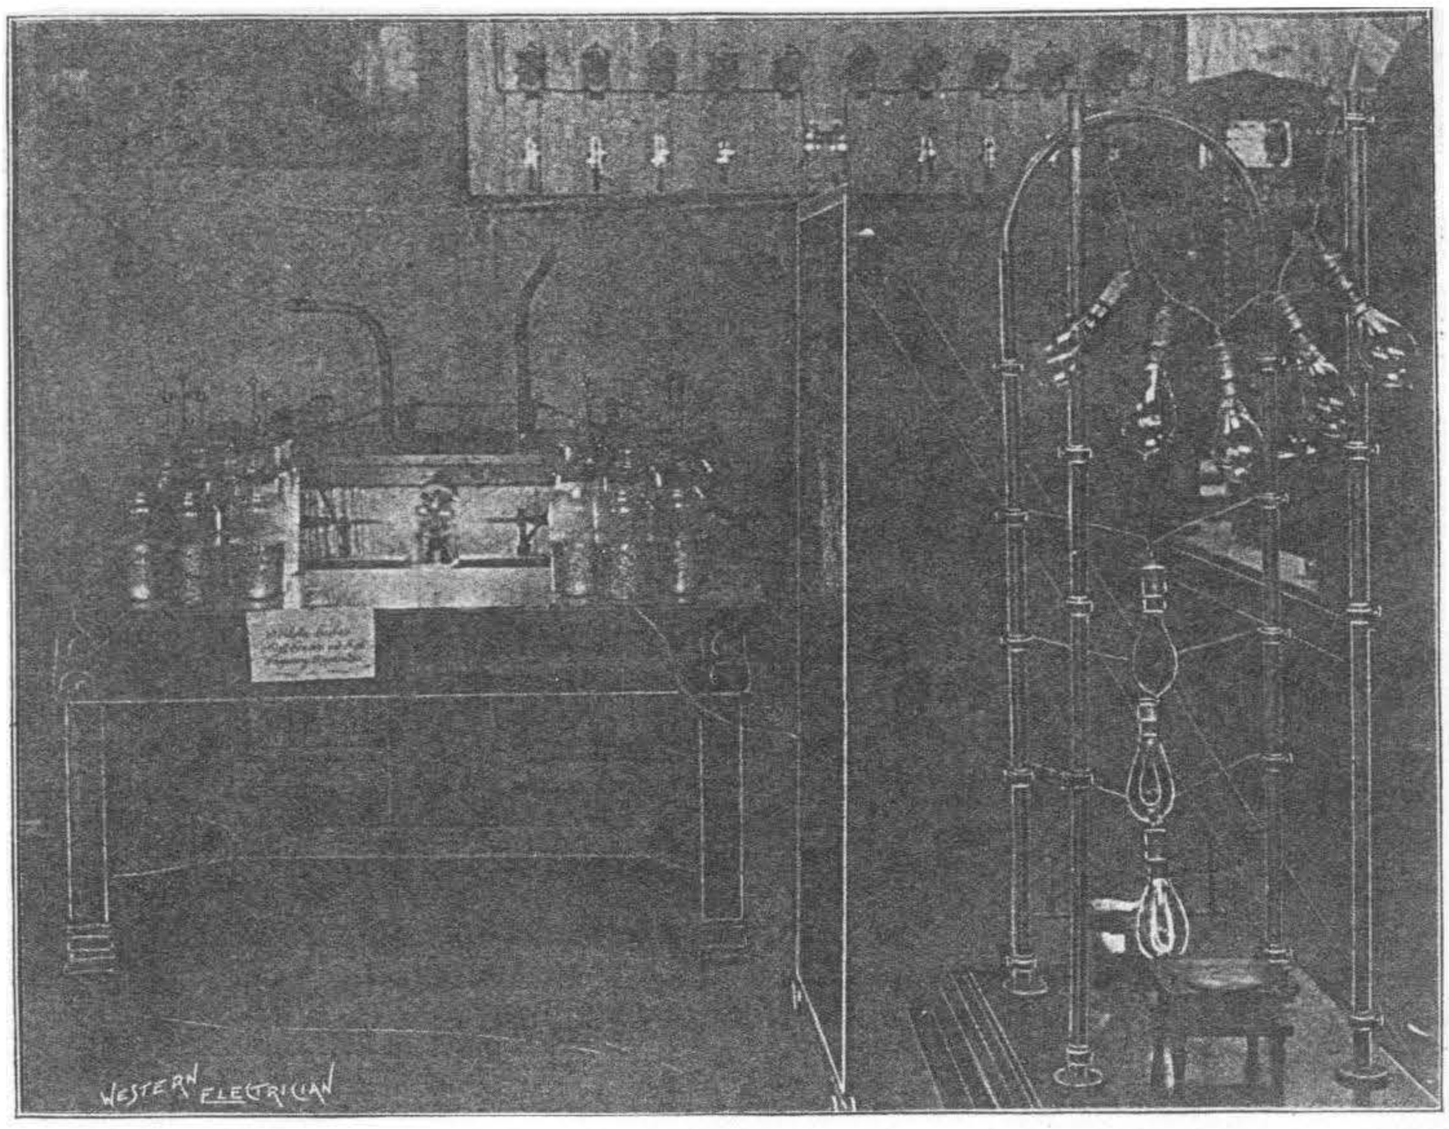

FIG 3. ELECTRICITY AT THE WORLD'S FAIR.—TESLA EXPERIMENTAL APPARATUS, ELECTRICITY BUILDING.

Atlas Engine Works, Indianapolis, Ind.—Tandem compound steam engine.
Babcock & Wilcox company, New York, N. Y.—Model water tube boilers and details.
Ball Engine company, Erie, Pa.—500 horse power cross high speed compound condensing engine.
Ball & Wood company, New York, N. Y.—High speed engines.
Baragwanath, Wm. & Son, Chicago, Ill.—Steam jacket feed and water heater.
Bates Machine company, Joliet, Ill.—Bates' Corliss engines.
Battle Creek Machinery company, Battle Creek, Mich.—Marsh steam pump.
Bilgram, Hugo, Philadelphia, Pa.—Smooth running gears

MR. TESLA'S PERSONAL EXHIBIT AT THE WORLD'S FAIR.

WHILE the exhibits of firms engaged in the manufacture of electrical apparatus of every description, at the Fair, afforded the visitor ample opportunity for gaining an excellent knowledge of the state of the art, there were also numbers of exhibits which brought out into strong relief the work of the individual inventor, which lies at the foundation of much, if not all, of our present achievement. Prominent among such personal exhibits was that of Mr. Nikola Tesla, whose apparatus occupied part of the space of the Westinghouse Company.

This apparatus represents the results of work and thought covering a period of ten years. It embraces a large number of different alternating motors and Mr. Tesla's earlier high frequency apparatus. The motor exhibit consisted of a variety of fields and armatures for two, three and multiphase circuits, and gave a fair idea of the gradual evolution of the fundamental idea of the rotating magnetic field. The high frequency exhibit included Mr. Tesla's earlier machines and disruptive discharge coils and high frequency transformers, which he used in his investigations and some of which are referred to in his published papers.

Our engraving, Fig. 1, shows a view of part of the exhibits containing the motor apparatus. Among these there is shown at A a large ring which is intended to exhibit the phenomena of the rotating magnetic field. The field produced was very powerful and exhibited striking effects, revolving copper balls and eggs and bodies of various shapes at considerable distances and at great speeds. This ring was wound for two-phase circuits, and the winding was so distributed that a practically uniform field was obtained. This ring was prepared for Mr. Tesla's exhibit by Mr. C. F. Scott, electrician of the Westinghouse Electric and Manufacturing Company.

A smaller ring, shown at B, was arranged like the one exhibited at A but designed specially to exhibit the rotation of an armature in a rotating field. In connection with these two rings there was an interesting exhibit shown by Mr. Tesla which consisted of a magnet with a coil, the magnet being arranged to rotate in bearings. With this magnet he first demonstrated the identity between a rotating field and a rotating magnet, the latter, when rotated, exhibiting the same phenomena as the rings when they were energized by currents of differing phase. Another prominent exhibit is a model illustrated at C which is a two-phase motor, as well as an induction motor and transformer. It consists of a large outer ring of laminated iron wound with two superimposed, separated windings which can be connected in a variety of ways. This is one of the first models used by Mr. Tesla as an induction motor and rotating transformer. The armature was either a steel or wrought iron disc with a closed coil. When the motor was operated from a two phase generator the windings were connected in two groups, as usual. When used as an induction motor then the current induced in one of the windings of the ring was passed through the other winding on the ring and so the motor operated with only two wires. When used as a transformer the outer winding served, for instance, as a secondary and the inner as a primary. The model shown at D is one of the earliest rotating field motors, consisting of a thin iron ring wound with two sets of coils and an armature consisting of a series of steel discs partly cut away and arranged on a small arbor.

At E is shown one of the first rotating field or induction motors used for the regulation of an arc lamp and for other purposes. It comprises a ring of discs with two sets of coils having different self-inductions, one set being of German silver and the other of copper wire. The armature is wound with two closed circuited coils at right angles to each other. To the armature shaft are fastened levers and other devices to effect the regulation. At F is shown a model of a magnetic lag motor; this embodies a casting with pole projections protruding from two coils between which is arranged to rotate a smooth iron body. When an alternating current is sent through the two coils the

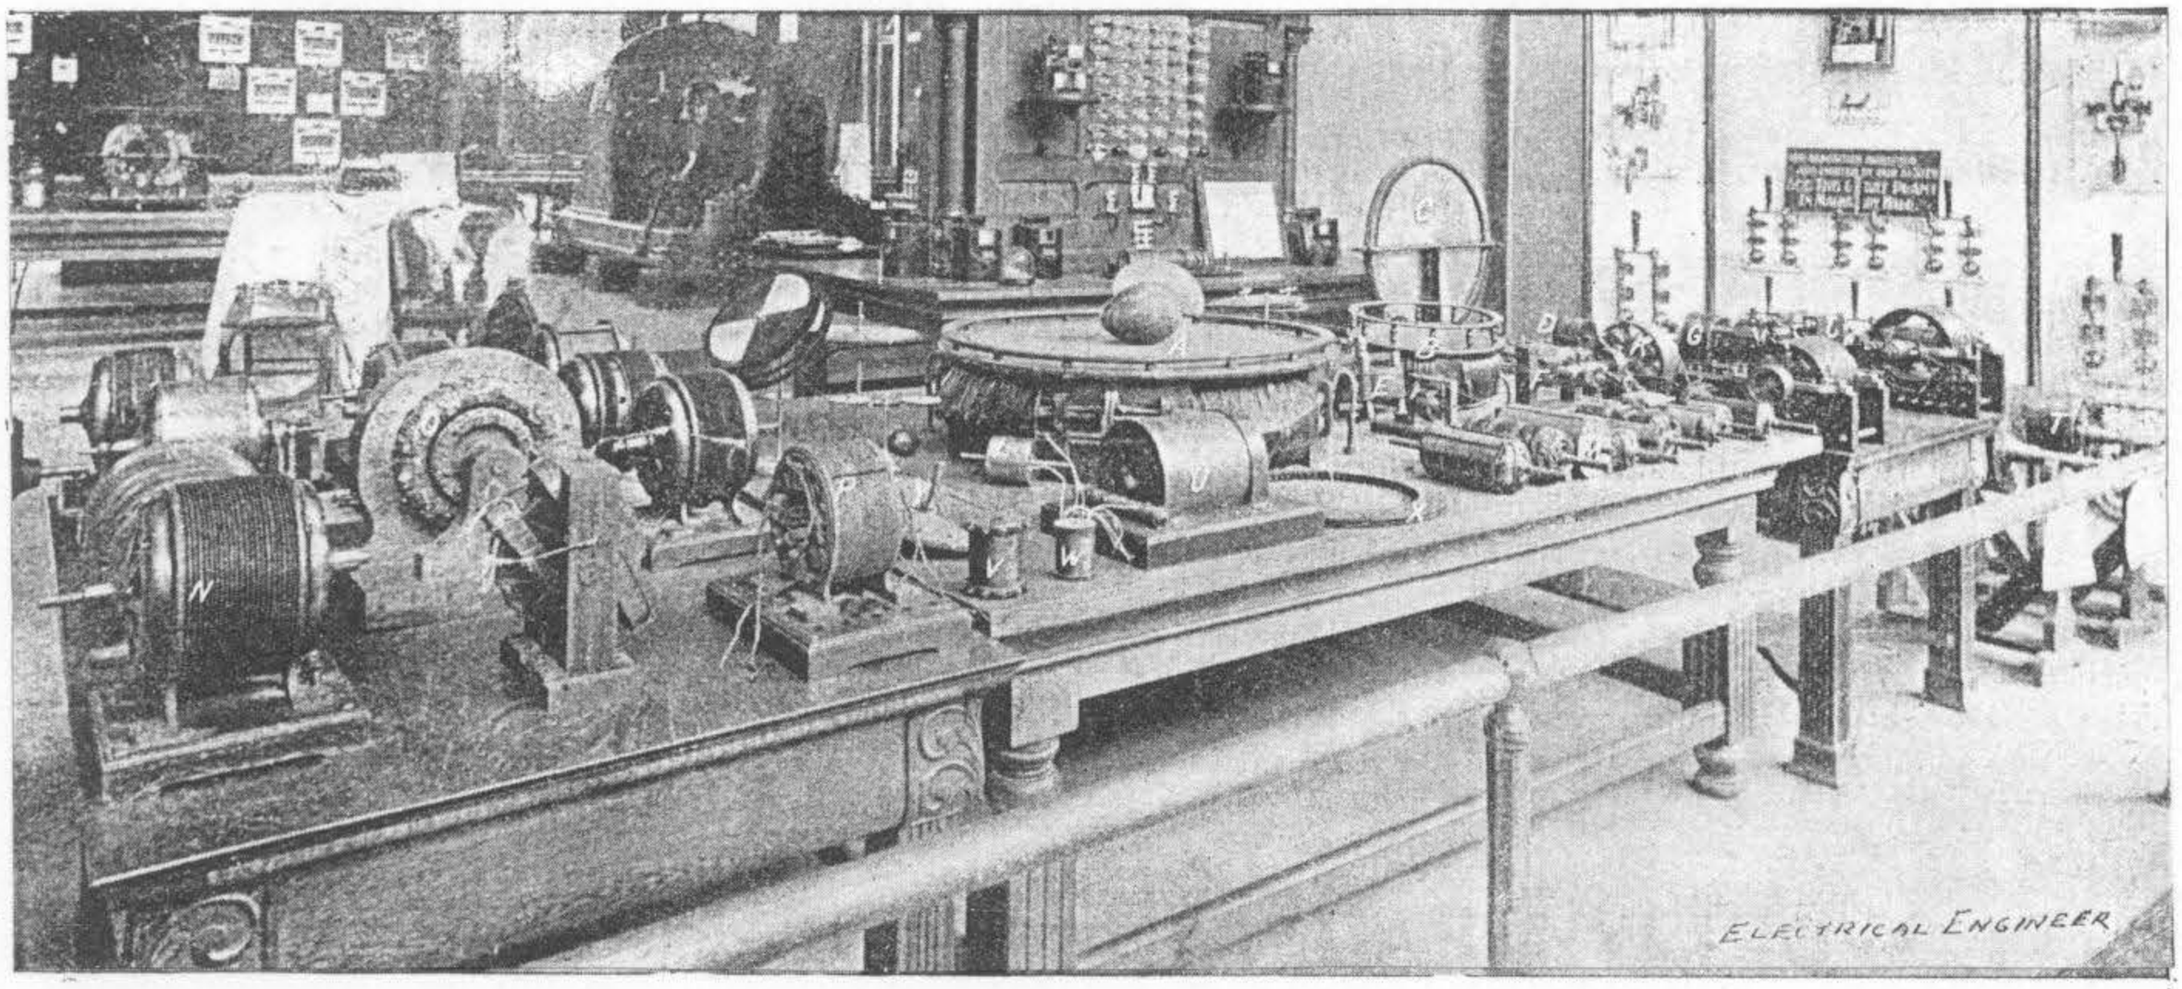

FIG. 1.—MR. TESLA'S PERSONAL EXHIBIT AT THE WORLD'S FAIR.

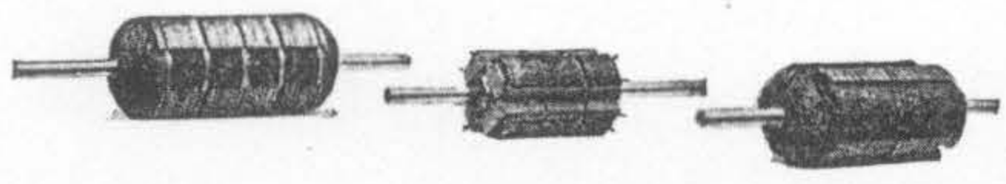
pole projections of the field and armature within it are similarly magnetized, and upon the cessation or reversal of the current the armature and field repel each other and rotation is produced in this way. Another interesting exhibit, shown at G, is an early model of a two field motor energized by currents of different phase. There are two independent fields of laminated iron joined by brass bolts; in each field is mounted an armature, both armatures being on the same shaft. The armatures were originally so arranged as to be placed in any position relatively to each other and the fields also were arranged to be connected in a number of ways. The motor has served for the exhibition of a number of features; among other things, it has been used as a dynamo for the production of currents of any frequency between wide limits. In this case the field, instead of being energized by direct current was energized by currents differing in phase, which produced a rotation of the field; the armature was then rotated in the same or in opposite direction to the movement of the field and so any number of alternations of the currents induced in the armature, from a small to a high number, determined by the frequency of the energizing field coils and the speed of the armature, was obtained.

The models H, I, J, represent a variety of rotating field synchronous motors which are of special value in long distance transmission work. The principle embodied in these motors was enunciated by Mr. Tesla in his lecture before the American Institute of Electrical Engineers, in May, 1888. It involves the production of the rotating field in one of the elements of the motor by currents differing in phase and energizing the other element by direct currents. The armatures are of the two and three phase type. K is a model of a motor shown in an enlarged view in Fig. 2. This machine together with that shown in Fig. 3 were models exhibited at the same lecture, in May, 1888. They were the first rotating field motors which were independently tested, having for that purpose been placed in the hands of Prof. Anthony in the winter of 1887–88. From these tests it was shown that the efficiency and output of these motors was quite satisfactory in every respect.

FIGS. 4, 5 AND 6.

It was intended to exhibit the model shown in Fig. 3 but it was unavailable for that purpose owing to the fact that it was some time ago handed over to the care of Prof. Ayrton in England. This model was originally provided with twelve independent coils; this number, as Mr. Tesla pointed out in his first lecture, being divisible by two and three, was selected in order to make various connections for 2 and 3-phase operations, and during Mr. Tesla's experiments was used in many ways with from 2 to 6 phases.



FIGS. 7, 8 AND 9.

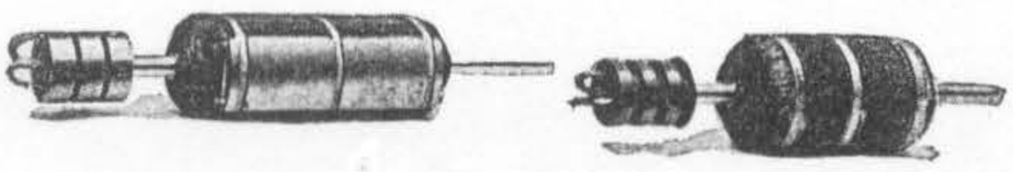
The model, Fig. 2, consists of a magnetic frame of laminated iron with four polar projections between which an armature is supported on brass bolts passing through the frame. A great variety of armatures was used in connection with these two and other fields. Some of the armatures are shown in front on the table, Fig. 1, and several are also shown enlarged in Figs. 4 to 14. An interesting exhibit is that shown at I, Fig. 1. This is an armature of hardened steel which was used in a demonstration before the Society of Arts in Boston, by Prof. Anthony. Another curious exhibit is shown enlarged in Fig. 5. This consists of thick discs of wrought iron placed lengthwise, with a mass of copper cast around them. The discs were arranged longitudinally to afford an easier starting by reason of the induced current formed in the iron discs, which differed in phase from those in the copper. This armature would start with a single circuit and run in synchronism, and represents one of the earliest types of such an armature. Fig. 9 is another striking exhibit. This is one of the earliest types of an armature with holes beneath the periphery, in which copper conductors are embedded. The armature has eight closed circuits and was used in many different ways. Fig. 8 is a type of synchronous armature consisting of a block of soft steel wound with a coil closed upon itself. This armature was used in connection with the field shown in Fig. 2 and gave excellent results.

FIGS. 2 AND 3.—TESLA ROTATING FIELD MOTORS EXHIBITED IN HIS LECTURE BEFORE THE A. I. E. E., MAY, 1888.

Fig. 6 represents a synchronous armature with a large coil around a body of iron. There is another very small coil at right angles to the first. This small coil was used for the purpose of increasing the starting torque and was found very effective in this connection. Figs. 10 and 12 show a favorite construction of armature; the iron body is made up of two sets of discs cut away and placed at right angles to each other, the interstices being wound with coils. The one shown in Fig. 12 is provided with an additional groove on each of the projections formed by the discs, for the purpose of increasing the starting torque by a wire wound in these projections. Fig. 11 is a form of armature similarly constructed, but with four independent coils wound upon the four projections. This armature was

used to reduce the speed of the motor with reference to that of the generator. Fig. 4 is still another armature with a great number of independent circuits closed upon themselves, so that all the dead points on the armature are done away with and the armature has a large starting torque. Fig. 7 is another type of armature for a four-pole motor but with coils wound upon a smooth surface. A number

FIGS. 10, 11 AND 12.



of these armatures have hollow shafts, as they have been used in many ways. Figs. 13 and 14 represent armatures to which either alternating or direct current was conveyed by means of sliding rings. Fig. 13 consists of a soft iron body with a single coil wound around it, the ends of the coil being connected to two sliding rings to which usually direct current was conveyed. The armature shown in Fig. 14 has three insulated rings on a shaft and was used in connection with two or three phase circuits.

All these models shown represent early work, and the enlarged engravings are made from photographs taken early in 1888. There is a great number of other models which were exhibited, but which are not sharply brought out in the engraving Fig. 1. For example at M is a model of a motor comprising an armature with a hollow shaft wound with two or three coils for 2 or 3-phase circuits; the armature was arranged to be stationary and the generating circuits were connected directly to the generator. Around the armature is arranged to rotate on its shaft a casting forming six closed circuits. On the outside this casting was turned smooth and the belt was placed on it for driving with any desired appliance. This also is a very early model.

On the left side of the table there is shown a large variety of models, N, O, P, etc., with fields of various shapes. Each of these models involves some distinct idea and they all represent the gradual development chiefly interesting as showing Mr. Tesla's efforts to adapt his sysem to the existing high frequencies.

On the right side of the table, at S, T, are shown, on separate supports, larger and more perfected armatures of commercial motors, and in the space around the table a variety of motors and generators supplying current to them was exhibited.

The high frequency exhibit embraced Mr. Tesla's first original apparatus used in his investigations. There was exhibited a glass tube with one layer of silk covered wire wound at the top and a copper ribbon on the inside. This was the first disruptive discharge coil constructed by him. At U is shown the disruptive discharge coil exhibited by him in his lecture before the American Institute of Electrical Engineers, in May, 1891. At V and W are shown some of the first high frequency transformers. A number

FIGS. 13 AND 14.

of various fields and armatures of small models of high frequency apparatus is shown at X and Y and others not visible in the picture were exhibited. In the annexed space the dynamo used by Mr. Tesla at Columbia College was exhibited; also another form of high frequency dynamo used.

In this space also was arranged a battery of Leyden jars and his large disruptive discharge coil which was used for exhibiting the light phenomena in the dark room. The coil was operated at only a small fraction of its capacity as the necessary condensers and transformers could not be had and as Mr. Tesla's stay was limited to one week; notwithstanding, the phenomena were of a striking character. In the room were arranged two large plates placed at a distance of about eighteen feet from each other. Between them were placed two long tables with all sorts of phosphorescent bulbs and tubes; many of these were prepared with great care and marked legibly with the names which would shine with phosphorescent glow. Among them we noted some with the names of Helmholtz, Faraday, Maxwell, Henry, Franklin, etc. Mr. Tesla had also not forgotten the greatest living poet of his own country Zmaj Jovan; two or three were prepared with inscriptions, like "Welcome Electricians," and produced a beautiful effect. Each represented some phase of this work and stood for some individual experiment of importance. Outside the room was the small battery seen in Fig. 15, for the exhibition of some of the impedance and other phenomena of interest. Thus, for instance, a thick copper bar bent in arched form was provided with clamps for the attachment of lamps, and a number of lamps were kept at incandescence on the bar; there was also a little motor shown on the table operated by the disruptive discharge.

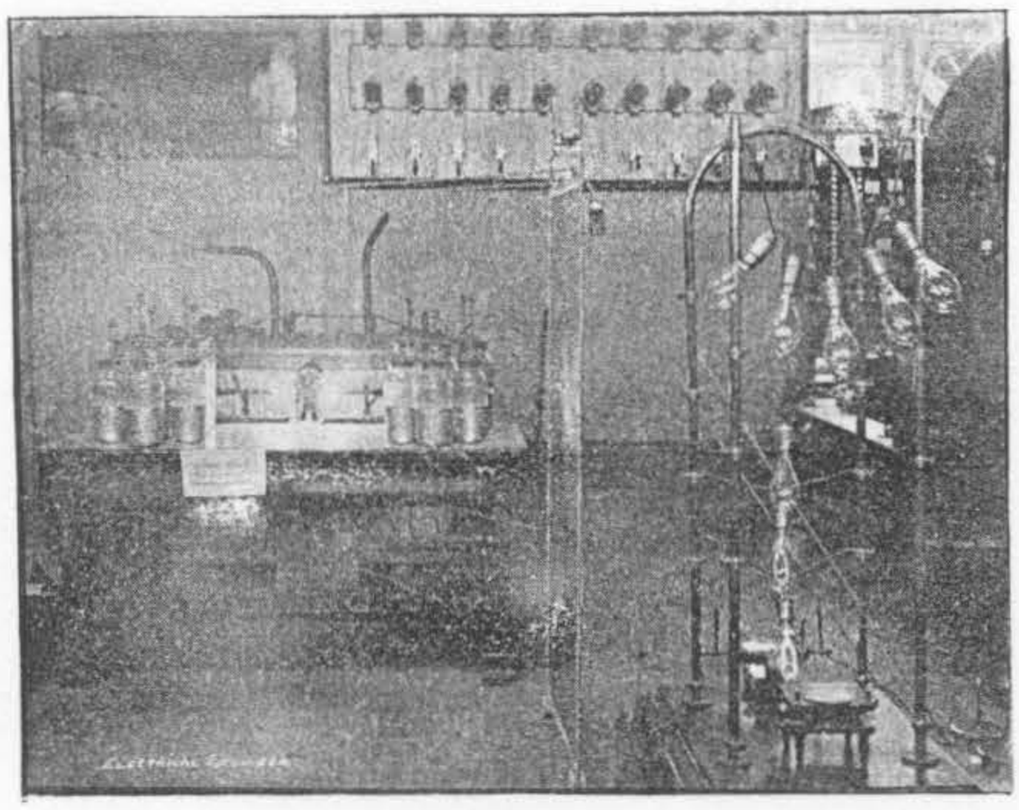


FIG. 15.

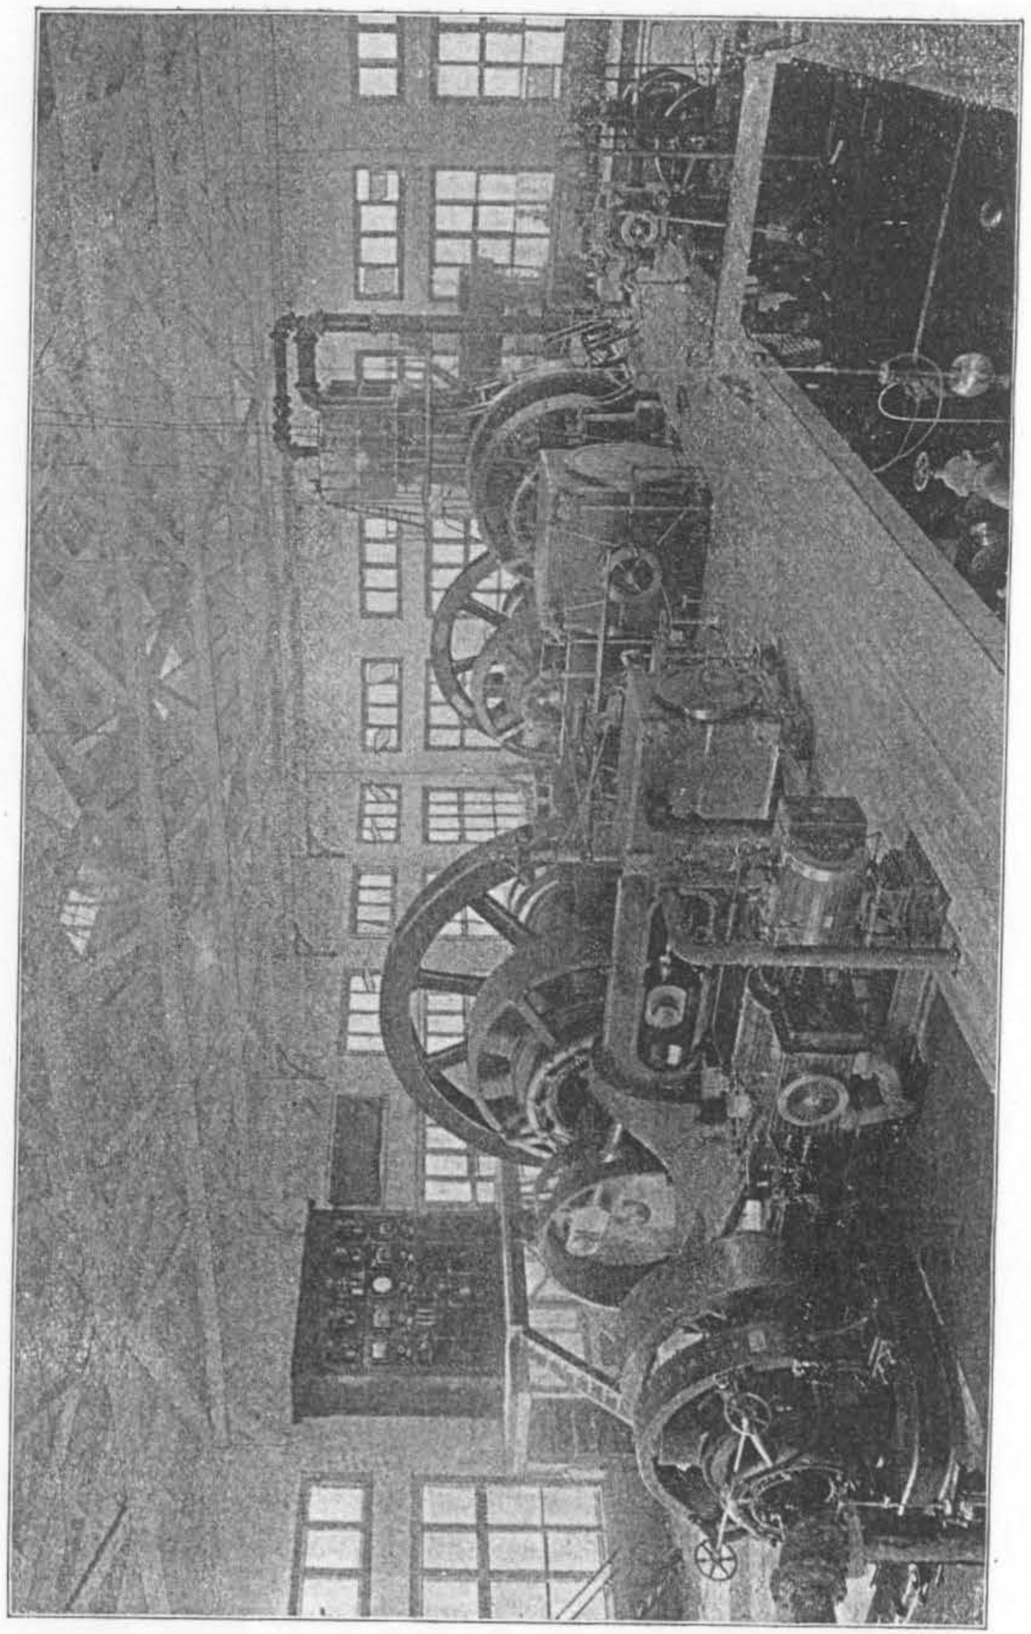
As will be remembered the Westinghouse Company made a fine exhibit of the various commercial motors of the Tesla system and also the twelve generators in Machinery Hall were of the two-phase type constructed for distributing light and power. Mr. Tesla, as is also known, exhibited some models of his oscillators. It was Mr. Tesla's intention to exhibit his motor and high frequency apparatus only during the Congress week, but it was allowed to remain on exhibition on account of a generally expressed desire. Furthermore as Mr. Tesla had only a week's notice to prepare his lecture all his time was taken up for this purpose, otherwise his motor, and especially his high frequency, exhibit would have been more complete.

THE FAIR IN '94.

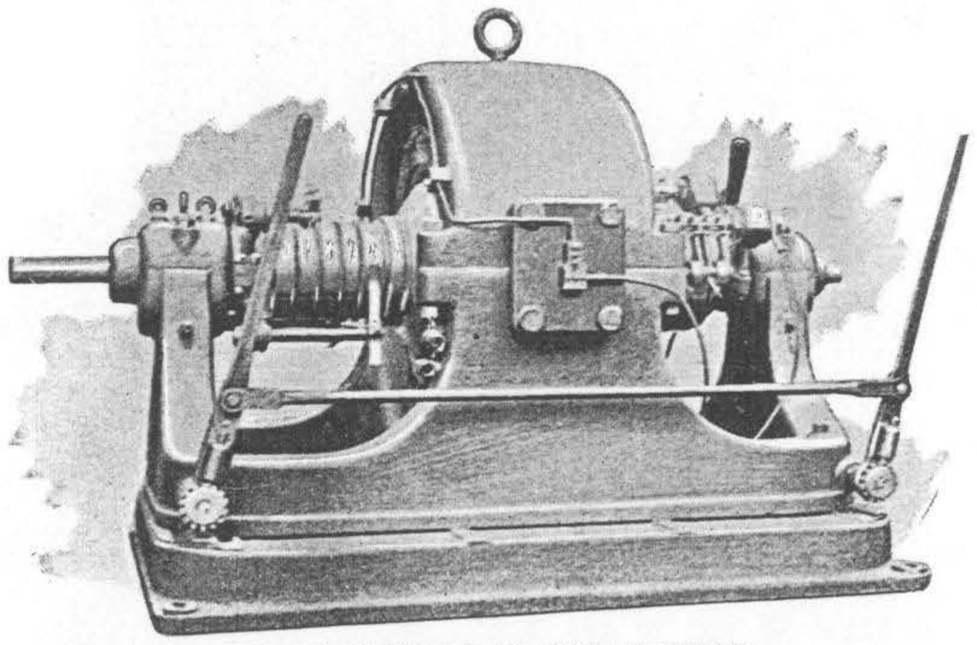
THE South Park Board of Commissioners of Chicago held a joint meeting with the executive committee of the World's Fair directory recently and decided to accept the Fair buildings and a sum of money sufficient to keep them in repair for some time. The state buildings and many of the foreign buildings will be removed. The park will be improved, and next season there will be electric displays, fireworks, etc. All the buildings will be open and the walks and roadways will be kept in perfect condition.



ELECTRIC POWER AT THE WORLD'S FAIR.

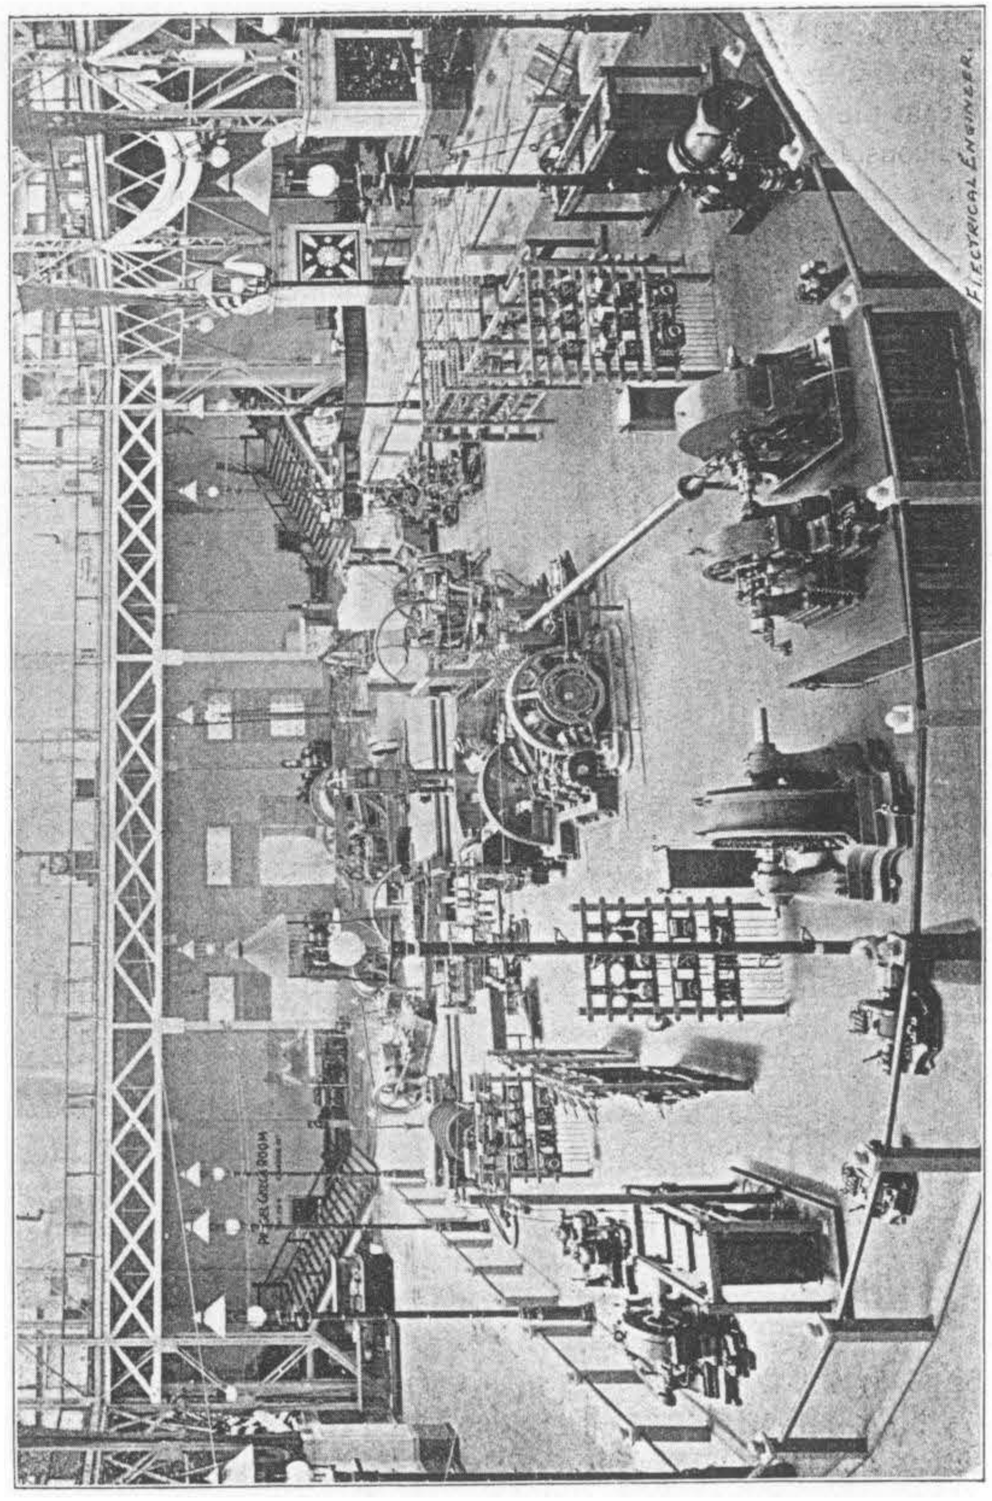
By Nelson W. Perry, E. M.

MACHINERY in motion has a charm that is lacking in the mechanism when at rest, yet to the student or specialist the latter may have a special interest akin to that which the corpse has for the anatomist. But the masses are not anatomists and are interested only in the moving wheels. Therefore, because much of the machinery in the Electricity building at the World's Fair was not in motion, many visitors criticised the display. "Separating the motive power from the tool," they said "is like divorcing the breath of life from the body." The exigencies of the case were such, however, that it would have been impracticable to furnish steam throughout the grounds, and it was properly confined in its uses to the Machinery Hall. Upon electricity therefore devolved the duty of transmitting power to the various buildings where it was to be used, and how well it performed the task there are millions who can attest.



The fact that in some cases the energy thus transmitted had to undergo several transformations to adapt it to the desired use was a source of annoyance and expense which some exhibitors were unwilling to bear. The excessive demand for current which could be met by the supply only in part, and sometimes only at exorbitant charges for wiring and service, furnished a cause for many more idle wheels, but when it has been stated that all the machinery in motion at the Fair outside of Machinery Hall, as well as some of that within, was moved through the agency of electricity, enough has been said to indicate in a general way the extent to which it was thus used. Two exceptions must be made, however, to the statement regarding power outside of Machinery Hall: the power-house of the Intramural railway had its own boiler and engine-plant, and a portion of the power in the Mining building was furnished direct by steam.

Exactly how much energy was transmitted electrically for power purposes it is impossible to tell, but as a basis for an estimate it may be mentioned that in the great power-plant in Machinery Hall the generators catalogued on page 332 were employed for power purposes alone:



INTRAMURAL RAILWAY POWER-PLANT AT THE WORLD'S FAIR.

Makers.	No. of Generators.	Kilowatts.	Voltage.	Total Kilowatts.
Exposition :

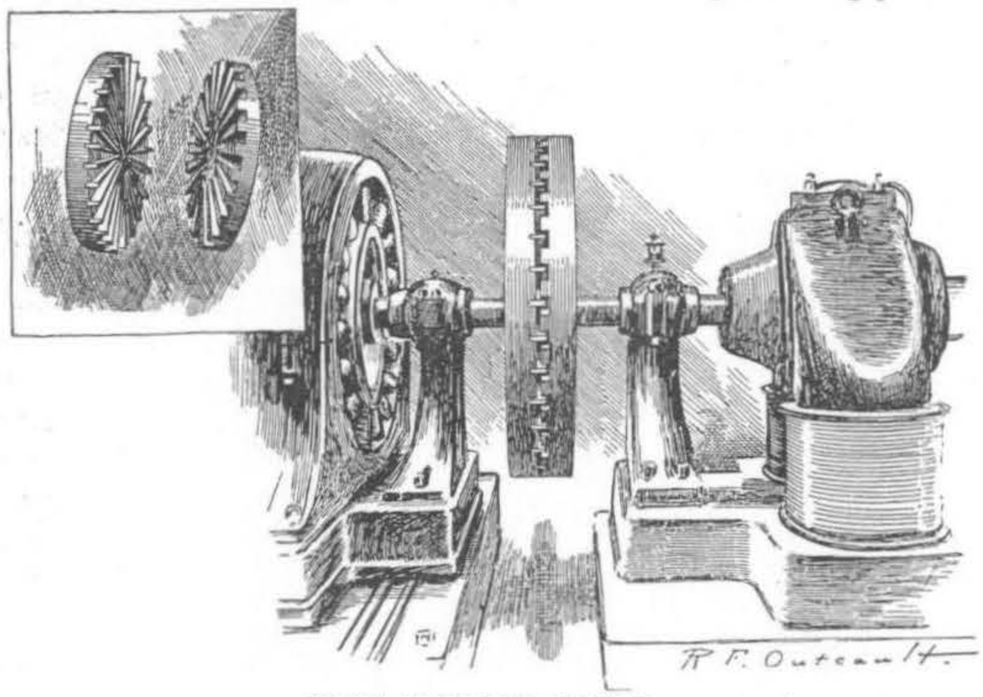
Grand total, kilowatts				6,504

TESLA TWO-PHASE MOTOR AND MOTOR TRANSFORMER.

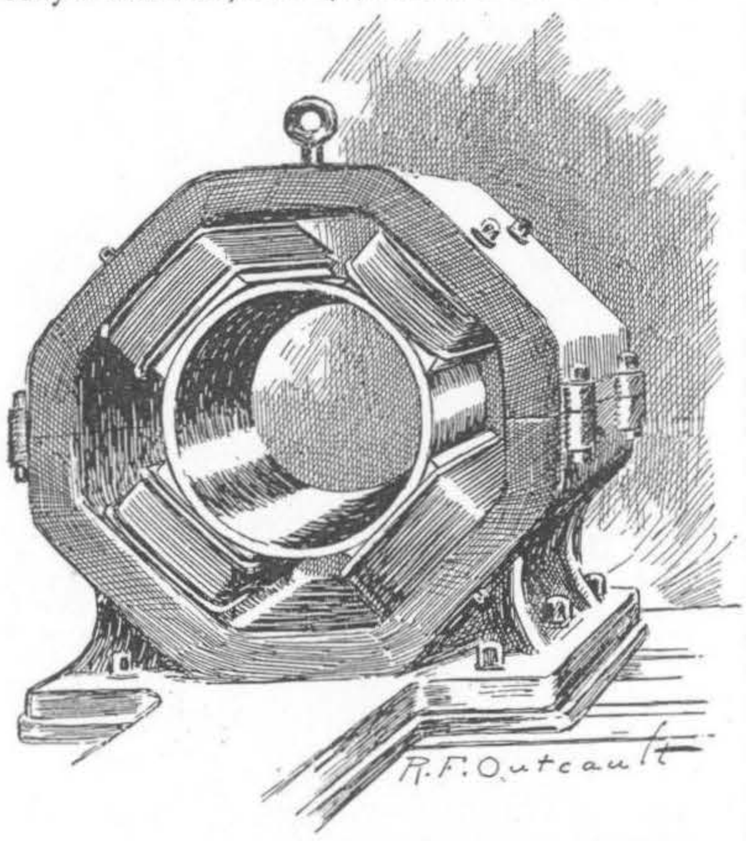


To this may properly be added the power generated more especially for lighting purposes, but which was employed in part by exhibitors or concessionaires for other purposes, and here is where the figures may become uncertain. As an illustration may be cited the four 150-kilowatt Edison generators primarily intended to supply current to the electrical fountains, but which after 10 o'clock at night were employed to charge the storage-batteries in the electric launches. There were fifty-eight of these launches, each equipped with a 4-horse-power motor. The Westinghouse com-

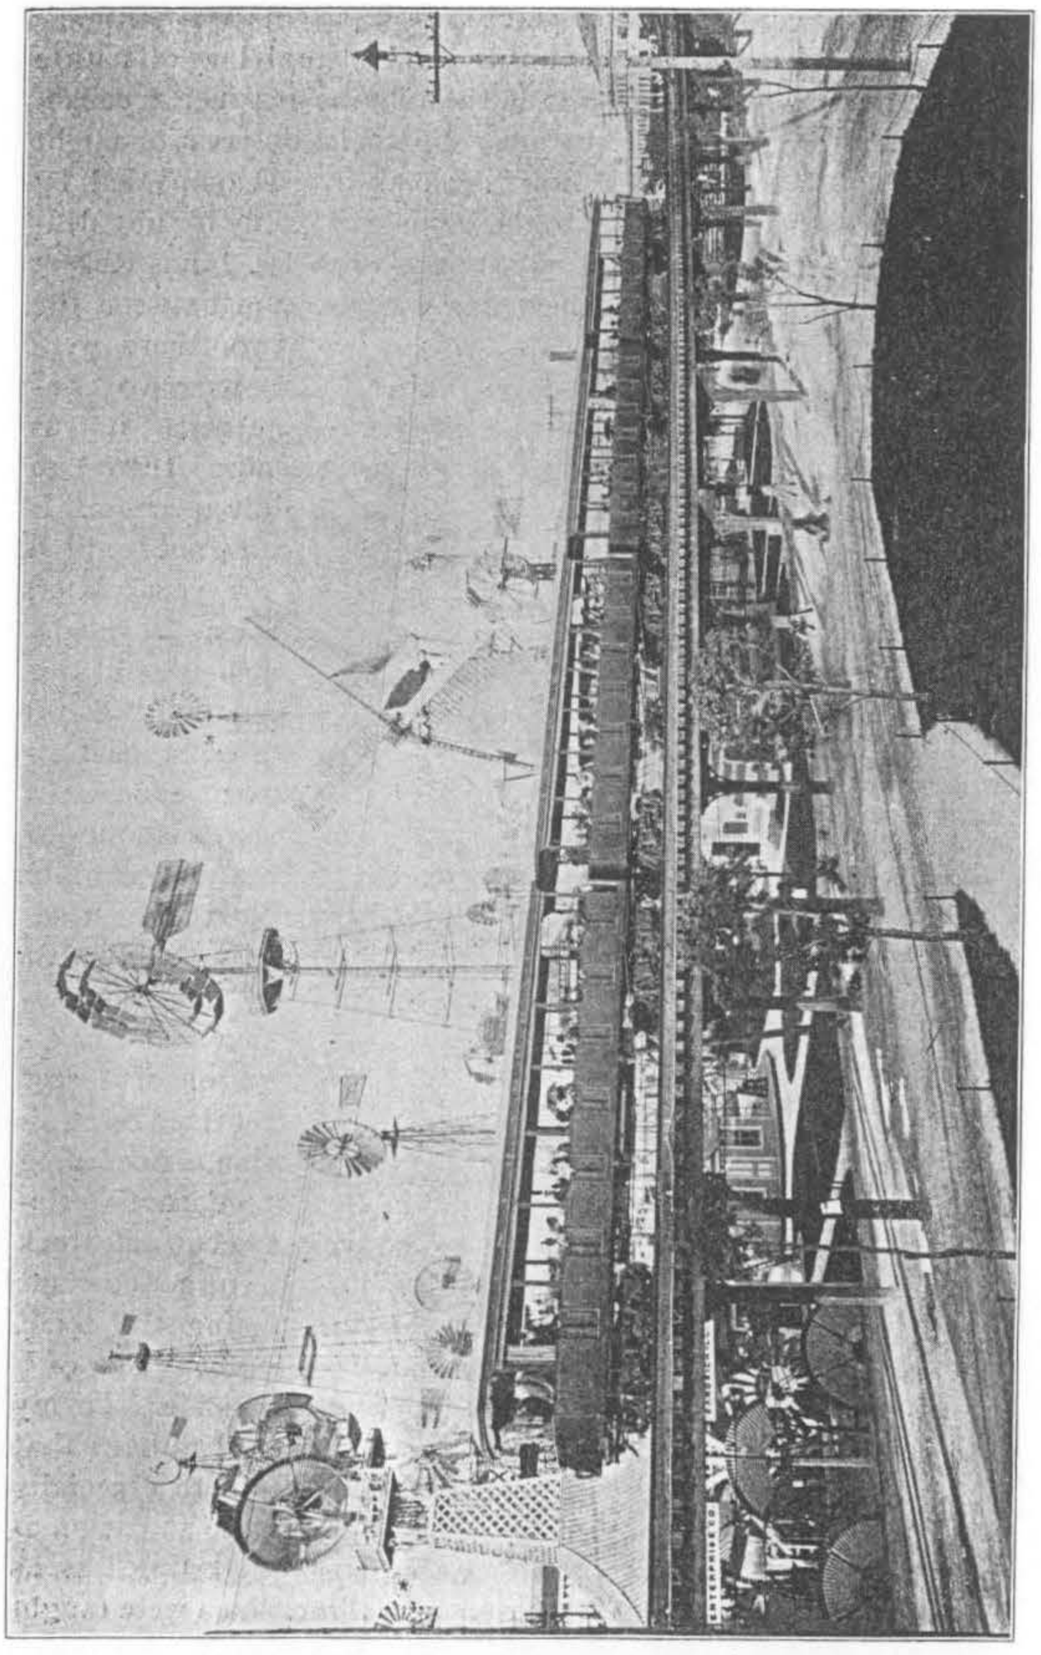
THREE-PHASE POWER-TRANSMISSION PLANT OF THE GENERAL ELECTRIC COMPANY.

pany used two of their single-phase lighting circuits to supply current to their polyphase power-plant, the central figure of their display in Electricity building, and other lighting as well as power currents were transformed by other exhibitors for power purposes, so that the actual horse-power of motors in operation at the Fair was considerably in excess of that indicated by the table. Certainly the rated capacity of electric machinery actually doing work at the Fair did not fall far short of 9000 horse-power, and the work performed embraced almost every variety known to the arts.

Owing to the fact that no steam was permitted in the Electricity building, all generators there shown in operation were driven by electric motors deriving current from the main generating plant in



CLUTCH, OR COUPLING, IN DETAIL.



Machinery Hall, and these generators, in order to give them a load, not infrequently supplied current to other motors, besides furnishing the individual lighting supply of the various exhibitors. In this way such an exhibit became a subordinate central-station, itself operated by electricity, and which, in the cases of the Western Electric Co. and the Fort Wayne Electric Co., supplied current for power and light at a stipulated rate to other exhibitors. All of the direct-current incandescent lighting in Electricity building, as well as a considerable portion of the alternating-current incandescent and direct-current arc-lighting of individual exhibitors, was thus provided, constituting this by long odds the most extensive

illustration on a practical commercial scale of the principle of the correlation and conservation of energy.

It seems a little strange that this fundamental law of nature should have been first discovered in the relation between mechanical work and heat, for while the most superficial observation might have taught that mechanical work was always accompanied by heat, it was not so apparent that there could possibly be any definite relation between the two. Therefore when Dr. Julius Robert Mayer asserted, in 1842, that there was a connection between the two, there were few who regarded it as more than an idle assertion. It was not until a few years later, when Joule demonstrated this relation, and still later, when Carnot enunciated the principle of the reversibility of the heat engine, that the law of the correlation and conservation of forces received recognition. According to Carnot's principle, it was theoretically possible to convert mechanical work into heat and by utilizing that resulting heat perform the same amount of mechanical work again, thus completing the cycle. This having become an accepted dogma, it was not much of a step to conceive that other cycles might be possible. To my mind the greatest object lesson of modern times has been that furnished by the facility with which electricity—more especially in the form of alternating currents—lends itself to the extension of the radius of cyclic changes. To me the most interesting lessons of the World's Columbian Exposition were those which were taught by the exhibits showing a few of the possibilities in this line.

FIELD-MAGNETS WITH POLAR RING, IN THE GERMAN EXHIBIT.

A VIEW OF THE INTRAMURAL ELECTRIC RAILWAY.

When, in 1891, the experiment was tried of transmitting power derived from the falls of the Neckar to Frankfort by electrical means, crowds flocked to see the falls pumping water after their energy had passed through a cycle of six changes. To be sure, the problems of chief interest to engineers were those of insulation against high pressures and the practicability of the three-phased current in power transmissions, then first prominently brought forward, but the principle upon which these problems ultimately depended was that first enunciated by Joule and Carnot.

It will be remembered that in the Lauffen-Frankfort experiment some 300 horse-power were transmitted a distance of 108 miles at 30,000 volts with an efficiency in transmission of about 70 per cent. and utilized at the Frankfort exhibition in part in lighting a bank of lights and in pumping water for an artificial waterfall. This experiment was epoch-making and has lent an unusual interest to the methods there employed. One of the most interesting power exhibits at Chicago, therefore, was that of the Allgemeine Electricitäts-Gesellschaft, the company which built and installed the transmission plant above referred to. In this exhibit were shown all the parts involved in the experiment, including the three-phased generator, step-up and step-down transformers, and three-phased motors. The machines shown were not exact duplicates of those originally employed, but embraced such improvements as later experience had suggested.

The foreign displays of electrical apparatus were looked forward to by American electricians with the keenest interest, as it was hoped that they would abundantly illustrate electrical practice, so far as it might be said to be typical, of competing companies abroad, in order that a comparison might be drawn between their machinery and our own. These anticipations, so far as generators and motors were concerned, were only fulfilled partially by Germany alone. England showed absolutely nothing, and France only a few generators, alternating current and direct, which performed no functions of a useful or instructive nature.

The two great houses of Germany—Siemens & Halske and the Algemeine Electricitäts-Gesellschaft—had interesting though small displays. The latter was especially interesting, not only for the reason already assigned, but because it contained several features entirely new to this country. One of these novelties was the adoption of what has been termed the "polar ring" for the fields of direct-current motors and generators. This consists of a cylinder

of soft iron about an inch thick, enveloping the armature and connecting the pole-pieces of the field magnets. This was claimed to have advantages in prevention of sparking, for which purpose it was employed, which more than compensated for the magnetic short-circuiting which it must inevitably have produced.

This polar ring is strongly advocated by Dobrowolski, to whom I believe it is due, but it requires great effort on our part to believe the remedy is not worse than the disease. Certain types of field magnets have heretofore been so universally condemned by electricians simply because their shape has been such as to conduce to magnetic leakage that they have almost, if not quite, disappeared from the market. A deliberate short-circuiting of the magnetic field such as was illustrated in these machines was therefore astonishing, especially in view of the fact that sparking has been remedied in what would seem to be more rational and more economical ways. But *any* remedy is expensive that does not alleviate the disease, if one has to pay for the prescription, and I believe this is an expensive remedy, both because we pay for it in the lines of force short-circuited through the polar ring and because these machines *do* spark quite as much as well-constructed machines not employing the polar ring.

Another novelty in this exhibit which had real merit was the flexible coupling for directly connecting two shafts in approximate alignment, which consisted of two heavy iron disks, upon the face of one of which were a series of radial slots and upon the face of the other a similar series of brush-like rays of a number of thicknesses of thin sheet-iron, so arranged as to take into the slots on the opposite disk. Considerable play is allowed, permitting the two disks to gear easily, even if their shafts be perceptibly out of alignment, and the flexibility of the brushes is such as to take up the sudden strains, if moderate, or to permit them to slip a cog or two if excessive.

Siemens & Halske also showed three-phase motors and transformers. Of the latter there were two of 50,000 watts capacity each. In these air alone was used as insulation.

Until recently it has been urged by some practical men as an argument against the adoption of electricity in their business that, although it might accomplish some things better than agencies already in use, it was not sufficiently elastic to accomplish *all*, and that its adoption only meant an additional plant capable of doing one or two things a little better than existing plants, making of

electricity a luxury. This was undoubtedly true, and in no direction more so than in the field of mining. For this reason the application of electricity in mining has not kept pace with its applications in other industries.

The two largest electrical companies of America made displays side by side which must forever remove from the popular mind all idea of the lack of flexibility of electricity. The electrical exhibit at the World's Fair would have been a marked success had nothing else been shown than what were called "the transmission of power" schemes of the General Electric Company and of the Westinghouse Electric and Manufacturing Company. These two rivals presented each its own choice of methods—both well known to the electrical fraternity in each of their several parts, but neither of them ever before so completely illustrated on a working commercial scale. Additional significance was given to these two displays because it was generally believed that they represented between them, in all essentials, the system that would be employed in the Niagara Falls transmission-plant.

The General Electric Company followed the lines of the Frankfort-Lauffen experiment in so far as it employed the three-phase system, while the Westinghouse company employed the two-phase or Tesla system, but in each the most prominent feature was the flexibility of the system in hand. Each of these displays will be best illustrated by following the current from its point of entrance to the exhibit through its various transformations and translating devices which were selected so as to illustrate how, from a single source, energy could be transmitted and distributed on a large commercial scale for almost every conceivable practical use. Both of these exhibits assumed a waterfall as the source of energy, but they obtained their water-power in different ways. The General Electric Company employed a deep-mine triplex pump capable of raising water against a head of 650 feet, to furnish the water-power. This was operated by a 100 horse-power 220-volt direct-current motor, receiving current from Machinery Hall by the Edison three-wire system. The water from the pump was directed against the buckets of a Pelton water-wheel, which was directly connected with a 35-kilowatt three-phase generator, whence the currents passed to step-up transformers having a ratio of 20 to 1. They were thence transmitted at the higher potential on three No. 18 wires a short distance to what was called the Mining exhibit. Here they were transformed down again to 110 volts and carried to a

distributing switchboard whence lighting- and motor-circuits radiated. On one of the former a bank of incandescent lamps constituted the load ; on another, arc-lamps, and on a third, a series of small three-phased motors were operated, thus repeating all the links in the chain which bound Lauffen and Frankfort in the memorable experiments of 1891. The extreme potentials, long distance, and volume of power, however, were lacking.

The General Electric Company also showed both here and on the battle ship *Illinois* motor-transformers, the latter being fed from the Intramural railway trolley-wire, transforming the 500-volt current down to one of 80 volts. The secondary armature of this was compounded for the usual percentage of loss. As the current was to be used for lighting purposes, which required that its voltage be maintained constant between very narrow limits, it became a very pretty problem to compensate for the wide fluctuation in the primary. This was partially accomplished by commutating the field windings on the motor and further by inserting in parallel with the shunt winding of the generator a storage-battery which absorbed energy when the E. M. F. was too high, and gave it out when it was below normal.

The Westinghouse transmission-plant received its energy from two alternating currents in quadrature, derived from the two armatures of one of their 750-kilowatt generators in Machinery Hall. These currents at 2000 volts and 7200 alternations were transformed down to 200 volts in the building and then led to a 500-horse-power two-phase Tesla alternating current motor. Upon the same shaft, to simulate a prime mover, was a Pelton water-wheel, but this was merely a dummy operated by, instead of driving the motor. This latter, however, drove a 500-horse-power alternating-current generator. On one side of this generator, from four collecting rings, there were taken two alternating currents in quadrature with each other of about 4000 alternations and at a potential of 360 volts. On the other side was a direct-current commutator connected with the same winding, from which could be delivered a direct current at 500 volts. All three of these circuits were led to appropriate terminals on a switchboard for the distribution and control of their currents. By the alternating currents there was operated a 500-horse-power two-phase Tesla motor similar to the generator just described. This was also connected as a rotary transformer.

By means of special field connections this could be started as a

two-phase motor, and after it had gained its speed, by means of a switch, changed over to a self-exciting synchronous motor. As a motor it was employed to drive a Worthington pump and a 40-light Westinghouse alternating-current arc-light dynamo, and as a direct-current generator it furnished current at 500 volts to two 30-horse-power street-railway motors, to a 60-horse-power motor driving an Ingersoll-Sargeant air-compressor, and to a series of constant potential arc-lamps.

Another circuit from the switchboard was connected to a 60-horse-power two-phase motor and transformer, which, receiving alternating current at 360 volts, delivered a direct current at 50 volts, which was used in operating a large Shuckert search-light and which was suitable for electrolytic and other work. Still another circuit from the switchboard supplied current to a 60-horse-power two-phase Tesla motor of the synchronous type directly connected to a 45-kilowatt constant-potential alternator employed for incandescent lighting, and another circuit furnished current without further transformation to incandescent lamps. All of the transformations and all of the uses indicated in the above-mentioned applications were at different times, and when not incompatible with one another, simultaneously exhibited, and, being in every case on a commercial scale, constituted the crowning triumph of the electrical display. It was an object-lesson which must have satisfied those who had questioned the flexibility of the electrical method of transmission of power and transformation of energy. It was a realization of the theory of the correlation of forces such as neither Mayer nor Joule could have dreamed of when they first announced it.

But perhaps the part which electricity played in the transportation problem at the World's Fair came more nearly home to the masses. Within the enclosure there were three principal means of conveyance, viz. : the electric launches on the lagoons, the Intramural electric railway, extending around something more than three sides of the grounds, and the movable sidewalk, extending along the steamboat pier from the Casino to the further end. Subsidiary means of transportation were furnished by the three large traveling cranes, of 20 tons capacity each, in Machinery Hall, which ran the whole length of the building, and which, after having done duty in installing the heavy machinery, were pressed into service to give visitors a bird's-eye view of the great mechanical exhibit, the numerous elevators in the several buildings, and the

roller-chairs. All of these, except the last, were electrically propelled, and in the aggregate carried many millions of passengers.

The movable sidewalk was interesting as pointing a wide departure from established methods in transporting passengers. In this, a continuously moving carrying platform, supported upon and propelled by the periphery of the wheels of the trucks and therefore having double the speed of the latter, receives and discharges passengers while in motion by means of an intermediate slowly moving platform supported upon the axles of the trucks running upon an endless track. The relative speeds of the faster and slower platforms and the absolute speed of the latter are such as to render passage from one to the other, while motion is maintained, safe even for women and children. Since both platforms are continuous and run in closed paths, there is as much up hill as down hill and the path is therefore reduced to a plane. Since there is neither starting nor stopping, the element of the overcoming of inertia is likewise eliminated, and on theoretical grounds, at least, ideal economies should be maintained. Just what the economy was in this case can only be told when the final figures are published, but it will undoubtedly be large. In some careful experiments made by Frank J. Sprague some years ago on the Third-avenue Elevated railroad in New York, it was found that 83 per cent. of all the power utilized was consumed in overcoming gravity and the inertia of trains and that but 17 per cent. was required to maintain them in motion. It may be mentioned that the movable sidewalk was the most formidable competitor for the franchise which was finally granted to the Intramural railway, and that it has been seriously proposed as a solution of the congested transportation facilities in New York city, but it would appear to be of questionable availability for the latter purpose. The electric launches were a success financially, electrically, and popularly,—upon this all are agreed.*

Although the route pursued by the electric launches was almost an ideal one, bringing into direct communication with one another all the principal points of interest within the grounds, it was not used as a *convenience* by the masses, because of the exorbitant fares charged which made the use of the launches a luxury. In strong contrast with the launch route was that followed by the line of the Intramural railway. This led *from* nowhere *to* nowhere, and al-

* Some figures presented in the Department of "Electricity" this month give an idea of the work performed by these launches and of the cost.—THE EDITOR.

though the charges were fairly reasonable, no one thought of patronizing its cars for convenience. The concessionaries, however, were not responsible for the bad location, as they were obliged to content themselves with what they could get. That it carried without serious hitch or accident nearly six million passengers during the term of the Fair speaks volumes for the success of the experiment.

The General Electric Company, who under the name of the Western Dummy Company were the successful competitors for the franchise, have in the Intramural railway apparently solved in a satisfactory manner one of the burning questions of the day, viz.: electrical traction for elevated lines and others having their own right of way. Whether or not all of the technical and financial details have been satisfactorily solved, no one but the General Electric Company yet knows, but the public were satisfied with the service which was maintained without interruption, and this must be counted a long step in its favor.

From one point of view, the Intramural railway experiment is the most important that has ever been tried in the practical application of electricity. It has demonstrated to the public the entire practicability (from their point of view) of the application of electricity in large units to the traction problem. It has furnished to its projectors the first authentic data upon which to base future estimates, and if mistakes have been made it will enable them to correct them in future installations. In brief the system employed was as follows: Trains were made up of three trail cars and a motor car upon which latter were placed four motors—one to each axle. The method of control was what is known as the "series parallel," by which the four motors, each of 133 horse-power capacity, are thrown at starting in series of four, followed by a parallel arrangement of two in series and finally of all four in parallel. By this arrangement the required maximum torque at starting is obtained with a minimum flow of current and a more uniform consumption is maintained at all speeds. The current is carried to the motors by means of two overrunning trolley shoes running upon a third or trolley rail to one side of the track and is returned to the generator by means of the track and the iron girders of the elevated structure. A fourth rail, extending about three-fifths of the length of the structure and connected at frequent intervals with the trolley rail, does service as a feeder. The actual length of the road is 14,800 feet of double track and 1900 feet of single track, and in this dis-

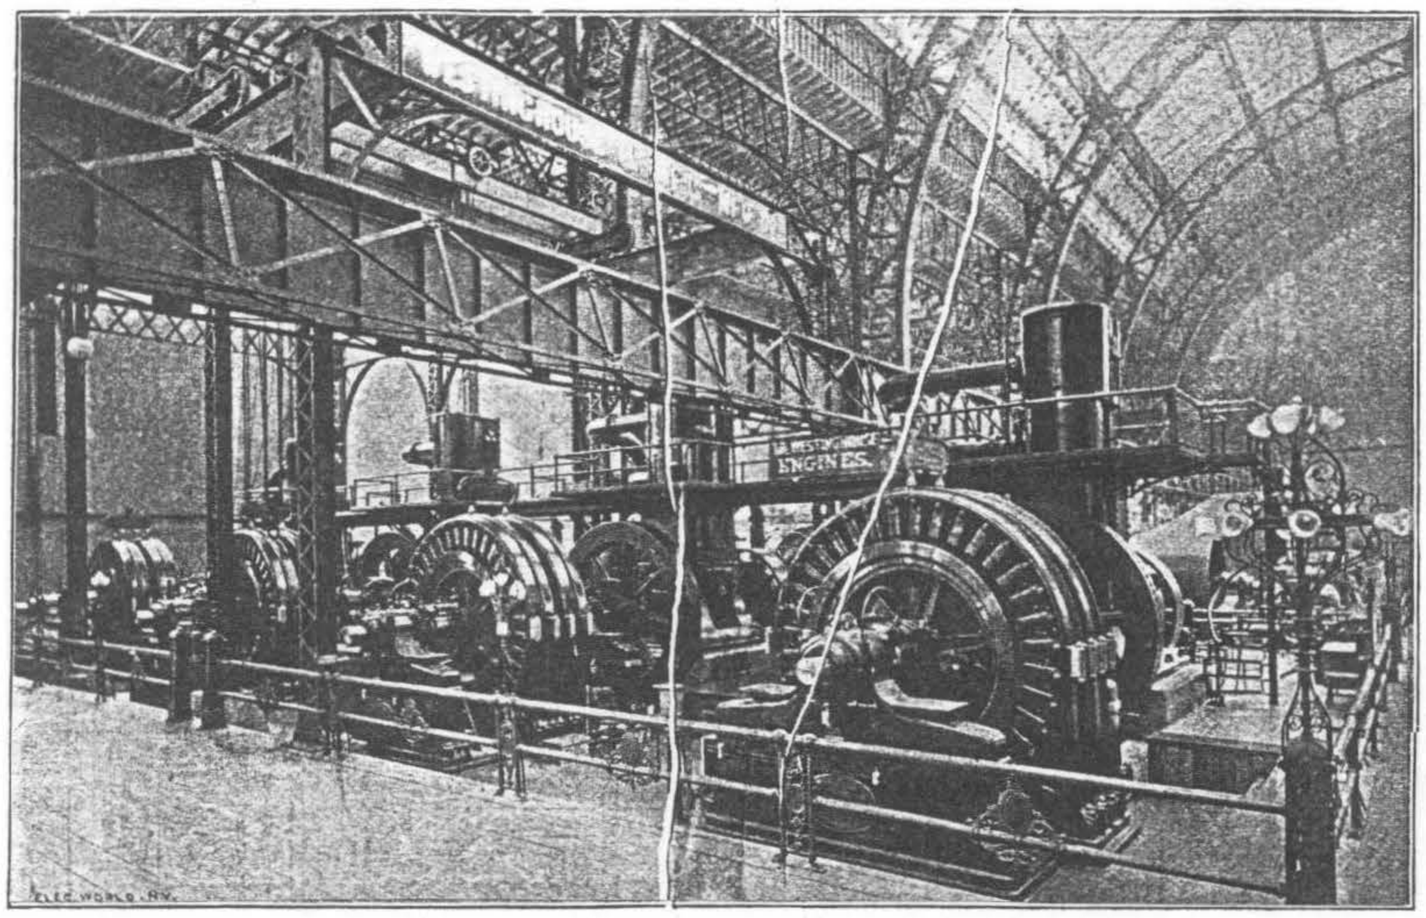
tance grades of from 0.42 per cent. to 2 per cent. are encountered and numerous curves down to 100 feet radius.

All of the cars are 50 feet in' length and weigh, the trailers 20 tons and the motor cars 30 tons, when filled with passengers. Thus it will be seen that the conditions met with in the elevated roads of New York and elsewhere were in all points fairly duplicated. The maximum number of trains in service was fifteen, and these were run at a five minutes headway.

The Intramural power-plant, which comprised by far the largest part of the generating apparatus intended for power purposes at the Fair, did double duty. First it served as an exhibit for the General Electric Company of their largest sized railway and power generators and the various methods in vogue of hanging the armature and of driving it. There were in all five enormous generators shown—one 500 kilowatts four pole generator, driven by belt, and one 250 kilowatts, six pole, one 400 kilowatts, twelve pole, one 750 kilowatts, twelve pole, and one 1500 kilowatts, 12-pole generator —all directly connected to various makes of engines. The last is the largest dynamo thus far constructed, but so rapidly are large units growing in favor that there are already several others exceeding this in output either under way or contracted for. The capacity of this plant was of course far in excess of the demands made upon it by the Intramural railway, so that the various generators took turn either singly or in multiple in supplying these wants.

The enormous outlay required for this magnificent exhibit precludes the possibility of its having made in dollars and cents an adequate return to the exhibitors. They evidently relied for reimbursement upon the experience and prestige it would give them in this hitherto practically untouched field of electric traction, and the renewed consideration which electricity is receiving in our larger centers of population on urban elevated and interurban routes gives promise that their confidence was not misplaced. For obvious reasons the General Electric Company have declined to make public the technical results of the experiment, but however much this may be regretted from a professional point of view, there are few who in their hearts will blame them.

Engineering Magazine December 1893



ELECTRICITY

Conducted by Franklin L. Pope.

A LARGE contract for electrical machinery for the Niagara plant has been awarded to the Westinghouse Company, of Pittsburgh. The system which has been adopted is known as the Tesla polyphase. The present contract calls for three 5000-horse-power generators, with a corresponding equipment of motors, switches, etc. The rotating fields are carried on the upper ends of vertical shafts, and are thus coupled direct to the turbines. The upward pressure of the water supports the entire weight of the turbines, shafts, and rotating parts of the generators, thus doing away with nearly all the step-friction. The electromotive force of the dynamos will be from 2000 to 2400 volts, which will be raised and lowered by transformers at different points as required. The system adopted would seem to provide for every possible requirement of an electric service, either in the way of illumination or power.

Among the many and varied scenic effects produced at the World's Columbian Exposition there was probably none which more impressed the observer or was more universally admired than the Court of Honor electrically lighted The lagoons fringed with innumerable lights. the buildings with their cornices aglow and, most picturesque, the great dome of the Administration Building outlined by incandescent lamps, all combined to produce a picture which has probably never been equaled, and which cannot be reproduced in either its novelty or uniqueness.

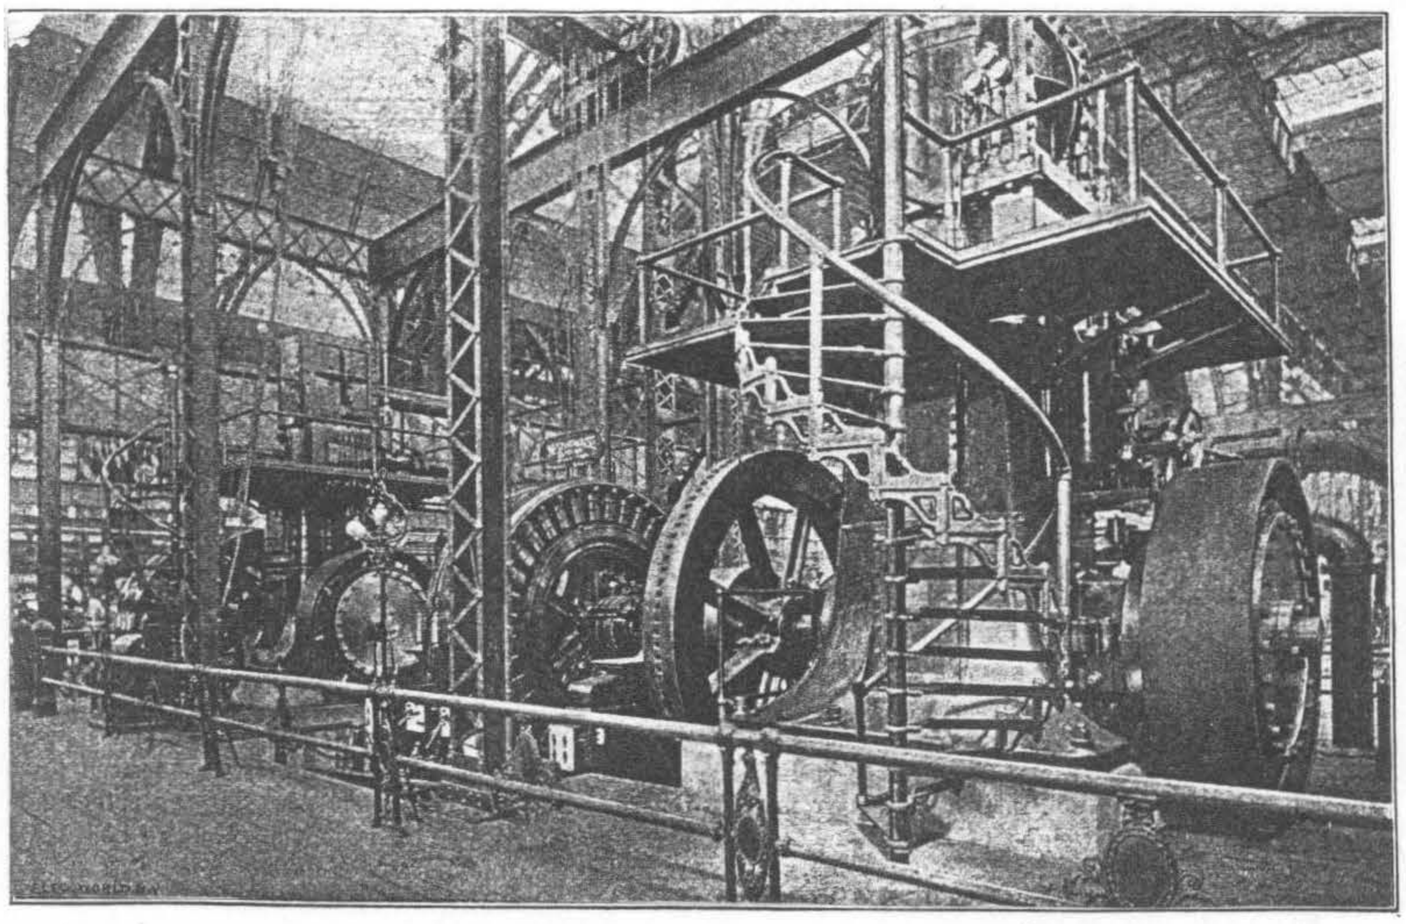
AN INTERESTING SECTION OF MACHINERY HALL.

It will probably be remembered that when the contract for lighting the World's Fair was awarded to the Westinghouse Electric and Manufacturing Company, its competitors were very pronounced in the expression of their opinion as to the ability of the Westinghouse company to carry out its contract, especially in the face of the decision of the long contested lamp suit which was rendered about that time. The successful performance of the contract, and the artistic illumination of the Court of Honor, as well as the incandescent lighting of the grounds and buildings of the Exposition, have been so satisfactorily carried out that an illustration and description, not only of the machinery and apparatus of the great plant furnishing the light, but also of the instructive electric exhibits made by the Westinghouse Electric and Manufacturing Company, have been deemed of interest.

To carry out the contract which had been secured only after long continued and keen competition, the Westinghouse company installed in Machinery Hall a complete alternating current central station equipment. This station was by far the largest plant in existence, and illustrated on a very large scale the high degree of excellence to which alternating current machinery, adapted to power purposes as well as to arc and incandescent lighting, has been brought by this company. The plant was located adjacent to the south wall of Machinery Hall and about the centre of the building, occupying a space of some 31,000 square feet. The general arrangement of the apparatus is shown in the accompanying ground plan illustration.

The installation comprised the following apparatus: Two 750-kw. two phase alternators, belt driven by a 3,000-h. p. quadruple expansion engine built by the E. P. Allis Company, Milwaukee, Wis.; one 750-kw. two-phase alternator, belt driven by a 1,000-h. p Fraser & Chalmers engine of the Corliss type; one 750-kw. two-phase alternator, belt driven by a 1,000 h. p. McIntosh & Seymour engine; one 750-kw. two-phase alternator, belt driven by a 1,000-h. p. Buckeye engine; one 750-kw. two-phase alternator, belt driven by a 1,000-h. p. Atlas engine; six 750-kw. two-phase alternators, each driven direct by a 1,000-h. p. Westinghouse Columbian steeple engine; two 240-kw. single-phase alternators, each belt driven by a 350-h. p. Westinghouse compound engine; three 75-kw. exciters each driven direct by a Westinghouse 100-h. p. comound engine; a complete marble switchboard for 12 two-phase alternators, 2 single-phase alternators, 4 exciters and 40 circuits.

The total output of the plant was 9,480 kw. The records of readings of the current and potential, which were taken at the switchboard every half hour from the time the Exposition was thrown open to the public, showed that about 55 watts at the generator terminals were required for each 16-c. p lamp connected to the circuit. The station, therefore, was capable of simultaneously supplying about 172,000 16-c. p. lamps.



The accompanying plan indicates the location of each engine, alternator, exciter and the switchboard. Alternators numbered 1, 2, 6, 7, 8 and 9 were direct driven by Westinghouse engines. Nos. 3, 4, 5 and 10 were respectively belt driven by Buckeye, Atlas Corliss, McIntosh & Seymour, and Fraser & Chalmers engines, while machines numbered 11 and 12 were driven by tandem belts from the 3,000-h. p. engine of the E. P. Allis Company. Alternators numbered 13 and 14 were 240-kw., high speed, standard single-phase machines, belt driven by Westinghouse engines. The Kodak exciters, direct coupled to 100-h. p. Westinghouse engines, are shown at *A*, *B* and *C*, while the plan view of the feeder and dynamo switchboard will be noted in the space adjacent to the Fraser & Chalmers engine and alternator No. 10. All of the engines and dynamos were erected upon massive foundations, installed under the supervision of the mechanical engineers of the Exposition. In the case of alternators Nos. 6, 7, 8 and 9, with their engines, a single concrete foundation was used.

The plant illustrated on a very large scale the methods of driving by direct coupling of engine shaft to the dynamo shaft, and by the use of belting. The two alternators belted to the large Allis engine—the engine started by President Cleveland when he opened the Exposition—were tandem driven by belts 72 inches in width; the distance from the centre of the engine shaft to the centre of the shaft of its nearest dynamo was 47 feet; that to the centre of the more distant dynamo, 65 feet. To foreign engineers, who are unaccustomed to our high grade belting, these large and fine quality belts, furnished by the Page Belting Company, of Concord, N. H., proved to be an extremely interesting feature of the installation.

The advantage of the direct connected over a belt driven machine, as regards the saving in floor space, is well illustrated by a comparison of the space occupied by one of the 1,000-h. p. "engine-dynamos," as they are called, consisting of a 1,000-h. p. Westinghouse Columbian steeple engine and a 750-kw. alternator, with that occupied by belted engines and alternators. The outside measurement of the direct connected unit was 31 feet 8½ inches by 13 feet. The space occupied by the smallest belt connected engine and alternator was greatly in excess of this, being about 65 feet by 27 feet.

THE DYNAMOS.

Each alternator, electrically considered, is a double machine which delivers to its circuits two-phase currents, the difference between the phases being almost exactly 90 degrees. The frequency is 60 periods per second, or 7,200 alternations per minute, and the potential at the terminals of the machine varies from 2,000 volts to about 2,300 volts, depending upon the load, drop in primary circuits and transformers, secondary wire, and upon the potential required by the lamps. The speeds of the alternators, both belt driven and direct connected, are 200 revolutions per minute. Each machine has two armatures which are mounted upon the same shaft and are magnetized by two fields electrically and mechanically independent of each other,

LARGE DIRECT CONNECTED ENGINES AND DYNAMOS.

This construction is shown in the double page illustration, in the centre of which a direct connected alternator and Westinghouse engine will be noticed, while the belt driven machine is illustrated at the top.

The fields are of the circular or ring type, having 36 inwardly projecting poles built up of mild steel, laminated, and cast solid into the yoke. Lathe-wound coils are slipped upon the poles and securely fastened in position by bolts. The armatures are of the toothed type, generally employed by the Westinghouse company for alternating current work. The armature coils are lathe-wound and any one of them may be readily removed and replaced without disturbing the other coils upon the same armature. Each armature has 36 teeth, to correspond with the same number of poles on each field. The armature shafts are of forged steel, in self-aligning ball bearings, equipped with automatic oilers. The armature shaft carries at each end, between the armatures and bearings, two ring collectors which serve to receive the alternating current from each armature. The shaft also carries two commutators from which a rectified current is conveyed to the auxiliary winding of the field coils. The excitation of the field is chiefly derived from separate exciters, hereinafter described, but the auxiliary excitation is employed to secure automatic increase of the magnetic field proportioned to the reaction due to the currents flowing in the armature.

The current for the auxiliary excitation is derived from small transformers carried in the spider of the armature. The main current of the armature traverses the primary of the transformers, while the secondary current of the transformers is rectified by the commutators. In this manner the automatic compounding of the field is attained without the introduction of high potential current into the field coils.

In the belt driven machines provision was made for adjustment of the belt by sliding the machine as a whole upon foundation rails. The connection between the Westinghouse engines and their alternators was made by a rigid coupling. The size of the alternators is well shown in the illustrations; they stood 15 feet 1 inch in height from the top to the foundation. The weight of a machine of the belt driven type was a little over 140,000 pounds, while that of a direct connected alternator was 106,000 pounds.

THE EXCITERS.

Current for exciting the fields of the alternators was obtained from three 75-kw. continuous current machines, of multipolar type, direct driven by Westinghouse automatic engines. These exciters made 300 revolutions per minute, and delivered current at 250 volts. Two of them furnished current to excite 10 alternators, and the third was held in reserve. At the close of the Exposition, one of these machines had been running continuously for about three months, and in that time made over 37,000,000 revolutions.

THE SWITCHBOARD.

A switchboard was erected upon a double gallery against the south wall of Machinery Hall. This board has been fully described in THE ELECTRICAL WORLD of May 20, 1893, but a general résumé will not be out of place here. The floor of the first gallery was about 10 feet above the level of the space occupied by the engines and alternators, while the floor of the second gallery was 8 feet higher. The board was made up of marble panels, which were supported by an iron framework, consisting of angle iron supported upon floor beams of the galleries, and securely braced. The uniform width of all panels was 20 inches. The panels, most of which, themselves, constituted the bases upon which the instruments were mounted, extended into the framework of angle iron and were secured by bolts and vertical metal strips. These nickel plated strips were of semi-circular section, and extended from the floor line to the top of each board, covering the abutting edges of the marble panels, and assisting to hold the panels in position. A narrow frieze of marble was carried along the top of each board, and a vertical strip 5 inches wide at each end served as a decorative finish.

The board on the lower gallery was the dynamo and exciter board; that on the upper gallery was the supply circuit or feeder board. The circuits from the alternators were carried to the lower board through lead covered cables, and thence through switching devices to the upper board. Instruments for measuring the current and potential of each set of the two-phase alternators and of the two single-phase machines were provided on 13 panels, one panel being allotted to each of the 12 double machines, and the thirteenth panel being provided for the two single-phase machines. Provision was made for quickly substituting a relay or reserve dynamo for any one of those in operation. Two-way switches were used for each dynamo circuit, and the terminals at one end of these switches were always kept charged by the reserve alternator, so that by simply throwing the switch of the machine which was in difficulty, or which for any reason it was desired to shut down, the load was easily and instantly transferred from any alternator to the reserve machine. The board was so arranged as to make it impossible for a careless attendant to accidentally throw two alternators together. Multiple arcing the machines was considered inadvisable, and the board was so designed as to make this practically impossible. Four panels were provided in the lower board for exciters and the fifth for instruments measuring the combined output of the exciters when in multiple. One of these panels was not in use, as three exciters proved ample for the number of machines required.

The upper board comprised 40 panels and provided for a like number of supply circuits. Each panel contained a switchboard converter, a compensator, voltmeter, ammeter, Stillwell regulator, switch, fuses and plug receptacles for the connection of the supply circuit to any of the 14 alternators. Each circuit was protected from lightning by the Wurts non-arcing arrester.

The specifications under which the contract was awarded made it necessary to provide for supplying any circuit from any alternator, and inasmuch as the two-phase type of dynamo was selected, it became necessary to design a board which would permit any one of several hundred combinations to be made. The generating plant was equivalent to 26 single-phase machines, and provision was made for supplying each of the 40 distributing circuits from any one of these 26 sources; at the same time the arrangement was such that mistakes were impossible and the wiring of the board symmetrical and comparatively simple.

The panels were each lighted by etched lamps suspended from goosenecks from the top of the board, and in addition to these, four highly ornamental arc lamps, of the constant potential, alternating current type, were hung from arching wrought iron posts at the ends of the boards. Access to the lower board was secured by an artistic spiral stairway of iron. The upper platform was reached by means of two stairways from the lower gallery. Handsome ornamental railing of wrought iron inclosed the front and ends of both galleries.

The operation of this board proved satisfactory in the highest degree. The distributing circuits throughout the grounds of the Exposition were limited to 200 kw. each, and it is worthy of note that a board capable of distributing five or even ten times as much energy—that is to say 40,000 or 80,000 kw.—embodying the sectional features of this board, can be constructed to occupy practically the same space. This board, which was probably the largest ever constructed, measured in the upper gallery 71 feet in length and 9 feet 6½ inches in height. The lower part was 32 feet 6 inches long, and 11 feet 3½ inches high. The claims made by the Westinghouse company for this most interesting piece of electrical apparatus are as follows: 1. Safety against fire risk, being built entirely of non-combustible material. 2. Safety as against possible injury to attendants, as no high tension circuit or terminal is exposed on the front of the board, hence contact with dangerous circuits is impossible. 3. Safety as against accidental connection of two alternators, secured by the arrangement of the board itself. 4. Flexibility, in that any machine can be made to supply any circuit or set of circuits. 5. Capability of extension; the sectional construction adopted renders it easy to extend the board to accommodate additional machines without materially changing the wiring. 6. Sectional construction; the entire face of the board being built up of small units, transportation and erection are facilitated. 7. Accessibility, as all the wires are exposed and terminals readily accessible back of the board. 8. Uniformity and simplicity. Though there is a large amount of wiring on the board, the panels are alike and hence uniformity and simplicity are secured.

THE LAMPS.

It is a noteworthy fact that for all the incandescent lighting at the Exposition the new Sawyer-Man stopper lamp was used. Burned out lamps were periodically returned to the factory in Pittsburgh and there taken apart and supplied with new carbon burners and returned to be again used. The lighting of the Exposition has therefore afforded the Westinghouse company an excellent opportunity to test the value of the two-part lamp, of which the globe, stopper and leading-in wires can be used over and over again. The percentage broken in shipment was very small, and the success of this form of construction was claimed to have been demonstrated.

Above the gallery covering the entire eastern wall of the Electricity Building, the Westinghouse company made a very handsome exhibit by the use of the new stopper lamp. The photograph in the upper right-hand corner of the large illustration reproduces the design, but cannot accurately portray the beautiful effects produced by the various colored lamps.

EXHIBIT OF STREET RAILWAY APPARATUS.

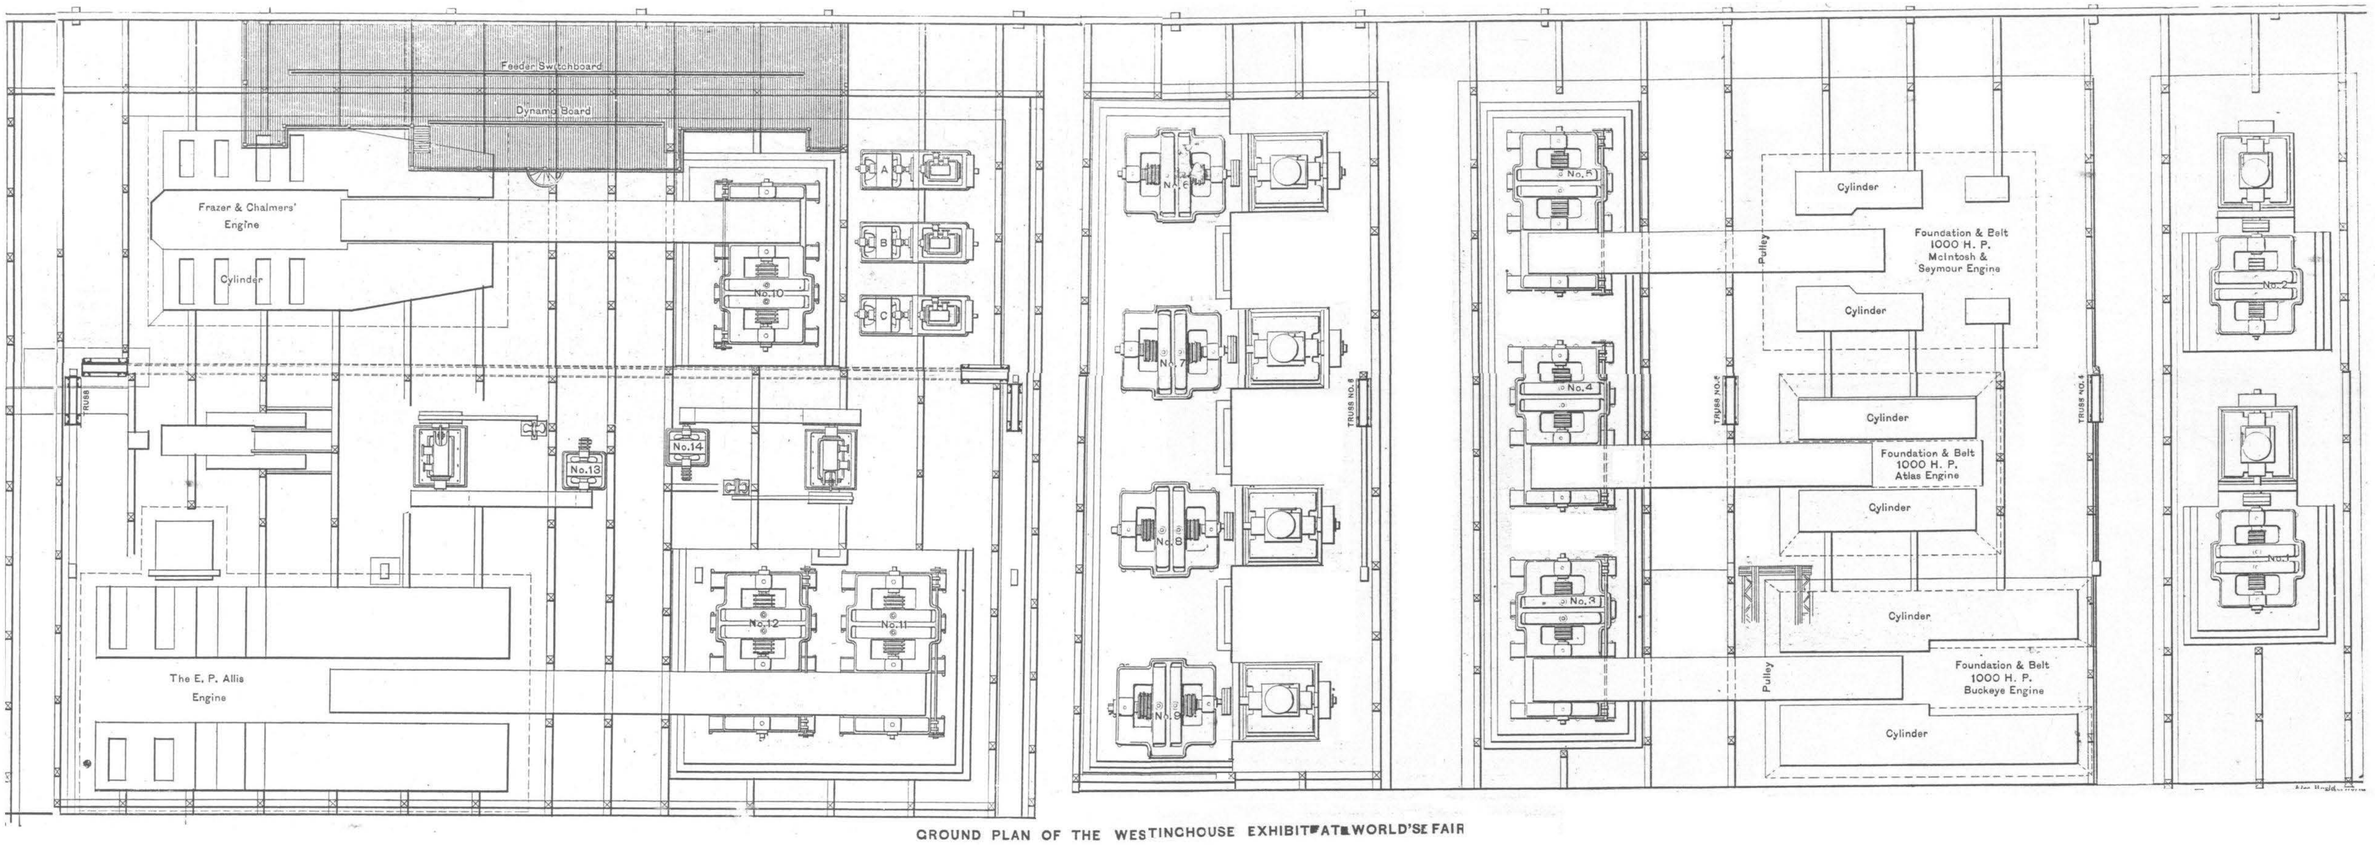
In preparing the exhibit of street railway apparatus, and indeed in all of its exhibits in the Electricity Building, the Westinghouse company adopted the policy of selecting only apparatus illustrating new and valuable features. Duplication of exhibits was avoided wherever practicable. Therefore the railway exhibit was not as extensive as it might have been made, but it clearly illustrated the methods used by the Westinghouse company in the construction of railway generators and motors, and the method of mounting motors upon car trucks. The principal exhibit was located in Section H, Space 1, just south of the centre of Electricity Building and north of the exhibit of the Bell Telephone Company. The apparatus shown comprised one 270-h. p. generator direct driven by a Westinghouse automatic compound engine, to which it was connected by a flexible coupling, constituting what is known as the "Westinghouse Kodak Outfit." This arrangement is extremely compact and substantial. A general view of the space containing railway apparatus is shown in the lower left hand corner of the double page illustration. Beyond the handsome octagonal pavilion shown in the centre of the space was located a 400-h. p. multipolar railway generator, of the belt driven type. Several armatures such as are employed in these generators were exhibited, and were specially noteworthy for the simplicity and mechanical excellence of their construction. The fields are composed of four pole pieces, projecting radially inward from a circular yoke. The pole pieces are built up of hundreds of plates of sheet steel manufactured to a certain formula adopted by the Westinghouse company, which it is claimed secures magnetic qualities superior to anything hitherto obtained. The plates are pressed tightly together and secured by iron rods riveted to cast-iron end plates. The pole pieces thus constructed are then cast into the yoke, or field ring, which is of high grade cast iron. A distinctive feature of these generators as compared with others of corresponding size is the use of the single casting constituting the lower half of the field and the supports for the bearings; a construction which secures great rigidity of form. We have already said the armatures shown were examples of high class mechanical design and workmanship. The conductors pass through insulating tubes placed in slots about the periphery of the armature core. These insulating tubes are threaded through from one end of the armature core to the other, the slot in the core being of such a form that it is impossible to slide the tube out of place radially. It is thus impossible for the conductors and tubes to be thrown out by centrifugal force, and no band wires are required to hold them in place, as they are absolutely secured by the iron core.

The Westinghouse street railway motors of the single reduction type were fully exhibited. They were shown complete on trucks, dismounted, and with their fields thrown back. An extremely valuable characteristic of the Westinghouse motors resulting from the multipolar construction and method of armature winding employed, lies in the fact that the proper distribution of current in the armature conductors does not depend upon the uniformity of magnetization of the pole pieces, nor in the clearance of the armature, as measured from different poles of the field. If the bearings become worn and the armature is consequently decentralized, there results no unbalancing of the work which the armature conductors are called upon to perform. These points were well illustrated by the rotation of the armature of a motor which had the upper half of its field thrown back and only the lower half magnetized. The armature rotated at any desired speed, being controlled by the rheostat in its circuit, without sparking at the brushes and without abnormal heating of the armature conductors.

Complete lines of switches, ammeters, voltmeters, circuit breakers, both hand and automatic, lightning arresters of the Keystone and Tank type, as well as the smaller details, such as trolley wheels, fuse boxes, brushes, etc., were all fully shown.

A Three Rivers truck, built by the Sheffield Velocipede Car Company, of Three Rivers, Mich., was fully equipped with two 25 h. p. motors, controllers, diverter, etc., and shown in operation. A handsome 20-foot "accelerator" car of the Brownell company, St. Louis, Mo., was shown, equipped with two 30-h. p. motors, series multiple controllers, etc. The John Stephenson Company, Limited, loaned an 18 foot car with the new Tackaberry truck, which the Westinghouse company also electrically equipped and furnished with a glass floor, which allowed satisfactory inspection of the motors in operation, the car being raised from the track.

In addition to the exhibits of railway apparatus in Electricity Building, the Lamokin Car Works, of Chester, Pa., had an 18-foot car equipped with two 30-h. p. Westinghouse motors of the single reduction type shown in the Transportation Building, Section L-N, Spaces 9 to 11, and on the outside exhibition track, near the north end of the Terminal station, was a 20 foot car of the Laclede Car Company, St. Louis, Mo., completely equipped with Westinghouse apparatus.



In Machinery Hall a 600-h. p. six pole railway generator, of the direct connected type, was in operation, supplying current for the power circuits of the Exposition. The armature of the generator was carried on the shaft of a Corliss compound engine, which operated at the extremely low speed of 90 revolutions per minute. The construction of this machine was massive in a noteworthy degree. As an illustration of this it may be mentioned that the radial depth of the commutator bars was four inches. The field poles were of mild steel, and the armature winding similar to that of the multipolar generators in Electricity Building.

Some idea of the size of this machine can be gained from our reproduction in the upper part of the large illustration. The generator rested in a pit in order that the armature shaft might be on a proper level for the engine. A very heavy flywheel served to maintain the momentum of the armature. The six sets of brushes were so connected that three of them supplied current to one terminal and the other three to the other terminal. The brushes were all controlled by a single holder that was operated by a handwheel. In connection with this generator was a complete marble switchboard, equipped for one generator and four supply circuits.

The Westinghouse Electric and Manufacturing Company did not deem it necessary to make an exhibition of railway motors in service, inasmuch as their apparatus is exclusively used by the South Chicago Street Railway Company and the Chicago City Railway Company. Upon these two roads there were daily carried thousands of passengers to and from the Exposition. The Chicago City Railway Company very kindly offered the judges on the National Commission the opportunity of carrying out tests with the apparatus on these cars, which the Westinghouse company very much desired them to do, but on account of scarcity of funds appropriated for testing purposes the judges were unable to make what would have been a very interesting and valuable test.

EXHIBIT OF POWER TRANSMISSION APPARATUS.

In Section J, Space 2, north of the centre of Electricity Building, and south of the French section, the Westinghouse Electric and Manufacturing Company showed in operation the most extensive plant of the Tesla polyphase type which has been erected up to the present time, either for exhibition purposes or for practical work. The question has frequently been asked, "Why cannot the electric companies show any polyphase plants in practical operation?" and the Westinghouse company here showed its

GROUND PLAN OF THE WESTINGHOUSE EXHIBIT AT WORLD'S FAIR

faith in its apparatus constructed under Tesla patents by building and installing an operative plant on a very large scale.

The centre of the space was occupied by a handsome gilt pavilion, shown in the upper left hand corner of the large illustration. This booth served at once for ornament, advertisement and office; chairs and tables being provided for visitors and representatives of the company.

The power for operating the machinery was obtained from the lighting circuits supplied by the Westinghouse plant in Machinery Hall. Two-phase currents from this source were employed to operate two Tesla motors, one a 500-h. p. machine, which took the place of the turbine or engine which would be used in practical operation to drive the generator, the other a 5-h. p. motor, direct connected to a small continuous current machine, which furnished the field excitation for the generator. Neither of the Tesla motors were intended to constitute a part of the exhibit proper, but served to furnish the power necessary for the plant, and proved that the two phase alternating current of 60 periods per second, supplied by the large installation in Machinery Hall, was adapted, not only to supplying incandescent lamps and arc lights, but also to the operation of motors.

The transmission exhibit proper consisted of a complete generating station north of the pavilion, an overhead transmission circuit, and a receiving and distributing station south of the pavilion. The apparatus in the generating station comprised one 500-h. p. two-phase alternating current generator; one 5-h. p. direct current exciter; marble switchboard, with instruments, and raising or step-up transformers, which received alternating current at a potential of 400 volts from the generator and delivered current at 1,200 volts to the transmission circuit. The generator was a six-pole machine making 600 revolutions per minute, the frequency employed being 30 periods per second, or 3,600 alternations per minute. The machines were of the multipolar type and similar in general appearance to the railway generators manufactured by this company, except that in addition to the commutator there were four collecting rings provided, which were carried upon the opposite end of the shaft. The machine as here used served simply as a generator of alternating current, but the construction permitted its being used as a rotary transformer, as a direct current generator, or as a motor operated by either direct or alternating current. The step-up transformers were located behind the switchboard, and, as before noted, they delivered current to the transmission circuit at a potential of about 1,200 volts. In practical transmission over very great distances much higher potentials would, of course, be employed, but it was not considered advisable to introduce extremely high voltages in an exhibit.

The line was carried to the pole located near the step up transformers, and thence to another pole located near the switchboard of the receiving and distributing station. The wires were supported upon special glass insulators designed by the Westinghouse company. No oil was used in these insulators, which were similar to those in successful use in transmitting energy from the power station in the San Antonio Canyon to the city of San Bernardino in south California, a distance of 28 miles. The step-down transformers were located behind the switchboard in the receiving and distributing station south of the pavilion, where the potential was reduced to 400 volts. The switchboard, like that in the generating station north of the pavilion, was non-combustible, consisting of marble panels on which the switches and instruments were mounted. These panels were fitted into skeleton frames of angle iron, similar to the big switchboard in Machinery Hall. All terminals charged with high potential were behind the board, and only accessible to the attendant, who, in order to reach them, had first to unlock a door and go behind the board; it was impossible from the front of the board to receive a discharge shock by contact with any part of an instrument or switch.

From the distributing switchboard in the receiving and distributing station, alternating current was conveyed to the 500-h. p. rotary transformer, a 60-h. p. motor of the two phase synchronous type, and a 60-h. p. rotary transformer delivering direct current at a potential of about 50 volts, intended for electrolytic purposes.

The 500-h. p. rotary transformer, like the generator north of the pavilion, was provided with a commutator at one end, and a four ring collector on the other end of the shaft. Alternating current was supplied to the armature through the collectors, and continuous current was delivered from the commutator, and used to operate a Dorner & cuit, and it was identical in every respect save one with the system which has been adopted by the Cataract Construction Company for its large installation at Niagara Falls. The one difference between the two is the frequency employed, which, instead of being 30 periods, has been reduced to 25 periods per second.

EXHIBIT OF ARC AND INCANDESCENT LIGHTING APPARATUS.

In Spaces 1 and 2, Section B, Electricity Building, were shown very complete lines of Westinghouse lightning arresters, switches, ammeters, voltmeters and transformers, both complete and dismounted, illustrating very clearly the method of construction. The new features shown in this exhibit of particular interest were the non-arcing metal lightning arresters introduced into converters, the new Sawyer-Man stopper lamp in various processes of manufacture, and converters in the various stages of construction, showing clearly the method of building up the iron, and the use of entirely separate and thoroughly insulated primary and secondary coils.

As the machines used for lighting purposes were to be seen in actual operation in the large plant in Machinery Hall, the company did not make any extensive exhibit of such machinery in Electricity Building: but here was shown a standard 450-kw. alternator field casting which very clearly illustrated the Westinghouse method of casting laminated poles into a cast iron frame. There were also shown, complete, two of the smaller alternators, viz., of 40-kw. and 60-kw. capacity, and one 25 light alternating arc machine. Supported in backets, to permit thorough inspection, the Westinghouse toothed armatures were exhibited, both complete and partially dismounted, disclosing very clearly the advantages and simplicity of this method of armature winding. The direct current lighting apparatus was well represented by various sizes of the letter type and Horizontal type machines. The Manchester motor, which seems to be commanding considerable attention and commendation for use with cranes, was shown complete and dismounted A 60-h. p. multipolar Dutton railway truck equipped with two 30-h. p. single reduction motors. Direct current from the same source was also employed to drive a 60-h. p. direct current motor mounted upon an 18-inch Ingersoll-Sergeant air compressor, shown at the bottom of the large illustration; and also to supply direct current arc lamps of the constant potential type, arranged in sets of nine across the 500-volt circuit. The rotary transformer was also used as a motor, and by means of belts was made to drive a Worthington pump and an alternating current arc light machine.

The power transmission proper, it will be noted, did not include the 500-h. p. motor which was used to drive the generator, nor the 5-h. p. motor which was directly connected to the exciter in the generating station. It began properly with the two-phase generator, which was driven by a motor supplied with current from the lighting cir- generator of low voltage and very large current was no the least attractive of the exhibits in this space. One curiosity shown in this exhibit, probably overlooked by many on account of its size, was a small dynamo and steam engine. The dynamo stood $\frac{5}{16}$ inch in height, and yet was so perfect in every detail as to be capable of operation. The engine matched the dynamo, and was run by compressed air.

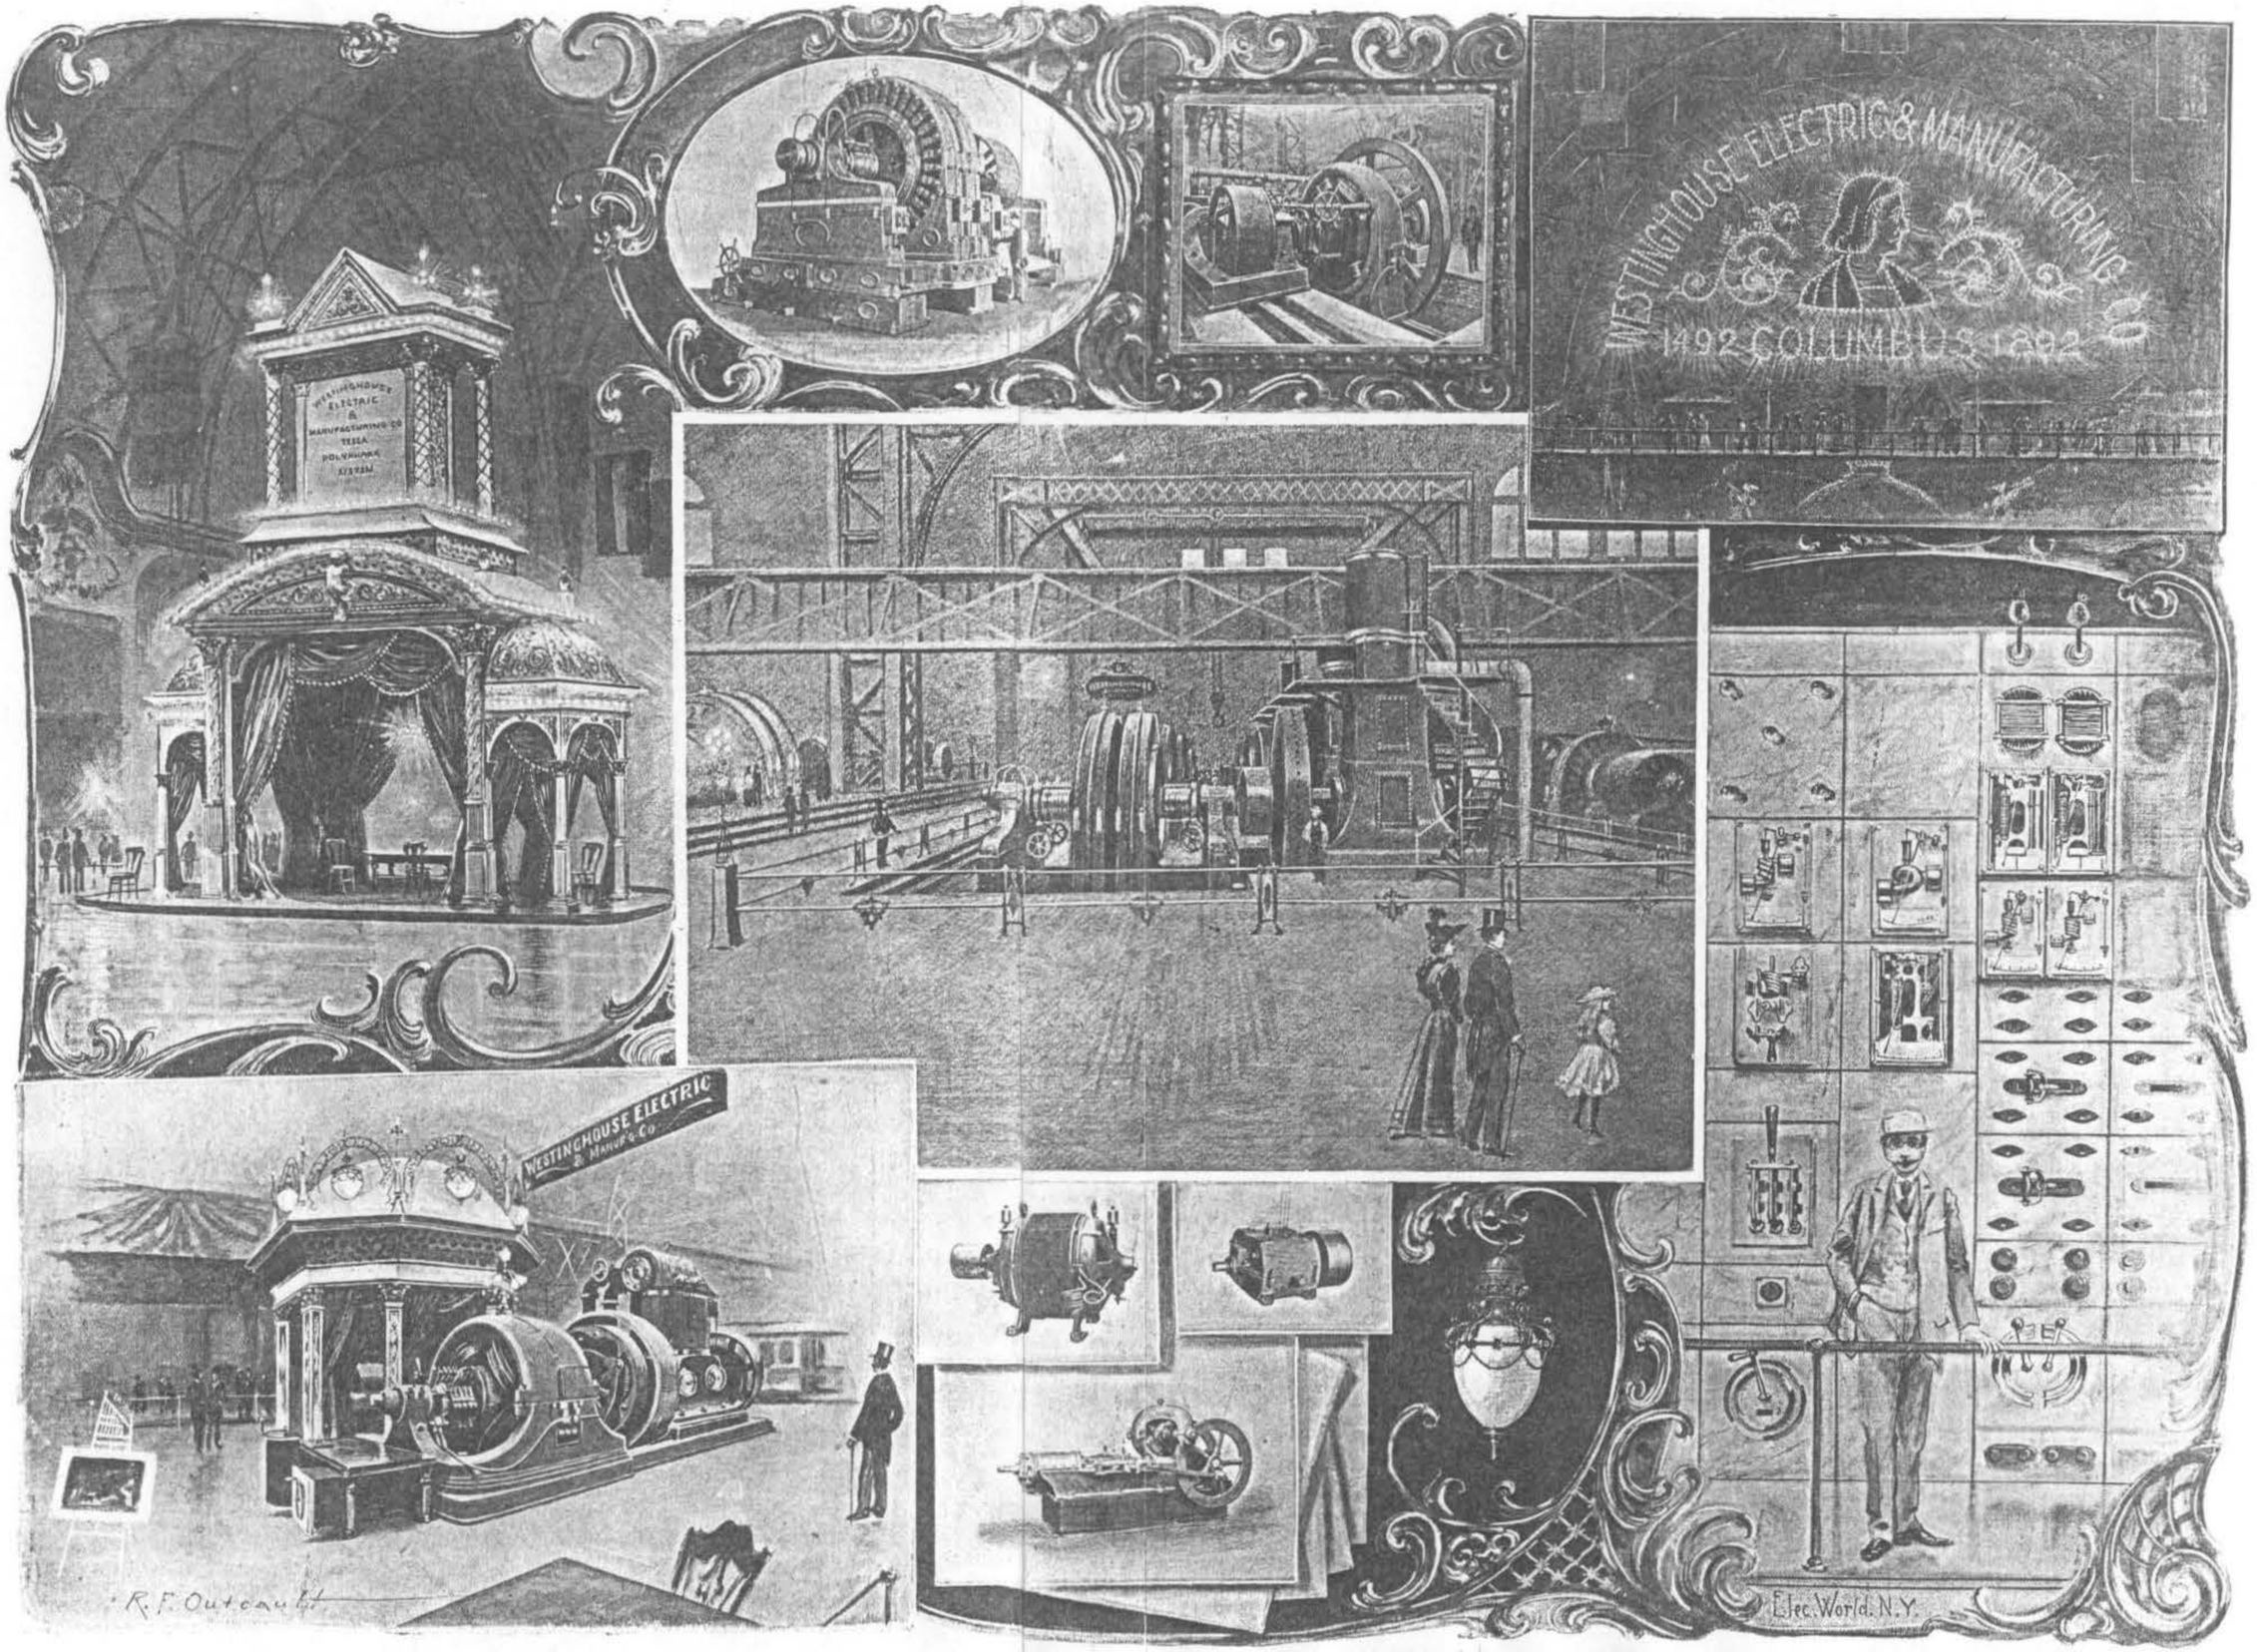


EXHIBIT OF TESLA APPARATUS AND HIGH POTENTIAL, HIGH FREQUENCY PHENOMENA.

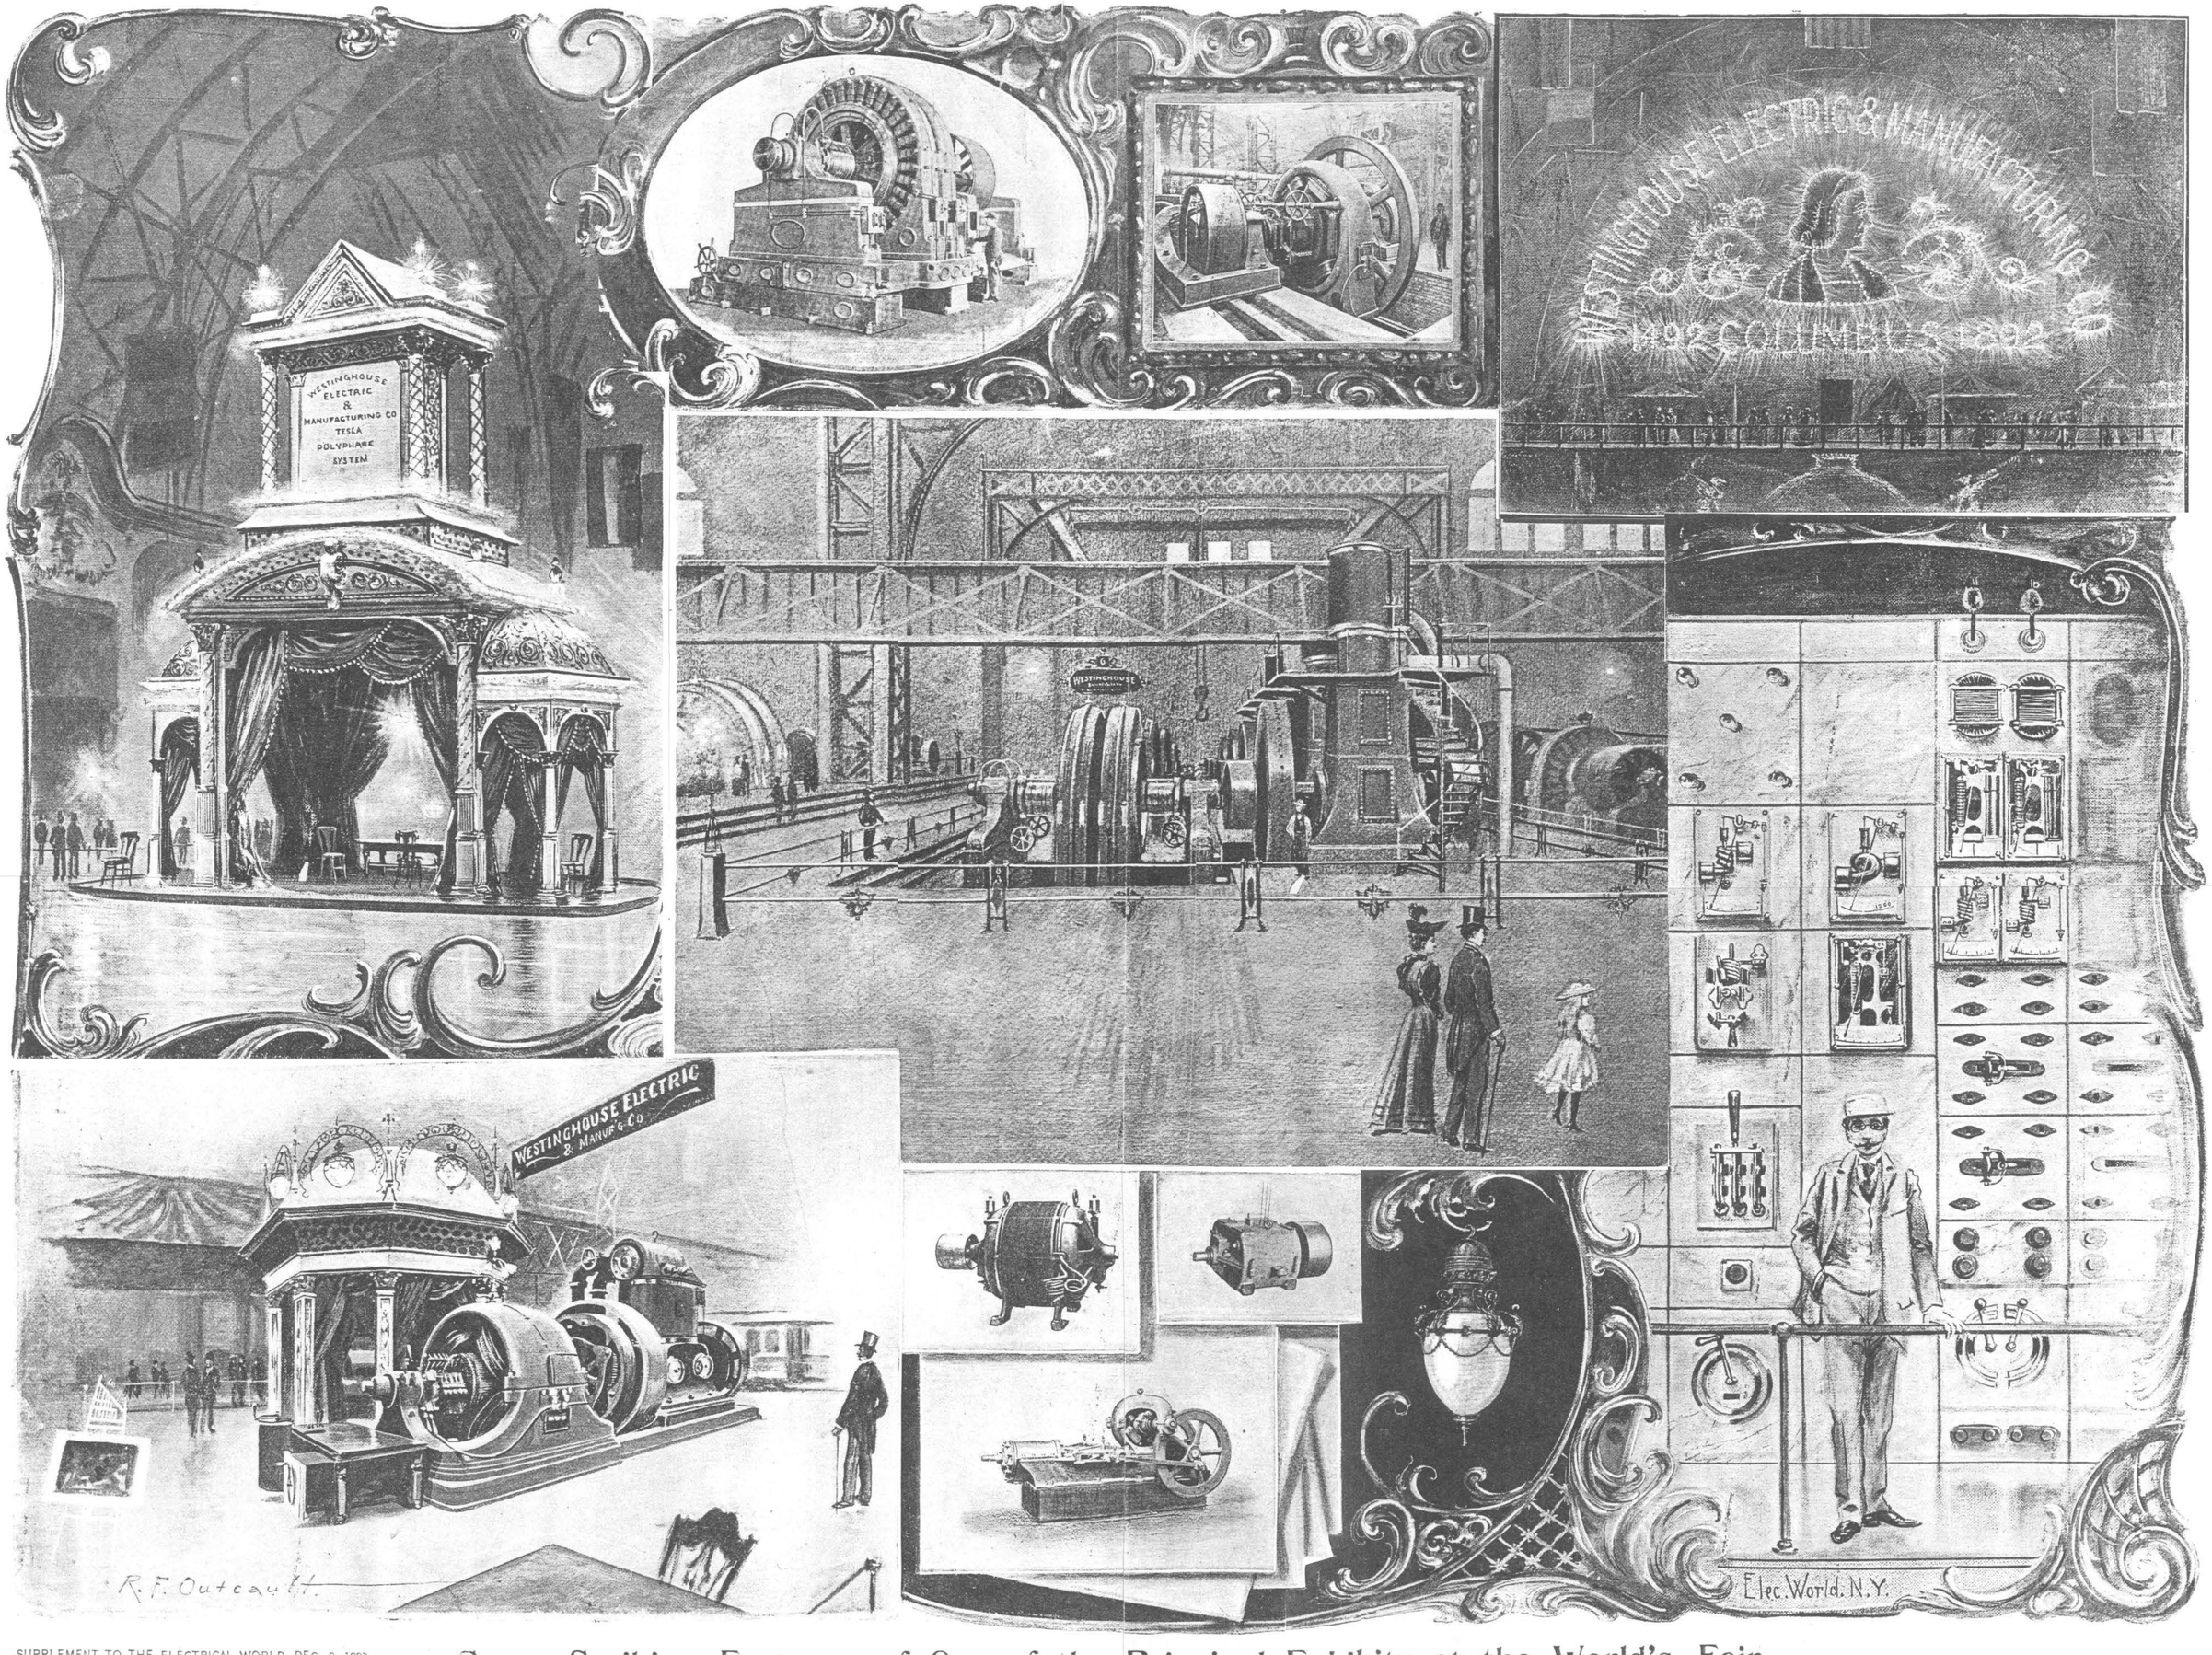
In one corner of Space B-1 was erected a room, perhaps 30-feet square, in which were daily shown experiments illustrating the remarkable results obtained by Mr. Tesla by the use of high frequency high potential currents. Current was taken from the lighting circuits connected with the plant in Machinery Hall, and transformed up to perhaps 1,000,000 volts by oil transformers situated back of the room The rate of alternation was increased from 7,200 alternations per minute to about 400,000 per second by the use of condensers and an arc breaking device. Within the room were suspended two hard rubber plates covered with tinfoil; these were about 15 feet apart and served as terminals of the wires leading from the transformers. When the current was turned on, the condition in the vicinity of the plates was made such as to render luminous vacuum bulbs which had no wires connected to them, but lay on a table between the plates, or which might be held in the hand in almost any part of the room. These were the same experiments and same apparatus shown by Mr. Tesla in London about two years ago, where they produced so much wonder and astonishment.

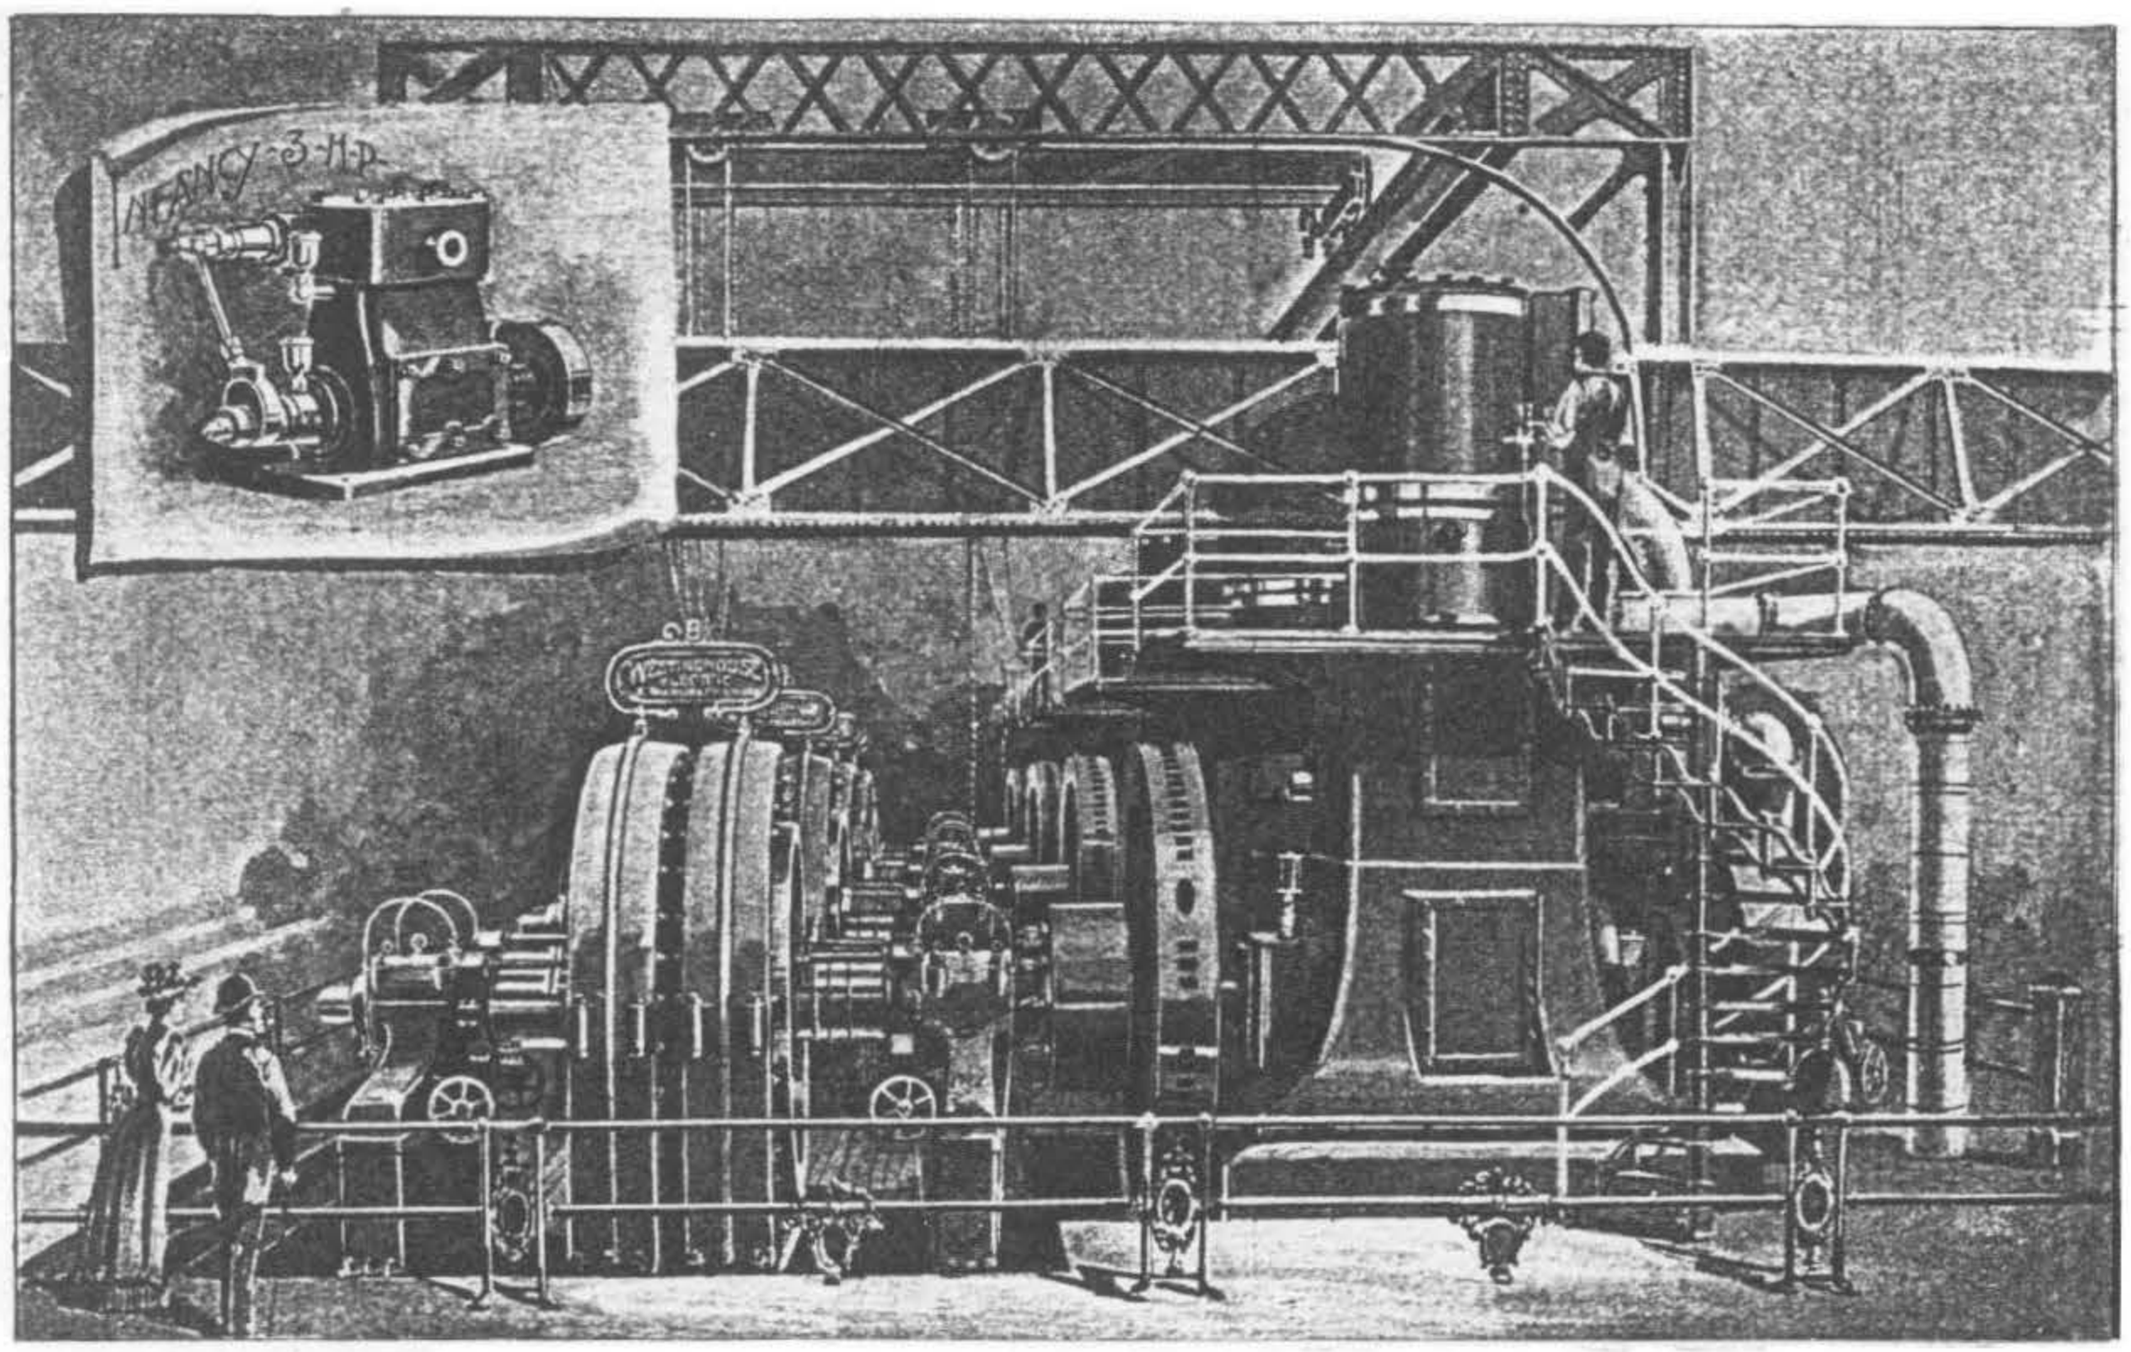


Over the entrance to this room was a glass sign bearing in its centre the name "Westinghouse." Current of high potential was led from one transformer terminal to the letters by means of invisible wires; the other terminal was connected to tinfoil on the back of the glass plate. When current was turned on the electricity would discharge across the surface of the plate, and over its edge to the tinfoil on the back, producing the effect of a modified lightning discharge, and accompanied by a similar deafening noise. This was probably one of the most novel and interesting attractions in a sensational way seen in the building, as the noise could be heard several hundred feet away, and the miniature lightning flash was very brilliant and startling.

Outside of the booth was exhibited a collection of the various forms of motors and other apparatus employed by Mr. Tesla in the discovery and development of his polyphase system. Here were to be seen also the oscillators, the subject of a lecture by Mr. Tesla before the American Institute of Electrical Engineers at the World's Fair, in August last, which attracted so much scientific interest. On a table was a Tesla ring which illustrated the principle of the rotary magnetic field. The ring consisted of an iron core wrapped with two coils of wire, through which a two-phase current was passed. The effect produced upon metallic bodies placed within the influence of this field was practically the same as though a magnet were rapidly carried along the axes of the coils.

Altogether, from a scientific as well as a popular standpoint, the Westinghouse Electric Manufacturing Company made an exhibit which was not only a great credit to themselves, but was one of the most interesting features of the Columbian Exposition.

Some Striking Features of One of the Principal Exhibits at the World's Fair.



SUPPLEMENT TO THE ELECTRICAL WORLD, DEC. 2, 1893.

Some Striking Features of One of the Principal Exhibits at the World's Fair.

Westinghouse Engines at the World's Fair.

The exhibit of Westinghouse engines attracted much attention among engineers and the public in general, through its size and varied character. The main exhibit of six 1,000-h. p. engines, direct connected to Westinghouse

EARLIEST AND LATEST TYPES OF WESTINGHOUSE ENGINES.

alternating current dynamos, was the most noticeable feature, but in addition to this there were eight of smaller sizes, making in all 14 engines, aggregating 7,695 h. p., being by far the largest exhibit of this kind ever made at any exposition. The accompanying cut illustrates the development of 12 years of practice in this line, the small figure being the first engine constructed and the large one an excellent view of the row of four engines which place 4,000 h. p. developed and utilized within a smaller space than has ever before been attempted on land. The other two engines of 1,000 h. p. were in an adjacent block, similarly connected to dynamos of the same pattern. The history of the construction of these six engines indicates the constructive development which a shop can reach, for they were built from new designs and patterns within four months—in fact seven were built in this time—without losing a casting or spoiling a part. The seventh engine was provided to insure against delay through possible accident in shipment or erection, and upon the successful starting of the six engines at Chicago, the seventh was sold to the Missouri Electric Light Company, of St. Louis, where it is now in operation. This type, while a departure from the regular Westinghouse pattern, involves most of the salient features which have become so well known, and contains various new ones, especially the pneumatic inertia balance which relieves the governor of all weight and inertia of valve parts, and which by the simple turn of a valve is immediately transformed into a steam starting gear. It is believed that this type of compound engine will come into favor rapidly where large units are required, as it combines a high steam efficiency with various approved features of the Westinghouse design. A fact not generally known, but of some interest regarding the operation of these

engines, is their relation to the practical service of the Exposition lighting, for, while many lights were carried by other engines on exhibit, operating during Exposition hours, the Westinghouse engines carried lights not only during the regular hours, but all night, Sundays and various odd hours, thus rendering more extended service than is usual in the operation of exhibits.

The two 400-h. p. compound engines of the regular Westinghouse type, in operation in the central block, between the two large Corliss engines, were sold to the Exposition. and will continue to operate through such time as lighting is required. These engines were the first placed in operation last year, furnishing power for incandescent lights previous to the starting of the main exhibits. In the Electricity Building a 270-h. p. Kodak outfit of the regular type, shown in the small cut, was operated in a rather novel way. It being inconvenient to obtain steam in that location, the generator was operated as a motor. driving the engine, the latter being piped to give all the appearance of running under steam. It was difficult to perceive that it was not operated in the usual way, although a few of the more curious would investigate and easily ascertain the facts. This outfit was sold to the Lehigh Traction Company, of Hazleton, Pa.

A somewhat obscurely located though interesting and fine running set of engines were the three 125-h. p. Westinghouse compounds direct connected to three small Westinghouse multipolar dynamos, operating as exciters for the large alternating current machines. These were kept in practically continuous operation, and on Aug. 8 the engineers in charge started the one nearest the aisle for a run which should be absolutely continuous throughout the rest of the Exposition. It was operated for 85 consecutive days and nights, making in that time over 35,000,000 revolutions, and when shut down at the close of the Fair was running with perfect smoothness. Engines of this type have frequently been operated throughout longer periods, but this, so far as known, is the longest run ever made by any engine in a public place. A neighboring blackboard on which hourly records of time and revolutions were kept attracted much attention. Two Standard engines of 125 h. p. each were loaned to the Chicago Paper Trade Club to operate its paper making exhibit, and were sold to the Boone Street Railway Company, of Boone, Ia.

The display of steam engines generally at the Exposition was, on the whole, highly creditable and representative, but no exhibit was more characteristic of the product and magnitude of the interests represented than the above.

The First Three-Phase Transmission Plant in the United States.

The first water power in Southern California to be utilized for the distribution of power, as well as lights, is that situated at the mouth of Mill Creek Canon, nine miles from the city of Redlands, one of the most flourishing of the younger cities of the State. Less than two years ago a few of the public spirited citizens of Redlands saw the chance of utilizing the fine Mill Creek power and organized a company, and the enterprise was rapidly pushed forward and about nine months ago a contract was closed with the General Electric Company for the necessary apparatus.

Mill Creek is a fine and unusually reliable mountain stream that springs from the slopes of mountains San Bernardino and Grayback, the two loftiest of the Sierra Madre range. The main body of the stream and a convenient intake were found near the mouth of the canyon and, by a comparatively small deflecting dam of masonry 40 feet long and head works it was possible to turn the water into a tunnel 160 feet in length, cut through the rock, and thence into a heavy steel pipe line, which was brought down the stream a distance of 7,250 feet, where was obtained a convenient site for a power house. At the end of the tunnel is a sand box 75 feet long by 25 feet wide to catch any sediment before the water can enter the pipe line. At this point the fall is in the neighborhood of 353 feet, giving exactly 160 pounds pressure to the square inch in the receiver that terminates the pipe line, which can deliver 2,400 cubic feet of water per minute.

The power house is for the most part an excavation not far from the bank of the creek. The roof is erected on very low side walls and under the lean-to, on the right, is the wheel pit with the receiver and Pelton wheels. The wheel shafts extend through iron shutters, set in windows in a massive rubble retaining wall that bounds the wheel pit into the dynamo room, where they are directly coupled to several machines. This dynamo room contains the following apparatus, as may be seen from the cut, which gives an excellent view of its interior: Two 250-kw. ten-pole three-phase generators delivering current directly to the lines at 2,500 volts between lines; two D-10 exciters, each capable of energizing the fields of both generators, and one 50-light, 2,000-c. p., Thomson-Houston arc dynamo. With the stream at its lowest 800 h. p. is developed at the generators. Room is left and foundations are in place for a third three-phase generator and a second similar arc machine. The large generators run at 600 revolutions, give 6,000 alternations per minute, and have a rated output of 100 amperes at 2,500 volts. The general arrangement of the station was planned before the contract for the apparatus was let (and in fact, before the character of the machinery was determined) substantially according to the designs of the late A. W. Decker, whose recent death was a serious loss to the electrical interest of the Pacific Coast.

To each of these large machines just mentioned a Pelton wheel is directly coupled, the three-phase generators being supplied with 200-h. p. double wheels, each operated by a double nozzle.

The regulation of the hydraulic power is by the ordinary differential nozzle operated by Pelton differential governors driven from one of the exciter shafts. A second small differential governor, driven from the other exciter shaft, steadies the action of the first by regulating the exciter wheels. The water having done its work is discharged into a ditch and utilized for irrigation purposes.

On the side of the dynamo room opposite the dynamos are located the switchboards. The chief interest of these lies in the three-phase switchboard for the two big

generators. This is elaborately devised to meet every condition or combination that it might be desired to make with the two machines, and the two circuits that run from the power house. Either machine can be thrown on either circuit and both machines in parallel on either or both circuits. At present the parallel connection is chiefly used in shifting over the load to obtain perfect continuity of service. A six-ton traveling crane permits ready handling of any of the machinery.

The interior of the station is a model of its kind. Particularly to be noted are the excellent foundations, and a result is an excellent alignment of shafts, the large generators running without even a tremor at the bearings.

From the power house are run two three-phase circuits, each composed of three 00 B. & S. wires. One of these runs to the company's office at Redlands, a distance of seven and a half miles, and from thence is distributed over the city for lighting and power purposes. On a substantially built pole line the other extends to Mentone, four and a half miles, where is located the artificial ice plant of the Union Ice Company.

In this plant is installed a self-starting 150-kw., triphase, 750-revolution, 6,000-alternation synchronous motor, belted through the medium of a countershaft to two large compressors for the ammonia, a circulating pump for the compressor jackets, a force pump to supply water for the ice, and a small elevator for handling the ice. In order to ascertain the point of synchronism, a Thomson acoustic synchronizer is employed, and gives unqualified success. The ice plant is of the so-called "pipe" type, and the freezing room and condenser contain nearly 20 miles of three-quarter inch iron pipe, in testing which the motor was stopped and started at short intervals for several weeks. The operation of the ice plant is continuous, the load being on the motor 24 hours a day, and, barring accidents, 365 days a year, The motor plant at this point is likely soon to be increased to keep up with an increase in the plant.

From the main Redlands circuit a number of lines are taken off from the ice plant and also for the neighboring town of Mentone. There are now in operation 30 arc lamps, besides over 1,000 16-c. p. incandescent lamps distributed over three legs of the circuit. A number of small induction motors without commutators or collecting rings are to be installed before the beginning of next year, to meet the demand already created by the success of the plant. The transformers are very similar to the ordinary General Electric type of transformer, except that they are designed for 50 cycles per second, and to reduce the pressure from 2,200 to 110 volts. So far as possible rather large transformers are used with comparatively long secondaries. These are used only directly at the point where light and power are delivered.

No trouble whatever has been experienced from any unbalancing of the lighting lines. In fact, shortly after the plant was started up the largest single block of lighting in the city, wired for three circuits, had these circuits worked for several nights on two legs of the triphase generators pending the setting up of the third transformer; and, although the lights from these two legs were set in adjacent rooms where both would be seen at once, not the slightest trouble from unbalancing was evident.

The first generator reached Redlands Sept. 1, and Sept. 7 incandescent lamps were turned on in Redlands, where arc lamps had been previously working since the latter part of July. Sept. 13 the motor at the ice plant went into commercial operation. The whole plant has been running steadily and doing good service ever since.

SOCIETY AND CLUB NOTES.

THE NEW YORK ELECTRICAL SOCIETY'S WORLD'S FAIR SYMPOSIUM.—I.

ON Wednesday Nov. 29 the New York Electrical Society meeting at Columbia College, held a "symposium," the subject being "Electricity at the World's Fair." Brief addresses had been announced by a number of gentlemen, but lack of time necessitated the postponement of some of them until the next meeting of the Society. Interest in the subject was shown by the fact that the room was filled to overflowing.

The meeting was presided over by the vice-president, MR. C. O. MAILLOUX who introduced the speakers in a very happy style, and who himself opened the evening's discourses by giving an account of the

STORAGE BATTERIES AT THE FAIR.

The only interesting feature involving storage batteries at the World's Fair, said Mr. Mailloux, were the electric launches, and these involved more attention to detail than a high order of engineering. The exhibits of various types of batteries was very meagre, including only three foreign exhibits. Among these the portable battery of Wladimiroff[1] exhibited in the Russian section of Machinery Hall, presented some interesting features. Some three or four American batteries were exhibited with which most of us were familiar. The speaker also referred to the storage batteries exhibited by Mr. Ch. Pollak of Frankfort, Germany, and to his ingenious device for commutating alternating currents into continuous for the purpose of charging storage batteries.[2] According to Mr. Mailloux there still remained the necessity of making the apparatus give an alternating from a continuous battery current. Reference was also made to storage batteries used on the floats in the Chicago Day procession and on the self-propelling electric carriage at the Fair. Mr. Mailloux also drew attention to the fact that we had not yet made as much progress in the application of storage batteries as was to be found abroad, and also to the large sizes of cells used there.

DR. CHARLES E. EMERY then being introduced spoke on

THE ELECTRIC LIGHT AND POWER ENGINES AT THE FAIR.

While there was nothing specially new there, progress was shown in the perfection of detail, increase of size and adaptability to special purposes. The Corliss type was shown in many forms. Views of the principal engines exhibited at the Fair were thrown on the screen and commented on by the speaker. Among them was the Edison 2,800 kilowatt generator; the Westinghouse engine driving the 10,000-light alternators; the Schichau engine coupled direct to the large Siemens and Halske generator and having a Ryder valve. The Lake Erie Iron Works engine which drove the 750 k. w. generator in the Intramural Railway power station and which had made a remarkable record. This engine was the first to be started and was a little to small for its work, but worked very well and he thought this feature would be copied as it was a safeguard against using too much current all at once.

Among the other engines shown was the Willans[3], the large 2,000 h. p. Allis engine and the Williams and also a number of views of other interesting mechanical subjects.

PROF. F. B. CROCKER then spoke on

ELECTRIC CONGRESSES.

In three respects the Electrical Congress at Chicago had been unique. First, it had given final values and names to electrical units; secondly, it had given official sanction to the use of the henry, in honor of an American, and which thus constituted a recognition of America in electrical science; and third, on account of the importance of the papers read and the eminence of the men who read them. The presence of most of the prominent electricians at Chicago, must also be considered an extraordinary result. The speaker thought that the somewhat lax business management apparent at the Congress was an insignificant matter, and did not in any way interfere with its success. PROF. CROCKER did not agree with Prof. Rowland in the view that there never would be occasion to hold another electrical congress, and he suggested as work for a future congress the fixing of magnetic units and names for them, a standard of light, and an international nomenclature for electrical terms and quantities.

MR. NIKOLA TESLA, then being introduced, spoke, as follows on his

ELECTRICAL OSCILLATOR.

You may perhaps know, at least those of you who have followed the electrical development more closely, that the subject about which I am to say something is one which I recently presented before the Electrical Congress. During the past two years or so I have been gathering results and preparing a work which I had the intention to present before the last annual meeting of the American Institute as one of its members. Now, as a matter of fact, at that time I had gone considerably into the study of the practical aspects of the work which I was completing and my notion was that I was touching upon something very important, which would lay the foundations of a novel industry, perhaps of more than one industry. But to speak in that strain before such a gathering as I had the honor to address at the Chicago Congress would have required a nerve which I did not possess; or if I did possess it, it would be sure to leave me when I wanted to use it; and so I dwelt chiefly on those features which possessed a purely scientific interest, my desire being to present the subject very modestly, as I was not quite sure of the practical side of some of the questions involved. Right after the lecture I asked one of my friends what he thought of it. He said it was good enough but it could have been better. A prominent engineer came to me and said "Mr. Tesla, I want to tell you something but I fear it may offend you." I knew what was coming and so I asked what it was. He said "Well, don't you work on steam engines. You have done some work in electricity. If you stick to it you will do some good work, but if you work on steam engines you are bound to fail." (Laughter.) All these men that I mention are some of the most prominent men in the profession. Another said, "I wonder what Tesla is going to do with his blessed engine." Another, to whom I showed the advantage of doing away with complicated mechanism and generating electricity directly, said, after he had watched for a long time an apparatus running some incandescent lamps, "Couldn't you apply this to *rotating* motion?" Now this is the way in which my work was received. (Laughter.) But I was quite prepared for that because for fully two years I had myself rejected these ideas again and again, though I had in my mind the construction of the apparatus in many details; but it was not until I overcame experimentally some difficulties which at first seemed to me insuperable that I gained faith in the principle, that I finally resolved myself to this work.

One of the first impulses which have guided me was to produce an absolutely constant oscillation which would be independent of friction losses, or gravity, or temperature changes within very wide limits. Now, we can employ a pendulum, a clock work or a vibrating spring, or some such device as that, But they are very unreliable. I wanted to produce a positive motion, so that I might operate what I called some time ago a disruptive discharge coil. I may assume that some of you know that some time ago I advanced a method of producing currents of high frequency from direct or alternating currents. The method consists in charging condensers, discharging them either through a primary and then inducing in coils of the secondary, or in its own, currents of high potential. The lamp to be operated with such coils is already perfected. A nearly exhausted vessel would be good enough for the purpose. But the devices themselves are inefficient in the production of these currents, and one reason is that these devices do not yield a perfectly constant vibration. I had to depend on a disruptive gap and I used in connection an air blast or oil stream or a mechanical interrupter. Now with this device which I invented subsequently I was able to maintain a vibration with perfect constancy. This device consisted of a powerful spring which required several tons of force to spring it a certain distance and which was constantly kept in vibration by steam or air pressure. In the beginning I used springs of tempered steel. These steel springs would break, though they had a section of two or three square inches. So I resorted to air springs. The air springs would not break, but the air springs had no constant resilience. Then I made the chambers of the air springs communicate with the outer air. This gives a vibration constant enough, but the temperature of the air in the chambers can be maintained quite constant as by boiling water in the jacket surrounding them. The device yields a constant vibration, and as the force which is driving it is many tons and the friction but a very small matter, it is unaffected by the variations of the steam or air pressure. This was one of the chief features I wanted to present.

The Calculations of Alternating Current Motors.—IV.

BY E. ARNOLD.

It has only now been possible for me to continue the communications which appeared in THE ELECTRICAL WORLD of May 13, 1893. In that section there are a few typographical errors which I wish to correct.

The last three equations should read :

$$I_2 = \frac{3}{2} \cdot \frac{p_1 M I_1}{\sqrt{R_2^2 + p_1^2 L_2^2}} \qquad (31)$$

$$A_2 = \frac{9}{8} \cdot \frac{p_1^2 M^2 I_1^2 \cdot s_2 \cdot R_2}{R_2^2 + p_1^2 L_2^2} \qquad (32)$$

$$D = \frac{A_2}{p_1} = \frac{9}{8} \cdot \frac{p_1 M^2 I_1^2 \cdot s_2 \cdot R_2}{R_2^2 + p_1^2 L_2^2} \qquad (33)$$

Also in Fig. 6 the side $B\,c = \frac{3}{2} \cdot p_1 L_1 I$, instead of $p_1 L_1 I_1$.

We will now make the assumption that there is present only one primary and only one secondary phase, and that both coils are in the relative position of maximum mutual induction. The energy induced in the secondary coil by the first will then be :

$$A_0 = \frac{1}{2} \cdot \frac{p_1^2 M^2 I_1^2 R_2}{R_2^2 + p_1^2 L_2^2} \qquad (33a)$$

Now in order to determine for this case the relation between the work A_0 and the primary E. M. F. we calculate the energy A_0 in functions of E_1.

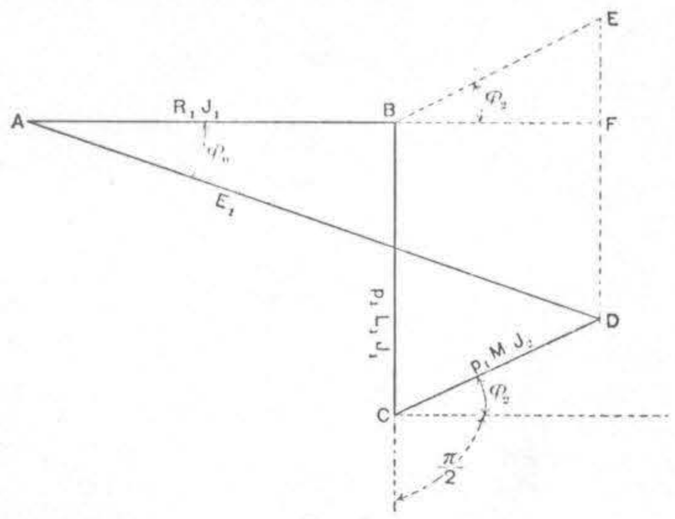

FIG. 7.

Then in Fig. 7 we make $A\,B = R_1\ I_1$, perpendicular to it.

$B\,C = p_1\ L\ I_1$ and at an angle $= \frac{\pi}{2} + \varphi_2$.

$C\,D = p_1\ M\ I_2$; then $A\,D = E_1$.

From the figure $E_1^2 = \overline{A\,F}^2 + \overline{F\,D}^2$, or

$$E_1^2 (R_1\ I_1 - p_1\ M\ I_2 \cdot \cos\varphi_2)^2 + (p_1\ L_1\ I_1 - p_1\ M\ I_2 \sin\varphi_2)^2 \qquad (34)$$

where

$$\cos\varphi_2 = \frac{R_2}{\sqrt{R_2^2 + p_1^2 L_2^2}} \qquad (35)$$

$$\sin\varphi_2 = \frac{p_1 L_2}{\sqrt{R_2^2 + p_1^2 L_2^2}} \qquad (36)$$

$$I_2 = \frac{p_1 M I_1}{\sqrt{R_2^2 + p_1^2 L_2^2}} \qquad (37)$$

and thus

$$E_1^2 = I_1^2 \left[\left(R_1 + \frac{p_1^2 M^2 R_2}{R_2^2 + p_1^2 L_2^2} \right)^2 + p_1^2 \left(L_1 - \frac{p_1^2 M^2 L_2}{R_2^2 + p_1^2 L_2^2} \right)^2 \right] \qquad (38)$$

If to abreviate we make

$$q = \frac{p_1^2 M^2}{R_2^2 + p_1^2 L_2^2}$$

and put the value of I_1^2 from equation (38) in equation (33a), then

$$A = \frac{1}{2} \cdot \frac{p_1^2 M^2 E_1^2 R_2}{(R_2^2 + p_1^2 L_2^2)[(R_1 + q R_2)^2 + p_1^2 (L_1 - q L_2)^2]} \qquad (39)$$

Also

$$q = \frac{M^2}{\left(\frac{R_2}{p_1}\right)^2 + L_2^2}.$$

The number $R_2 : p_1$ being small can be neglected in practice. Then

$$q = \frac{M^2}{L_2^2}.$$

But $M : L_2$ indicates the transforming ratio between a phase in the inducing and a phase in the induced current winding, assuming that every line of force of the primary system cuts the secondary system. For instance, if the induced circuit consists of s_2 coils (instead of simple windings, as are considered in Fig. 5), and every coil consists of z short circuited windings in series, then

$$\frac{M}{L_2} = \frac{s_2}{z}$$

R_2 thus represents the resistance of the z windings.

But as the primary and secondary windings are on separate iron cores, between which there is an air space, there will be a considerable leakage of lines of force. While the armature is at rest when the motor is being started the leakage reaches its maximum, as the excitation of the field is then many times what it is when the motor is running at normal load.

The leakage is also greatly dependent upon whether drum or ring winding is chosen, and increases with the increase of air space between field and armature, with the increase of induction of the iron of the magnet and armature and the air.

If there were no scattering of lines of force then would

$$M^2 = L_1 L_2.$$

Considering the leakage, we make

$$b^2 M^2 = L_1 L_2 \qquad (40)$$

b representing the coefficient of magnetic leakage, and $b < 1$; and, furthermore,

$$L_1 = \frac{4\pi \cdot s_1^2}{10^9 \cdot \rho} \qquad (41)$$

$$L_2 = \frac{4\pi z^2}{10^9 \cdot \rho} \qquad (42)$$

where ρ stands for the resistance of the magnetic circuit; and so we find that

$$q = \frac{b^2 L_1 L_2}{L_2^2} = b^2 \cdot \frac{s_1^2}{z^2} \qquad (43)$$

If we now divide numerator and denominator in equation (39) by p_1^2, and neglect the member $R_2 : p_1$,

$$A_0 = \frac{1}{2} \cdot \frac{b^2 \cdot E_1^2 \cdot \frac{s_1^2}{z^2} \cdot R_2}{\left(R_1 + b^2 \frac{s_1^2}{z^2} R_2\right)^2 + p_1^2 \left(L_1 - b^2 \frac{s_1^2}{z^2} L_2\right)^2} \qquad (44)$$

for $b = 1$; that is, when there is no magnetic leakage the second member of the denominator becomes zero. As this member is proportional to the square of p_1, and as we have b^2 in the numerator, this equation shows us that the energy A_0, and therefore also the torque, is greatly diminished by the magnetic leakage. This equation also shows us that the torque is proportional to the square of the primary tension E_1, that it is dependent upon the grouping of the armature windings (the total number of which $= s_2 \cdot z$), the sum of the armature resistances, $s_2 \cdot R_2$, and the transforming ratio $s_1 : z$.

The equation (38) can also be written in the following form :

$$I_1^2 = \frac{E_1^2 (R_2^2 + p_1^2 L_2^2)}{p_1^2 (R_2^2 L_2^2 + R_2^2 L_1^2 + 2 M^2 R_1 R_2) + p^4 (L_1 L_2 - M^2)^2 + R_1^2 R_2^2}. \qquad (45)$$

If we now substitute this value of I_1 in equation (33a), and neglect $R_1^2\ R_2^2$, which is small,

$$A_0 = \frac{1}{2} \cdot \frac{b^2 \cdot E_1^2 \cdot R_2}{\left(R_1^2 \frac{L_2}{L_1} + R_2^2 \frac{L_1}{L_2} + 2 b^2 R_1 R_2\right) + p_1^2 L_1 L_2 (1 - b^2)^2}. \qquad (46)$$

For $b = 1$, in case of no leakage, the second member of the denominator $= 0$; the member

$$R_1^2 \frac{L_2}{L_1} + R_2^2 \frac{L_1}{L_2} + 2 R_1 R_2$$

becomes a maximum for a particular relation of $L_1 : L_2$, namely, for

$$\frac{L_1}{L_2} = \frac{R_1}{R_2},$$

or for a transforming ratio,

$$\frac{s_1}{z} = \sqrt{\frac{R_1}{R_2}}, \qquad (47)$$

or for

$$R_2 = R_1 \cdot \frac{z^2}{s_1^2}. \qquad (47a)$$

Thus if we make the assumption that b nearly equals 1, so that the second member of the denominator can be neglected, then for the above transforming ratio or for the resistance R_2 given in equation (47a), the torque at the starting of the motor becomes a maximum. Now as s_1 depends upon the primary E. M. F., and, supposing the dimensions of the core to remain the same, increases with E_1, then the rational construction of the closed circuited armature becomes dependent upon the primary winding.

The dependence of the torque upon R_2 and the transforming ratio $s_1 : z$ can be best shown graphically. If we consider in equation (46) the quantities R_2 and $L_1 : L_2$ as the only variables, and let $b = 1$, then naturally A_0 becomes the torque.

$$D_0 = \frac{a_1 R_2}{R_1^2 \frac{L_2}{L_1} + R_2^2 \frac{L_1}{L_2} + 2 R_1 R_2}$$

where a is a constant.

For $R_1 = 0.1$; $\frac{L_1}{L_2} = 10$; $\frac{s_1}{z} = \sqrt{10}$

we obtain with different values of R_2 the curve A, Fig. 8;

for $R_1 = 0.1$; $\frac{L_1}{L} = 100$; $\frac{s_1}{z} = 10$, the curve B.

As R_2 increases the torque increases and reaches a maximum for a particular value of R_2 given by equation (47a). The resistance R_2 which corresponds to the maximum torque becomes smaller, the greater the transforming ratio $s_1 : z$; or with a constant resistance R_2, the torque increases with the increase of transforming ratio.

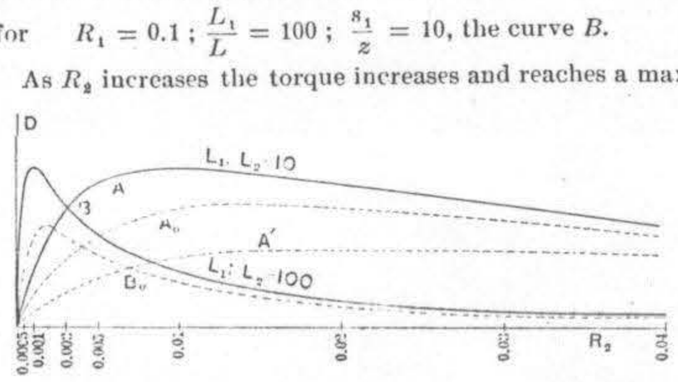

FIG. 8.

The magnetic leakage makes itself perceptible, as the torque is thereby lessened and the resistance R_2, which corresponds to the maximum torque, is increased. If we consider the leakage we will obtain instead of A and B the curves A_0 and B_0; or with heavy leakage A'. It is difficult to determine the exact form of these curves by calculation, as the value of the coefficient of leakage b is very variable. The smaller the armature resistance R_2, that is as we increase the amount of copper with which the surface of the armature is covered, the fewer will be the number of lines of force which penetrate the core of the armature, and consequently the smaller b becomes. Therefore the curves A and A_0 and B and B_0 respectively come nearer each other as R_2 increases.

Now to obtain an expression for the total torque produced by m primary and s_2 secondary phases, we make use of Fig. 9. As was done before in Fig. 6, we here make

$A\,B = R_1\ I_1$, and perpendicular to it

$$B\,C = \frac{m}{2} \cdot p_1\ L_1\ I_1,$$

$$C\,D = \frac{s_2}{2} \cdot p_1\ M\ I_1.$$

Then $A\,B = E_1$.

Furthermore in Fig. 10,

$A\,B = R_2\ I_2$,

$$A\,C = \frac{s_2}{2} p_1\ L_2\ I_2,$$

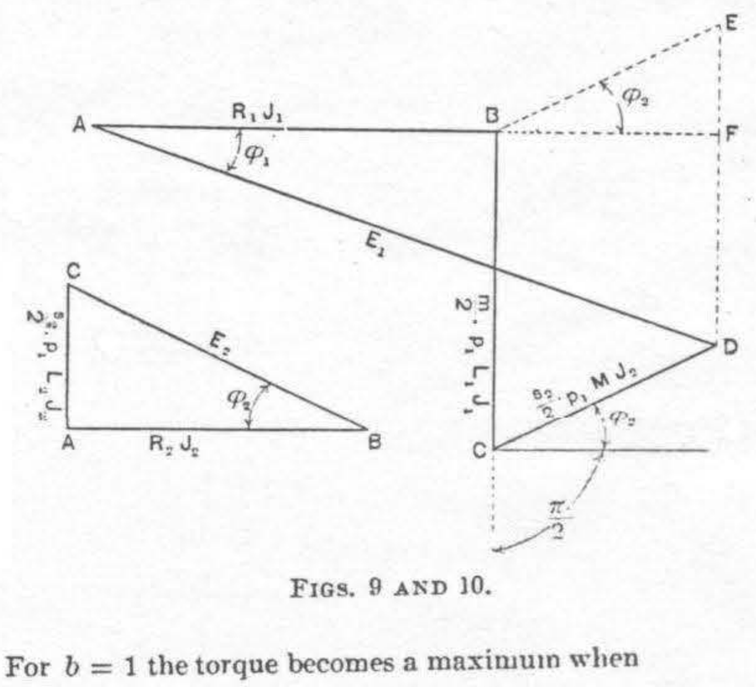
$B\,C = E_2$.

It follows that

$$\left.\begin{aligned} \cos\varphi_2 &= \frac{R_2}{\sqrt{R_2^2 + \frac{s_2^2}{4} \cdot p_1^2 L_2^2}} \\ \sin\varphi_2 &= \frac{s_2}{2} \cdot \frac{p_1 L_2}{\sqrt{R_2^2 + \frac{s_2^2}{4} \cdot p_1^2 L_2^2}} \\ I_2 &= \frac{m}{2} \cdot \frac{p_1 M I_1}{\sqrt{R_2^2 + \frac{s_2^2}{4} \cdot p_1^2 L_2^2}} \end{aligned}\right\} \qquad (48)$$

From Fig. 9 we deduce the value

$$E_1^2 = \left(R_1\ I_1 + \frac{s_2}{2} \cdot p_1\ M\ I_2 \cos\varphi_2\right)^2 + \left(\frac{m}{2} \cdot p_1 L_1\ I_1 - \frac{s_2}{2} \cdot p_1\ M\ I_2 \sin\varphi_2\right)^2 \qquad (49)$$



and

$$D = \frac{R_2 \cdot I_2^2 \cdot s_2}{2 p_1} = \frac{m^2}{8} \cdot \frac{p_1 M^2 I_1^2 s_2 R_2}{R_2^2 + \left(\frac{s_2}{2} \cdot p_1 L_2\right)^2}. \qquad (50)$$

Putting the value obtained in equation (48) in equation (49), and calculating I_1^2, it follows from equation (50):

$$D = \frac{m}{2} \cdot \frac{b^2 \cdot E_1^2 R_2}{p_1 \left(R_1^2 \cdot \frac{s_2 L_2}{m L_1} + R_2^2 \cdot \frac{m L_1}{s_2 L_2} + 2 b^2 R_1 R_2\right) + \frac{m \cdot s_2}{4} \cdot p_1^3 L_1 L_2 (1 - b^2)^2} \qquad (51)$$

This equation is constituted similarly to equation (46).

FIGS. 9 AND 10.

For $b = 1$ the torque becomes a maximum when

$$\frac{m L}{s_2 L_2} = \frac{R_1}{R_2} \qquad (51a)$$

or for

$$R_2 = R_1 \cdot \frac{s_2 L_2}{m L_1} = R_1 \cdot \frac{s_2 z^2}{m \cdot s_1^2}. \qquad (52)$$

(To be continued.)

Meeting of the New York Electrical Society.

The meeting of the New York Electrical Society on Wednesday, Nov. 29, was one of the most interesting which has taken place during its long career, the subject being "Electricity at the World's Fair and Its Lessons." The speakers were so well known and so eminently qualified to deliver addresses upon the subjects assigned to them that, as was expected, the attendance was large.

In the absence of the president the meeting was called to order by Mr. C. O. Mailloux. As Mr. Mailloux was on the programme for a brief address on "Storage Batteries," he opened the meeting with a few remarks on that subject. He stated that little had been done with storage batteries at the World's Fair, in fact the one interesting feature in which the storage battery played a part was the electric launches on the lagoons. But this application of the storage battery

did not involve any extraordinary features, and the conditions were not those which make the storage battery problem usually so difficult. The exhibits of storage batteries were rather meagre. There were three foreign displays, but with one exception they were little more than samples. This exception was an interesting battery in the Mechanic Arts Building, in the Russian section, which attracted attention on account of the peculiarity of construction rather than the results which it gave. In the French section a battery made on the Plante principle presented some features of interest. Among American exhibits there were three or four types of batteries which are already quite familiar. The exhibit of Mr. Pollak, of Frankfort, was instructive not only on account of the construction of the storage batteries themselves, but from the fact that it was shown in connection with a very ingenious device for commutating alternating currents for the purpose of charging storage batteries. This apparatus performs its work quite satisfactorily, and is not as complicated as one would expect. It consists merely of a system of rectifying the impulses. This was perhaps the most interesting exhibit relative to storage batteries shown at the Fair, as it suggested a new line of progress. It is in Europe that the most progress has been made in storage batteries, and while American manufacturers have been content to make batteries of two, three or perhaps four hundred ampere hours, in Europe it is current practice to use batteries of three, four and even five thousand ampere hours, weighing as much as two or three thousand pounds per cell. Another interesting feature at the Fair was an electric carriage, which suggested what we may expect in that line in the future.

Dr. Charles Emery was then introduced by the chairman and spoke briefly on "Electric Light Engines." He stated that there was nothing particularly new at the Exposition in this line; there was progress shown, but as a general rule it was more in the line of perfection in detail, increase in size and adaptability to special purposes. A large number of lantern slides were shown, and Dr. Emery described the salient features of each type.

Prof. F. B. Crocker was then called upon for remarks upon electrical congresses. He said that the recent International Electrical Congress at Chicago was remarkable in at least three respects. In the first place it gave final names and values to the electrical units. It is a fact that these definitions and values have been used before, but they had never been internationally accepted. The adoption of the name "henry" for the unit of self-induction is also another important result of the congress and a recognition both of the service of Prof. Henry and the work of Americans in general in this field. The third respect in which this congress equaled and perhaps surpassed all previous ones was in the importance of the papers and discussions brought forward there. The most important electricians of Europe as well as of this country were present, and this fact greatly added to the value of the work of the congress. As to future congresses, there was little left to be done; Prof. Rowland had said that he thought there would never be occasion to hold another congress, but this was perhaps going a little too far. Prof. Crocker thought that magnetic units and names for them, a standard of light and an international nomenclature for electrical terms and quantities would have to be taken up by some future congress.

The chairman here mentioned the fact that Prof. Crocker first suggested that the name "henry" be given to the unit of self-induction.

Mr. Nikola Tesla was then gracefully introduced by the chairman and spoke as follows, being allowed to exceed the 10-minute limit:

I have with great reluctance accepted these compliments, because I had no right to interrupt the flow of speech of our chairman. You may perhaps know, at least those of you who have followed the electrical development more closely, that the subject about which I am to say something is one which I recently presented before the Electrical Congress. During the past two years or so I have been gathering results and preparing work which I had in mind to present before the annual meeting of the American Institute as one of its members. But, as the date grew near, I found that the problems became so complicated and difficult that I could not do justice to the subject in this limited time, and so I made up my mind to drop the work for a little while, and go to the Exhibition and learn what I could, as any reasonable man would do. But the pressure at that time exerted upon me was so great that I could not resist when a number of scientific men urged me on to do something—deliver a lecture. A great many promised that they would come, but at the last moment they became ill, and when the programme was sifted down I was the only healthy man left, who had the time to deliver a lecture; and so I managed to take some of my apparatus, and through the courtesy of some officials of the American Express Company—especially Mr. Sherman, to whom I am indebted—was able to arrive in time, pretty nearly losing my opportunity by the impoliteness of one of the officials of the Fair; and so I gave a brief outline of this work.

Now, as a matter of fact, at that time I had gone considerably into the study of the practical aspects of the work which I was to present, and my notion was that I was touching upon something very important, something which would lead perhaps—so I thought in my enthusiasm—something which would lay the foundations of a novel industry, perhaps of more than one industry. But to speak in that strain before such a gathering as I had the honor to address there would have required a nerve which I did not possess, or if I did possess it it would be sure to leave me when I wanted to use it; and so I dwelt chiefly on those features which possessed a purely scientific interest, my desire being to present the subject very modestly, as I was not quite sure of some of the questions involved. Right after the lecture I asked one of my friends what he thought of it. He said it was well enough, but it could have been better. A prominent engineer came to me and said, "Mr. Tesla, I want to tell you something, but I fear it may offend you." I knew what was coming and so I asked what it was. He said: "Well, don't you work on steam engines. You have done some work in electricity. If you stick to it you will do some good work, but if you work on steam engines you are bound to fail." All these men that I mention are the most prominent men in the profession. Another said, "I wonder what Tesla is going to do with his blessed engine." Another, to whom I showed the advantage of doing away with complicated mechanism and generating electricity directly, said, after he had watched it for a long time, "Couldn't you apply this to rotating motion?" Now this is the way that my work was received. But I was quite prepared for that because for fully two years I had had these ideas in my mind. I rejected them and rejected them again and again, until I got in my mind the construction of the apparatus, until I overcame some difficulties which at first seemed to me insuperable, and finally I devoted myself to this work. One of the first impulses which guided me was to produce an absolutely constant motion, which would be independent of any friction losses, or gravity, or temperature changes within very minute limits. Now, you can employ a pendulum, you can employ a clockwork of a vibrating spring, or some such device as that. But they are very unreliable. I wanted to produce a positive motion, so that I might operate what I called some time ago a disruptive discharge coil. I may assume that some of you know that some time ago I advanced a method of producing currents of high frequency from direct or alternating currents. The method consists of charging condensers, discharging them either through a primary and then introduce devices in coils of the secondary or in its own current of high potential. Now the lamp to be operated with such coils is perfect enough. A nearly exhausted vessel would be good enough. But the devices themselves are inefficient in the production of these currents, and one reason was that these devices did not yield a perfectly constant vibration. I had to depend on a disruptive gap. I used air blasts, or oil streams, or a mechanical interrupter. Now with this device which I invented subsequently I was able to maintain a vibration with perfect constancy. This device consisted of a spring, which required several tons of force to spring a certain distance, and which was constantly kept in vibration by steam pressure or air pressure. In the beginning I used springs of tempered steel. These steel springs would break, though they had a section of two or three square inches. So I resorted to air springs. The air springs would not break, but they had no constant resilience. Then I made the chambers of the hair springs communicate with the outer air. Then I maintained boiler water around the jacket. Now you know this device yields a constant vibration, and as the force which is driving it is many tons and the friction but a very small matter, it is unaffected by the pressure, and so I have a constant vibration. This was one of the chief features I wanted to present. This is the device which I believe will be used for many purposes, for instance, governing all sorts of mechanism, engines and so on. This was one of the features which had interest for scientific men, because with this I am now enabled to produce currents of perfectly constant frequency. But this was merely the tail of the work which I have been doing. You have seen a few designs of engines described by the eminent speaker who is one of the most competent to talk on the subject, and who has shown us a great many complicated mechanisms. They are exactly adapted to illustrating what I have to say, and I would ask whether it is not worth while to attempt to simplify those mechanisms, which we have been using heretofore for the production of electric currents. When we look at a steam engine and inquire where the power comes from that drives the steam engine, we will always find that the power comes from a little box—a cylinder with a piston in it—and all the other appurtenances are really but to keep it going. You may do away with the flywheel, with the cross-heads, with the eccentrics, with all the appliances provided that you can in some other simple way govern the motion of the mechanism. So then my first idea was to apply the motion of the piston, which is freely movable, to a magnetic field, to move a magnet or a coil in a magnetic field and so generate currents by this direct motion. Now let us see what we can do in that respect. First, we reduce the weight of the engine for the same pressure and the same piston speed to one-thirtieth or one-fortieth if not one-fiftieth of its weight. Furthermore, we do away with all mechanical frictions. The engine designed according to my ideas has a mechanical efficiency of 99¾ per cent. Now that is in itself a very big item and renders it worth while endeavoring to make this mechanism a commercial success. But there are other far greater things. You will find that engineers often say what an advantage it is to apply the direct motion of the steam piston to a pump. In reality the advantage in a pump is but a very minute one. The water column has got an enormous inertia, and what we do gain in the direct acting pump is merely a matter of overcoming some additional frictions which we have in the ordinary engine. We may take the mechanical efficiency—I gather the data from various works—we may take the efficiency as say 81 to 82 per cent. at the full load. But the efficiency is much less on a varying load. Then, furthermore, we have got these variously estimated. I take the figures which I have found to be fair, giving this as the efficiency. Now the dynamo again has got mechanical losses due to friction, and, furthermore, the wire is never utilized fully in the dynamo. In my construction the dynamo may consist of a simple coil of the magnet, and a simpler coil which is all immersed in the magnetic field. There is no useless wire. Consequently dynamo and engine, if they are reduced considerably in weight, increase in efficiency. There is only one engine which can equal it in output, and that is the turbine. With the steam turbine we can obtain an enormous output, and that is the reason why the steam turbine, in my opinion, may be found a valuable adaptation for driving dynamos; and then convert the motion by means of alternating dynamos; and I think the steam turbine has in itself a physical cause why it cannot surpass a certain efficiency, and that is that we drive turbines by impact. A turbine might be very efficient if the medium which propels it were incompressible and homogeneous. But it cannot be efficient if we drive it by means of isolated shocks. Furthermore, we cannot in a turbine gain all the expansion. These causes, I think, will limit the efficiency obtained in turbines. But in reciprocating mechanisms we can, provided we obtain a sufficient high speed of the piston, expand the steam at an enormous rate. It is perfectly practicable in these mechanisms which I have been working up to obtain, if you want, a speed of 100 metres a second, and while I do not contemplate producing such speeds yet it is quite possible to do it. But since we can produce higher speeds we might as well increase the speed two or three times, and so augment the activity of the mechanism and raise the efficiency. Furthermore, as I am enabled now to work without a packing, I found that in these mechanisms the packing is actually objectionable, the expansion occurring at an enormous rate, and the engine being of such character that the exhaust can be reduced to pretty nearly the atmospheric pressure very easily. The mechanical friction is reduced to such a small figure that we can raise the temperature of the steam very considerably. You know that in high pressure steam engines one of the greatest troubles is the lubrication. We can go so far with the mineral oil, we can go so far with ordinary oil, but then we reach a point at which we cannot go any further, the lubricant will not work; and I am informed by very able practical engineers that about 250 pounds per square inch of steam pressure is as high as we practically go. With this engine we can go much higher. I am now preparing a boiler which will give me up to 350 pounds pressure. It is very important, of course, to get the pressure very high. In these mechanisms we are confronted with two things. For what are they going to be used—for light or for power? If we want to drive motors we must have a long stroke and a slow frequency. If we want to operate lamps then we want a very short stroke and a very rapid motion. To have a high speed with short stroke we must have a great initial pressure, because you know the number of vibrations increase only as the square root of the pressure. So if we want to have twice the number of vibrations we must have four times the pressure. But, on the other hand, four times the pressure and twice the number of vibrations means eight times the output. So it is very important in this mechanism in which the power depends on the square to obtain as high a pressure as possible. It is on this line now that I am working.

We have had such reciprocating engines as far back as 1868 or 1870, and it would be a very erroneous idea to think that I had evolved something radically novel in that part of the mechanism.

It is more economical to produce rapid vibrations than low vibrations. But so far as the economy of the dynamo is concerned, and so far as the economy of the engine in general is concerned, it is better to

produce a long stroke, because a long stroke means a high velocity.

I have an apparatus which runs lights in the laboratory, and shortly I think I will have something which will be ready for practical application. I think I am not mistaken in believing that we are going to have very shortly a means at hand of producing twice as much electricity from coal as we can produce at the present time—provided I am not mistaken. This is subject, of course, to a test, but I am quite confident that it can be done. This is not, however, a subject which occupies me altogether. There are also other subjects.

Mr. J. J. Carty was the next speaker, and his subject "The Telephone." He said that to give a proper idea of the telephone exhibit at the World's Fair would mean a review of the present state of the art of telephony, and this he did not propose to undertake. The foreign manufacturers had little to show of interest or novelty. The general features of the display were interesting more from the tendencies which they exhibited than from any details of structure, and the latter work in this line has been confined more to doing things which we know how to do, and doing them well, than trying to find out things which we do not know. The long distance line from Chicago to New York was perhaps the most striking exception presented. The movement has lately been away from series work toward multiple arc work. The exhibition of American underground cables was particularly complete, and in this respect this country may be said to excel; the material generally used is paper put loosely upon the wires so that the dielectric is really a mixture of paper and air. This gives a very low capacity, and is specially suited for telephonic purposes.

Mr. James Hamblet next spoke upon the subject of "Electric Clocks." About 10 years ago the first decade of standard time in this country was completed. Electric clocks were first exhibited in the exposition of 1851, but with small success. The kind of clock then used was driven entirely by electricity, but within a few years inventions have been brought out by which the clock is simply wound by electricity at stated intervals. The Self-Winding Clock Company is making arrangements with the Western Union Telegraph Company to introduce these clocks to all the large cities of the United States, and they have something like 20,000 already in operation. An elaborate exhibit of these clocks was made at the Exposition. They were scattered all over the grounds, many of the buildings containing a number; they were all wound once an hour and corrected every hour by a fine standard clock, which in turn was corrected daily by a signal from Washington. One of the newest features in the exhibit was the tower clock in the middle of the Manufactures and Liberal Arts Building. Such a clock makes it possible to dispense with the cumbersome weights and mechanism of the ordinary tower clock.

A motion to postpone remainder of programme until some future date was made and carried.

Mr. Hamblet then exhibited a collection of views showing the principal features of the World's Fair.

Dr. Emery also made a few remarks supplementing his address earlier in the evening, in which he called attention to a steam turbine exhibited in the Danish section, which ran as high as 20,000 to 30,000 revolutions per minute, and delivered 20 h. p. with a wheel about four inches in diameter at an efficiency of perhaps 80 per cent.

Mr. Tesla then stated that he did not mean to say that the turbine is mechanically inefficient, but what he meant was thermic inefficiency.

Before the adjournment a vote of thanks to the gentlemen who had favored the Society with remarks was unanimously passed.

THE TESLA OSCILLATOR.

THIS apparatus, exhibited by Tesla at the World's Fair, Chicago, attracted some attention. From a description in the *Electrical Engineer*, of New York, we take a sectional view, fig. 1, of the apparatus, and our readers may gather some notion of its construction from that and the description.

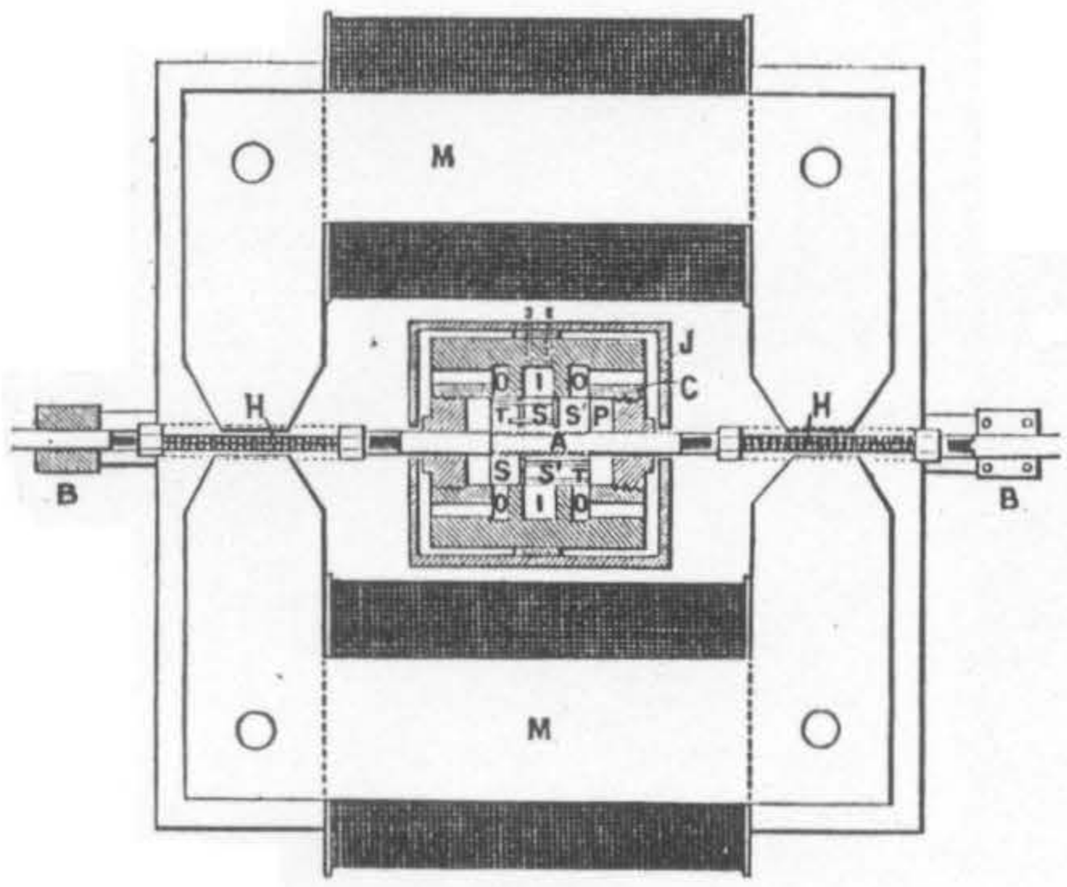


FIG. 1.

Just what this apparatus accomplishes is not made clear; no figures are given upon which one could calculate. It seems to be a kind of alternator designed to give very high frequency by imparting a rapid to and fro motion to two pairs of coils in a very strong magnetic field. The greatest frequency thus obtained is not stated, so that we are unable to compare it with rotary alternators; in that respect it would be interesting to compare it with Prof. Ewing's oscillator or alternator for high frequency, consisting of a Parsons steam turbine and a multipolar alternator.

In the sectional view a piston, P, is seen fitted into the hollow of a cylinder, C, which is provided with channel posts, O, O, and I, extending all round the inside surface. In this particular apparatus there are two channels, O, O, for the outlet of the steam or air used to drive the piston to and fro; I, being the inlet for the air or steam. The piston, P, is provided with two slots, S, S′, at a carefully determined distance, one from the other. The tubes, T, T, which are screwed into the holes drilled into the piston, establish communication between the slots, S, S′, and chambers on each side of the piston, each of these chambers connecting with the slot which is remote from it. The piston, P, is screwed tightly on a shaft, A, which passes through fitting boxes at the end of the cylinder, C. The boxes project to a carefully determined distance into the hollow of the cylinder, C, thus determining the length of the stroke. Surrounding the whole is a jacket, J, to deaden the sound produced by the action of the oscillator.

A magnetic frame, M, M, is fastened so as to closely surround the oscillator and is provided with energising coils which establish two strong magnetic fields on opposite sides. The magnetic frame is made up of thin sheet iron. In the intensely concentrated field thus produced, there are arranged two pairs of coils, H, H, supported in metallic frames which are screwed on the shaft, A, of the piston and have additional bearings in the boxes, B, B, on each side. The whole is mounted on a metallic base resting on two wooden blocks.

The operation of the device is as follows: The working fluid being admitted through an inlet pipe to the slot, I, and the piston being supposed to be in the position indicated, it is sufficient, though not necessary, to give a gentle tap on one of the shaft ends protruding from the boxes, B. Assuming that the motion imparted be such as to move the piston to the left (when looking at the diagram), then the air rushes through the slot, S′, and tube, T, into the chamber to the left. The pressure now drives the piston towards the right and, owing to its inertia, it overshoots the position of equilibrium and allows the air to rush through the slot, S, and tube, T, into the chamber to the right, while the communication to the left hand chamber is cut off, the air of the latter chamber escaping through the outlet, O, on the left. On the return stroke a similar operation takes place on the right hand side. The oscillation is maintained continuously and the apparatus performs vibrations from a scarcely perceptible quiver amounting to no more than $\frac{1}{64}$th of an inch, to vibrations of a little over $\frac{3}{8}$ths of an inch, according to the air pressure and load. It is, indeed, interesting to see how an incandescent lamp is kept burning with the apparatus showing a scarcely perceptible quiver.

The piston cushions against the enclosed air in the cylinder so that even at high velocities it is stopped and reversed without shock. As an apparatus for experimental research on high frequency alternating currents this alternator or oscillator may have the advantages claimed for it, but it does not possess any recommendations as a practical alternator.

As to the novelty of the air or steam oscillator for producing the rapid to and fro motions there is none; a common stone-cutting or engraving tool has long been in use in which this very same idea has been worked out in a thoroughly efficient manner, a piston and cylinder working a small chisel to and fro at a speed of 20,000 per minute by means of compressed air.

NOTES.

The Tesla Engine.—Speaking at a meeting of the New York Electrical Society, Mr. Nikola Tesla referred to his improved engine, which is to do away with fly-wheels, cross-heads, and eccentrics; everything, in fact, but the piston and cylinder, all the control mechanism being electro-magnetic. Mr. Tesla's address is reported in the N.Y. *Electrical Review*, December 6th.

NEW BOOKS.

Light and Other High-Frequency Phenomena. By NIKOLA TESLA.

Introduction. — Mr. Tesla introduces his lecture about as follows: — In our study of the physical universe we find that our sense of sight is superior to all other senses, because it enables us to penetrate much deeper into the fathomless depths of Nature's mysterious activities. The activity by means of which Nature reveals herself to us through our organ of sight, the activity which we call light, deserves our closest attention. What is light? It is an electromagnetic activity, according to most advanced views; hence the importance of investigating those forms of electromagnetic activities which approach the phenomena of light as near as experimental possibilities of the present day will permit.

The introduction might lead one to expect that Mr. Tesla intends to describe a novel class of high-frequency electrical oscillations for the purpose of illustrating and giving new evidence in favor of the electromagnetic theory of light. In that case one would perhaps feel somewhat disappointed to find that Mr. Tesla's experiments are simply Hertz's experiments in a modified form, a form by which it can be shown that in the first place the Hertzian oscillations enable us to transmit a considerable amount of energy along a single wire, and in the second place that novel vacuum tube effects can be produced by rapid alternations of the electromagnetic field.

But this feeling of disappointment, if it should occur at all, would be soon dispelled and quickly give way to a feeling of admiration for the patient work of an enthusiastic inventor who has brought all the ingenuity of his remarkable engineering skill to bear upon the problem before him, and that problem is contained in the question: — What immediate benefits can modern electrotechnics derive from Hertzian oscillations? This problem Mr. Tesla handles with extraordinary ability.

Method of Conversion. — To produce the oscillations Mr. Tesla connects a direct or alternating current dynamo to an oscillatory transformer. The primary of this transformer, consisting of a small number of turns of stranded wire, corresponds to the Hertzian exciter, and the secondary, consisting of an appropriate number of turns of wire surrounding the primary, corresponds to the Hertzian resonator. Hertz worked with oscillations of about 10^8 periods per second. Mr. Tesla is satisfied with a

frequency of 10^6 or even smaller, hence his primary and secondary coils have a much larger self-induction than that of the Hertzian exciters and oscillators. By a suitable arrangement of the ratio of the turns in the primary and secondary, the oscillatory transformer can be an up or a down transformer. The primary spark space is similarly located as in the Hertzian experiments. Capacity is generally added to both the primary and the secondary coils.

Precautions which must be observed in order to render the Primary Impulses very Powerful. — No arc formation should be allowed in the primary spark space. Four different devices for this purpose are described, the purpose of each being to blow out the arc as soon as it begins to form.

1. Spark space is placed between the poles of a sufficiently powerful magnet.

2. Current of hot air sweeps continually through the spark space (especially when dielectrically weak air is required between the discharge knobs).

3. Spark space is placed in a partially exhausted glass tube, the tube being placed between the poles of a strong magnet to prevent arc formation.

4. Two objections against a spark space through a gaseous medium are pointed out: (*a*) the discharges are not sufficiently disruptive; (*b*) there is too much dissipation. To improve both, a liquid dielectric was tried. A hollow pulley was partially filled with oil (the quality of oil not mentioned); the pulley being rotated rapidly, the oil was thrown out centrifugally and compressed against the rim; discharge through oil improved the disruptive character of the primary sparks and diminished losses. These discharges were effective for producing great spark length, but not for luminous effects, since for these, according to Mr. Tesla, a harmonically varying electromagnetic force is preferable.

The best form of generator is then discussed; it is pointed out that the most convenient method is to use a low-tension dyna-motor, to transform direct currents into low frequency alternating currents of low voltage. The low-voltage alternating current thus obtained is then transformed into high tension alternating by a stationary transformer, and this high-tension current is then employed to feed the oscillatory transformer.

Phenomena produced by Electrostatic Force. — In the introduction to these phenomena, Mr. Tesla makes the following statement concerning electrostatic force: "It is the force which governs the motion of the atoms, which causes them to collide and develop the life-sustaining energy of heat and light, and which causes them to aggregate in an infinite variety of ways according to Nature's fanciful designs, and to form all these wondrous structures we perceive around us. . . ."

Evidently Mr. Tesla makes even a broader claim for the electrostatic

force than Professor J. J. Thomson does for Faraday's tubes of electrostatic induction. (Compare also H. von Helmholtz's lecture on Faraday.[1])

Experiment 1. — One pole of the oscillatory transformer is touched with one hand, and the other hand approaches the other pole. A brush discharge passes from the free hand to the free pole. The frequency of the current is said to be a million, and the electromotive force $= 2 \times 10^5$ volts. Mr. Tesla calculates that, with four times the frequency, and a potential of 3×10^6 volts, his whole body would be surrounded by a flame, but the current would do him no harm, because the body offers a large cross-section to the high-frequency current, and the current *in its passage through the body distributes itself uniformly*, so that the current density is small at any point. This interpretation takes it for granted that Hertzian oscillations pass through the human body just the same as an ordinary direct current would pass through a good conductor.

Experiment 2. — Illustrates difference between discharges at high and low frequency. Two circular brass plates, each connected to a pole of an oscillatory transformer, are placed at a distance of 12 inches. At high frequency the luminosity of the discharge between the plates is steady and perfectly uniform; at low frequency, the discharge is in the form of numerous, quivering, and noisy spark filaments. Mr. Tesla admits the impossibility of disruption at high-frequency; he observes the powerful chemical action of the high-frequency discharge; he seems, however, to fail to recognize in the difference of the two discharges a confirmation of the generally accepted dissociation theory of electrical conduction through gases.

Experiment 3. — An incandescent lamp bulb with a single straight carbon filament is attached to one pole of the oscillatory transformer. An apparently unipolar discharge takes place. (The luminosity in the immediate neighborhood of the external surface of the lamp is evidently due to the varying condenser charges of that surface. If that surface has any sharp points, the current density there will be large, and the point will be heated.[2]) A bulb drawn out into a point is (therefore) heated and is ultimately broken at that point. Mr. Tesla ascribes this heating to molecular bombardment which, according to his opinion, will take place in *heterogeneous media like gases*, because *the molecules* or atoms in such bodies are free to move under the impulse of electrical forces. Mr. Tesla does not seem to be aware of the fact that nobody has succeeded yet in electrifying the molecules of a perfect gas. Several experiments are then described in support of the bombardment theory, but they do not seem to be convincing.

[1] Vorträge und Reden, Vol. 2, p. 302, 1884.

[2] The reviewer is responsible for the opinion enclosed in parentheses in this paragraph.

On Currents or Dynamic Electricity Phenomena. — In these experiments it is shown that electrical energy can be transmitted along a single open-circuited wire. The *modus operandi* is the following: — One end of a wire is attached to one of the poles of the secondary of an oscillatory transformer; the other end is attached to a large plate. An adjustable coil is also inserted in this circuit. The plate gives this open circuit its principal capacity, the adjustable coil, which the reviewer calls the inertia coil, enables the experimenter to regulate its self-induction or inertia. When the frequency is very high, the capacity of the plate can be dispensed with, the capacity of the remaining part of the circuit being sufficient to bring the circuit in resonance with the impressed electromotive force.

Two methods are then employed to demonstrate the flow in the open circuit and its dependence on the constants of the circuit; namely, capacity, self-induction, and frequency.

Method I. — The circuit of several turns of wire surrounding the auxiliary inertia coil is closed by a 50-volt, 16-C.P. lamp, and the flow studied by the intensity of the glow of this lamp.

Method II. — The flow in the open circuit is transformed in various ways, and various simple devices are then employed to cause a disc to rotate under the electromagnetic or electrodynamic action of the oscillatory currents thus employed. The first method points out the possibility of a distribution of oscillatory currents for electric lighting; the second method demonstrates in a certain way the feasibility of employing such currents for operating electromotors. The difficulties which would necessarily attend such an employment of oscillatory currents might have been discussed a little more fully, in order to prevent a misconception on the part of those who are not familiar with the subject. To show the effects of impedance (a wave distribution of potential energy along a short, stout wire), Mr. Tesla employs Lecher's well-known and generally adopted method of producing very rapid Hertzian oscillations. He devotes, then, twelve pages to a discussion of electrical resonance, and particularly of the bearing of electrical resonance upon the problem of transmitting signals all over the earth by causing the electrical charge of the earth to oscillate.

This discussion is evidently introduced to relieve somewhat the serious character of the rest of the lecture, and seems to bear the same relation to the rest of the lecture as the amusing gravediggers' dialogue in "Hamlet" bears to the rest of the play. In the reviewer's opinion, Mr. Tesla does not wish to be taken *au serieux* in this part of his lecture.

Vacuum Tube Effects produced by Hertzian Oscillations.

1. *Incandescence of a Solid.* — It was observed a long time ago that the electrodes of a Geissler tube, especially the cathode, become very hot, although the current through the tube may be exceedingly small.

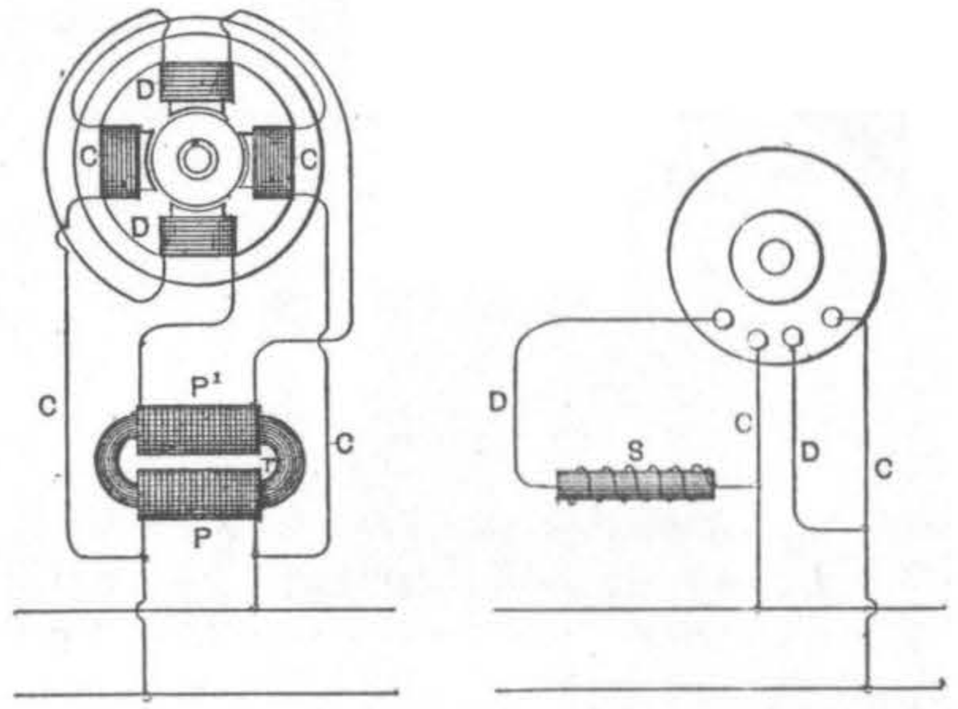
Mr. Crookes, it seems, was the first to suggest that this heating was due to molecular bombardment. Mr. Tesla shows that by means of this property of the vacuum-tube discharge carbon filaments and carbon buttons, when enclosed in the vacuum of an incandescent lamp, can be rendered incandescent by an exceedingly small current, provided that the potential of these carbons is very high and the frequency considerable; the higher the frequency, the slower will be the process of disintegration of the carbons. He also ascribes this heating to molecular bombardment, but his arguments in favor of this view are open to the same objections which were brought, long ago, against the molecular bombardment theory of Crookes. Some of the heating in such tubes is very probably due to molecular, or rather atomic, bombardment, but according to the splendid investigations of E. Wiedemann, Schuster, Elster and Geitel, J. J. Thomson, Giese, and others, the chemical process going on in such tubes owing to the action of the electrical forces will account easily for a very large part of the heat. It should also be remembered that the spectrum of an incandescent gas is very rich in ultra-violet light, which part of the luminous energy of the gas never leaves the bulb, being absorbed by the same and transformed into heat. To ascribe all the various heat phenomena in a vacuum tube simply to molecular bombardment means to turn a sharp corner, in order to get out of the way of difficulties instead of forcing the difficulties themselves to get out of the way. The same criticism applies to Mr. Tesla's view of the cause which produces phosphorescence and fluorescence in vacuum tubes. It is, of course, a well-known fact that mechanical shocks can produce phosphorescence and fluorescence; but it is equally well known that no agent is as powerful as ultra-violet light and purely chemical processes to produce these phenomena. Why, then, refer these phenomena in vacuum tubes to molecular bombardment and to nothing else?

It must be observed, however, that the value of Mr. Tesla's work is, of course, independent of the view which he may have formed of the causes of all these various phenomena which he investigated by means of extremely powerful electrical oscillations. The real value of Mr. Tesla's work is due to the fact that he was the first to succeed in constructing a magnificent array of physical apparatus, by means of which these exceedingly powerful Hertzian oscillations can be produced, and to point out a way of attacking old but still puzzling phenomena by weapons with which the refinements of modern electrotechnics can furnish us. It is a work which, for some time to come, will be consulted by the electrical engineer who wishes to become acquainted with the tendencies of recent advances in electricity, and it will be consulted by the physicist who wishes to make himself familiar with the practical bearing of these advances. In the per-

formance of this work Mr. Tesla has, therefore, rendered invaluable service to all those who are interested in the science of electricity.

M. I. PUPIN.

COLUMBIA COLLEGE, New York, Oct. 15, 1893.



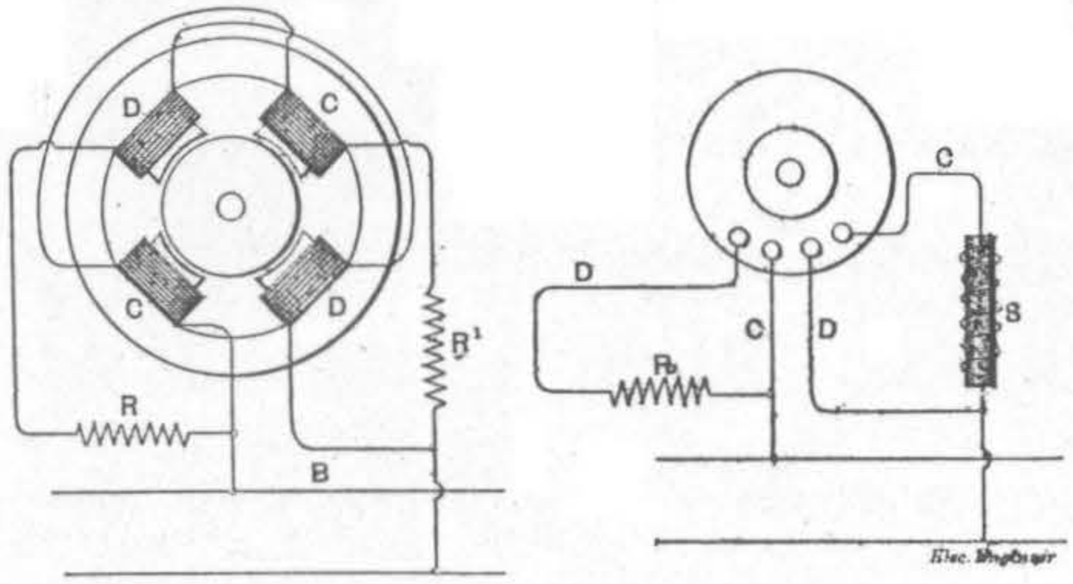
TESLA MOTORS OPERATED FROM SINGLE PHASE TWO-WIRE ALTERNATING CIRCUITS.

THOSE who have followed Mr. Tesla's work in alternating motors will recall that in 1888 he first drew public attention to his new multiphase system of operating alternating current motors, in a paper read before the American Institute of Electrical Engineers, in which he laid down the principles which have since been practically applied in many ways. In this system, it will be remembered, each motor contains two or more independent energizing circuits through which are passed alternating currents, having in each circuit such a difference of phase that by their combined or resultant action they produce a rotary progression of the poles or points of maximum magnetic effect of the motor and thereby maintain the rotation of the armature.

A multiphase system of this kind, however, requires at least three wires for its successful operation, to convey the currents differing in phase, and Mr. Tesla, therefore, early set about to devise means for operating phase motors from the ordinary single-phase alternating circuit, by creating the difference of phase locally at and in the motor. The various ways in which this can be done are described in two patents just granted to Mr. Tesla, which are of special interest at this time.

In all the methods described below, the fundamental idea involved is to pass a single alternating current through both of the energizing circuits of the motor, and to retard the phase of the current in one circuit to a greater or less extent than in the other. The distribution of current between the two motor circuits is effected either by induction or by derivation.

The diagram Fig. 1 shows a motor with two energizing circuits, C and D. One of these circuits, C, is connected directly with the line circuit, while the other set of coils D, is connected up in the secondary circuit of a transformer T. The primary coil P of this transformer, is connected to the line circuit. The alternations of current in the line tend to establish in their passage through the coils C, a polarity opposed to that set up in the coils D, and if the currents in the two sets of coils coincided in their phases, no rotary effect would be produced. But the secondary current developed in the coil P' of the transformer, will lag

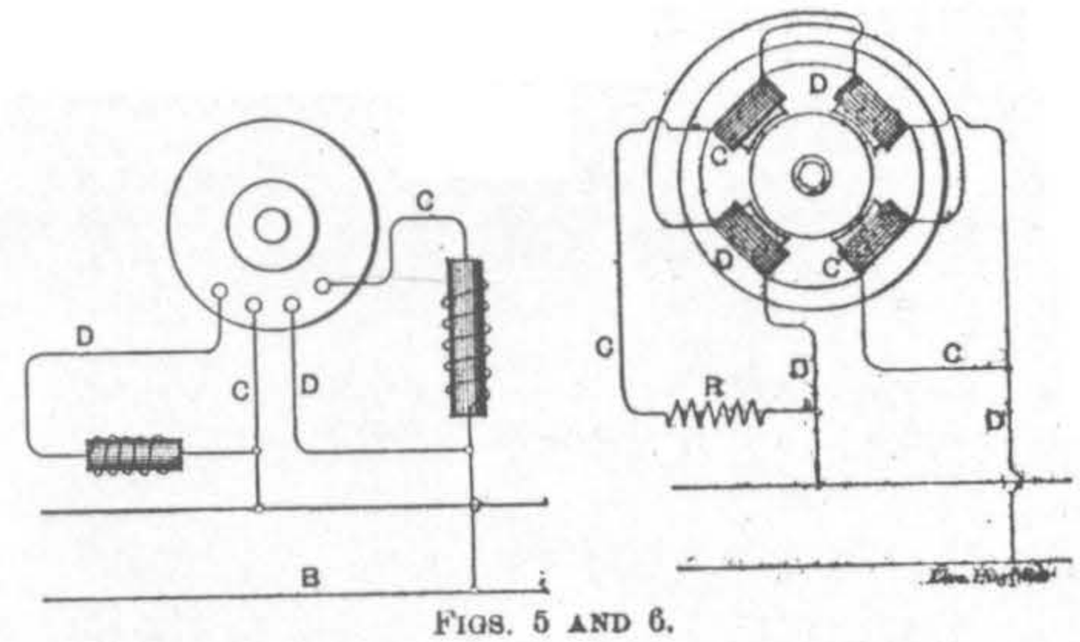


FIGS. 1 AND 2.

behind that in the primary, which lag may be increased to a sufficient extent to practically obtain the same result as though two independent currents were used to energize the motor.

In another form, shown in Fig. 2, the arrangement of the parts is similar to that shown in Fig. 6, except that a self-induction coil S, is introduced into one energizing circuit of the motor. The effect of thus increasing the self-induction in one of the circuits is to retard the phases of the current passing therein to a greater extent than in the other circuit, and in this way to secure the necessary difference in phase

between the two energizing currents to produce the rotation of the motor.



In Fig. 3 there is shown diagrammatically a type of motor in which two dead resistances R R′ are included respectively in the energizing coils of the motor. No rotary effect will be produced as long as the resistances are equal, but by varying the resistance in one circuit the retardation of the current in that circuit will be varied and correspond-

FIGS. 3 AND 4.

ing effects produced. For example, a reduction of the resistance in one circuit imparts to the motor rotation in one direction while a reduction of the resistance in the other circuit will produce a rotation in the opposite direction. By means of the two resistances, therefore, capable of variation or of being bodily withdrawn from or inserted in the circuits by simple means, rotation of the motor is secured.

In Fig. 4 a self-induction coil S is included in one of the motor circuits and a dead resistance R in the other. The increased self-induction in one circuit thus produced acts to increase the difference of phase between the current in that motor circuit and the unretarded current in the line circuit. On the other hand, the introduction of the dead resistance in the other motor circuit reduces the retardation and brings the phases of the current in it more closely in accord with those of the unretarded current, thus producing a correspondingly greater difference of phase between the two currents in the energizing circuits C and D.

FIGS. 5 AND 6.

In Fig. 5, two self-induction coils are shown, one in each motor or energizing circuit. One of these coils is much smaller than the other and has less self-induction or counter-E. M. F. than the other, so that the phases of current will be retarded to a less extent than in the other.

In Fig. 6 the two energizing circuits of the motor are shown connected in multiple arc to the line circuit and in one of these circuits is a resistance R. Assuming the two motor circuits to have the same degree of self-induction no rotary effect will be produced by the passage through them of an alternating current from the line. But if one of the motor circuits, as C, be varied or modified by the introduction of a dead resistance R, the self-induction of that circuit or branch is reduced, and the phases of current therein retarded to a correspondingly less extent. The relative degrees of retardation of the phases of the current in the two motor circuits with respect to those of the unretarded current in the circuit B thus produced, will set up a rotation of the motor.

Finally we may mention another type in which one set of energizing coils is of finer wire than the other or has a greater number of convolutions; or each circuit may contain the same number of convolutions, but composed of different conductors, as, for instance, one of copper, and the other of German silver.

Mr. Tesla has devised still other methods for accomplishing the same purpose, but those described will give a fair idea of the wonderful flexibility of the system.

Tesla Motors Operated from Single Phase Two Wire Alternating Circuits.

The reader who has followed up the line of work in which Mr. Tesla has been recently engaged will, no doubt, be interested to hear of some results which have been crystallized into two patents recently granted to Mr. Tesla.

As early as 1888 a paper was read before the American Institute of Electrical Engineers, in which Mr. Tesla first publicly described his new multiphase system of operating alternating current motors. As an outgrowth of this, results have been obtained by others working in the same direction, and valuable and interesting have been the observations and practical devices obtained.

In the system above mentioned, each motor is supplied with two or more energizing circuits, through which are passed alternating currents, having in each circuit such a difference of phase, that by their combined or resultant action they produce a rotary progression of the poles or points of maximum magnetic effect of the motor, and thereby maintain the rotation of the armature.

Three wires are necessary in a system of this kind, but in order to avoid this, Mr. Tesla set to work to devise a means whereby the phase motors could be operated from the ordinary single phase alternating circuit by creating a difference of phase locally at and in the motor.

The patents below referred to had this object in view, and it will be noticed that

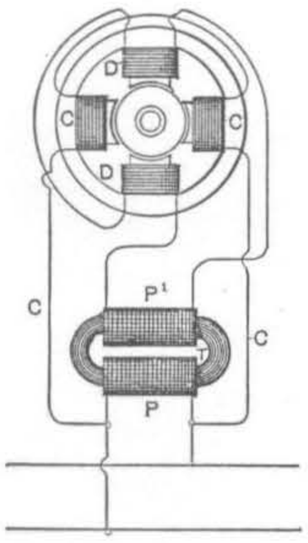


FIG. 1.—TESLA MOTOR WITH TWO ENERGIZING CIRCUITS.

the fundamental idea involved is to pass a single alternating current through both of the energizing circuits of the motor, and to retard the phase of the current in one circuit to a greater or less extent than in the other, either by induction or by derivation, is the distribution of current between the two motor circuits.

The diagram Fig. 1 shows a motor with two energizing circuits, C and D. One of these circuits, C, is connected directly with the line circuit, while the other set of coils D, is connected up in the secondary circuit of a transformer T. The primary coil P of this transformer is connected to the line circuit. The alternations of current in the line tend to establish in their passage through the coils C, a polarity opposed to that set up in the coils D, and if the currents in the two sets of coils accorded in their phases, no rotary effect would be produced. But the secondary current developed in the coil P' of the transformer will lag behind that in the primary, which lag may be increased to a *sufficient extent* to practically obtain the same result as though two independent currents were used to energize the motor.

In another form, shown in Fig. 2, the arrangement of the parts is similar to that shown in Fig. 6, except that a self-induction coil S is introduced into one energizing circuit of the motor. The effect of thus increasing the self-induction in one of the circuits is to retard the phases of the current passing therein to a greater extent than in the other circuit, and in this way to secure the necessary difference in phase between the two energizing currents to produce the rotation of the motor.

Shown diagrammatically in Fig. 3 is a type of motor in which two dead resistances R R'are included, respectively, in the energizing coils of the motor. No rotary effect will be produced as long as the resistances are equal, but by varying the resistance in one circuit the retardation of the current in that circuit will be varied and corresponding effects produced. For example, a reduction of the resistance in one circuit imparts to the motor rotation in one direction, while a reduction of the resistance in the other circuit will produce a rotation in the opposite direction. By means of the two resistances,

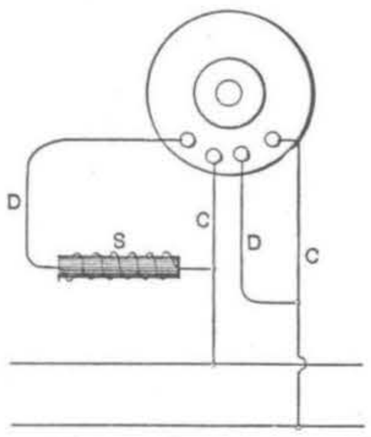

FIG. 2.—TESLA MOTOR WITH SELF-INDUCTION COIL.

therefore, capable of variation or of being bodily withdrawn from or inserted in the circuits by simple means, rotation of the motor is secured.

In Fig. 4 a self-induction coil S is included in one of the motor circuits and a dead resistance R in the other. The increased self-induction in one circuit thus produced acts to increase the difference of phase between the current in that motor circuit and the unretarded current in the line circuit. On the other hand, the introduction of the dead resistance in the other motor circuit reduces the retardation and brings the phases of the current in it more closely in accord with those of the unretarded current, thus producing a correspondingly greater difference of phase between the two currents in the energizing circuits C and D.

Two self-induction coils are shown in Fig. 5, one in each motor or energizing circuit. One of these coils, is much smaller than the other, and has less self-induction or counter electro-motive force than the other, so that the phases of current will be retarded to a less extent than in the other.

The two energizing circuits of the motor are shown in Fig. 6, connected in multiple arc to the line circuit, and in one of these circuits is a resistance R. Assuming the two motor circuits to have the same degree of self-induction, no rotary effect will be produced by the passage through them of an alternating current from the line. But if one of the motor circuits, as C, be varied or modified by the introduction of a dead resistance R, the self-induction of that circuit or branch is reduced, and the phases of current therein retarded to a correspondingly less extent. The relative degrees of retarda-

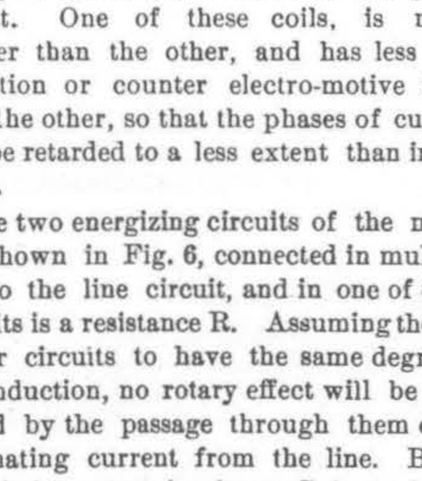

FIG. 3.—TESLA MOTOR WITH TWO DEAD RESISTANCES.

tion of the phases of the current in the two motor circuits with respect to those of the unretarded current in the circuit B thus produced will set up a rotation of the motor. Another type may be mentioned in which one set of energizing coils is of finer wire than the other or has a greater number of convolutions; or each circuit may contain the same number of convolutions, but composed of different conductors, as, for instance, one of copper and the other of German silver.

Electricity.

Nikola Tesla.

Perhaps the most daring of the experimenters of the latest decade of the nineteenth century is Nikola Tesla, who was unknown to the scientific world five or six years ago, but who to-day is regarded as a second Edison, and who has achieved more magnificent results than any half-dozen of his contemporaries combined.

To sum up his achievements in a few words is impossible, says *Paper and Press*. He has discovered, or, rather, demonstrated, the possibility of illumination without wires or globules in almost exact imitation of daylight. This lot he can vary to order, and although he has not been able to bring it to what he termed a commercial basis, he has advanced so far in the direction that comparatively little remains to be done before the public can buy daylight by the room instead of by the lamp or light. And this is but one of his marvels. He has produced a flame which does not consume and which gives out no heat whatever, and has thus laid the foundation for untold developments in every phase of electrical work. In the production of ozone by electricity he has also scored a distinct triumph. He has shown that nearly all sanitary problems can be solved by the aid of electricity, and he has also made immense strides in the direction of solving the problem of parceling out electrical force and enabling it to be applied to manual labor in every possible direction.

He was invited to visit London and explain his experiments on the very spot made immortal by Faraday. He went, and was received by the Royal Institution with due honors. The moment his fingers grasped his long glass tubes they glowed with a softened splendor, and when he waved them over his head they gleamed with a radiance which was described as weird, if not ghostly. He manufactured flames which appeared dangerous in the extreme, and then placed them in a wooden box, which was absolutely unaffected by them. He repeated these experiments, with several others, while the guest of the National Electric Convention in St. Louis, at the end of February, and he also explained the details somewhat more fully.

THE

Electrical Engineer.

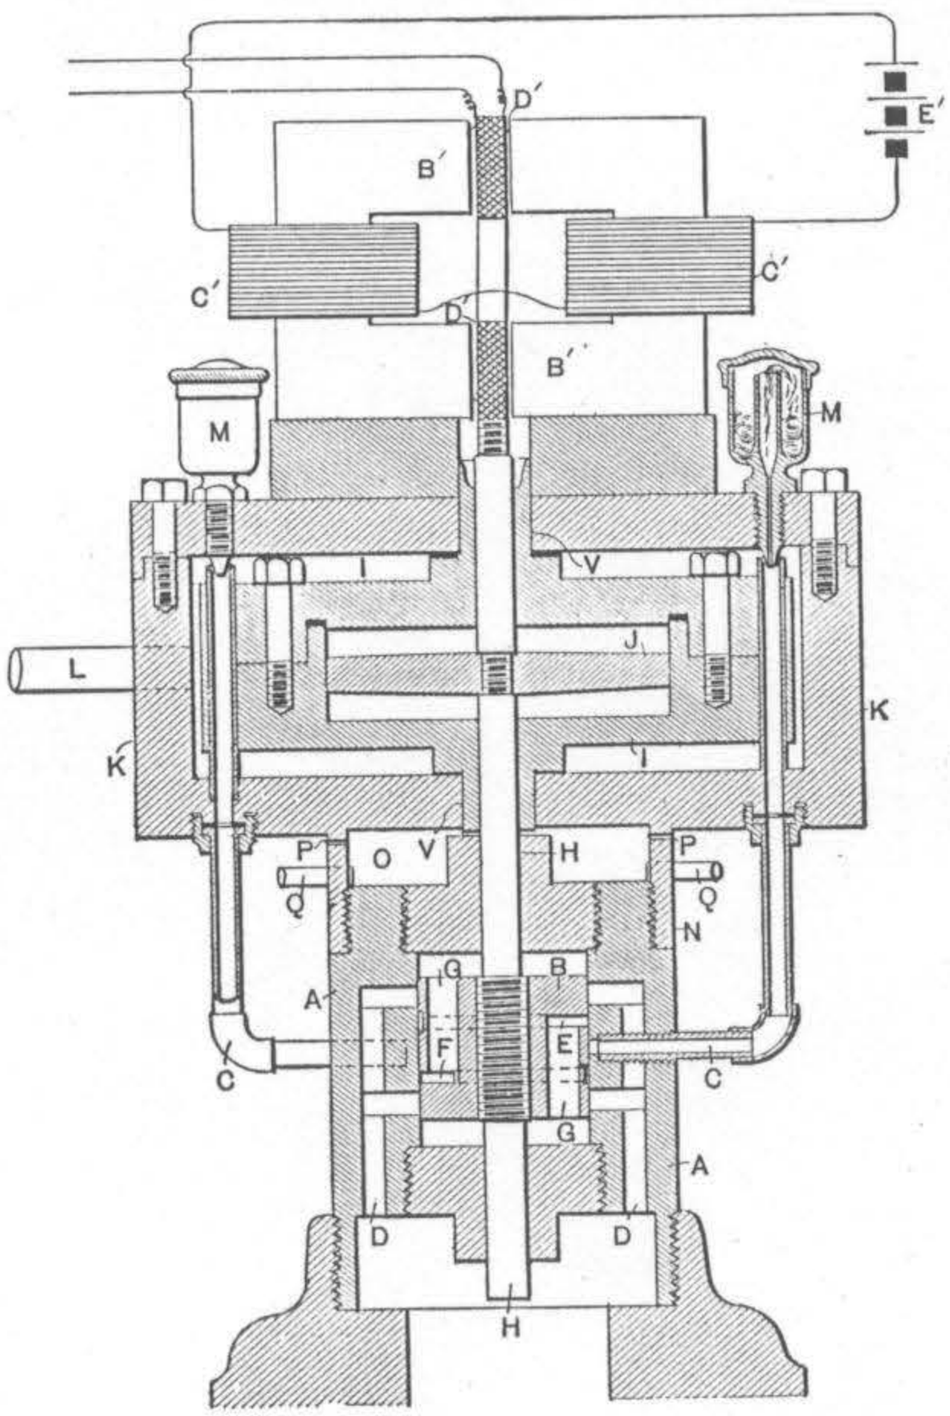
THE TESLA ELECTRICAL OSCILLATOR.

IN the lecture delivered before the Chicago Electrical Congress, Mr. Nikola Tesla first drew attention[1] to the method and means which he had devised for the continuous production of alternating currents of constant period in which all rotating parts are avoided by the employment of his oscillating engine directly to the movement of the generating coil in the magnetic field.



The main reason why no engine heretofore has been capable of producing results of this nature is that it has been customary to connect with the reciprocating parts a heavy fly-wheel or some equivalent rotary system of relatively very great inertia, or in other cases where no rotary system was employed, as in certain reciprocating engines or tools, no regard has been paid to the obtainment of the conditions essential to the end which Mr. Tesla had in view.

In applying the Tesla oscillator for the generation of currents of constant period certain conditions are encountered which must be taken into consideration in order to satisfactorily secure the desired result. When a conductor is moved in a magnetic field and a current caused to circulate therein, the electromagnetic reaction between it and the field might disturb the mechanical oscillation to such an extent as to throw it out of isochronism. This, for instance, might occur when the electromagnetic reaction is very great in comparison with the power of the engine, and there is a retardation of the current so that the electromagnetic reaction might have an effect similar to that which would result from a variation of the tension of the spring; but if the circuit of the generator be adjusted so that the phases of the electromotive force and current coincide in time, that is to say, when the current is not retarded, then the generator driven by the engine acts merely as a frictional resistance and will not, as a rule, alter the period of the mechanical vibration, although it may alter its amplitude. This condition may be readily secured by properly proportioning the self induction and capacity of the circuit including the generator.

Mr. Tesla has, however, observed the further fact in connection with the use of such engines as a means for running a generator, that it is advantageous that the period of the engine and the natural period of electrical vibration of the generator should be the same, as in such case the best conditions for electrical resonance are established and the possibility of disturbing the period of mechanical vibrations is reduced to a minimum. Mr. Tesla has found that even if the theoretical conditions necessary for maintaining a constant period in the engine itself are not exactly maintained, still the engine and generator combined will vibrate at a constant period. For example, if instead of using in the engine an independent cylinder and plunger, as an air spring of practically constant rigidity, the piston may impinge upon air cushions at the ends of its own cylinder. Although the rigidity of such cushions or springs might be considerably affected and varied by the variations of pressure within the cylinder, still by combining with such an engine a generator which has a period of its own, approximately that of the engine, constant vibration may be maintained even through a considerable range of varying pressure, owing to the controlling action of the electromagnetic system.

Indeed Mr. Tesla has even found that under certain conditions the influence of the electromagnetic system may be made so great as to entirely control the period of the mechanical vibration within wide limits of varying pressure. This is likely to occur in those instances where the power of the engine, while fully capable of maintaining a vibration once started, is not sufficient to change its rate.

In our issue of November 8, 1893, we gave the details of construction of the Tesla oscillator and a patent just issued

Elec. Engineer

FIG. 1.—TESLA ELECTRICAL OSCILLATOR.

to Mr. Tesla now enables us to supplement our previous descriptions with those of other types employed by him in this work. The accompanying engraving, Fig. 1, is a sectional view of an oscillator fulfilling the conditions laid down above.

Referring to Fig. 1, A is the main cylinder in which works a piston B. Inlet ports C C pass through the sides of the cylinder opening at the middle and on opposite sides. Exhaust ports D D extend through the walls of the cylinder and are formed with branches that open into the interior of the cylinder on each side of the inlet ports and on opposite sides of the cylinder. The piston B has two circumfer-

1. See THE ELECTRICAL ENGINEER, August 30, 1893.

ential grooves E F which communicate through openings G in the piston with the cylinder on opposite sides of the piston respectively.

The particular construction of the cylinder, the piston and the ports controlling it may be very much varied, and is not in itself material, except that in the special case under consideration it is desirable that all the ports, and more especially the exhaust ports, should be made very much larger than is usually the case so that no force due to the action of the steam or compressed air will tend to retard or affect the return of the piston in either direction.

The piston B is secured to a piston rod H which works in suitable stuffing boxes in the heads of the cylinder A. This rod is prolonged on one side and extends through bearings V in a cylinder I mounted in line with the first, and within which is a disc or plunger J carried by the rod H. The cylinder I is without parts of any kind and is airtight except as a small leakage may occur through the bearings V, which experience has shown need not be fitted with any very considerable accuracy.

The cylinder I is surrounded by a jacket K which leaves an open space or chamber around it. The bearings V in the cylinder, extend through the jacket to the outside air and the chamber between the cylinder and jacket is made steam or air-tight by a suitable packing. The main supply pipe L for steam or compressed air leads into this chamber, and the two pipes that lead to cylinder A run from this chamber, oil cups M being conveniently arranged to deliver oil into the pipes for lubricating the piston.

In the particular form of engine shown, the jacket K which contains the cylinder I is provided with a flange N by which it is screwed to the end of the cylinder A. A small chamber O is thus formed which has air vents P in its sides and drip pipes Q leading out from it through which the oil which collects in it is carried off.

In the position of the parts shown, or when the piston is at the middle point of its stroke, the plunger J is at the centre of the cylinder I and the air on both sides of the same is at the normal pressure of the outside atmosphere. If a source of steam or compressed air be then connected to the inlet ports C-C of the cylinder A and a movement be imparted to the piston as by a sudden blow, the latter begins to reciprocate in the well-known way.

The movements of the piston compress and rarefy the air in the cylinder I at opposite ends, alternately. A forward stroke compresses the air ahead of the plunger J which acts as a spring to return it; similarly, on the back stroke the air is compressed on the opposite side of the plunger J and tends to drive it forward.

The compressions of the air in the cylinder I and the consequent loss of energy due mainly to the imperfect elasticity of the air, give rise to a very considerable amount of heat. This heat is utilized by conducting the steam or compressed air to the engine cylinder through the chamber formed by the jacket surrounding the air-spring cylinder, the heat thus taken up and used to raise the temperature of the steam or air acting upon the piston is availed of to increase the efficiency of the engine.

In any given engine of this kind the normal pressure will produce a stroke of determined length, and this will be increased or diminished according to the increase of pressure above, or the reduction of pressure below, the normal. In constructing the apparatus proper allowance is made for a variation in the length of stroke by giving to the confining cylinder I of the air spring properly determined dimensions. The greater the pressuse upon the piston, the higher will be the degree of compression of the air-spring, and the consequent counteracting force upon the plunger.

The rate or period of reciprocation of the piston, however, is mainly determined by the rigidity of the air spring and the inertia of the moving system, and any period of oscillation within very wide limits may be secured by properly proportioning these factors, as by varying the dimensions of the air chamber, which is equivalent to varying the rigidity of the spring, or by adjusting the weight of the moving parts. These conditions are all readily determinable, and an engine constructed as above described maintains a perfectly uniform period through very wide limits of pressure.

The pressure of the air confined in the cylinder when the plunger I is in its central position will always be practically that of the surrounding atmosphere, for while the cylinder is so constructed as not to permit such sudden escape of air as to sensibly impair or modify the action of the air-spring, there will still be a slow leakage of air into or out of it around the piston rod, according to the pressure therein, so that the pressure of the air on opposite sides of the plunger will always tend to remain at that of the outside atmosphere.

To the piston rod H is secured a coil D′ which, by the

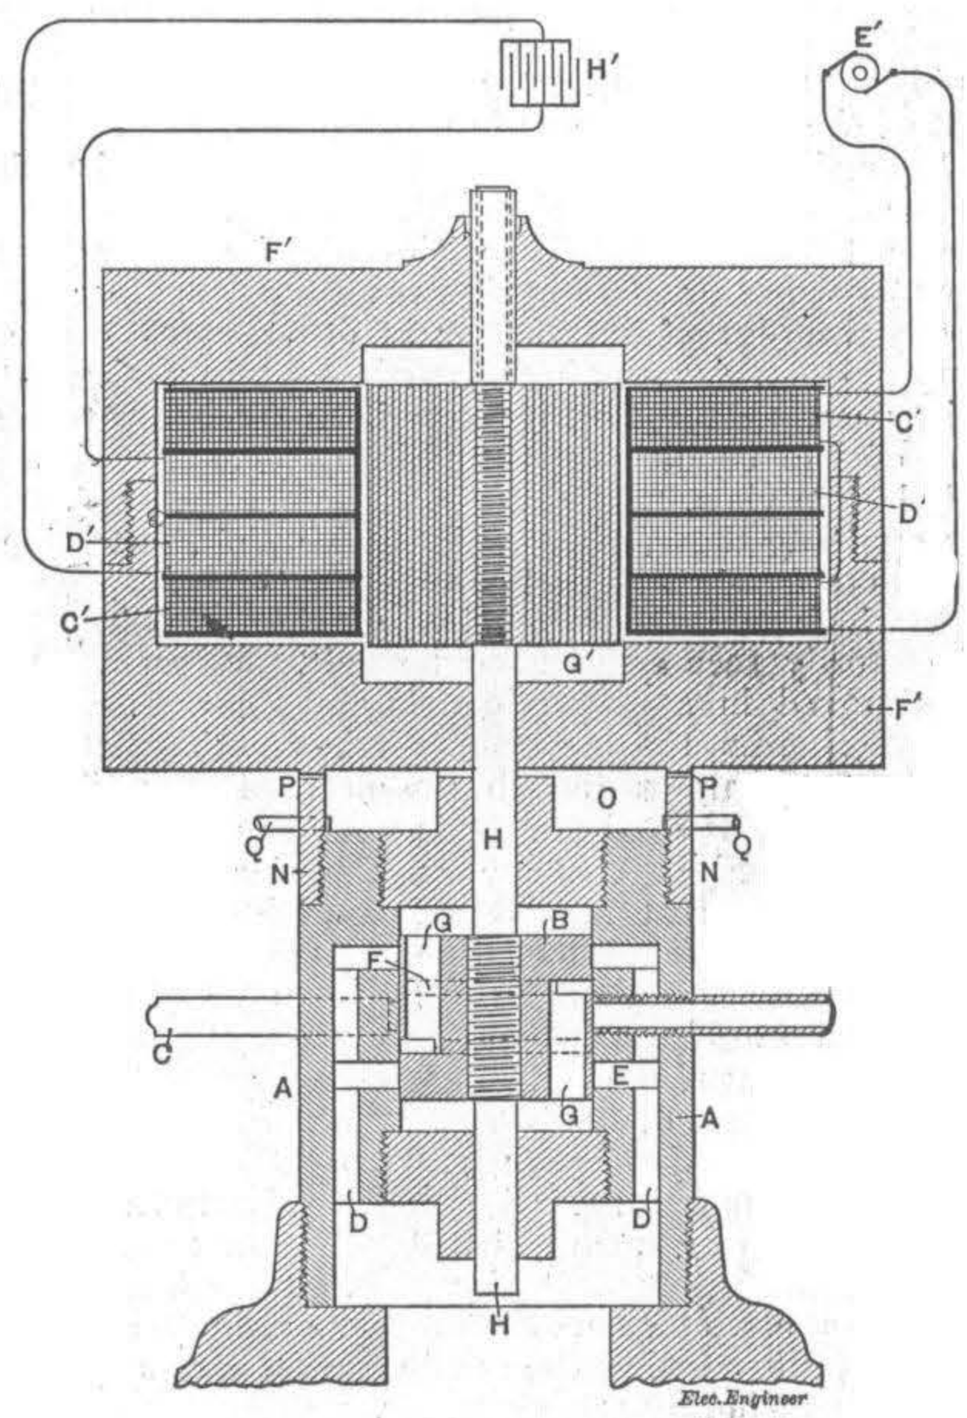


FIG. 2.—TESLA ELECTRICAL OSCILLATOR.

movements of the piston, is oscillated in the magnetic field produced by two magnets B′ B′ which may be permanent magnets or energized by coils C′ C′ connected with a source of continuous current E′. The movement of the coil D′ across the lines of force established by the magnets gives rise to alternating currents in the coil. These currents, if the period of mechanical oscillation be constant will be of constant period.

In the case under consideration it is assumed as a necessary condition that the inertia of the movable element of the generator and the electromagnetic reaction which it exerts will not be of such a character as to materially disturb the action of the engine.

Fig. 2 is an example of a combination in which the engine is not of itself capable of determining entirely the period of oscillation, but in which the generator contributes to this end. In this figure the engine is the same as that shown in Fig. 1. The exterior air spring is however omitted and the air spaces at the ends of the cylinder A

relied on for accomplishing the same purpose. As the pressure in these spaces is liable to variations from variations in the steam or gas used in impelling the piston they might affect the period of oscillation, and the conditions are not as stable and certain as in the case of an engine constructed as in Fig. 1. But if the natural period of vibration of the electric system be made to approximately accord with the average period of the engine such tendencies to variation are very largely overcome and the engine will preserve its period even through a considerable range of variation of pressure.

The generator in this case is composed of a magnetic casing F′ in which a laminated core G′ secured to the piston rod H is caused to vibrate. Surrounding the plunger are two exciting coils C′ C′, and one or more induced coils D′ D′. The coils C′ C′ are connected with a generator of continuous currents E′ and are wound to produce consequent poles in the core G′. Any movement of the latter will therefore shift the lines of force through coils D′ D′ and produce currents therein.

In the circuit of coils D′ is shown a condenser H′. By the use of a proper condenser the self-induction of this circuit may be neutralized. Such a circuit will have a certain natural period of vibration, and, as this depends upon the capacity and self induction, the period may be varied to approximately accord with the period of the engine.

In case the power of the engine be comparatively small, as when the pressure is applied through a very small fraction of the total stroke, the electrical vibration will tend to control the period, and it is clear that if the character of such vibration be not very widely different from the average period of vibration of the engine under ordinary working conditions that such control may be entirely adequate to produce the desired results.

THE WESTINGHOUSE PLANS FOR THE NIAGARA CONTRACT.

THE work now being done in connection with the electrical utilization of Niagara is attracting universal attention, and public interest has again been greatly stimulated by the paper read before the English Institution of Electrical Engineers, by Prof. George Forbes, and reprinted and discussed in our pages. We now have the pleasure of printing a very important communication on the subject from Mr. L. B. Stillwell, electrical engineer of the Westinghouse Electric and Manufacturing Company, signed by him on behalf of the company.

"We have read the leading editorial on 'The Niagara Project' in THE ELECTRICAL ENGINEER of December 20th, and note with interest the following:

> It was hardly to be expected that the promoters of the Niagara enterprise would accept the individual opinion of any one man on the various points of prominent importance, which had to be considered, and Prof. Forbes' paper may therefore be looked upon as a fair representation of the views of the most advanced electrical engineers, as well as the results of Prof. Forbes' own careful study of the literature on the subject and information gained from other sources. The paper may thus be considered not less an expression of the author's personal opinion than an epitome of the views of a large number of prominent electrical and mechanical engineers, and, as such, it will be of interest to determine in how far these views have been applied at Niagara.

"The fact that the engineers and electricians of the Westinghouse Electric and Manufacturing Company have for several years devoted much attention to the subject of power transmission is well known, as is also the fact that our company has received from the Cataract Construction Company the order for the initial installation of electrical apparatus at Niagara. It seems, therefore, a fair inference that you intend to include the engineers of this company among the electrical engineers of whose views you assume that Prof. Forbes' paper is a fair representation.

"The system which has been adopted for the installation at Niagara Falls is simply the Tesla polyphase system as developed by the technical staff of the Westinghouse Electric and Manufacturing Company. It has not been modified in any particular by the engineers of the Cataract Construction Company or of the Niagara Falls Power Company. It is fully described in publications of this company and was demonstrated on a large scale by one of our exhibits in the Electricity Building at the recent Columbian Exposition in Chicago. In developing and perfecting the system, we have not only been guided by a wide experience in the design, manufacture and use of electrical machinery but we have carried out a large amount of experimental work, much of it on an extensive scale, and have made a careful, theoretical and practical study of the subject. Prof. Forbes' views, as stated in his paper, are naturally in accord with ours upon many points. In others, his paper fails to fully state the facts as we see them, and, in others still, we think his views are incorrect. We cannot, therefore, in justice to our company, consent to the assumption that his paper be accepted as a "fair representation" of our views.

"Some of the technical journals have apparently received the impression that the generator described in Prof. Forbes' paper under the heading "General Description of a 5,000 H. P. Alternator" is that which has been adopted by the Cataract Construction Company. This is not the case. The drawings and specifications of the generator, which Prof. Forbes describes were laid before us in August last, and were fully explained by Dr. Coleman Sellers and Prof. Forbes. After careful consideration, we accepted the general mechanical features of the construction proposed as excellent, but, in the opinion of our electricians and engineers, the electrical features—the method of winding, the insulation, etc.—were impracticable, and realizing that we could not undertake the construction of such a machine with credit to our company, we declined to submit proposals. We were thereupon requested by the officers of the Cataract Construction Company to submit our own plans and specifications and this was done early in August. We followed closely the mechanical features approved by Dr. Sellers but the electrical features are wholly our own. These plans were accepted by the Cataract Construction Company and are those under which the generators for Niagara are now being constructed.

"Prof. Forbes is undoubtedly qualified to speak with authority as to the assumptions and reasoning which have led him to agree with other engineers of the Cataract Construction Company in recommending to his Board of Directors the adoption of the system, which has been selected, but the premises and the reasoning which guided the engineers of the Westinghouse Electric and Manufacturing Company in the development of the Tesla polyphase system, as it will be used at Niagara, differ widely in some respects from those which are set forth in the paper to which your editorial refers.

"We trust that you will give to this explanation suitable prominence as we are unwilling, for the reasons stated, to have Prof. Forbes' paper accepted by your readers as a statement of our views."

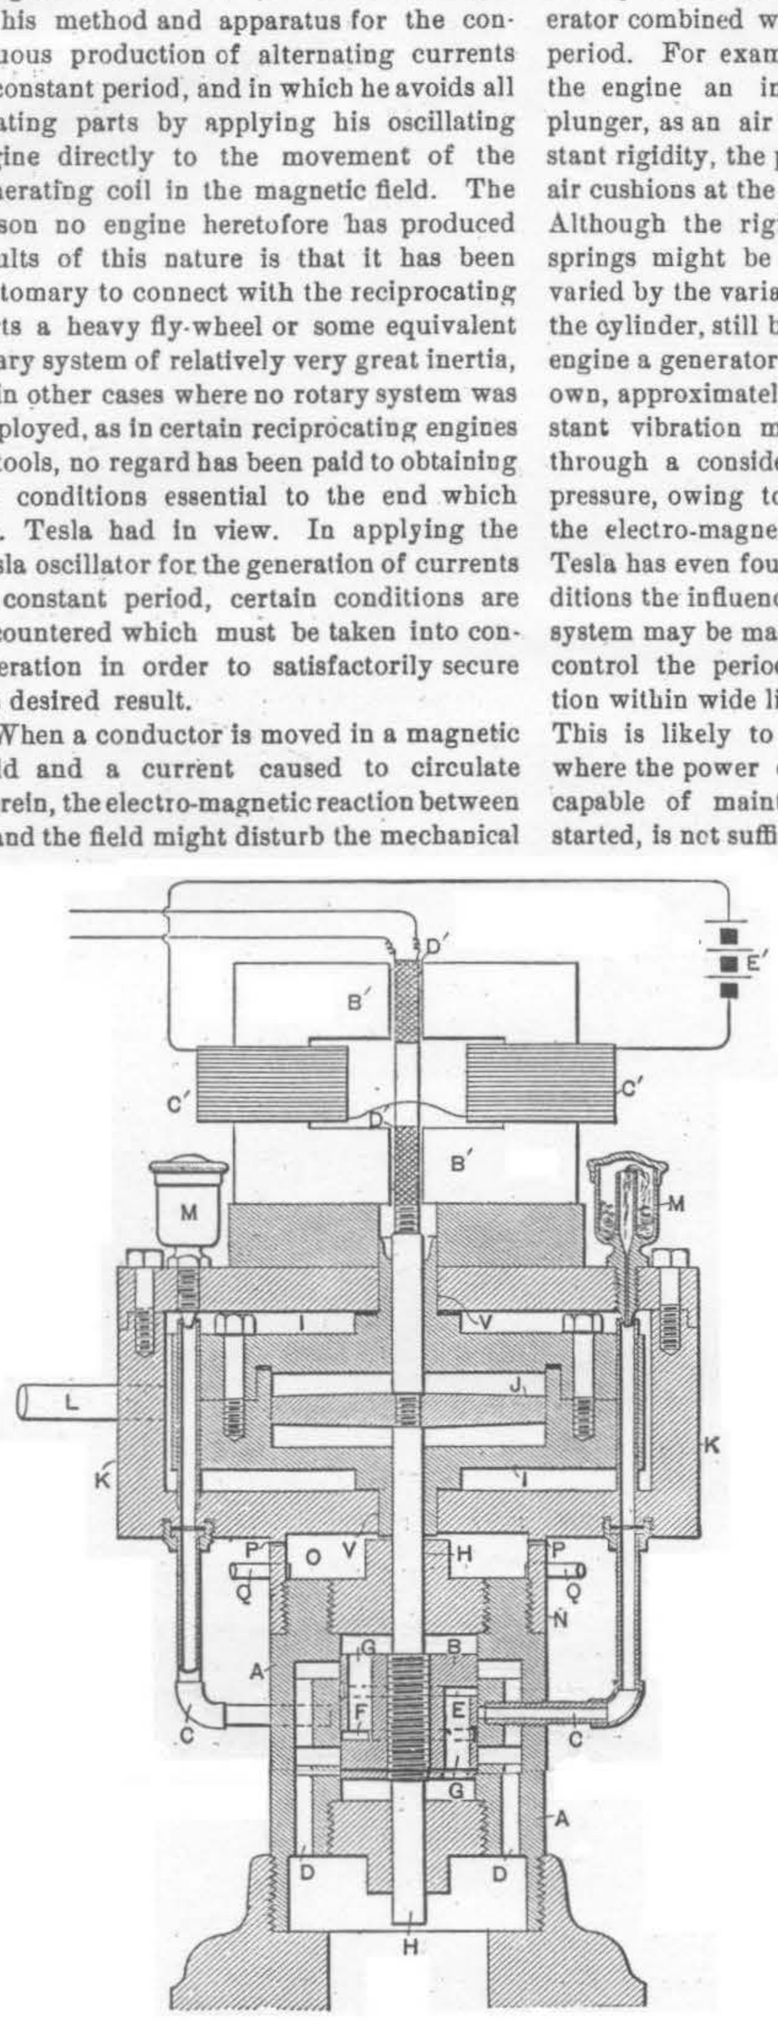
THE WESTINGHOUSE COMPANY AND THE NIAGARA CONTRACT.

WE print elsewhere in this issue an important communication from Mr. L. B. Stillwell, on behalf of the Westinghouse Co., which sheds a strong side light on the information embodied in Prof. Forbes' paper on the electrical features of the Niagara transmission plant. This communication, taken in connection with Prof. Forbes' own statements, would make it appear that so far as essential features are concerned; the promoters of the Niagara scheme deemed it wise to accept the advice of experienced constructors in preference to that of their consulting electrical engineer. And this brings us back to the old question of the relation between these two frequently antagonistic elements. The consulting electrical engineer's services have from the very outset been little availed of in this country, purchasers of electrical plants having in the large majority of cases left matters entirely in the hands of the contracting companies, which practice has, it must be admitted, given rise to but few conflicts. In the case of the work at Niagara, it would appear that the consulting electrical engineer, instead of confining himself to laying down the conditions and leaving to the contractors to devise the best methods of carrying out the specifications, actually entered into competition with them, with the result that might have been foreseen. According to Mr. Stillwell it would also seem that while the engineers of the Westinghouse Co., are in accord with Prof. Forbes on the selection of the methods adopted, they differ from him radically in the assumptions and reasoning which led them to advocate the final plans adopted.

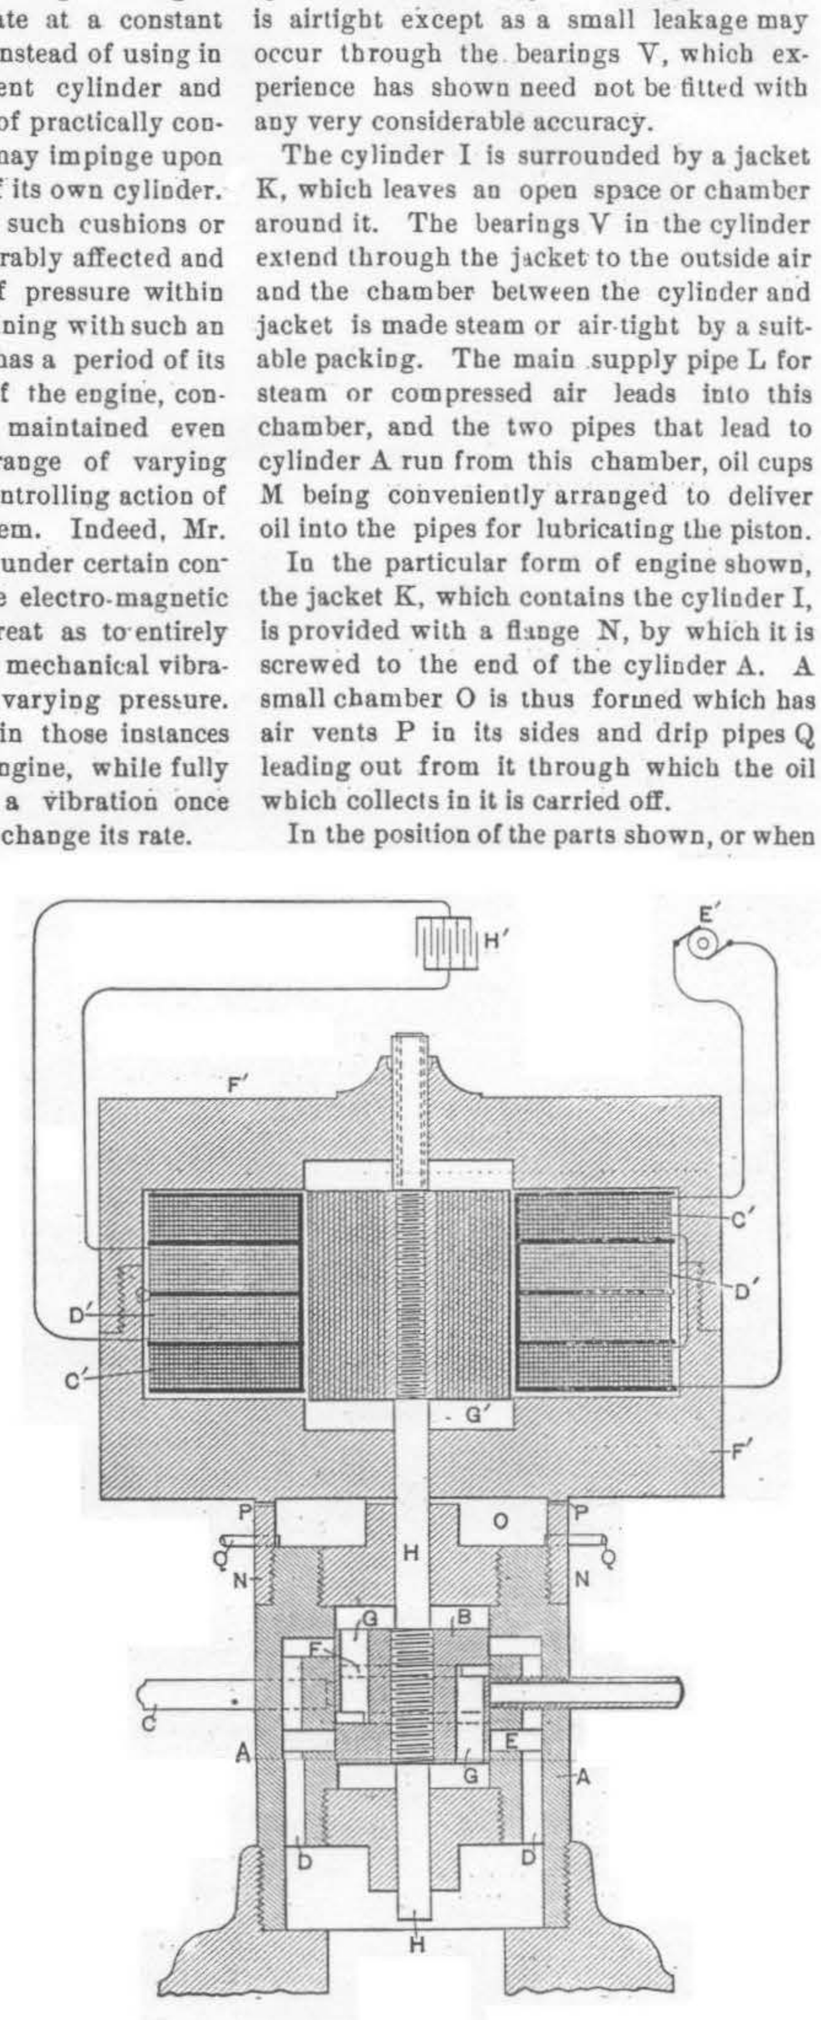
It would be interesting to know the details of these differences and it is to be hoped that the electrical profession will not be kept in ignorance of them. For this reason it is perhaps a pity that Prof. Forbes' paper could not have been read and discussed on this side of the water also. Probably an early opportunity may be afforded by the Institute for such a timely discussion.

THE TESLA ELECTRICAL OSCILLATOR.

WHILE Mr. Tesla has until the last year or two confined himself to purely electrical work,his most recent labors have been devoted to the solution of a mechanical problem intimately connected with the generation of electric currents, the outcome being his electrical oscillators, of which we describe two additional types in this week's issue. Aside from the numerous possibilities in other fields it would seem that if the "oscillator" fulfills the expectations of its inventor, it is destined to create little short of a revolution in our present methods of power generation and distribution. It must be confessed that in spite of the numerous obvious cases in which the application of motors to the driving of machines and line shafting would prove a gain over the present methods, and despite even the successful working of such plants, the conservative factory owner and machinist still looks with a doubtful glance at these innovations of the last ten years. But, if, as Mr. Tesla claims, he will be able to furnish electric current by means of his oscillator, at anything like one half the cost for fuel now required and with much simpler apparatus, the aspect becomes quite a



different one. Such an accomplishment would immediately appeal to every power user and would at once determine the direction of future methods of local power transmission. Indeed it might not be inapt to inquire here also into the probable effect of such an achievement on long distance electrical transmission. With the potentials which have been practically handled up to date, the size of conductors required has not permitted of the extension of power transmission plants utilizing water power, to the distances hoped for, although we note small but constant gains in this respect. With the initial source of energy in the shape of fuel reduced to one half the present cost, it would indeed require an exceptional set of conditions such for example, as those existing at Niagara or in regions far remote from fuel supply to make the utilization of water-powers worth considering for any considerable distance from the fall. Already the cost of water power even locally distributed has in numerous conspicuous instances proved less economical in competition with modern steam engines and a still further improvement in the latter added to the benefits to be derived from electric motors must still further tend to decrease the comparative margin of economy with water power. It seems strange indeed that a power available on the spot should not be able to compete in economy with another form of energy hauled frequently for a distance of hundreds of miles, but experience bears out the conclusions just stated. While the above remarks refer merely to power distribution they are equally applicable to the question of electric lighting and current distribution in general. From Mr. Tesla's observations before the recent meeting of the New York Electrical Society (see THE ELECTRICAL ENGINEER, Dec. 6 and 13, 1893) we infer that he has so far gone into the study of the methods he advocates that we shall not have to wait long for their practical realization.



Tesla's Electrical Oscillators.

Mr. Nikola Tesla, at the World's Fair Congress of Electricians, first drew attention to his method and apparatus for the continuous production of alternating currents of constant period, and in which he avoids all rotating parts by applying his oscillating engine directly to the movement of the generating coil in the magnetic field. The reason no engine heretofore has produced results of this nature is that it has been customary to connect with the reciprocating parts a heavy fly-wheel or some equivalent rotary system of relatively very great inertia, or in other cases where no rotary system was employed, as in certain reciprocating engines or tools, no regard has been paid to obtaining the conditions essential to the end which Mr. Tesla had in view. In applying the Tesla oscillator for the generation of currents of constant period, certain conditions are encountered which must be taken into consideration in order to satisfactorily secure the desired result.

When a conductor is moved in a magnetic field and a current caused to circulate therein, the electro-magnetic reaction between it and the field might disturb the mechanical oscillation to such an extent as to throw it out of isochronism. This, for instance, might occur when the electro magnetic reaction is very great in comparison to the power of the engine, and there is a retardation of the current so that the electro-magnetic reaction might have an effect similar to that which would result from a variation of the tension of the spring; but if the circuit of the generator be adjusted so that the phases of the electro-motive force and current coincide in time, that is to say, when the current is not retarded, then the generator driven by the engine acts merely as a fractional resistance and will not, as a rule, alter the period of the mechanical vibration, although it may its amplitude. This condition may be readily secured by properly proportioning the self-induction and capacity of the circuit including the generator. Mr. Tesla has, however, observed the further fact in connection with the use of such engines as a means for running a generator, that it is advantageous that the period of the engine and the natural period of electrical vibration of the generator should be the same, as in such case the best conditions for electrical resonance are established, and the possibility of disturbing the period of mechanical vibrations is reduced to a minimum.

Mr. Tesla has found that even if the theoretical conditions necessary for maintaining a constant period in the engine itself are not exactly maintained, still the engine and generator combined will vibrate at a constant period. For example, if instead of using in the engine an independent cylinder and plunger, as an air spring of practically constant rigidity, the piston may impinge upon air cushions at the ends of its own cylinder. Although the rigidity of such cushions or springs might be considerably affected and varied by the variations of pressure within the cylinder, still by combining with such an engine a generator which has a period of its own, approximately that of the engine, constant vibration may be maintained even through a considerable range of varying pressure, owing to the controlling action of the electro-magnetic system. Indeed, Mr. Tesla has even found that under certain conditions the influence of the electro-magnetic system may be made so great as to entirely control the period of the mechanical vibration within wide limits of varying pressure. This is likely to occur in those instances where the power of the engine, while fully capable of maintaining a vibration once started, is not sufficient to change its rate.

FIGS. 1 AND 2.—NIKOLA TESLA'S ELECTRICAL OSCILLATORS.

The accompanying illustration, Fig. 1, is a sectional view of an oscillator fulfilling the conditions laid down above. Referring to Fig. 1, A is the main cylinder in which works a piston B. Inlet ports C C pass through the sides of the cylinder opening at the middle and on opposite sides. Exhaust ports D D extend through the walls of the cylinder and are formed with branches that open into the interior of the cylinder on each side of the inlet ports and on opposite sides of the cylinder. The piston B has two circumferential grooves E F, which communicate through openings G in the piston with the cylinder on opposite sides of the piston respectively.

The particular construction of the cylinder, the piston and the ports controlling it may be greatly varied, and is not in itself material, except that in the special case under consideration it is desirable that all the ports, and more especially the exhaust ports, should be made very much larger than is usually the case, so that no force due to the action of the steam or compressed air will tend to retard or affect the return of the piston in either direction.

The piston B is secured to a piston rod H, which works in suitable stuffing boxes in the heads of cylinder A. This rod is prolonged on one side and extends through bearings V in a cylinder I, mounted in line with the first, and within which is a disk or plunger J carried by the rod H. The cylinder I is without parts of any kind and is airtight except as a small leakage may occur through the bearings V, which experience has shown need not be fitted with any very considerable accuracy.

The cylinder I is surrounded by a jacket K, which leaves an open space or chamber around it. The bearings V in the cylinder extend through the jacket to the outside air and the chamber between the cylinder and jacket is made steam or air-tight by a suitable packing. The main supply pipe L for steam or compressed air leads into this chamber, and the two pipes that lead to cylinder A run from this chamber, oil cups M being conveniently arranged to deliver oil into the pipes for lubricating the piston.

In the particular form of engine shown, the jacket K, which contains the cylinder I, is provided with a flange N, by which it is screwed to the end of the cylinder A. A small chamber O is thus formed which has air vents P in its sides and drip pipes Q leading out from it through which the oil which collects in it is carried off.

In the position of the parts shown, or when the piston is at the middle point of its stroke, the plunger J is at the center of the cylinder I, and the air on both sides of the same is at the normal pressure of the outside atmosphere. If a source of steam or compressed air be then connected to the inlet ports C C of the cylinder A, and a movement be imparted to the piston as by a sudden blow, the latter begins to reciprocate in the well-known way.

The movements of the piston compress and rarefy the air in the cylinder I at opposite ends, alternately. A forward stroke compresses the air ahead of the plunger J, which acts as a spring to return it; similarly, on the back stroke the air is compressed on the opposite side of the plunger J and tends to drive it forward.

The compressions of the air in the cylinder I and the consequent loss of energy due mainly to the imperfect elasticity of the air, give rise to a very considerable amount of heat. This heat is utilized by conducting the steam or compressed air to the engine cylinder through the chamber formed by the jacket surrounding the air spring cylinder, the heat thus taken up and used to raise the temperature of the steam or air acting upon the piston is availed of to increase the efficiency of the engine.

In any given engine of this kind the normal pressure will produce a stroke of determined length, and this will be increased or diminished according to the increase of pressure above, or the reduction of pressure below, the normal. In constructing the apparatus proper allowance is made for a variation in the length of stroke by giving to the confining cylinder I of the air spring properly determined dimensions. The greater the pressure upon the piston, the higher will be the degree of compression of the air spring, and the consequent counter-acting force upon the plunger.

The rate or period of reciprocation of the piston, however, is mainly determined by the rigidity of the air spring and the inertia of the moving system, and any period of oscillation within very wide limits may be secured by properly portioning these factors, as by varying the dimensions of the air chamber, which is equivalent to varying the rigidity of the spring, or by adjusting the weight of the moving parts. These conditions are all readily determinable, and an engine constructed as above described maintains a perfectly uniform period through very wide limits of pressure.

The pressure of the air confined in the cylinder when the plunger I is in its central position will always be practically that of the surrounding atmosphere, for while the cylinder is so constructed as not to permit such sudden escape of air as to sensibly impair or modify the action of the air spring, there will still be a slow leakage of air into or out of it around the piston rod according to the pressure therein, so that the pressure of the air on opposite sides of the plunger will always tend to remain at that of the outside atmosphere. To the piston rod H is secured a coil D′ which, by the movements of the piston, is oscillated in the magnetic field produced by two magnets B′ B′, which may be permanent magnets or energized by coils C′ C′ connected with a source of continuous current E′. The movement of the coil D′ across the lines of force established by the magnets gives rise to alternating currents in the coil. These currents, if the period of mechanical oscillation be constant, will be of constant period. In the case under consideration it is assumed as a necessary condition that the inertia of the movable element of the generator and the electro-magnetic reaction which it exerts will not be of such a character as to materially disturb the action of the engine.

In Fig. 2 is shown an example of a combination in which the engine is not of itself capable of determining entirely the period of oscillation, but in which the generator contributes to this end. In this figure the engine is the same as that shown in Fig. 1. The exterior air spring is, however, omitted, and the air spaces at the ends of the cylinder A relied on for accomplishing the same purpose. As the pressure in these spaces is liable to variations from variations in the steam or gas used in impelling the piston, they might affect the period of oscillation, and the conditions are not as stable and certain as in the case of an engine constructed as in Fig. 1. But if the natural period of vibration of the elastic system be made to approximately accord with the average period of the engine, such tendencies to variation are very largely overcome and the engine will preserve its period even through a considerable range of variation of pressure.

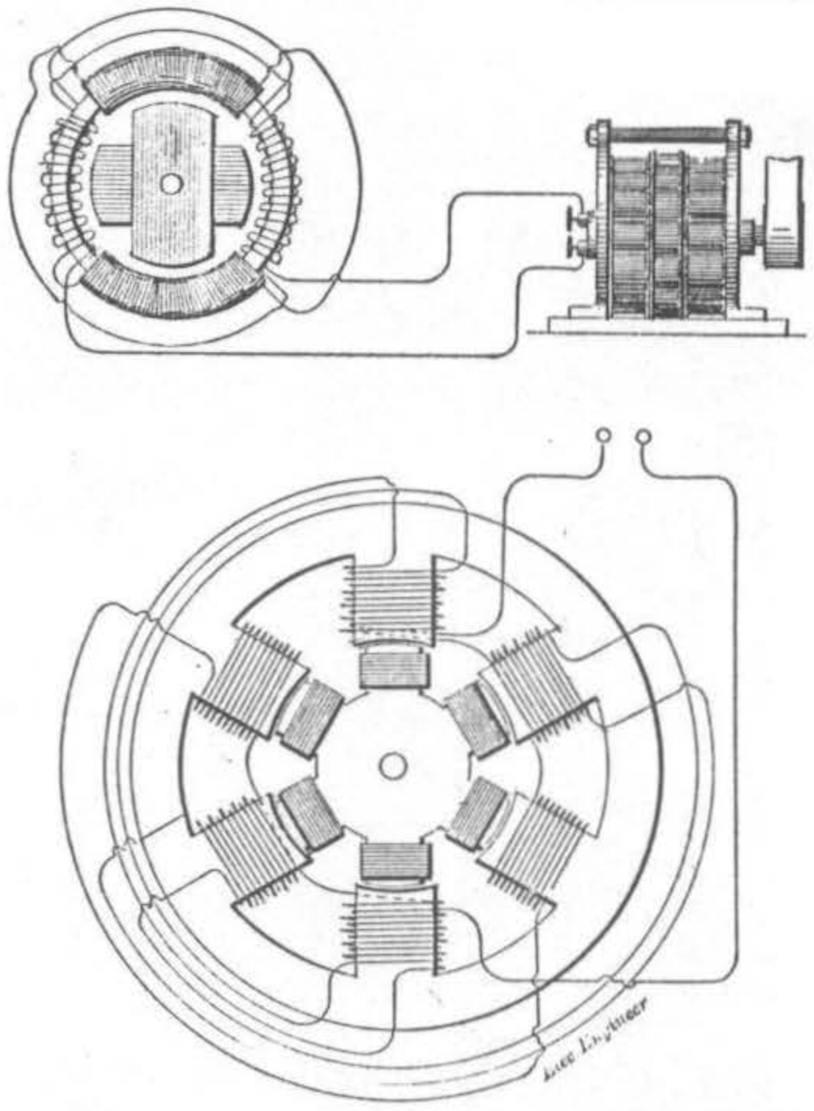
The generator in this case is composed of a magnetic casing F′, in which a laminated core G′, secured to the piston rod H, is caused to vibrate. Surrounding the plunger are two exciting coils C′ C′, and one or more induced coils D′ D′. The coils C′ C′ are connected with a generator of continuous currents E′ and are wound to produce consequent poles in the core G′. Any movement of the latter will, therefore, shift the lines of force through coils D′ D′ and produce currents therein.

In the circuit of coils D′ is shown a condenser H′. By the use of a proper condenser the self-induction of this circuit may be neutralized. Such a circuit will have a certain natural period of vibration, and, as this depends upon the capacity and self-induction, the period may be varied to approximately accord with the period of the engine. In case the power of the engine be comparatively small, as when the pressure is applied through a very small fraction of the total stroke, the electrical vibration will tend to control the period, and it is clear that if the character of such vibration be not very widely different from the average period of vibration of the engine under ordinary working conditions, that such control may be entirely adequate to produce the desired results.

ELECTRICAL PATENTS.

Issued December 26, 1893.

511,559. Electrical Transmission of Power. Nikola Tesla, New York, N. Y.



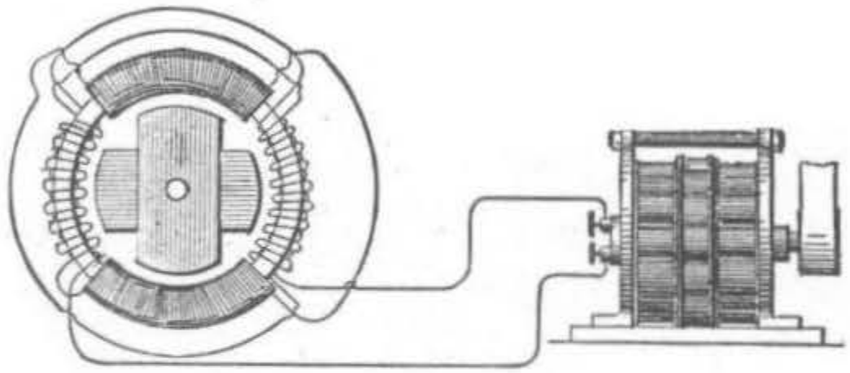
The invention relates to the operation of motors having independent energizing circuits; alternating currents are passed through both of the circuits, the phase in one being retarded to a greater or less extent than in the other.

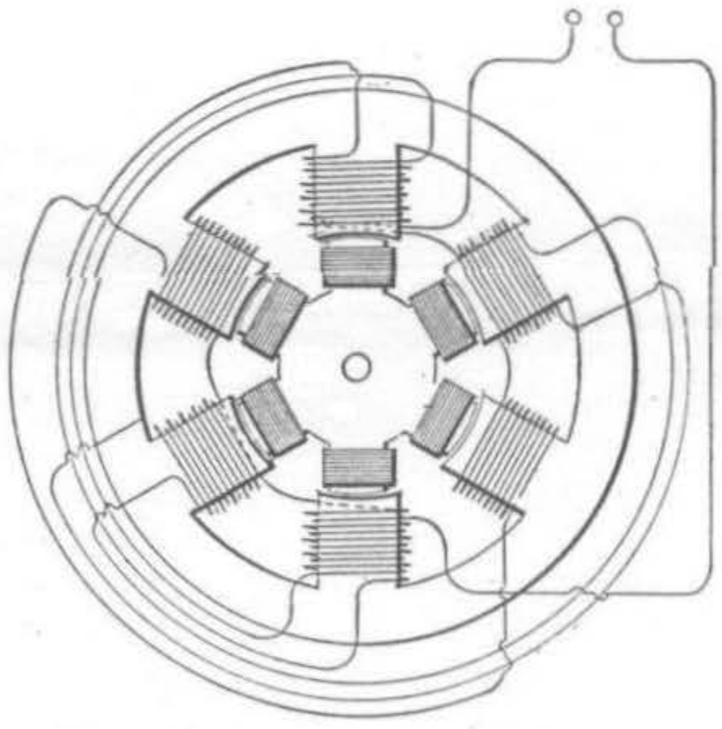
511,560. System of Electrical Power Transmission. Nikola Tesla, New York, N. Y.

PATENT NOTES.

TESLA SINGLE CIRCUIT ALTERNATING MOTOR.

IN a patent issued to Mr. Nikola Tesla, on Jan. 2, entitled "Electrical Transmission of Power," No. 311,915 originally filed





TESLA SINGLE CIRCUIT ALTERNATING MOTOR.

May 15, 1888, that inventor describes a method of operating motors from a two-wire alternating circuit. The method employed is set forth in the two claims of the patent which we give below :

1. The method of operating electro-magnetic motors having independent energizing circuits, as herein described, which consists in passing an alternating current through one of the energizing circuits and inducing by such current the current in the other energizing circuit of the motor, as set forth.

2. The method of operating electro-magnetic motors having independent energizing circuits as herein described, which consists in developing an alternating current in one of said energizing circuits and inducing thereby currents in the other energizing circuit or circuits, as herein set forth.

TESLA SINGLE CIRCUIT ALTERNATING MOTOR.

Tesla Single Circuit Alternating Motor.

In a patent issued to Mr. Nikola Tesla on January 2, entitled, "Electrical Transmission of Power, No. 311,915, originally filed May 15, 1888," is described a method of operating motors from a two-wire alternating circuit. The method employed is set forth in the two claims of the patent as follows:

1. The method of operating electro-magnetic motors having independent energizing circuits, as herein described, which consists in passing an alternating current through one of the energizing circuits and inducing by such current the current in the other energizing circuit of the motor, as set forth.

2. The method of operating electro-magnetic motors having independent energizing circuits, as herein described, which consists in developing an alternating current in one of said energizing circuits, and inducing thereby currents in the other energizing circuit or circuits, as herein set forth.

THE TESLA ELECTRICAL OSCILLATOR.*

In the lecture delivered before the Chicago Electrical Congress, Mr. Nikola Tesla first drew attention to the method and means which he had devised for the continuous production of alternating currents of constant period, and in which all rotating parts are avoided by the employment of his oscillating engine directly to the movement of the generating coil in the magnetic field.

The main reason why no engine heretofore has been capable of producing results of this nature is that it has been customary to connect with the reciprocating parts a heavy flywheel, or some equivalent rotary system of relatively very great inertia, or in other cases where no rotary

* From an advance proof of the *Electrical Engineer* (New York).

system was employed, as in certain reciprocating engines or tools, no regard has been paid to the obtainment of the conditions essential to the end which Mr. Tesla had in view.

In applying the Tesla oscillator for the generation of currents of constant period, certain conditions are encountered which must be taken into consideration in order to satisfactorily secure the desired result. When a conductor is moved in a magnetic field and a current caused to circulate therein, the electromagnetic reaction between it and the field might disturb the mechanical oscillation to such an extent as to throw it out of isochronism. This, for instance, might occur when the electromagnetic reaction is very great in comparison to the power of the engine, and there is a retardation of the current, so that the electromagnetic reaction might have an effect similar to that which would result from a variation of the tension of the spring; but if the circuit of the generator be adjusted so that the phases of the E.M.F. and current coincide in time—that is to say, when the current is not retarded—then the generator driven by the engine acts merely as a fractional resistance, and will not, as a rule, alter the period of the mechanical vibration, although it may its amplitude. This condition may be readily secured by properly proportioning the self-induction and capacity of the circuit, including the generator.

Mr. Tesla has, however, observed the further fact in connection with the use of such engines as a means for running a generator, that it is advantageous that the period of the engine and the natural period of electrical vibration of the generator should be the same, as in such case the best conditions for electrical resonance are established, and the possibility of disturbing the period of mechanical vibrations is reduced to a minimum. Mr. Tesla has found that even if the theoretical conditions necessary for maintaining a constant period in the engine itself are not exactly maintained, still the engine and generator combined will vibrate at a constant period. For example, if instead of using in the engine an independent cylinder and plunger, as an air spring of practically constant rigidity, the piston may impinge upon air cushions at the ends of its own cylinder. Although the rigidity of such cushions or springs might be considerably affected and varied by the variations of pressure within the cylinder, still by combining with such an engine a generator which has a period of its own, approximately that of the engine, constant vibration may be maintained even through a considerable range of varying pressure, owing to the controlling action of the electromagnetic system.

Indeed, Mr. Tesla has even found that under certain conditions the influence of the electromagnetic system may be made so great as to entirely control the period of the mechanical vibration within wide limits of varying pressure. This is likely to occur in those instances where the power of the engine, while fully capable of maintaining a vibration once started, is not sufficient to change its rate.

In our issue of November 8, 1893, we gave the details of construction of the Tesla oscillator, and a patent just issued to Mr. Tesla now enables us to supplement our previous descriptions with those of other types employed by him in this work. The accompanying engraving, Fig. 1, is a sectional view of an oscillator fulfilling the conditions laid down above.

Referring to Fig. 1, A is the main cylinder in which works a piston, B. Inlet ports, C C, pass through the sides of the cylinder opening at the middle and on opposite sides. Exhaust ports, D D, extend through the walls of the cylinder, and are formed with branches that open into the interior of the cylinder on each side of the inlet ports and on opposite sides of the cylinder. The piston, B, has two circumferential grooves, E F, which communicate through openings, G, in the piston with the cylinder on opposite sides of the piston respectively. The particular construction of the cylinder, the piston, and the ports controlling it may be very much varied, and is not in itself material, except that in the special case under consideration it is desirable that all the ports, and more especially the exhaust ports, should be made very much larger than is usually the case, so that no force due to the action of the steam or compressed air will tend to retard or affect the return of the piston in either direction. The piston, B, is secured to a piston-rod, H, which works in suitable stuffing-boxes in the heads of the cylinder A. This rod is prolonged on one side and extends through bearings, V, in a cylinder, I, mounted in line with the first, and within which is a disc or plunger, J, carried by the rod, H. The cylinder, I, is without parts of any kind, and is airtight except as a small leakage may occur through the bearings, V, which experience has shown need not be fitted with any very considerable accuracy. The cylinder I is surrounded by a jacket, K, which leaves an open space or chamber around it. The bearings, V, in the cylinder, extend through the jacket to the outside air, and the chamber between the cylinder and jacket is made steam or air tight by a suitable packing. The main supply pipe, L, for steam or compressed air leads into this chamber, and the two pipes that lead to cylinder A run from this chamber, oil-cups, M, being conveniently arranged to deliver oil into the pipes for lubricating the piston.

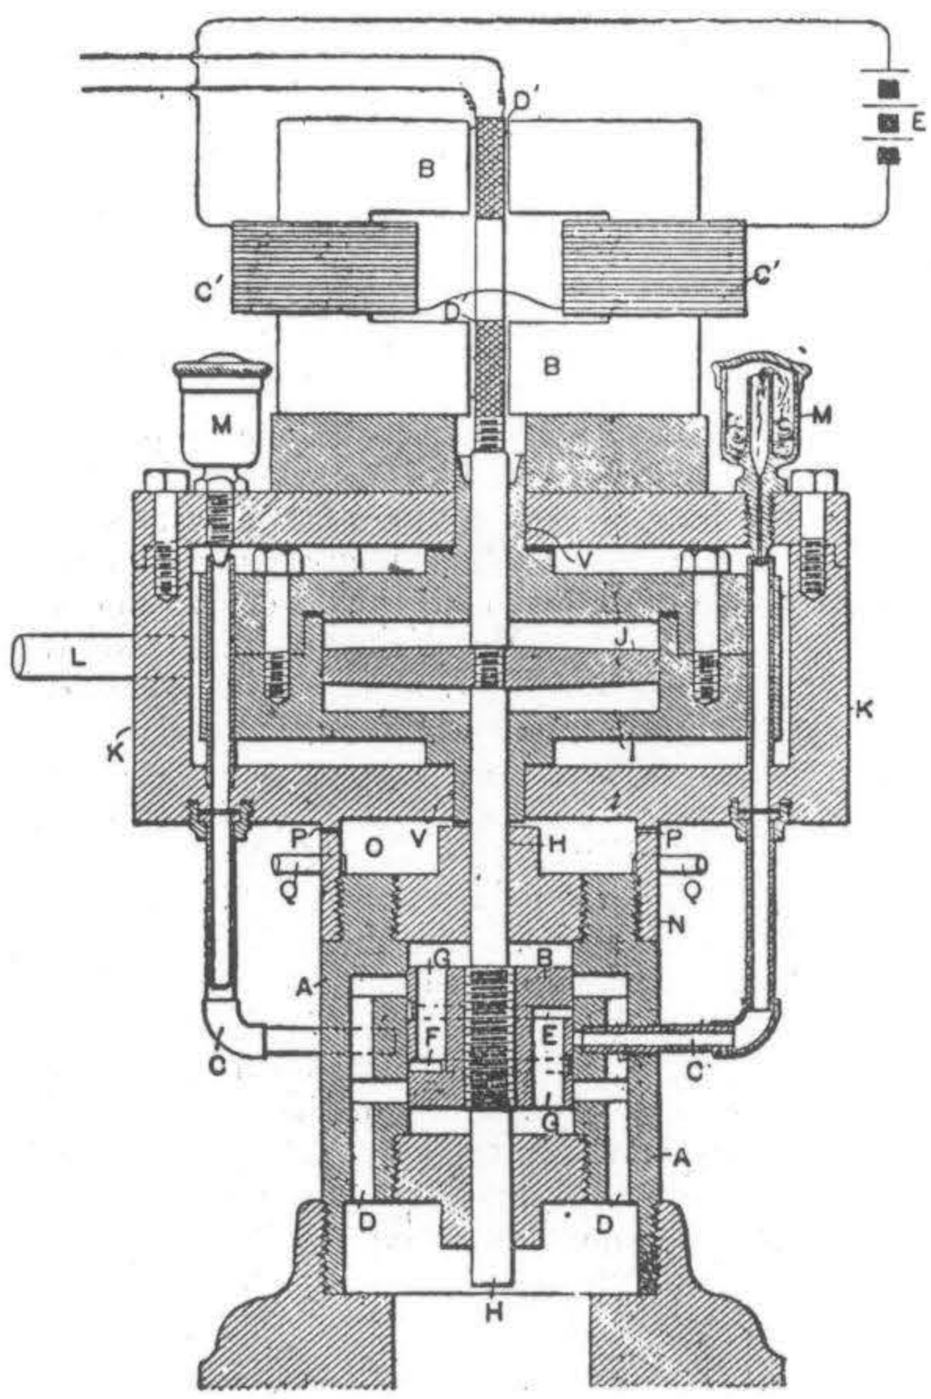


FIG. 1.

In the particular form of engine shown, the jacket, K, which contains the cylinder I is provided with a flange, N, by which it is screwed to the end of the cylinder A. A small chamber, O, is thus formed which has air-vents, P, in its sides, and drip pipes, Q, leading out from it through which the oil which collects in it is carried off. In the position of the parts shown, or when the piston is at the middle point of its stroke, the plunger, J, is at the centre of the cylinder I, and the air on both sides of the same is at the normal pressure of the outside atmosphere. If a source of steam or compressed air be then connected to the inlet ports, C C, of the cylinder A, and a movement be imparted to the piston as by a sudden blow, the latter begins to reciprocate in the well-known way. The movements of the piston compress and rarefy the air in the cylinder I at opposite ends, alternately. A forward stroke compresses the air ahead of the plunger, J, which acts as a spring to return it; similarly, on the back stroke the air is compressed on the opposite side of the plunger, J, and tends to drive it forward. The compressions of the air in the cylinder, I, and the consequent loss of energy due mainly to the imperfect elasticity of the air, gave rise to a very considerable amount of heat. This heat is utilised by conducting the steam or com-

pressed air to the engine cylinder through the chamber formed by the jacket surrounding the air-spring cylinder, the heat thus taken up and used to raise the temperature of the steam or air acting upon the piston is availed of to increase the efficiency of the engine.

In any given engine of this kind the normal pressure will produce a stroke of determined length, and this will be increased or diminished according to the increase of pressure above, or the reduction of pressure below, the normal. In constructing the apparatus proper allowance is made for a variation in the length of stroke by giving to the confining cylinder, I, of the air spring properly determined dimensions. The greater the pressure upon the piston, the higher will be the degree of compression of the air spring, and the consequent counteracting force upon the plunger. The rate or period of reciprocation of the piston, however, is mainly determined by the rigidity of the air spring and the inertia of the moving system, and any period of oscillation within very wide limits may be secured by properly portioning these factors, as by varying

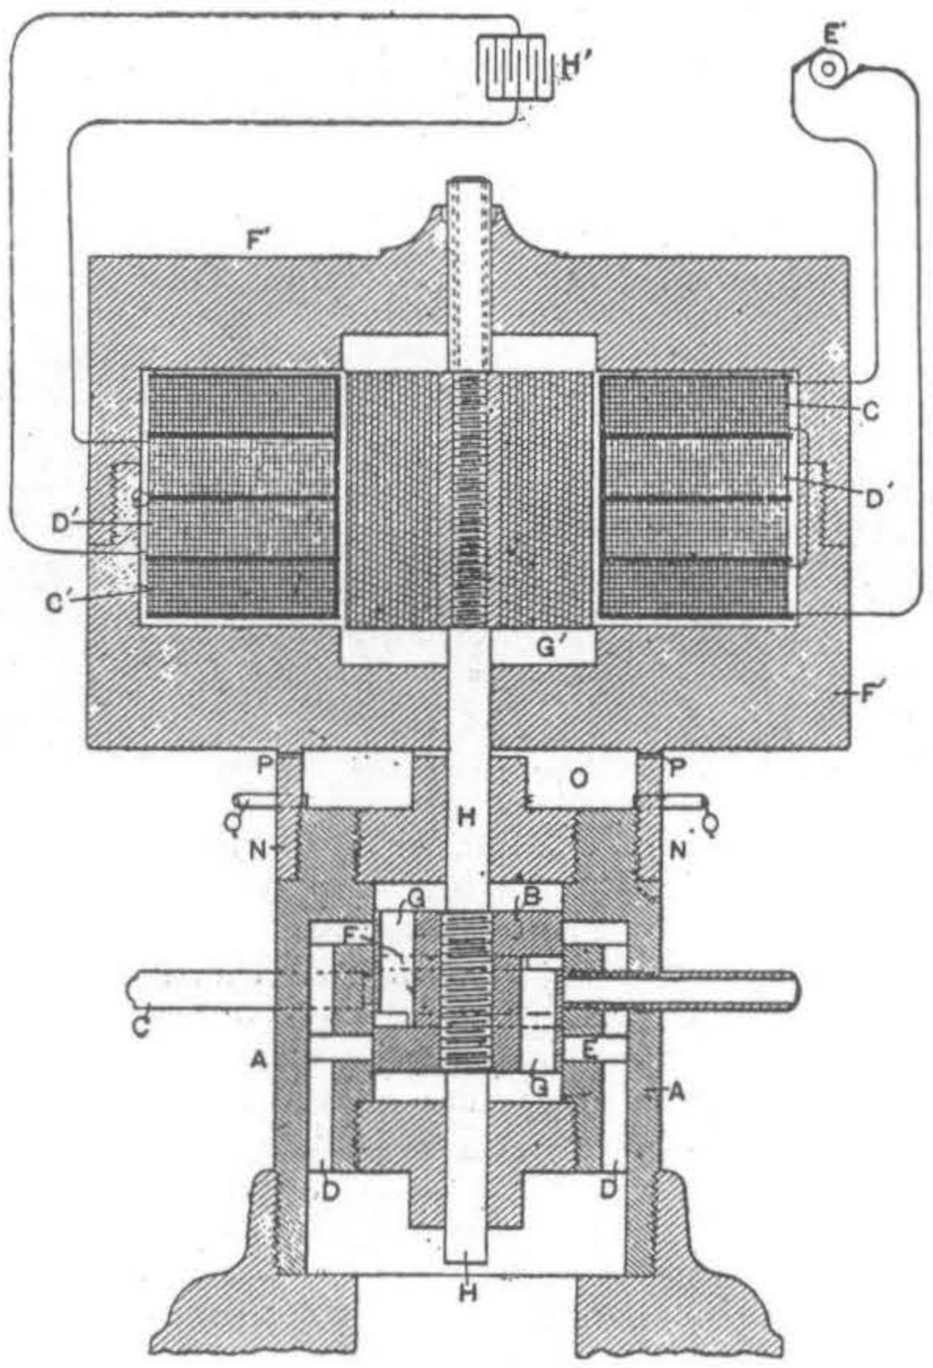

FIG. 2.

the dimensions of the air-chamber, which is equivalent to varying the rigidity of the spring, or by adjusting the weight of the moving parts. These conditions are all readily determinable, and an engine constructed as above described maintains a perfectly uniform period through very wide limits of pressure. The pressure of the air confined in the cylinder when the plunger, I, is in its central position will always be practically that of the surrounding atmosphere, for while the cylinder is so constructed as not to permit such sudden escape of air as to sensibly impair or modify the action of the air spring there will still be a slow leakage of air into or out of it around the piston-rod according to the pressure therein, so that the pressure of air on opposite sides of the plunger will always tend to remain at that of the outside atmosphere. To the piston-rod, H, is secured a coil, D', which, by the movements of the piston, is oscillated in the magnetic field produced by two magnets, B' B', which may be permanent magnets or energised by coils, C' C', connected with a source of continuous current, E'. The movement of the coil D' across the lines of force established by the magnets gives rise to alternating currents in the coil. These currents, if the period of mechanical oscillation be constant, will be of constant period. In the case under consideration it is assumed as a necessary condition that the inertia of the movable element of the generator and the electro magnetic reaction which it exerts will not be of such a character as to materially disturb the action of the engine.

Fig. 2 is an example of a combination in which the engine is not of itself capable of determining entirely the period of oscillation, but in which the generator contributes to this end. In this figure the engine is the same as that shown in Fig. 1. The exterior air spring is, however, omitted, and the air-spaces at the ends of the cylinder, A, relied on for accomplishing the same purpose. As the pressure in these spaces is liable to variations from variations in the steam or gas used in impelling the piston they might affect the period of oscillations, and the conditions are not as stable and certain as in the case of an engine constructed as in Fig. 1. But if the natural period of vibration of the elastic system be made to approximately accord with the average period of the engine, such tendencies to variation are very largely overcome, and the engine will preserve its period even through a considerable range of variation of pressure. The generator in this case is composed of a magnetic casing, F', in which a laminated core, G', secured to the piston-rod, H, is caused to vibrate. Surrounding the plunger are two exciting coils, C' C', and one or more induced coils, D' D'. The coils C' C' are connected with a generator of continuous currents, E', and are wound to produce consequent poles in the core, G'. Any movement of the latter will therefore shift the lines of force through coils D' D', and produce currents therein. In the circuit of coils D' is shown a condenser, H'. By the use of a proper condenser the self-induction of this circuit may be neutralised. Such a circuit will have a certain natural period of vibration, and, as this depends upon the capacity and self-induction, the period may be varied to approximately accord with the period of the engine.

In case the power of the engine be comparatively small, as when the pressure is applied through a very small fraction of the total stroke, the electrical vibration will tend to control the period, and it is clear that if the character of such vibration be not very widely different from the average period of vibration of the engine under ordinary working conditions, that such control may be entirely adequate to produce the desired results.

THE TESLA ELECTRICAL OSCILLATOR.

WE are indebted to the editors of the *Electrical Engineer*, of New York, for an advance proof of the following article :—

In the lecture delivered before the Chicago Electrical Congress, Mr. Nikola Tesla first drew attention * to the method and means which he had devised for the continuous production of alternating currents of constant period and in which all rotating parts are avoided by the employment of his oscillating engine directly to the movement of the generating coil in the magnetic field.

The main reason why no engine heretofore has been capable of producing results of this nature, is that it has been customary to connect with the reciprocating parts a heavy fly-wheel, or some equivalent rotary system of relatively very great inertia, or in other cases where no rotary system was employed, as in certain reciprocating engines or tools, no regard has been paid to the obtainment of the conditions essential to the end which Mr. Tesla had in view.

In applying the Tesla oscillator for the generation of currents of constant period, certain conditions are encountered which must be taken into consideration in order to satisfactorily secure the desired result. When a conductor is moved in a magnetic field and a current caused to circulate therein, the electro-magnetic reaction between it and the field might disturb the mechanical oscillation to such an extent as to throw it out of isochronism. This, for instance, might occur when the electro-magnetic reaction is very great in comparison to the power of the engine, and there is a retardation of the current so that the electro-magnetic reaction might have an effect similar to that which would result from a variation of the tension of the spring, but if the circuit of the generator be adjusted so that the phases of the electromotive force and current coincide in time, that is to say, when the current is not retarded, then the generator driven by the engine acts merely as a fractional resistance and will not, as a

* See the New York *Electrical Engineer*, August 30th, 1893; and the ELECTRICAL REVIEW, December 29th, 1893.

rule, alter the period of the mechanical vibration, although it may its amplitude. This condition may be readily secured by properly proportioning the self-induction and capacity of the circuit, including the generator.

Mr. Tesla, has however, observed the further fact in connection with the use of such engines as a means for running a generator, that it is advantageous that the period of the engine and the natural period of electrical vibration of the generator should be the same, as in such case the best conditions for electrical resonance are established and the possibility of disturbing the period of mechanical vibrations is reduced to a minimum. Mr. Tesla has found that even if the theoretical conditions necessary for maintaining a constant period in the engine itself are not exactly maintained, still the engine and generator combined will vibrate at a constant period. For example, if instead of using in the engine an independent cylinder and plunger, as an air spring of practically constant rigidity, the piston may impinge upon air cushions at the ends of its own cylinder. Although the rigidity of such cushions or springs might be considerably affected and varied by the variations of pressure within the cylinder, still by combining with such an engine a generator which has a period of its own, approximately that of the engine, constant vibration may be maintained even through a considerable range of varying pressure, owing to the controlling action of the electro-magnetic system.

Indeed, Mr. Tesla has even found that under certain conditions the influence of the electro-magnetic system may be made so great as to entirely control the period of the mechanical vibration within wide limits of varying pressure. This is likely to occur in those instances where the power of the engine while fully capable of maintaining a vibration once started, is not sufficient to change its rate.

In our issue of November 8th, 1893, we gave the details of construction of the Tesla oscillator, and a patent just issued to Mr. Tesla, now enables us to supplement our previous descriptions with those of other types employed by him in this work. The accompanying engraving, fig. 1, is a sectional view of an oscillator fulfilling the conditions laid down above.

Referring to fig. 1, A is the main cylinder in which works a piston, B. Inlet ports, C, C, pass through the sides of the cylinder opening at the middle and on opposite sides. Exhaust ports, D, D, extend through the walls of the cylinder and are formed with branches that open into the interior of the cylinder on each side of the inlet ports and on opposite sides of the cylinder. The piston, B, has two circumferential grooves, E, F, which communicate through openings, G, in the piston with the cylinder on opposite sides of the piston respectively.

The particular construction of the cylinder, the piston and the ports controlling it, may be very much varied, and is not in itself material, except that in the special case under consideration it is desirable that all the ports, and more especially the exhaust ports, should be made very much larger than is usually the case, so that no force due to the action of the steam or compressed air will tend to retard or affect the return of the piston in either direction.

The piston, B, is secured to a piston rod, H, which works in suitable stuffing boxes in the heads of the cylinder, A. This rod is prolonged on one side and extends through bearing, V, in a cylinder, I, mounted in line with the first, and within

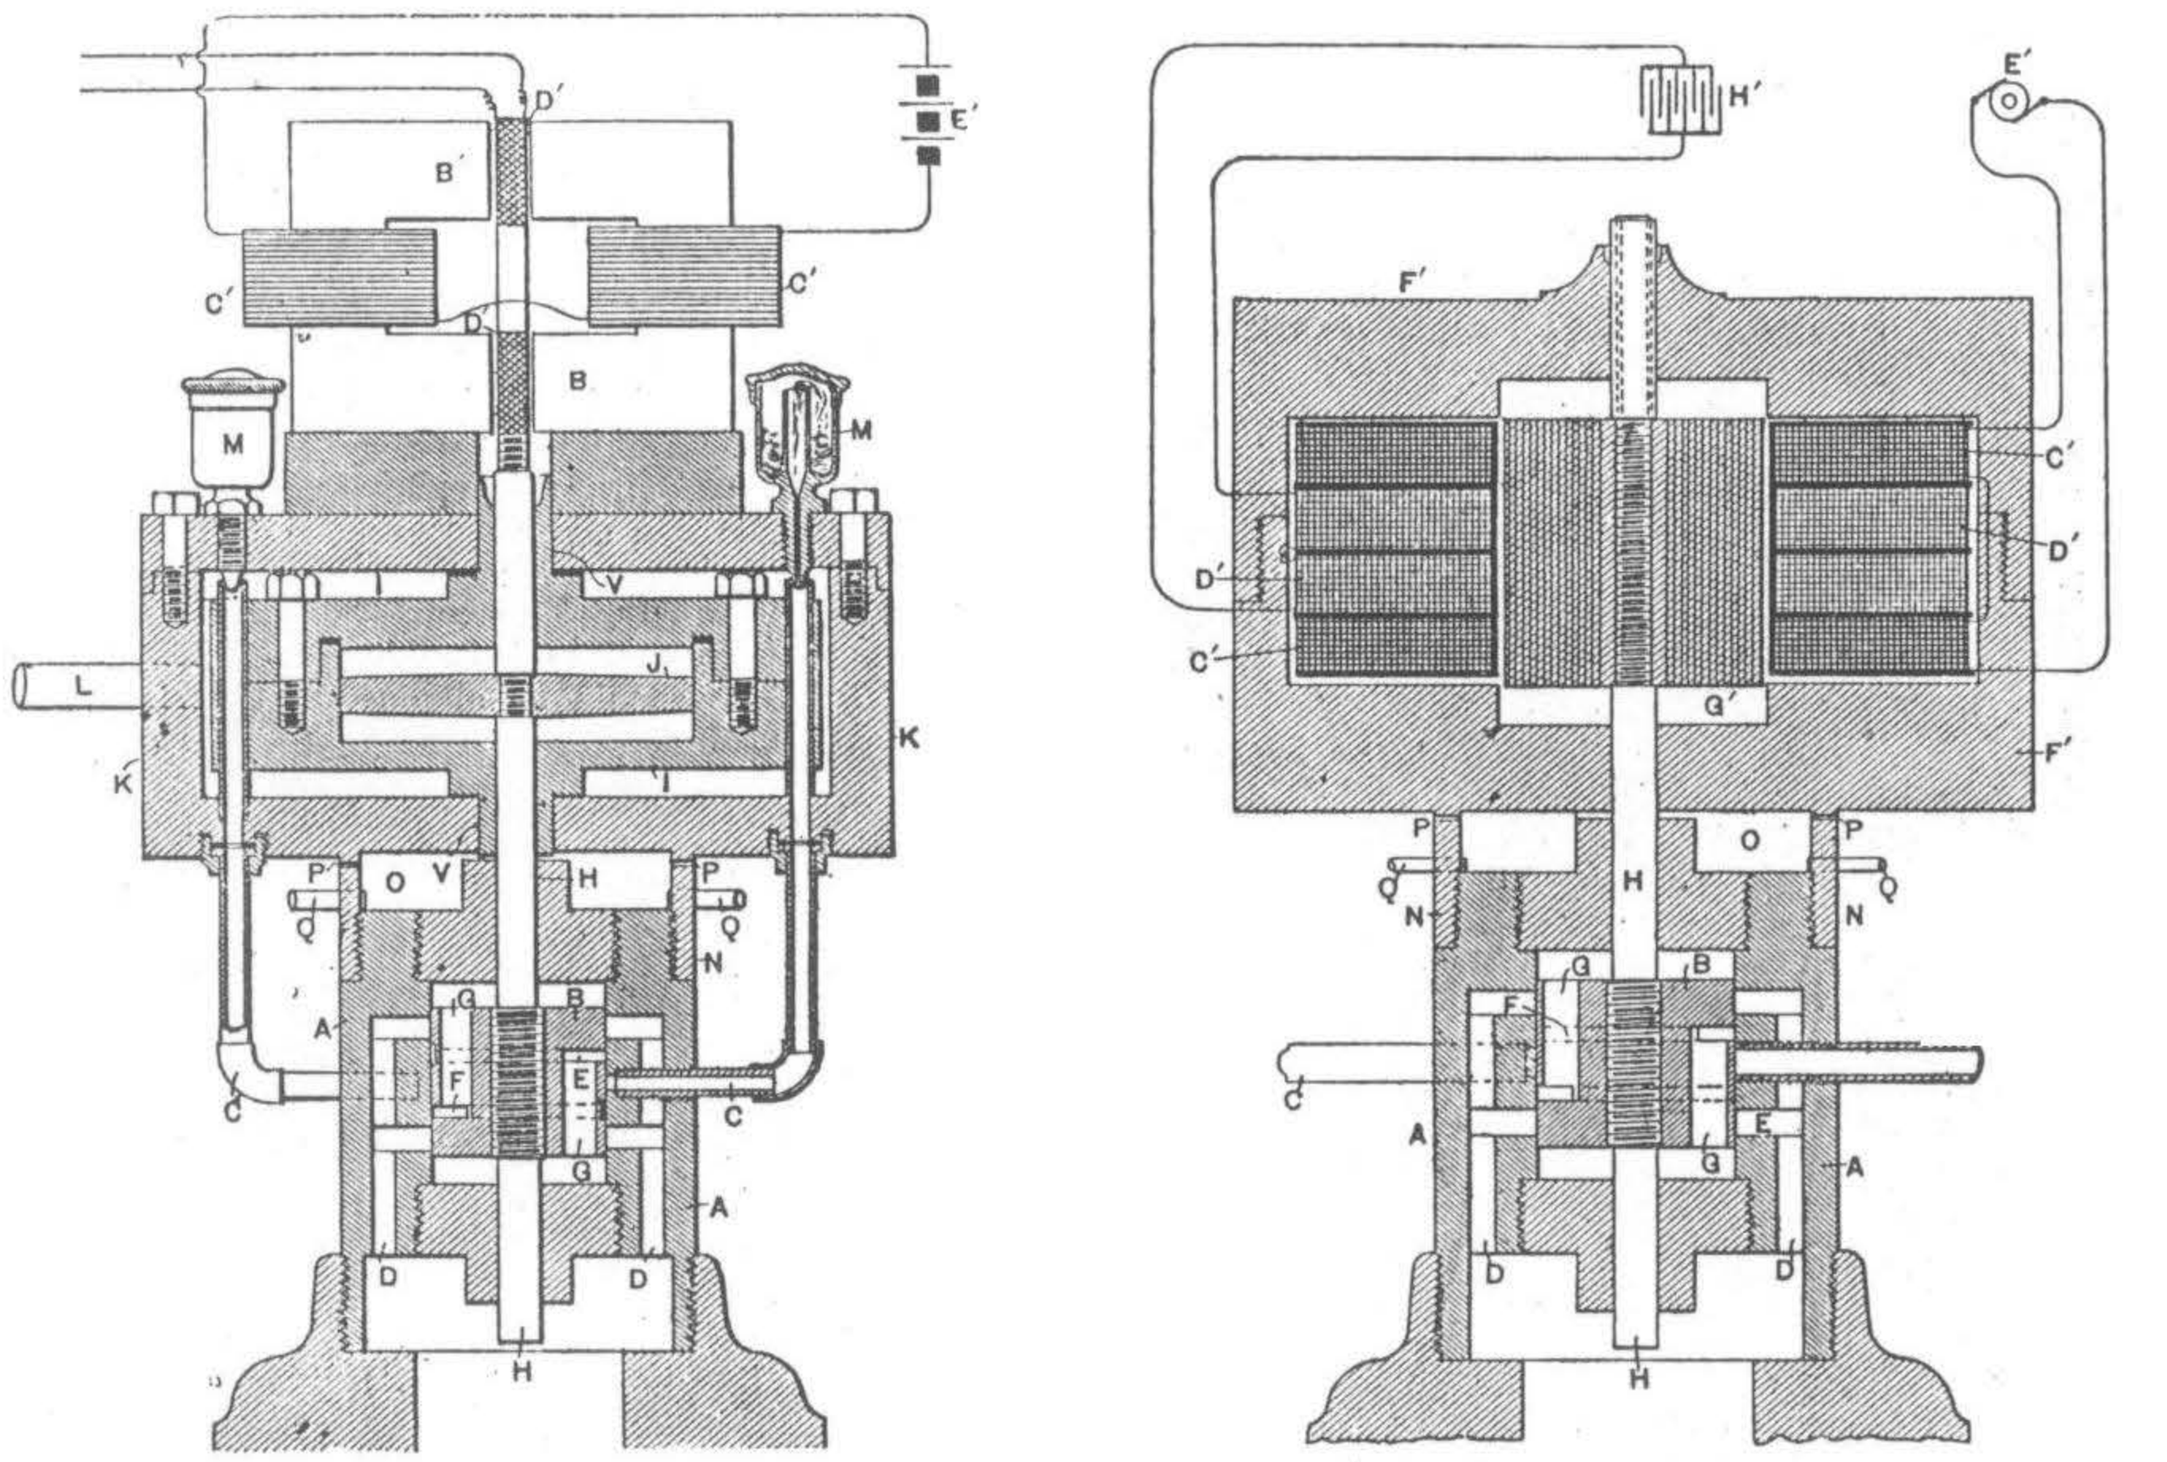

FIG. 1.

which is a disc or plunger, J, carried by the rod, H. The cylinder, I, is without parts of any kind and is airtight, except as a small leakage may occur through the bearings, V, which experience has shown need not be fitted with any very considerable accuracy.

The cylinder, I, is surrounded by a jacket, K, which leaves an open space or chamber around it. The bearings, V, in the cylinder, extend through the jacket to the outside air and the chamber between the cylinder and jacket is made steam or airtight by a suitable packing. The main supply pipe, L, for steam or compressed air leads into this chamber, and the two pipes that lead to cylinder, A, run from this chamber, oil cups, M, being conveniently arranged to deliver oil into the pipes for lubricating the piston.

In the particular form of engine shown, the jacket, K, which contains the cylinder, I, is provided with a flange, N, by which it is screwed to the end of the cylinder, A. A small chamber, O, is thus formed which has air vents, P, in its sides, and drip pipes, Q, leading out from it, through which the oil which collects in it is carried off.

In the position of the parts shown, or when the piston is

at the middle point of its stroke, the plunger, J, is at the centr of the cylinder, I, and the air on both sides of the same is the normal pressure of the outside atmosphere. If a source of steam or compressed air be then connected to the inlet ports, C, C, of the cylinder, A, and a movement be imparted to the piston as by a sudden blow, the latter begins to reciprocate in the well-known way.

The movements of the piston compress and rarefy the air in the cylinder, I, at opposite ends, alternately. A forward stroke compresses the air ahead of the plunger, J, which acts as a spring to return it; similarly, on the back stroke the air is compressed on the opposite side of the plunger, J, and tends to drive it forward.

The compressions of the air in the cylinder, I, and the consequent loss of energy, due mainly to the imperfect elasticity of the air, give rise to a very considerable amount of heat. This heat is utilised by conducting the steam or compressed air to the engine cylinder through the chamber formed by the jacket surrounding the air-spring cylinder; the heat thus taken up and used to raise the temperature of the steam or air acting upon the piston is availed of to increase the efficiency of the engine.

In any given engine of this kind the normal pressure will produce a stroke of determined length, and this will be increased or diminished according to the increase of pressure above, or the reduction of pressure below, the normal. In constructing the apparatus, proper allowance is made for a variation in the length of stroke by giving to the confining cylinder, I, of the air-spring properly determined dimensions. The greater the pressure upon the piston, the higher will be the degree of compression of the air-spring, and the consequent counteracting force upon the plunger.

The rate or period of reciprocation of the piston, however, is mainly determined by the rigidity of the air spring and the inertia of the moving system, and any period of oscillation within very wide limits may be secured by properly portioning these factors, as by varying the dimensions of the air chamber, which is equivalent to varying the rigidity of the spring, or by adjusting the weight of the moving parts. These conditions are all readily determinable, and an engine constructed as above described maintains a perfectly uniform period through very wide limits of pressure.

The pressure of the air confined in the cylinder when the plunger, I, is in its central position, will always be practically that of the surrounding atmosphere, for while the cylinder is so constructed as not to permit such sudden escape of air as to sensibly impair or modify the action of the air spring, there will still be a slow leakage of air into or out of it around the piston rod according to the pressure therein, so that the pressure of the air on opposite sides of the plunger will always tend to remain at that of the outside atmosphere.

To the piston rod, H, is secured a coil, D′, which, by the movements of the piston, is oscillated in the magnetic field produced by two magnets, B′, B′, which may be permanent magnets or energised by coils, C′, C′, connected with a source of continuous current, E′. The movement of the coil, D′ across the lines of force established by the magnets gives rise to alternating currents in the coil. These currents, if the period of mechanical oscillation be constant, will be of constant period.

In the case under consideration, it is assumed as a necessary condition that the inertia of the movable element of the generator and the electro-magnetic reaction which it exerts, will not be of such a character as to materially disturb the action of the engine.

Fig. 2 is an example of a combination in which the engine is not of itself capable of determining entirely the period of oscillation, but in which the generator contributes to this end. In this figure the engine is the same as that shown in fig. 1. The exterior air spring is, however, omitted, and the air spaces at the ends of the cylinder, A, relied on for accomplishing the same purpose. As the pressure in these spaces is liable to variations from variations in the steam or gas used in impelling the piston, they might affect the period of oscillation, and the conditions are not as stable and certain as in the case of an engine constructed as in fig. 1. But if the natural period of vibration of the elastic system be made to approximately accord with the average period of the engine, such tendencies to variation are very largely overcome, and the engine will preserve its period, even through a considerable range of variation of pressure.

The generator in this case is composed of a magnetic casing, F′, in which a laminated core, G′, secured to the piston rod, H, is caused to vibrate. Surrounding the plunger are two exciting coils, C′, C′, and one or more induced coils, D′, D′. The coils, C′, C′, are connected with a generator of continuous currents, E′, and are wound to produce consequent poles in the core, G′. Any movement of the latter will therefore shift the lines of force through coils, D′, D′, and produce currents therein.

In the circuit of coils, D′, is shown a condenser, H′. By the use of a proper condenser the self-induction of this circuit may be neutralised. Such a circuit will have a certain natural period of vibration, and, as this depends upon the capacity and self-induction, the period may be varied to approximately accord with the period of the engine.

In case the power of the engine be comparatively small, as when the pressure is applied through a very small fraction of the total stroke, the electrical vibration will tend to control the period, and it is clear that if the character of such vibration be not very widely different from the average period of vibration of the engine under ordinary working conditions, that such control may be entirely adequate to produce the desired results.

THERE have been, so far as we remember, only three attempts to apply simple reciprocating motion, instead of rotary movement round an axis, to the armature of a dynamo. The first of these was the "thunder-pump," a magneto device used for ringing-up in the early days of telegraphy. Perhaps this instrument ought not to be classed as a dynamo, but it was a practical success in its day. As much cannot be said for the Edison tuning-fork dynamo. Electrically, this second attempt was reasonable, but it was mechanically impossible and absurd. The third reciprocating dynamo is that of NIKOLA TESLA. This was first shown in a lecture delivered by the inventor before the Chicago Congress, and is illustrated and described elsewhere in our present issue. The account, for which we are indebted to the *Electrical Engineer* of New York does not allude to the principal object in view in designing this machine. We understand, from the reports of the lecture, that high frequency was Mr. TESLA's aim. In the *Electrical Engineer* of New York, for August 30, 1893, we find that a mass of about 20lb. was kept in vibration with a stroke of $\frac{7}{8}$in. at a frequency of about 80 per second, "but by shortening the stroke the weight could be vibrated many hundred times, and has been in other experiments." This result seems hardly sufficient to justify so complete a departure from ordinary practice, but on looking up the subject we found some more figures in the *Electrical World* of New York, for September 2, 1893. "The piston is operated by compressed air at 60lb. per square inch. . . . The compression reaches as much as 16 tons. . . . The number of oscillations used at the lecture was from 50 to 90 per second, although from 5,000 to 10,000 per second have been obtained, and as many more as desirable"!

THE TESLA ELECTRICAL OSCILLATOR.*

In the lecture delivered before the Chicago Electrical Congress, Mr. Nikola Tesla first drew attention to the method which he had devised for the continuous production of alternating currents of constant period by the employment of his oscillating engine, in which all rotating parts are avoided directly to the movement of the generating coil in the magnetic field. In applying the Tesla oscillator for the generation of currents of constant period certain conditions are encountered which must be taken into consideration in order to satisfactorily secure the desired result. These conditions may be secured by properly proportioning the self-induction and capacity of the circuit, including the generator.

Mr. Tesla has, however, observed the further fact in connection with the use of such engines as a means for running a generator, that it is advantageous that the period of the engine and the natural period of electrical vibration of the generator should be the same, as in such case the best conditions for electrical resonance are established, and the possibility of disturbing the period of mechanical vibrations is reduced to a minimum. Mr. Tesla has found that even if the theoretical conditions necessary for maintaining a constant period in the engine itself are not exactly maintained, still the engine and generator combined will vibrate at a constant period. For example, if instead of using in the engine an independent cylinder and plunger, as an airspring of practical constant rigidity, the piston may impinge upon air cushions at the ends of its own cylinder. Although the rigidity of such cushions or springs might be considerably affected and varied by the variations of pressure within the cylinder, still, by combining with such an engine a generator which has a period of its own, approximately that of the engine, constant vibration may be maintained even through a considerable range of varying pressure, owing to the controlling action of the electromagnetic system. Under certain conditions the influence of the electromagnetic system may be made so great as to entirely control the period of the mechanical vibration within wide limits of varying pressure. This is likely to occur in those instances where the power of the engine, while fully capable of maintaining a vibration once started, is not sufficient to change its rate.

Referring to Fig. 1, A is the main cylinder in which works a piston, B. Inlet ports, C C, pass through the sides of the cylinder opening at the middle and on opposite sides. Exhaust ports, D D, extend through the walls of the cylinder and are formed with branches that open into the interior of the cylinder on each side of the inlet ports and on opposite sides of the cylinder. The piston, B, has two circumferential grooves, E F, which communicate through

* Abstract from an advance proof, kindly sent by the *Electrical Engineer* of New York.

openings, G, in the piston with the cylinder on opposite sides of the piston respectively.

The particular construction of the cylinder, the piston and the ports controlling it, may be very much varied, and is not in itself material, except that in the special case under consideration it is desirable that all the ports, and more especially the exhaust ports, should be made very much larger than is usually the case so that no force due to the action of the steam or compressed air will tend to retard or affect the return of the piston in either direction.

The piston, B, is secured to a piston rod, H, which works in suitable stuffing boxes in the heads of the cylinder, A. This rod is prolonged on one side and extends through bearings V in a cylinder, I, mounted in line with the first, and within which is a disc or plunger, J, carried by the rod H. The cylinder I is without parts of any kind and is air-tight, except as a small leakage may occur through the bearings V, which experience has shown need not be fitted with any very considerable accuracy.

The cylinder I is surrounded by a jacket, K, which leaves an open space or chamber around it. The bearings V in the cylinder extend through the jacket to the outside air, and the chamber between the cylinder and the jacket is made steam or air-tight by

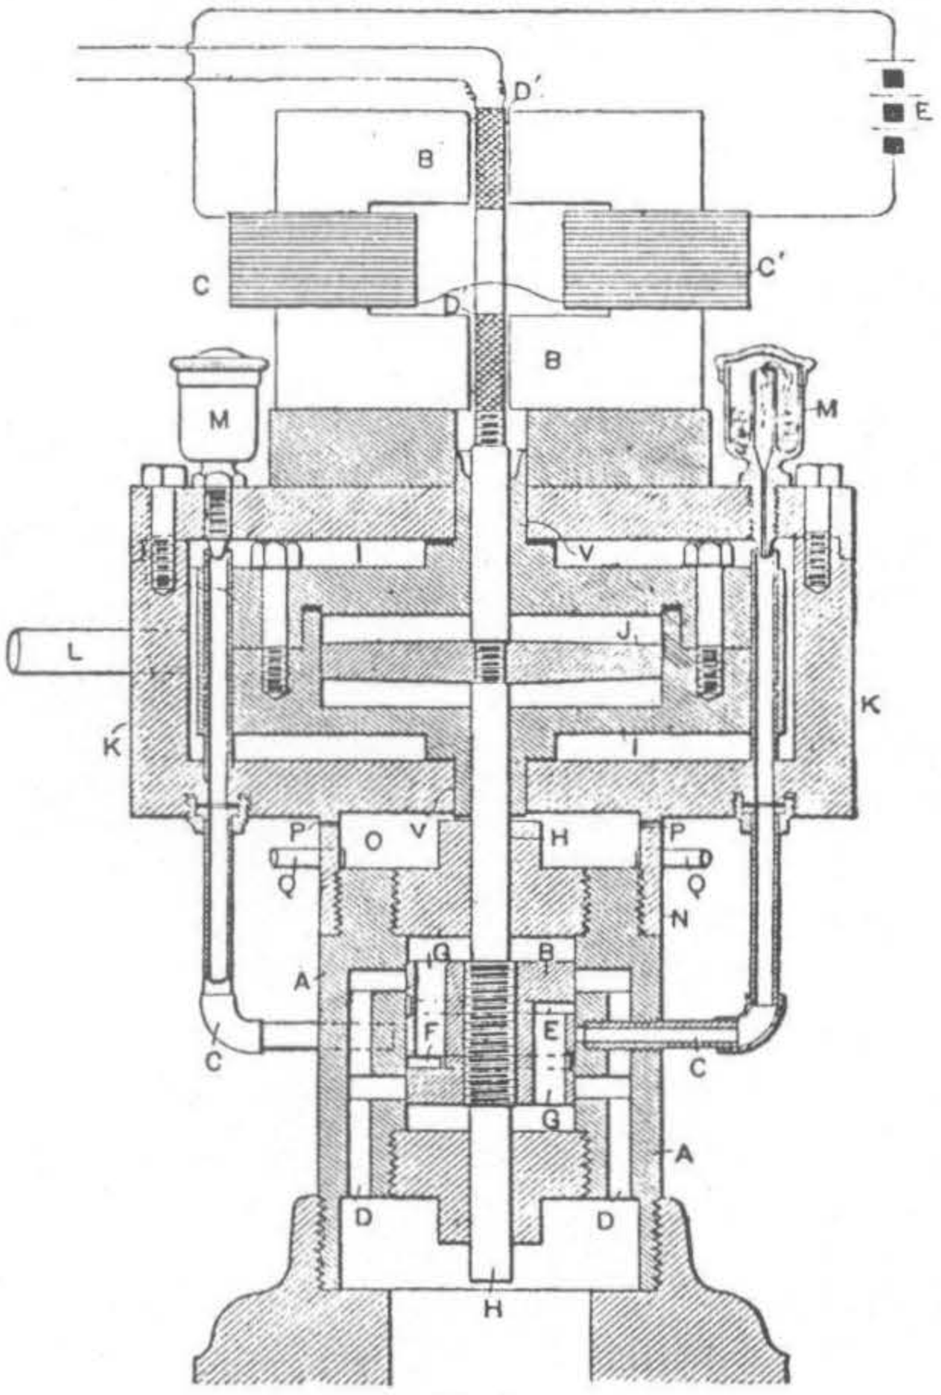

FIG. 1.

conducting the steam or compressed air to the engine cylinder through the chamber formed by the jacket surrounding the air-spring cylinder, the heat thus taken up and used to raise the temperature of the steam or air acting upon the piston is availed of to increase the efficiency of the engine.

In any given engine of this kind the normal pressure will produce a stroke of determined length, and this will be increased or diminished according to the increase of pressure above, or the reduction of pressure below, the normal. In constructing the apparatus proper allowance is made for a variation in the length of stroke by giving to the confining cylinder I of the air spring pro perly determined dimensions. The greater the pressure upon the piston the higher will be the degree of compression of the air spring, and the consequent counteracting force upon the plunger.

The rate or period of reciprocation of the piston, however, is mainly determined by the rigidity of the air spring and the inertia of the moving system, and any period of oscillation within very wide limits may be secured by properly portioning these factors, as by varying the dimensions of the air chamber, which is equivalent to varying the rigidity of the spring, or by adjusting the weight of the moving parts. These conditions are all readily

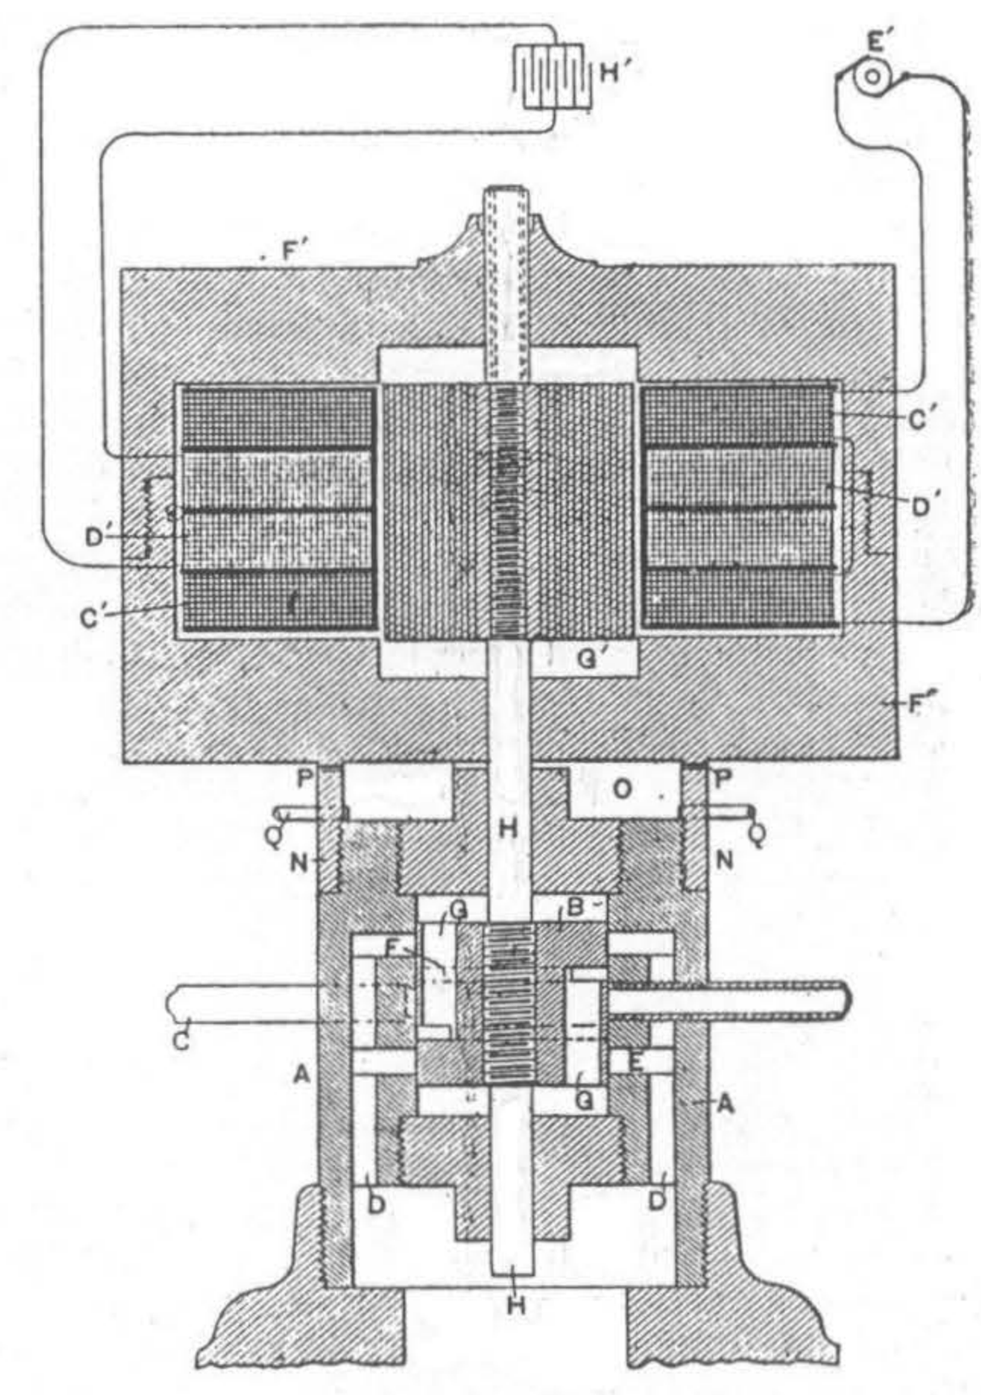

FIG. 2.

a suitable packing. The main supply pipe L, for steam or compressed air, leads into this chamber, and the two pipes that lead to cylinder A run from this chamber, oil cups M being conveniently arranged to deliver oil into the pipes for lubricating the piston.

In the particular form of engine shown, the jacket K, which contains the cylinder I is provided with a flange N, by which it is screwed to the end of the cylinder A. A small chamber O is thus formed, which has air vents, P, in its sides, and drip pipes Q leading out from it through which the oil which collects in it is carried off.

In the position of the parts shown, or when the piston is at the middle point of its stroke, the plunger J is at the centre of the cylinder I, and the air on both sides of the same is at the normal pressure of the outside atmosphere. If a source of steam or compressed air be then connected to the inlet ports C C of the cylinder A, and a movement be imparted to the piston as by a sudden blow, the latter begins to reciprocate in the well-known way.

The movements of the piston compress and rarefy the air in the cylinder I at opposite ends alternately. A forward stroke compresses the air ahead of the plunger J, which acts as a spring to return it; similarly, on the back stroke the air is compressed on the opposite side of the plunger J, and tends to drive it forward.

The compressions of the air in the cylinder I, and the consequent loss of energy due mainly to the imperfect elasticity of the air, give rise to a very considerable amount of heat. This heat is utilised by determinable, and an engine, constructed as above described, maintains a perfectly uniform period through very wide limits of pressure.

To the piston rod H is secured a coil, D', which, by the movements of the piston, is oscillated in the magnetic field produced by two magnets, B' B', which may be permanent magnets or energised by coils, C' C', connected with a source of continuous current, E'. The movement of the coil D' across the lines of force established by the magnets gives rise to alternating currents in the coil. These currents, if the period of mechanical oscillation be constant, will be of constant period.

In the case under consideration it is assumed as a necessary condition that the inertia of the movable element of the generator and the electromagnetic reaction which it exerts will not be of such a character as to materially disturb the action of the engine.

Fig. 2 is an example of a combination in which the engine is not of itself capable of determining entirely the period of oscillation, but in which the generator contributes to this end. In this figure the engine is the same as that shown in Fig. 1. The exterior air spring is, however, omitted, and the air spaces at the ends of the cylinder A relied on for accomplishing the same purpose. As the pressure in these spaces is liable to variations from variations in the steam or gas used in impelling the piston they might affect the period of oscillation, and the conditions are not as stable and cer-

tain as in the case of an engine constructed as in Fig. 1. But if the natural period of vibration of the elastic system be made to approximately accord with the average period of the engine such tendencies to variation are very largely overcome, and the engine will preserve its period even through a considerable range of variation of pressure.

The generator in this case is composed of a magnetic casing F′, in which a laminated core G′ secured to the piston rod H is caused to vibrate. Surrounding the plunger are two exciting coils, C′ C′, and one or more induced coils, D′ D′. The coils C′ C′ are connected with a generator of continuous currents, E′, and are wound to produce consequent poles in the core G′. Any movement of the latter will therefore shift the lines of force through coils D′ D′, and produce currents therein.

In the circuit of coils D′ is shown a condenser, H′. By the use of a proper condenser the self-induction of this circuit may be neutralised. Such a circuit will have a certain natural period of vibration, and as this depends upon the capacity and self-induction, the period may be varied to approximately accord with the period of the engine.

In case the power of the engine be comparatively small, as when the pressure is applied through a very small fraction of the total stroke, the electrical vibration will tend to control the period, and it is clear that if the character of such vibration be not very widely different from the average period of vibration of the engine under ordinary working conditions, that such control may be entirely adequate to produce the desired results.

After-Glow in Exhausted Bulbs.

BY H. M. MARTIN AND W. H. PALMER, JR.

Having failed to note in any communication on the subject of the phosphorescence of exhausted bulbs in a field of high potential and frequency any mention of what, for want of a better name, may be called the "after-glow," we are led to believe that a brief description of this phenomenon may be of general interest.

If an exhausted bulb having a sealed-in electrode be held in the hand and approached to a terminal of an induction coil giving moderately high potential and frequency, the whole interior of the bulb will be permeated by a phosphorescent glow; if, now, the bulb be slowly withdrawn from the field of excitation, the degree of luminosity will gradually diminish till a point is reached beyond which the intensity of the glow, now greatly attenuated, is practically unaffected by any further increase in distance from the terminal. It is this glow, entirely independent for its perpetuation of the field in which the bulb was charged, and continuing, we believe, until electrical equilibrium has been established between the rarefied gas and the electrode of the bulb, that we have called the "after-glow." That it is thus independent of the field of excitation may be proved by shutting off, after the "after-glow" has been established, the exciting current of the induction coil, when the glow will be entirely unaffected and continue, practically, for the same length of time as when the coil is in action. When the glow has become almost imperceptible it may often be stimulated into renewed life by shifting the position of the fingers on the surface of the bulb. After this has been done and the glow has again died away, a single bright flash may be obtained by touching with one finger the projecting end of the sealed-in electrode. That the hand of the experimenter is a factor in these effects may be shown by laying the glowing bulb on a table; the glow, though not extinguished, becomes very faint, especially if no object of capacity be near. The bright flash may still be obtained by again picking up the bulb and discharging as explained. We have repeatedly charged a bulb, shut off the primary current from the coil, carried the bulb to a remote part of the house, laid it on a table, and after picking it up again, obtained a flash on discharging that could be seen some yards away. Lack of apparatus has prevented us from following up these experiments, which are now some months old, but they are valuable, at least, as additional and ocular proof of the electrostatic origin of the "Tesla bulb effects."

The Electrical World's Current Technical Digest of Electrical Literature

COMPILED FROM THE PRINCIPAL FOREIGN ELECTRICAL JOURNALS.

BY CARL HERING.

Tesla's Researches.—The "Zeit. feur Elek.," Dec. 15, reprints a portion of an address by Prof. Ettingshausen, in which he gives a short description of the life and works of his countryman, Nikola Tesla.

The New York Times January 22, 1894

TESLA AND HIS RESEARCHES.

THE INVENTIONS, RESEARCHES, AND WRITINGS OF NIKOLA TESLA. With special reference to his work of Polyphase Currents and High Potential Lighting. By Thomas Commerford Martin. New-York: The Electrical Engineer.

We have not yet got at the bottom of the transmission of electrical power or of methods by means of which electrical force can be stored or distributed. But as to a motor, that may be, as Mr. Martin says, but secondary "to the radical improvement of the means and methods of illumination." Perhaps when we better appreciate the dynamo and the question is solved, we shall get to the economics of electrical lighting. To the many "who work in the domain of electrical invention, the apparatus and devices which are familiar appear cumbrous and wasteful, and subject to severe limitation." To bring this down to its simplest equation, we want a cheaper light.

Working toward this end, what has been already accomplished by Mr. Nikola Tesla is particularly worthy of attention. Mr. Tesla, having his theory by heart, has not alone inventive powers of the highest order, but possesses a practical mind. It is of no use to disparage the scientist who invents what may apparently be nothing more than an electrical toy. There are many now alive who remember when at college the electrical machine and the Leyden jar as simply sources of recreation to the Professor of Natural Sciences. No one forty years ago imagined the vast possibilities of electricity. And so it may happen that what is an electrical trick which astonishes to-day may be in the time to come of enormous practical advantage to us.

Mr. Tesla has a genius for electrical work, "with all the play and push of a vigorous and original mind." In brief biographical sketch we are told that Mr. Nikola Tesla was born in Austro-Hungary some thirty-seven years ago. He had a fair scientific education, and early devoted himself to the study of electricity and magnetism. When a school lecture was given on a dynamo, his instructor told the class that it was impossible "to operate a dynamo without commutator or brushes," and at once Mr. Tesla differed with his teacher. He had already "seen by quick intuition that a way could be found to dispense with them, and from that time he may be said to have begun work in the ideas that fructified ultimately in his rotating field motors."

His primary studies ended, Mr. Tesla found occupation at Prague and Buda-Pesth, in the Telegraph Engineering Department, and then went to Paris to enlarge his field of practical and theoretical study. In France he followed out his early idea of the rotating field principle. In coming to the United States he found his first occupation in the Edison works. To be there had been the "goal of his ambition," and for Mr. Edison Mr. Tesla always has had the strongest admiration. But the young electrician had master thoughts of his own, which required maturing. His own inventions in lighting might, too, in time be worth marketing. Mr. Tesla was right in trying to get the commercial value of his inventions, but still all through this period of earning his bread he returned unceasingly to his subject, the rotating field principle, and to-day "the application of it in motors has become known the world over."

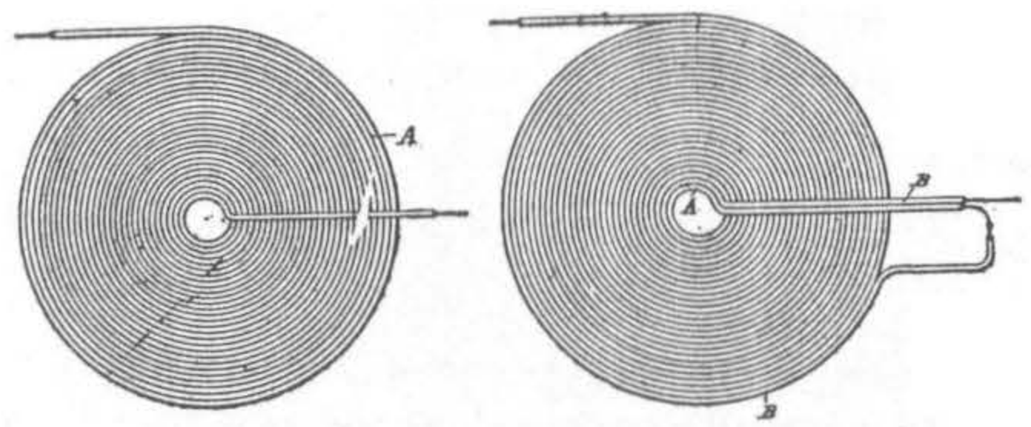
In this volume may be found a history of the many steps taken by Mr. Tesla before arriving at his conclusions. Nothing in nature goes by jumps, and it is all wrong to believe that the man of science clears his ground at one spring. Those plodding and cautious ways which belong to true genius are essentially Mr. Tesla's. It was hard study, perhaps many failures, which led to the working out of polyphase currents.

Mr. Tesla's lectures are given here, with a description of his exhibits at Chicago. The chapter which will particularly interest those who look to a newer method of illumination, contain the lecture delivered in New-York, entitled "Experiments with Alternate Currents of Very High Frequency and Their Application to Methods of Artificial Illumination." A by no means easy task has been successfully undertaken in this volume.

THE TESLA CONDENSER-MAGNET.

In electric apparatus or systems in which alternating currents are employed, the self-induction of the coils or conductors in many cases operates disadvantageously by giving rise to false currents which often reduce the commercial efficiency of the apparatus or operate detrimentally in other respects.

The effects of such self-induction, as is well known, can be neutralized by proportioning to a proper degree the capacity of the circuit with relation to the self-induction and frequency of the currents. This has been accomplished heretofore by the use of condensers applied as separate instruments. In order to avoid the employment of condensers, which involve additional expense, Mr. Nikola Tesla has devised a method of constructing the coils themselves so as to accomplish the same object as the condensers.



Mr. Tesla had found some years ago that in every coil there exists a certain relation between its self-induction and capacity that permits a current of given frequency and potential to pass through it with no other opposition than that of ohmic resistance, or, in other words, as though it possessed no self-induction. This is due to the mutual relations existing between the special character of the current and the self-induction and capacity of the coil, the latter quantity being just capable of neutralizing the self-induction for that frequency.

It is well known that the higher the frequency or potential difference of the current, the smaller the capacity required to counteract the self-induction; hence, in any coil, however small the capacity, it may be sufficient for the purpose stated if the proper conditions in other respects be secured. In the ordinary coils the difference of potential between adjacent turns or spires is very small, so that while they are in a sense condensers, they possess but very small capacity and the relations between the two quantities, self-induction and capacity, are not such as under any ordinary conditions satisfy the requirements contemplated by Mr. Tesla, because the capacity relatively to the self-induction is very small.

In order to attain his object and to properly increase the capacity of any given coil, Mr. Tesla winds it in such a way as to secure a greater difference of potential between its adjacent turns, and since the energy stored in the coil —considering the latter as a condenser—is proportional to the square of the potential difference between its adjacent convolutions, it is evident that in this way he may secure, by a proper disposition of these convolutions, a greatly increased capacity for a given increase in potential difference between the turns. The accompanying drawings show the general nature of the plan which he has adopted for carrying out this idea.

Fig. 1 is a diagram of a coil wound in the ordinary manner, while Fig. 2 shows the winding designed to secure the objects Mr. Tesla is aiming at.

In Fig. 1, A designates any coil the convolutions of which are wound insulated in the usual way. Let it be assumed that the terminals of this coil show a potential difference of 100 volts, and that there are 1,000 convolutions; then considering any two contiguous points on

FIGS. 1 AND 2.—THE TESLA CONDENSER-MAGNET.

adjacent convolutions let it be assumed that there will exist between them a potential difference of one-tenth of a volt.

If now, as shown in Fig. 2, a conductor B be wound parallel with the conductor A and insulated from it, and the end of A be connected with the starting point of B, the aggregate length of the two conductors being such that the assumed number of convolutions or turns is the same, viz., 1,000, then the potential difference between any two adjacent points in A and B will be 50 volts, and as the capacity effect is proportional to the square of this difference, the energy stored in the coil as a whole will now be 250,000 times as great.

Based on this principle, any given coil may be wound either in whole or in part, not only in the exact manner illustrated, but in a great variety of ways, so as to secure between adjacent convolutions such potential difference as will give the proper capacity to neutralize the self-induction for any given current that may be employed. Capacity secured in this particular way possesses an additional advantage in that it is evenly distributed, a consideration of the greatest importance in many cases, and the results both as to efficiency and economy are more readily and easily obtained as the size of the coils, the potential difference, or frequency of the currents are increased.

THE TROLLEY AND INSURANCE.

THE New York Board of Fire Underwriters' special committee on electrical hazards called upon Mayor Gilroy recently and protested against the introduction of the trolley upon Manhattan Island, also warning the Mayor that if the trolley was introduced the inevitable result would be an increase in fire insurance rates.

Century Magazine February 1894

NIKOLA TESLA.

SERVIAN poetry has so distinct a charm that Goethe is said to have learned the musical tongue in which it is written rather than lose any of its native beauty. History does not record, however, any similar instance in which the Servian language, though it be that of Boskovich, expounder of the atomic theory, has been studied for the sake of the scientific secrets that might lurk therein. The vivid imagination and ready fancy of the people have been literary in their manifestation and fruit. A great Slav orator has publicly reproached his one hundred and twenty million fellows in Eastern Europe with their utter inability to invent even a mouse-trap. They were all mere barren idealists. If this were true, to equalize matters, we might perhaps barter without loss some score of ordinary American patentees for a single singer of Illyrian love-songs. But racial conditions are hardly to be offset on any terms that do not leave genius its freedom, and once in a while Nature herself rights things by producing a man whose transcendent merit compensates his nation for the very defects to which it has long been sensitive. It does not follow that such a man shall remain in a confessedly unfavorable environment. Genius is its own passport, and has always been ready to change habitats until the natural one is found. Thus it is, perchance, that while some of our artists are impelled to set up their easels in Paris or Rome, many Europeans of mark in the fields of science and research are no less apt to adopt our nationality, of free choice. They are, indeed, Americans born in exile, and seek this country instinctively as their home, needing in reality no papers of naturalization. It was thus that we welcomed Agassiz, Ericsson, and Graham Bell. In like manner Nikola Tesla, the young Servian inventor with whose work a new age in electricity is beginning, now dwells among us in New York.

Mr. Tesla's career not only touches the two extremes of European civilization, east and west, in a very interesting way, but suggests an inquiry into the essential likeness between poet and inventor. He comes of an old Servian family whose members for centuries have kept watch and ward along the Turkish frontier, and whose blood was freely shed that our western vanguard might gain time for its advance upon these shores. Yet, remote as such people and conditions are to us, it is with apparatus based on ideas and principles originating among them that the energy from Niagara Falls is to be widely distributed by electricity, in the various forms of light, heat, and power. This, in itself, would seem enough to confer fame, but Mr. Tesla has done, and will do, much else. Could he be tamed to habits of moderation in work, it would be difficult to set limit to the solutions he might give us, through ripening years, of many deep problems; but when a man springs from a people who have a hundred words for knife and only one for bread, it is a little unreasonable to urge him to be careful even of his own life. Thirty-six years make a brief span, but when an inventor believes that creative fertility is restricted to the term of youth, it is no wonder that night and day witness his anxious activity, as of a relentless volcano, and that ideas well up like hot lava — till the crater be suddenly exhausted and hushed.

A Slav of the Slavs, with racial characteristics strongly stamped in look, speech, and action, Mr. Tesla is a notable exemplification of the outcropping in unwonted form of tendencies suppressed. I have never heard him speak of a picture or a piece of music, but his numerous inventions, and the noble lectures that embody his famous investigations with currents of high frequency and high potential, betray the poetic temperament throughout. One would expect the line separating fact from theory to fade at the altitudes of thought to which his later speculations reach; but this lithe, spare mountaineer is accustomed to the thin, dry air, and neither loses sharpness of sight nor breathes painfully. Has the Servian poet become inventor, or is the inventor a poet? Mr. Tesla has been held a visionary, deceived by the flash of casual shooting stars; but the growing conviction of his professional brethren is that because he saw farther he saw first the low lights flickering on tangible new continents of science. The perceptive and imaginative qualities of the mind are not often equally marked in the same man of genius. Overplus of imagination may argue dimness of perception; an ability to dream dreams may imply a want of skill in improving reapers. Now and then the two elements combine in the creative poet of epic and drama; occasionally they give us the prolific inventor like Tesla.

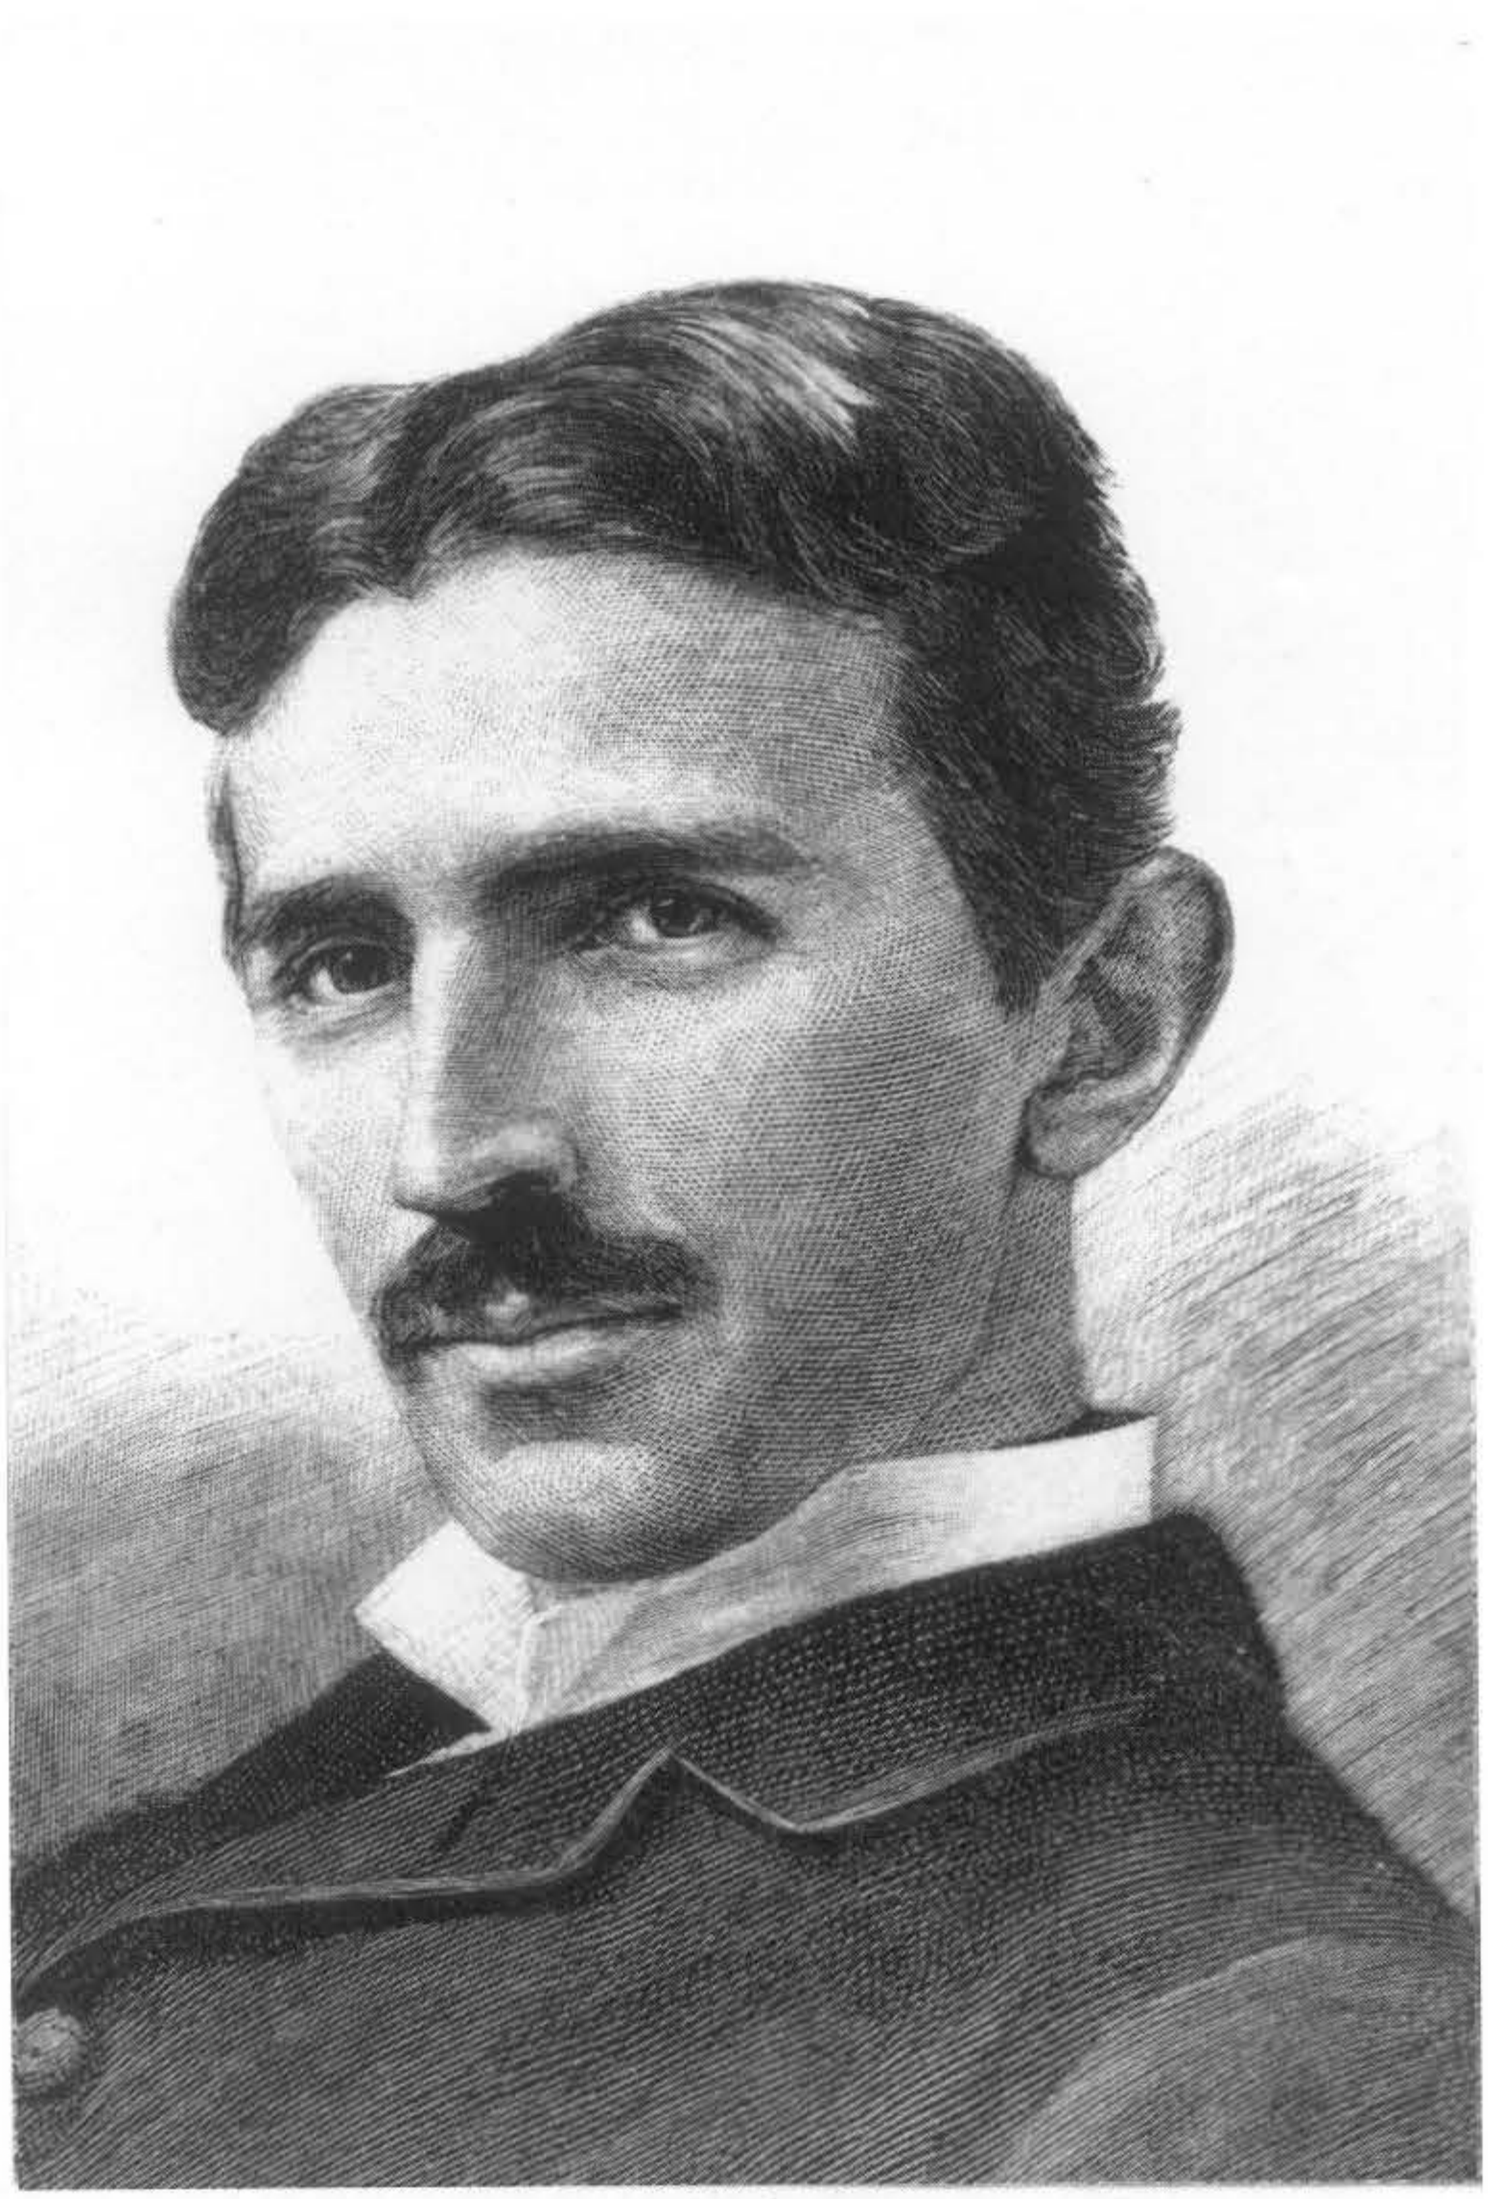
Jules Breton has spoken of the history of his life as being at the same time the genesis of his art. This is true of Nikola Tesla's evolution. His bent toward invention we may surely trace to his mother, who, as the wife of an eloquent

clergyman in the Greek Church, made looms and churns for a pastoral household while her husband preached. Tesla's electrical work started when, as a boy in the Polytechnic School at Gratz, he first saw a direct-current Gramme machine, and was told that the commutator was a vital and necessary feature in all such apparatus. His intuitive judgment or latent spirit of invention at once challenged the statement of his instructor, and that moment began the process of reasoning and experiment which led him to his discovery of the rotating magnetic field, and to the practical polyphase motors, in which the commutator and brushes, fruitful and endless source of trouble, are absolutely done away with. These perfected inventions did not come at once; they never do. The conditions that surrounded this youth in the airy fastnesses of the Dinaric Alps all made against the hopes he nursed of becoming an electrician; and not the least impediment was the fond wish of his parents at Smiljan Lika that he should maintain the priestly tradition, and benefit by the preferment likely to come through his uncle, now Metropolitan in Bosnia. But Tesla felt himself destined to serve at other altars than those of his ancient faith, with other means of approach to the invisible and unknown. He persevered in mathematical and mechanical studies, mastered incidentally half a dozen languages, and at last became an assistant in the Government Telegraph Engineering Department at Buda-Pest. His salary was small enough to please those who hold that the best endowment of genius is poverty, and he would make no appeals to his widowed mother for help. Experimenting, of course, went on all the time; at this juncture it was on telephony that he wasted his meager substance in riotous invention. Desirous of going to a fête with some friends, and anxious not to spend on clothes the money that might buy magnets and batteries, the brilliant idea occurred to him to turn his only pair of trousers inside out and to disport in them on the morrow as new. He sat up all night tailoring, but the fête came and went before he could reappear in public. This episode is quite in keeping with his boyish efforts to fly from the steep roof of the house at Smiljan, using an old umbrella as aërostat; or with the peculiar tests, stopped by the family doctor before the results could be determined, as to how long he could suspend the beating of his heart by will power.

Naturally enough for a young inventor seeking larger opportunity, Tesla soon drifted westward from Buda-Pest. He made his way to Paris, where he quickly secured employment in electric lighting, then a new art, and encountered an observant associate of Mr. Edison. Almost before he knew it, he was on his glad voyage across the Atlantic to work in one of the Edison shops, and to enter upon a new stage of development. He had profound faith in the value of the principles first meditated in the silence of the sterile mountains that border the Adriatic, and he knew that in a country where every new invention in electricity has its chance, his turn would come also, for he now had demonstrated his theories in actual apparatus.

If anything were needed to confirm Mr. Tesla in his hopes and enthusiasm, it would have been the close relation that he was thus thrown into with the robust, compelling genius who has created so many new things in electricity. Emerson has said that steam is half an Englishman; may we not, in view of what such men as Edison have done, add that electricity is half an American? The fiery zeal with which this young recruit flung himself on the most exacting tasks matched that of his chief. It went the length of a daily breakfast of Welsh rabbit, for weeks Mr. Tesla accepting as true, in spite of protesting stomach, the jocular suggestion that it was thus that his hero fortified himself successfully for renewed effort after their long vigils of toil. Mr. Edison, like most other people, had some difficulty in finding anywhere within the pale of civilization, as marked by the boundaries of maps, the isolated region of Mr. Tesla's birth, and once inquired seriously of his neophyte whether he had ever tasted human flesh. It was inevitable that a really delightful intimacy and apprenticeship should end. Even the most cometic genius has its orbit, and these two men are singularly representative of different kinds of training, different methods, and different aims. Mr. Tesla must needs draw apart; and stimulated by this powerful spirit, he went on his own way for his own work's sake.

Of late years a sharp controversy has raged in the electrical field as to the respective advantages of the continuous and the alternating current for light and power. In bitterness and frequent descent to personalities it has resembled the polemics of the old metaphysical schoolmen, and uninstructed, plain folk have mildly wondered whether it was really worth while to indulge in such terrible threatenings and slaughter over purely speculative topics. There is, however, a very practical aspect to the discussion, and from the first Mr. Tesla has been an advocate of the alternating current, not because he loved the direct current less, but because he knew that with the alternating he could achieve results otherwise impossible, especially in power transmission. Furthermore, all direct-current generators and motors have required commutators and brushes, but Mr. Tesla, who has himself perfected many inventions based on direct currents, has shown that with the ap-



plication of the rotating-field principle these elements of complication and restriction were no longer needed. This utilization of polyphase currents was a most distinct advance, made a deep imprint on the electric arts, and has been duly signalized. In America the invention found immediate sale. From Italy came an insistent cry of priority, reminding one of the "anticipations" that have clustered thick around the telegraph, the telephone, and the incandescent lamp. In Germany, with money raised by popular and imperial subscription, apparatus on the polyphase principle was built by which large powers were transmitted electrically more than a hundred miles from Neckar-on-the Rhine to Frankfort-on-the-Main; and now by equivalent agency Niagara is to drive the wheels of Buffalo and beyond.

So thoroughly has Mr. Tesla worked out his discovery of the rotating magnetic field, or "resultant attraction," that the record of his inventions contains no fewer than twenty-four chapters on varying forms of his polyphase-current apparatus and arrangements of circuit. But ever pursuing new researches, Mr. Tesla, after the enunciation of these fundamental ideas, next brought to notice his series of even more interesting investigations on several novel groups of phenomena produced with currents of high potential and high frequency. To familiarize the American public with some of his results, he lectured upon them at Columbia College, before the American Institute of Electrical Engineers, in May, 1891. The year following, with riper results to publish, and by special invitation, he lectured twice in England, appearing before the Institution of Electrical Engineers, a distinguished scientific body of which Professor Crookes was then president, and, later, at the Royal Institution, where the immortal Faraday lived and labored. From England he was called to France to repeat his demonstrations before the Société Internationale des Electriciens and the Société Française de Physique. In Germany he received the greetings of Hertz and Von Helmholtz, and from his own country came the Order of Saint Sava, conferred by the king. Since his return to this country he has lectured before the Franklin Institute at Philadelphia and the National Electric Light Association at St. Louis. But he has an intense dislike to the platform, and has returned to his laboratory with a remorseful sense of neglected work from which long months of abandonment to unremitting research will not free him.

I can only outline the vast range of the researches that these lectures, and the apparatus connected with the demonstrations, cover. Broadly stated, Mr. Tesla has advanced the opinion, and sustained it by brilliant experiments of startling beauty and grandeur, that light and heat are produced by electrostatic forces acting between charged molecules or atoms. Perfecting a generator that would give him currents of several thousand alternations per second, and inventing his disruptive discharge coil, he has created electrostatic conditions that have already modified not a few of the accepted notions about electricity. It has been supposed that ordinary currents of one or two thousand volts' potential would surely kill, but Mr. Tesla has been seen receiving through his hands currents at a potential of more than 200,000 volts, vibrating a million times per second, and manifesting themselves in dazzling streams of light. This is not a mere *tour de force*, but illustrates the principle that while currents of lower frequency destroy life, these are harmless. After such a striking test, which, by the way, no one has displayed a hurried inclination to repeat, Mr. Tesla's body and clothing have continued for some time to emit fine glimmers or halos of splintered light. In fact, an actual flame is produced by this agitation of electrostatically charged molecules, and the curious spectacle can be seen of puissant, white, ethereal flames, that do not consume anything, bursting from the ends of an induction coil as though it were the bush on holy ground. With such vibrations as can be maintained by a potential of 3,000,000 volts, Mr. Tesla expects some day to envelop himself in a complete sheet of lambent fire that will leave him quite uninjured. Such currents as he now uses would, he says, keep a naked man warm at the North Pole, and their use in therapeutics is but one of the practical possibilities that has been taken up.

Utilizing similar currents and mechanism, Mr. Tesla has demonstrated the fact that electric lamps and motors can not only be made to operate on one wire, instead of using a second wire on the ground to complete the circuit, but that we can operate them even by omitting the circuit. Our Subway Boards are to find their wires and occupations gone. Electric vibrations set up at any point of the earth may by resonance at any other spot serve for the transmission of either intelligence or power. With these impulses or wave discharges, Mr. Tesla also opens up an entirely new field of electric lighting. His lamps have no filaments as ordinarily known, but contain a straight fiber, a refractory button, or nothing but a gas. Tubes or bulbs of this kind, in which the imprisoned ether or air beats the crystal walls, when carried into the area or room through which these unsuspected currents are silently vibrating, burst into sudden light. If coated inwardly with phosphorescent substances, they glow in all the splendors of the sunset and the aurora.

These are only a scant handful of ideas and

PHOTOGRAPHED BY SARONY. ENGRAVED BY T. JOHNSON.

NIKOLA TESLA.

discoveries from the rich mint of Mr. Tesla's laboratory, where alone, secluded, intimates or assistants shut out, he reasons from cause to effect; and with severe, patient diligence not only elaborates his theories, but tries them by the rack and thumbscrew of experiment. He is of all men most dissatisfied with things as they are in his own field of work. Recently, the high-frequency generators with which he has done so much of this advanced work have been laid aside in discontent for an oscillator, which he thinks may not only replace the steam-engine with its ponderous fly-wheels and governors, but embodies the simplest possible form of efficient mechanical generator of electricity. He may be wrong, but misdirection will only suggest new avenues to the goal.

Mr. Tesla has often been urged to assume domestic ties, settle down, and till some corner of the new domain. But shall he farm or explore? Soon enough the proprietary fences will be set up; soon enough will the dusty, beaten highway, dotted with milestones and finger-posts, run straight ahead. If we would, we cannot leash the pioneers whose yearnings are for inner Nature, whose sense is keenest to her faint voices and odors, the quest of which lures onward through the trackless woods.

Thomas Commerford Martin.

TESLA MOTORS OPERATED FROM SINGLE PHASE TWO-WIRE ALTERNATING CIRCUITS.

THE reader who has followed up the line of work in which Mr. Tesla has been recently engaged will, no doubt, be interested to hear of some results which form the subject of two patents recently granted to him. The New York *Electrical Review*

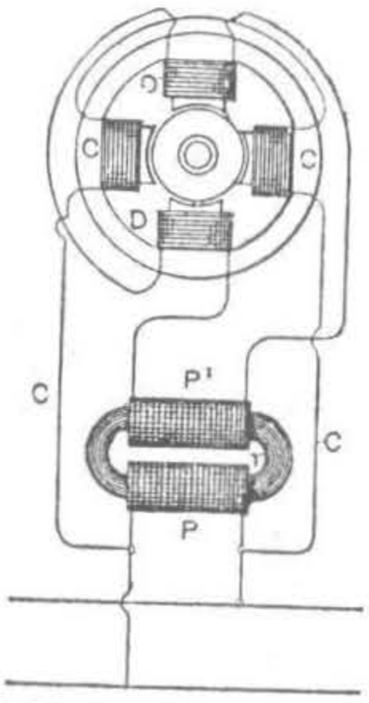


FIG. 1.—Tesla Motor with Two Energising Circuits.

says:—As early as 1888 a paper was read before the American Institute of Electrical Engineers, in which Mr. Tesla first publicly described his new multiphase system of operating alternating current motors. As an outgrowth of this, results have been obtained by others working in the same direction, and valuable and interesting have been the observations and practical devices obtained. In the system above mentioned, each motor is supplied with two or more energising circuits, through

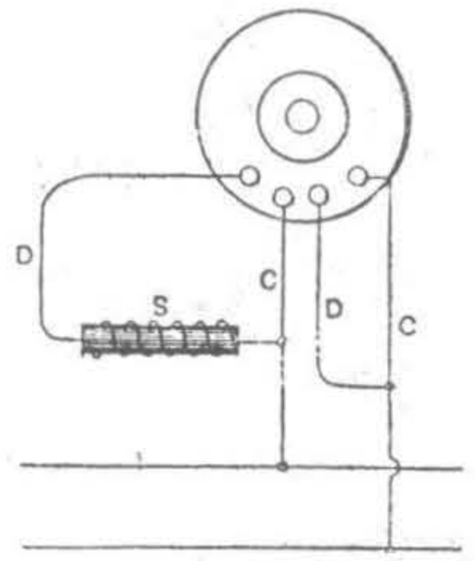

FIG. 2.—Tesla Motor with Self-Induction Coil.

which are passed alternating currents, having in each circuit such a difference of phase, that by their combined or resultant action they produce a rotary progression of the poles or points of maximum magnetic effect of the motor, and thereby maintain the rotation of the armature. Three wires are necessary in a system of this kind, but in order to avoid this Mr. Tesla set to work to devise a means whereby the phase motors could be operated from the ordinary single phase alternating circuit by creating a difference of phase locally at and in the motor. The patents below referred to had this object in view, and it will be noticed that

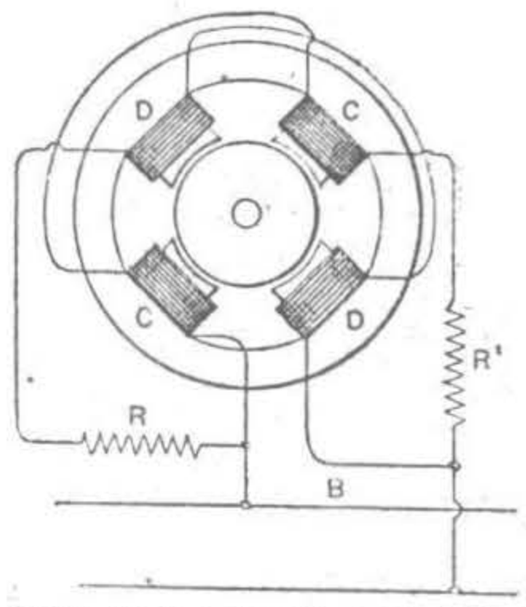

FIG. 3.—Tesla Motor with Two Dead Resistances.

the fundamental idea involved is to pass a single alternating current through both of the energising circuits of the motor, and to retard the phase of the current in one circuit to a greater or less extent than in the other, either by induction or by derivation, is the distribution of current between the two motor circuits.

The diagram, Fig. 1, shows a motor with two energising circuits, C and D. One of these circuits, C, is connected directly with the line circuit, while the other set of coils, D, is connected up in the secondary circuit of a transformer, T. The primary coil P of this transformer is connected to the line circuit. The alternations of current in the line tend

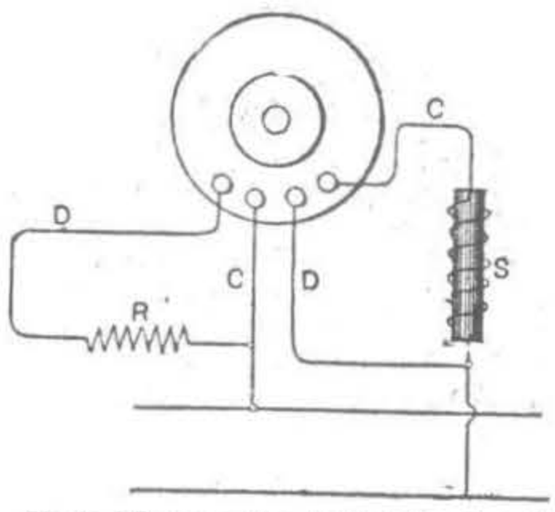

FIG. 4.—Tesla Motor with Self-Induction Coil and Dead Resistance.

to establish in their passage through the coils C a polarity opposed to that set up in the coils D, and if the currents in the two sets of coils accorded in their phases, no rotary effect would be produced. But the secondary current developed in the coil P^1 of the transformer will lag behind that in the primary, which lag may be increased to a sufficient extent to practically obtain the same result as

though two independent currents were used to energise the motor.

In another form, shown in Fig. 2, the arrangement of the parts is similar to that shown in Fig. 6, except that a self-induction coil S is introduced into one energising circuit of the motor. The effect of thus increasing the self-induction in one of the circuits is to retard the phases of the current passing therein to a greater extent than in the other circuit, and in this way to secure the necessary difference in phase between the energising currents to produce the rotation of the motor.

Shown diagrammatically in Fig. 3 is a type of motor in which two dead resistances, R R′, are included, respectively, in the energising coils of the motor. No rotary effect will be produced as long as the resistances are equal; but by varying the resistance in one circuit the retardation of the current in that circuit will be varied, and corresponding effects produced. For example, a reduction of the resistance in one circuit imparts to the motor rotation in one direction, while a reduction of the resistance in the other circuit will produce a rotation in the opposite direction. By means of the two resistances, therefore, capable of variation, or of

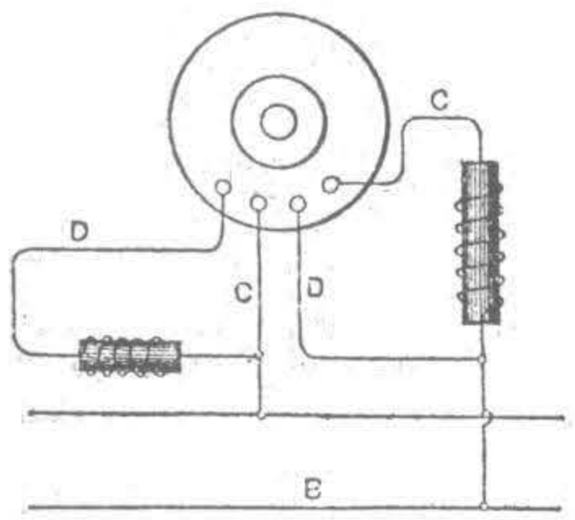

Fig. 5.—Tesla Motor with Two Self-Induction Coils.

being bodily withdrawn from, or inserted in, the circuits by simple means, rotation of the motor is secured.

In Fig. 4 a self-induction coil, S, is included in one of the motor circuits, and a dead resistance, R, in the other. The increased self-induction in one circuit thus produced acts to increase the difference of phase between the current in that motor circuit and the unretarded current in the line circuit. On the other hand, the introduction of the dead resistance in the other motor circuit reduces the retardation, and brings the phases of the current in it more closely in accord with those of the unretarded current, thus producing a correspondingly greater difference of phase between the two currents in the energising circuits C and D.

Two self-induction coils are shown in Fig. 5, one in each motor or energising circuit. One of these coils is much smaller than the other, and has less self-induction or counter electro-motive force than

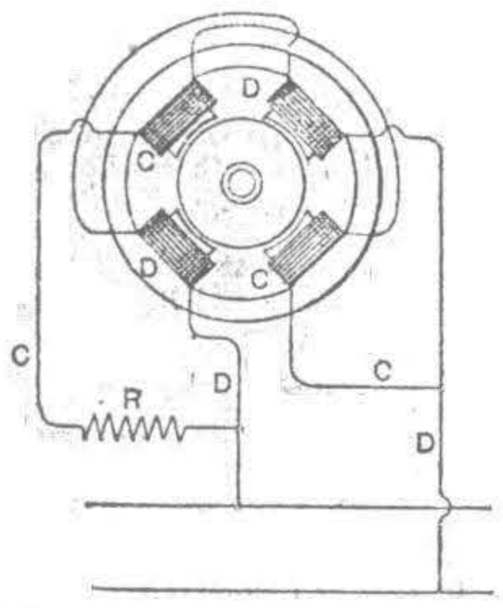

Fig. 6.—Tesla Motor with Energising Circuits in Multiple Arc.

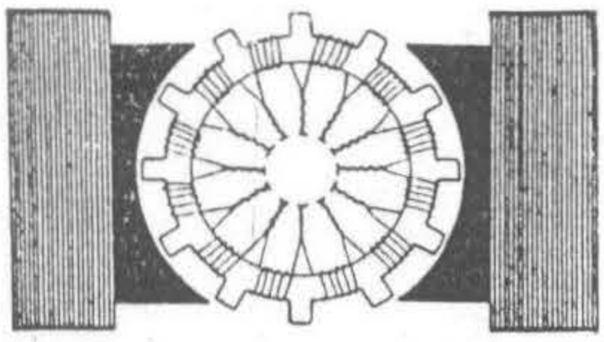
the other, so that the phases of current will be retarded to a less extent than in the other.

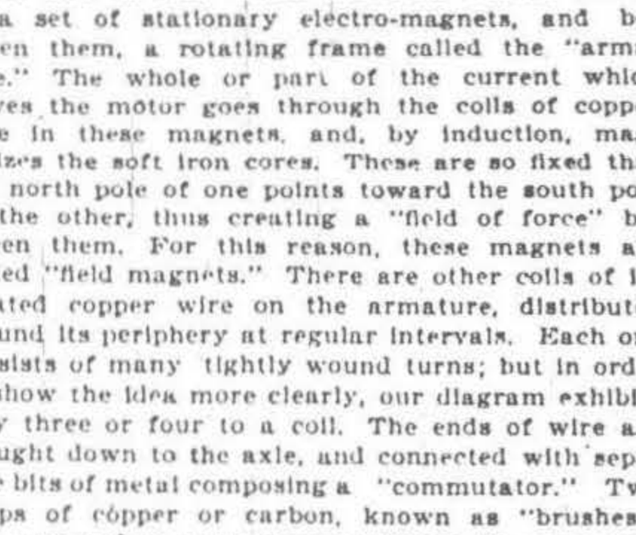
The two energising circuits of the motor are shown in Fig. 6, connected in multiple arc to the line circuit, and in one of these circuits is a resistance, R. Assuming the two motor circuits to have the same degree of self-induction, no rotary effect will be produced by the passage through them of an alternating current from the line. But if one of the motor circuits, as C, be varied or modified by the introduction of a dead resistance, R, the self-induction of that circuit or branch is reduced, and the phases of current therein retarded to a correspondingly less extent. The relative degrees of retardation of the phases of the current in the two motor circuits with respect to those of the unretarded current in the circuit B thus produced will set up a rotation of the motor. Another type may be mentioned in which one set of energising coils is of finer wire than the other, or has a greater number of convolutions; or each circuit may contain the same number of convolutions, but composed of different conductors, as, for instance, one of copper and the other of German-silver.



SCIENCE AND MECHANICS.

THE MULTIPHASE MOTOR.

ONE OF TESLA'S GREAT INVENTIONS.

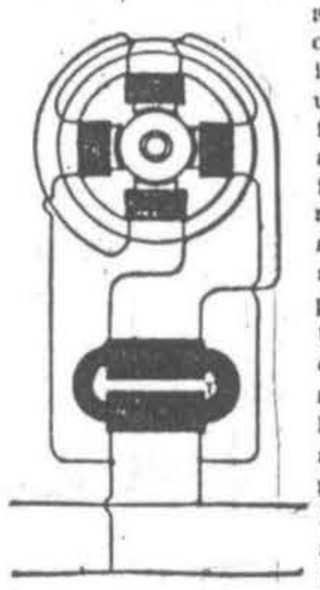


HIS RECENT IMPROVEMENT THEREIN—FEATURES OF THE HARNESS WHICH NIAGARA FALLS WILL WEAR.

In some of the accounts of that remarkable achievement in Germany nearly three years ago of transmitting 300 horse-power in the form of electricity from the waterfall at Lauffen to Frankfort, 108 miles away, we read that it was a notable illustration of the "three-phase" system. Similar expressions are used regarding a plant in Southern California, set in operation last September and furnishing the city of Redlands with electricity generated at Mill Creek Canyon, nine miles away. The equipment for like purposes at Sewall's Dam, near Concord, N. H., is of the same class. We also run across the term "two-phase." It has been announced, for instance, that the enormous dynamos soon to be set in operation by Niagara Falls are to be adapted to the distribution of power on the "two-phase" plan. "Polyphase" and "multiphase" are other words coming into increasing use by scientific periodicals in mentioning existing or proposed electrical installations. All this phraseology

relates to a new system of converting an alternating current into power, invented by our young and gifted fellow-countryman, Nikola Tesla. Ferraris, an Italian, hit upon the same idea at almost the same time, but he did not develop it in a practical way; and Shallenberger, Elihu Thomson and others in this country, as well as various foreigners, have utilized it in some form. The plan has not yet come into extensive use; but in the near future it is destined to attract wide attention.

The special features of the Tesla system will be better understood, perhaps, if the reader will first recall the general arrangement of the types of motor now in use. These machines consist chiefly of a set of stationary electro-magnets, and between them, a rotating frame called the "armature." The whole or part of the current which drives the motor goes through the coils of copper wire in these magnets, and, by induction, magnetizes the soft iron cores. These are so fixed that the north pole of one points toward the south pole of the other, thus creating a "field of force" between them. For this reason, these magnets are called "field magnets." There are other coils of insulated copper wire on the armature, distributed around its periphery at regular intervals. Each one consists of many tightly wound turns; but in order to show the idea more clearly, our diagram exhibits only three or four to a coil. The ends of wire are brought down to the axle, and connected with separate bits of metal composing a "commutator." Two strips of copper or carbon, known as "brushes," and mounted so as to press gently on the commutator as the armature revolves, are the terminals of the wires which conduct the electricity generated at a distance, first into one and then to another of the armature coils. That is, one brush leads it in and the other leads it out. It will be seen that so long as the motor is running the field magnets are constantly energized; but the armature coils are only momentarily and successively influenced. A magnet will attract a wire or coil of wire which bears an electric current if that current be flowing in one direction; but it will repel that wire or coil if the current goes in the other direction. Now, in a motor the current is so guided into the armature coils that the latter are, in succession, drawn toward the poles of the field magnets; but as soon as each coil approaches as nearly as possible the current in it is reversed by the commutator, and



then the coil is driven away. Both attraction and repulsion are so timed as to give motion to the revolving armature in the same direction. Meantime, the other magnet, on the other side of the machine, is co-operating in a similar manner. The armature, by the way, is a ring, not solid usually, but a lot of thin iron plates insulated from each other, often perforated to allow ventilation, and bound into one by the encircling coils.

The principle which Mr. Tesla uses in his polyphase motor is quite different. In its simplest form, his armature is a mere bar or plate of magnetic iron, like A in our second diagram, mounted on a spindle so as to rotate. His "field of force," instead of being stationary, is made to go around in a circle, dragging the armature along as it goes. The field magnets do not actually move, however, but act in such a manner as to keep the centre of attraction shifting, progressively. In a "two-phase" motor, for instance, the current from the dynamo is divided so as to come in and go out first by one route, which is designated as B in our diagram, and then by another, marked C. The magnets D and E are included in the first circuit, and are simultaneously energized; and then, while the wave-like impulse is subsiding another comes in by the second circuit and acts upon the other pair of magnets. Let us suppose that at starting the current first comes in by the route B, and makes the end of D facing the centre of our circle a "north" pole, and the corresponding end of E a "south" pole. We will also suppose that the armature has a slight magnetic predisposition of its own, which impels the end that is uppermost in our diagram to seek a north pole, wherever it can find one. At the outset, then, it will be drawn to D, while E will similarly attract the other end. If, now, the current is let into the circuit C, and makes a north pole at F, the armature will feel two attractions, and swing so as to be half way between those magnets. But the wave in D is dying out, and that in F is rising; so that the latter magnet is soon in supreme control, and the armature moves to a position at a right angle with its first one. Meantime, G has a "south" polarity, and attracts the other end of the armature. When the current next flows through the wires at B, its direction has been reversed, as it is an "alternating" current; so that D is a "south" pole, and E is a "north" pole. Hence E coaxes the arrow-marked end of the armature at first part of the way and then all of the way from F; and we have secured half a rotation. The other half is obtained by the same general method; and the armature is soon spinning at great speed. In a three-phase motor of this pattern there are six magnets instead of four; and there are three separate circuits instead of two.

Mr. Tesla found, after a little, that a circular disk would retain its polarity as well as a bar, and hence ceased to slice off the sides of his armature, as he did at first. He and his imitators have also tried many modifications of form for the field magnets, while retaining the principle of moving the field around in a circle. In its latest form the armature is a cylinder, not a disk. A few turns of heavy copper wire are distributed about it, wound from end to end, to intensify the magnetism of the iron inside.

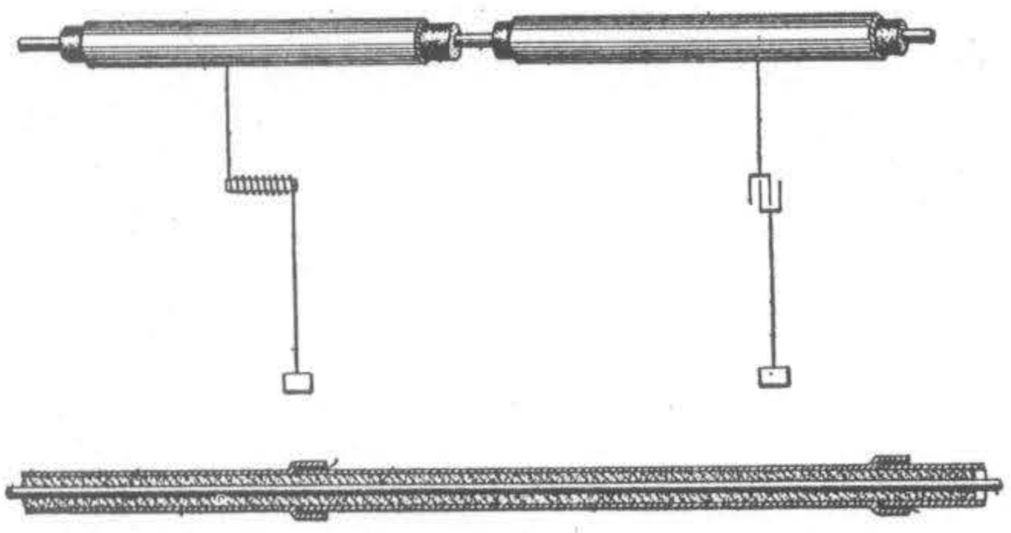
It was not long before this ingenious inventor discovered that three wires would do the work of four for a two-phase motor. It seemed necessary to have two separate ones for supply purposes, but not two for the return currents. The three-phase motor is also, at present, operated by three wires, two of which are made to carry the three sets of inflowing waves, since no two circuits are in full service at once. Mr. Tesla has even devised a way —several ways, in fact—by which the two (or three) currents may be separated, not at the dynamo which generates them, but close to the motor; so that the latter may, if desirable, be used on an ordinary two-wire circuit. It has been intimated, however, that the Niagara electrical output will be distributed by the four-wire system.

One of Mr. Tesla's means for effecting separation on the site of the motor is a transformer, or induction coil. This piece of apparatus consists of two coils of copper wire so insulated and combined that the primary current passing through one excites a

secondary current in the other. It should be borne in mind that the current used with polyphase motors is not a continuous but an alternating one; that is, it is made up of a series of minute oscillations in opposite directions. Thence the secondary, as well as the primary, alternates. But the impulses of the secondary lag an exceedingly small fraction of time behind those of the primary; and that lag can be magnified if desired. Thence, Mr. Tesla is able to energize one coil of his two-phase motor with the primary current and the other with the secondary. Our third diagram indicates the arrangement of the apparatus. He has devised several other schemes for dividing the current, at the place where it is used, instead of where it is generated.

Almost all the electric motors running to-day, on trolley cars, in workshops and mines and to operate elevators, are driven by a direct or continuous current, by a system similar to that described in the first part of this article. There are plenty of alternating current dynamos, which generate electricity for lighting and other purposes, but very few alternating current motors. Various difficulties have stood in the way of making one which would work as satisfactorily as those of the other type. There are several reasons, however, why it is desirable to have a good motor capable of being operated by an alternating current. A plant generating the latter for lighting purposes, for instance, could then supply electricity for power also. And in the application of this form of force to a vast variety of industries, in the near future, adaptability to all uses will be an important economic factor. Furthermore, the alternating current has advantages over the direct when it comes to production on a large scale and transmission to great distances.

One serious objection to the alternating motor, when run by a single current, has been that it was not self-starting. Other power was required to give the rotations of the armature a frequency equivalent to that of the waves of the energizing current before it would run alone. Possibly this may be overcome, some day, with a "singlephase" machine; but the multiphase motor is already a self-starter. The polyphase plan also gets rid of the commutator and brushes, which, in motors (as in dynamos), are liable to emit dangerous sparks. A disadvantage attaching to other motors, including those of the "direct" type, is that the armature coils become overheated, and "burn out," when more work than the machine is adapted to perform is imposed upon it. No such ruinous effect is experienced by the multiphase motor; if overloaded, it merely stops. For this reason and for others, it is said, less skilful workmen are needed to operate such motors.



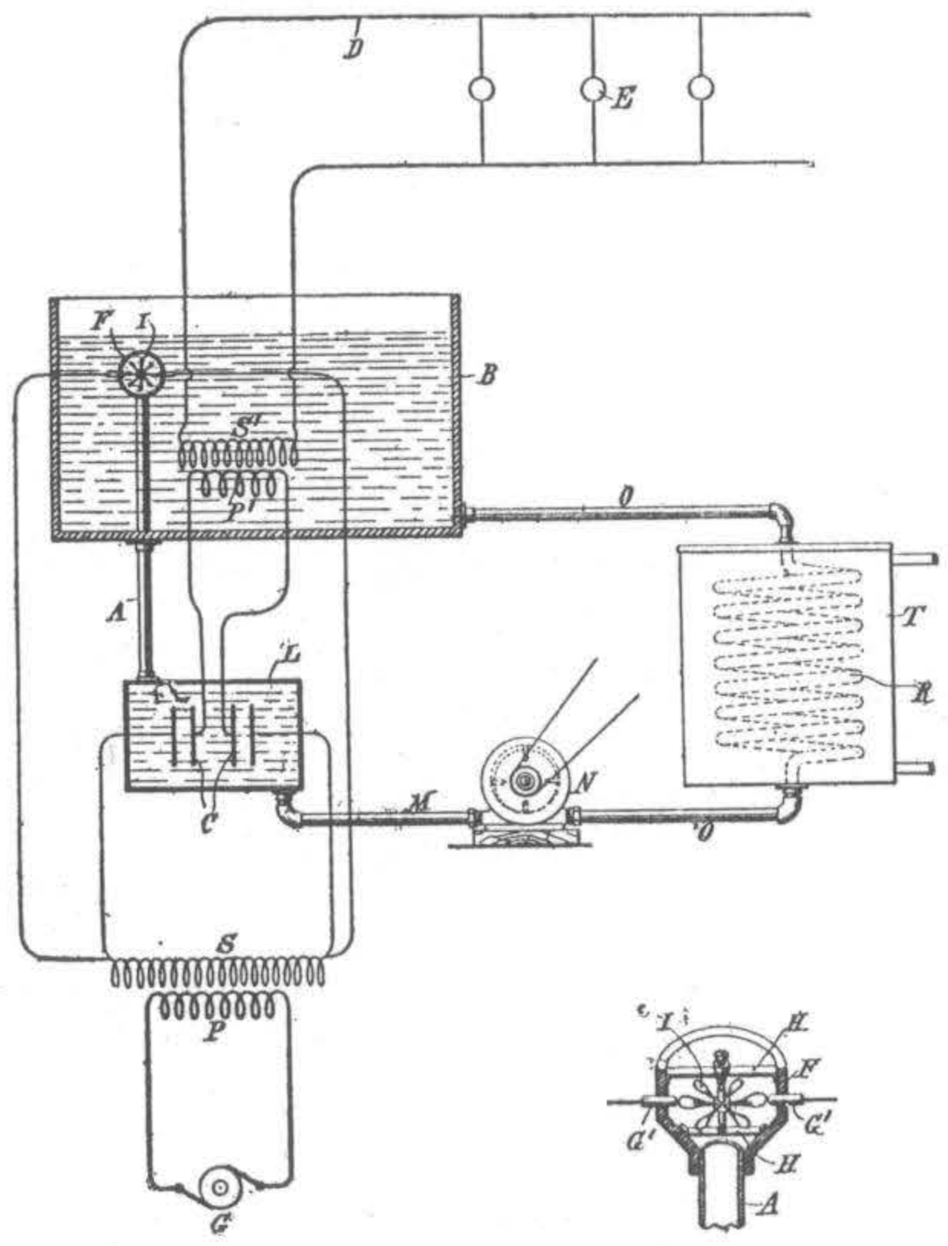
SCIENCE IN THE MAGAZINES.

The *Century* contains a biographical sketch of Mr. Nikola Tesla, by Mr. T. C. Martin, illustrated by an excellent portrait of that investigator. Mr. Tesla comes of an old Servian stock, and is but thirty-six years of age. His electrical work began in the Polytechnic School at Gratz, where he distinguished himself in experimentation. He afterwards became an assistant in the Government Telegraph Engineering Department at Buda-Pest, from which he passed into an electric-lighting establishment in Paris. A little later he crossed the Atlantic, and entered one of Mr. Edison's workshops. When his term of apprenticeship there had ended, he struck out for himself, his investigations eventually leading him to the brilliant phenomena produced with currents of high potential and high frequency. "Recently," says Mr. Martin, "the high-frequency generators with which he had done so much of this advanced work have been laid aside in discontent for an oscillator, which he thinks may not only replace the steam-engine with its ponderous fly-wheels and governors, but embodies the simplest possible form of efficient mechanical generator of electricity."

THE TESLA HIGH POTENTIAL CONDUCTOR.

In order to prevent loss by dissipation or interference by induction on line conductors carrying high potential alternating currents they have in some instances, such as at Deptford, London, been insulated and inclosed in a continuous conducting sheathing which is connected with the ground by a good conducting path.

While conducing to the safety of the system, Mr. Tesla has found that the use of a conducting sheath or screen around the line conductors and well grounded, or even brought into proximity to external conductors or large bodies is attended by an actual, and generally a serious, loss of energy which is the greater, the greater the number of alternations and the higher the potential. He therefore maintains the sheath either entirely isolated or connected directly or inductively to the ground, through a path which will practically prevent the passage of currents over it. He has also found that when a continuous isolated sheath or screen is employed, there is greater liability to loss of energy by inductive action; for, unless the sheath or screen be considerably shorter than the current waves passing in the conductor, electromotive forces will be set up between different points in the sheath, which will result in the passage between such points of induced currents. Mr. Tesla therefore, divides up the sheath or screen into short lengths, very much shorter than the wave lengths of the current used, so that the grounding of any one of such lengths or the approach thereto of a large body will result in an inappreciable loss, or at most a small local draining of the energy, while the tendency of currents to flow between different points in the sheath is effectually overcome. The function of the sheath as a static screen for preventing the dissipation of the electric energy, however, requires for its complete effectiveness an uninterrupted conducting partition or screen around the conductor. In the case of a sectional screen, this is obtained, by causing the ends of the insulated divisions or



FIGS. 1 AND 2.—THE TESLA HIGH POTENTIAL CONDUCTOR.

sections to overlap, and interposing insulating material between the overlapping portions.

For transmitting currents of very high potential and very high frequency, Mr. Tesla provides between the sheath and the ground a path of very high ohmic resistance, or one containing a self-induction coil properly determined with respect to the existing conditions so that it will effect the desired result, or a condenser of very small capacity, as shown in Fig. 1. In such cases the sheathing or screen for practical purposes may be regarded as isolated from the ground, since by the character of the connection employed no appreciable loss results from the passage of current from the sheath to the ground. Fig. 2 shows the construction of an actual conductor of embodying the idea.

TESLA'S AUTOMATIC FLUID INTERRUPTED FOR PRODUCING HIGH FREQUENCY CURRENTS.

The Tesla system of lighting and power transmission with high frequency and high potential currents, as is now well known, involves the maintenance of an intermittent or oscillatory discharge

TESLA'S AUTOMATIC FLUID INTERRUPTER.

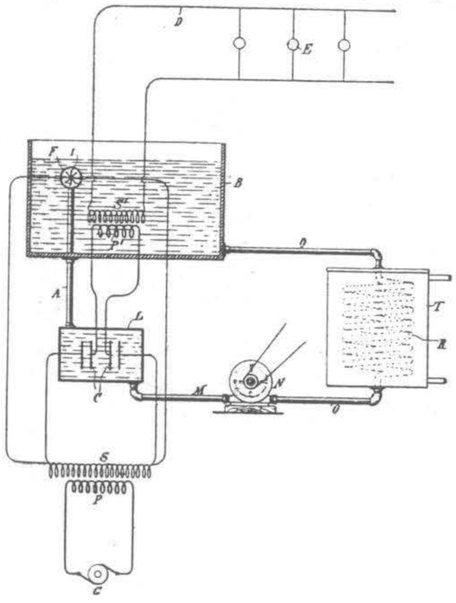
of a condenser or circuit of suitable capacity into a working circuit containing lamps or other devices. In systems of this character when the high frequency of the currents employed is due to the action of a disruptive or intermittent discharge across an air gap or break at some point of the circuit, Mr. Tesla has found it to be of advantage not only to destroy the least tendency to continuity of the arc, but to control the period of its re-establishment, and from investigations made with this object in view he has found that greatly improved results are secured by causing the discharge to take place in and through an insulating liquid, such as oil, and, instead of allowing the terminal points of the break to remain at a uniform distance from each other, to vary the distance by bringing them periodically in actual contact or sufficiently near to establish the discharge and then separating them, or what is the equivalent of this, throwing in and out of the gap or break a conducting bridge at predetermined intervals. To obtain the best results, moreover, Mr. Tesla finds it essential to maintain at the point of discharge a flow of the insulating medium, or, in general, such a circulation of the same as will constantly operate to cut off or break up the discharge as fast as it is established. The accomplishment of this latter result involves the employment of some mechanism for maintaining the flow or circulation of the insulating medium past the points of discharge, and he takes advantage of the presence of the same device to maintain the circulation of the insulating liquid in which the converter for raising the potential and the condenser plates are immersed; by this means the liquid is prevented from heating.

All this is accomplished by a pumping arrangement shown in Fig. 1, the spark gap being controlled by a small turbine which is shown enlarged in Fig. 2. When the pump is started up and the turbine I revolves, the blades bridge the space between the two terminals, nearly or quite touching the terminals in their movement. If now the tank B be filled with oil and the latter permitted to flow off through the tube A, the turbine will be rotated by the flow, the rate of rotation being dependent upon the rate of flow. By this means the arc or discharge is periodically established through a flow of oil, which secures in the most satisfactory manner the conditions best adapted for practical results. The flow of oil is regulated by the speed at which the pump N is driven, and by this means the period of re-establishment of the arc is controlled. A cooling tank T may be provided if necessary.

Recent Inventions of Nikola Tesla.

In conducting his experiments with alternating currents of high frequency and high potential Mr. Tesla has found it necessary to devise new forms of apparatus to produce and control the current with which he has achieved such interesting results. Three of the latest improvements of this description, all patented, are illustrated by the accompanying cuts.

In Fig. 1 is shown a new device for producing the



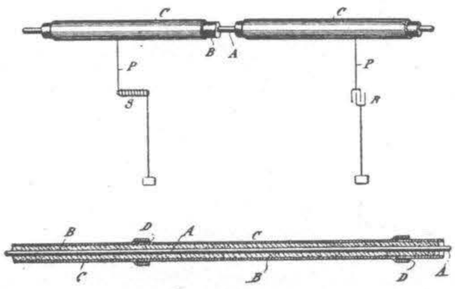


FIG. 1. RECENT INVENTIONS OF NIKOLA TESLA.

intermittent discharge across a break in the circuit, designed to replace the air gap in the production of alternating currents of high frequency. The advantages of this method lie in the fact that the disruptive discharge takes place in oil insulation and that the rate of discharge is under absolute control, obviating any tendency to a continuity of the arc or discharge. The inventor also takes advantage of the presence of the oil to secure a more effective insulation for the converter coils and condenser plates which are necessary in apparatus of this character. By reference to the diagram the method of operation will be readily understood. *G* is an ordinary alternator, connected to the primary winding *P* of a transformer, of which *S* is the secondary. To the latter are connected the plates of a condenser *C*, and at *F* is a break in the circuit at which occurs the disruptive discharge. In the secondary circuit, in series with the condenser, is a primary coil *P'* with which is associated a secondary *S'*, the latter constituting the ultimate source of current for the working circuit *D*, with which are connected translating devices *E*. By the disruptive discharge between the terminals at *I* the condenser is charged and discharged, producing a current of enormous frequency. The unique feature of the apparatus is the means by which the disruptive discharge is accomplished by interposing a series of rotating conductors *I* between the terminals. *A* is a pipe that leads into a tank *B*. To the end of this tube is secured an extension *F* of insulating material and the two terminals are caused to project through it. Within the extension are two cross-bars which afford bearings for the spindle of a small metallic turbine *I*, the blades of which, as the turbine revolves, bridge the space between the two terminals, nearly or quite touching the terminals in their movement. If the tank *B* be filled with oil and the latter is drawn off or permitted to flow off through the tube *A*, the turbine will be rotated by the flow, the rate of rotation being dependent upon the rate of flow. By this means the arc or discharge is periodically established through a flow of oil, which secures the object sought to be attained. A glance at the cut will show the manner of insulating in oil the second transformer *P' S'* in the tank *B* and the condenser in a receptacle *L*. A small rotary pump *N* causes the oil to circulate, and, of course, the rate of the disruptive discharge is regulated by the speed of this pump. The jacket *T* and coil *R* provide a means for cooling the oil if necessary.

A simple plan to prevent the dissipation of current on electrical conductors carrying excessively high potentials is shown in Figs. 2 and 3. Mr. Tesla has found that the use of grounded conducting sheaths is usually attended by a serious loss of energy. He therefore maintains the sheath either entirely isolated or connected directly or inductively to the ground through a path which will practically prevent the passage of current over it. He divides the screen into short lengths, much shorter than the wave lengths of the current used, so that the grounding of any one of such lengths or the approach thereto of a large body will result in an inappreciable loss, or at most a small local draining of the energy, while the tendency of currents to flow between different points in the sheath is effectually overcome. The function of the sheath as a static screen for preventing the dissipation of the electric energy, however, requires for its complete effectiveness an uninterrupted conducting partition or screen around the conductor. This requirement is met by causing the ends of the insulated sections to overlap, interposing a suitable insulating material between the overlapping portions. In the cuts *A* is the conductor, *B* the insulation, *C* the sheathing divided into overlapping sections insulated from one another by the material *D*. The ground connections are illustrated in Fig. 2. Mr. Tesla obtains the beneficial results of an earth connection, while preventing the generally serious loss that would occur in the use of such currents, by providing between the sheath and the ground a path *P* of very high ohmic resistance or one containing a self-induction coil *S* properly determined with respect to the existing conditions, so that it will effect the described result, or a condenser of very small capacity as shown at *R*. In such cases the sheathing or screen for practical purposes may be regarded as isolated from the ground, since by the character of the connection employed no appreciable loss results from the passage of current from the sheath to the ground.

An improved incandescent lamp for use on circuits carrying alternating currents of high potential and frequency is the third invention, the object of which is to prevent dissipation from the conductors in the lamp. This is accomplished by surrounding the leading-in and supporting conductors with a conductor which acts as a static screen. By this means the light-giving body or button which lies beyond the influence of the screen is quickly and efficiently brought to and maintained at higher incandescence, by reason of the fact that the electrical action to which the incandescence is due is confined mainly to the button. *A* is a glass globe of the usual form, in the base of which is sealed a very thin conducting wire *B*, passing up through a stem of glass or other refractory insulator *C*. To the upper or inner end of this

FIGS 2 AND 3. RECENT INVENTIONS OF NIKOLA TESLA.

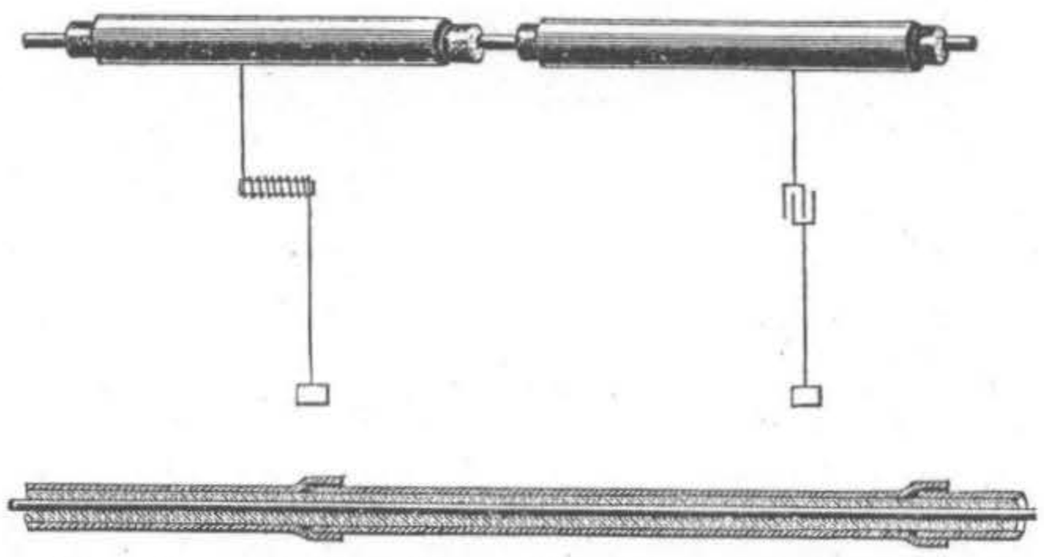
wire is united, as by means of a mass of carbon paste *D*, a carbon or other refractory stem *E*, that supports or carries a small button of carbon or other suitable substance *F*. Over the stem *C* is passed a metallic tube *G*. Mr. Tesla recommends for this purpose a very thin cylinder or tube of aluminum, and it should entirely surround all parts of the conductor within the globe except the button itself, extending to or nearly up to the point of union of the stem *E* with the button *F*. Such a device, by reason of its electrostatic action, reduces the loss of energy supplied to the bulb, preventing its radiation or dissipation into space except through the exposed or unprotected button. The tube or screen *G* is entirely insulated from the conductors within the globe and from all external conductors or bodies.

A NEW EDISON ON THE HORIZON.

IN the February *Century* Mr. T. C. Martin tells of the young Servian, Nikola Tesla, who has come to the New World to make what amounts to a revolution in many world-important departments of electrical invention. Mr. Tesla is only thirty-six years old, and, like Edison, has achieved his triumphs in the face of extreme poverty and other adverse influences. One of the most important of his inventions has had to do with the polyphase currents, on the principle of which large powers are "transmitted electrically more than a hundred miles from Neckar-on-the-Rhine to Frankfort-on-the-Main; and now, by equivalent agency, Niagara is to drive the wheels of Buffalo and beyond."

Mr. Martin tells of other marvelous discoveries of the young Servian:

"Broadly stated, Mr. Tesla has advanced the opinion, and sustained it by brilliant experiments of startling beauty and grandeur, that light and heat are produced by electrostatic forces acting between charged molecules or atoms. Perfecting a generator that would give him currents of several thousand alternations per second, and inventing his disruptive discharge coil, he has created electrostatic conditions that have already modified not a few of the accepted notions about electricity. It has been supposed that ordinary currents of one or two thousand volts' potential would surely kill, but Mr. Tesla has been seen receiving through his hands currents at a potential of more than 200,000 volts, vibrating a million times per second, and manifesting themselves in dazzling streams of light. This is not a mere *tour de force*, but illustrates the principle that while currents of lower frequency destroy life, these are harmless. After such a striking test, which by the way, no one has displayed a hurried inclination to repeat, Mr. Tesla's body and clothing have continued for some time to emit fine glimmers or halos of splintered light. In fact, an actual flame is produced by the agitation of electrostatically charged molecules, and the curious spectacle can be seen of puissant, white, ethereal flames that do not consume anything, bursting from the ends of an induction coil as though it were the bush on holy ground. With such vibrations as can be maintained by a potential of 3,000,000 volts, Mr. Tesla expects some day to envelop himself in a complete sheet of lambent fire that will leave him quite uninjured. Such currents as he now uses would, he says, keep a naked man warm at the North Pole, and their use in therapeutics is but one of the practical possibilities that has been taken up.



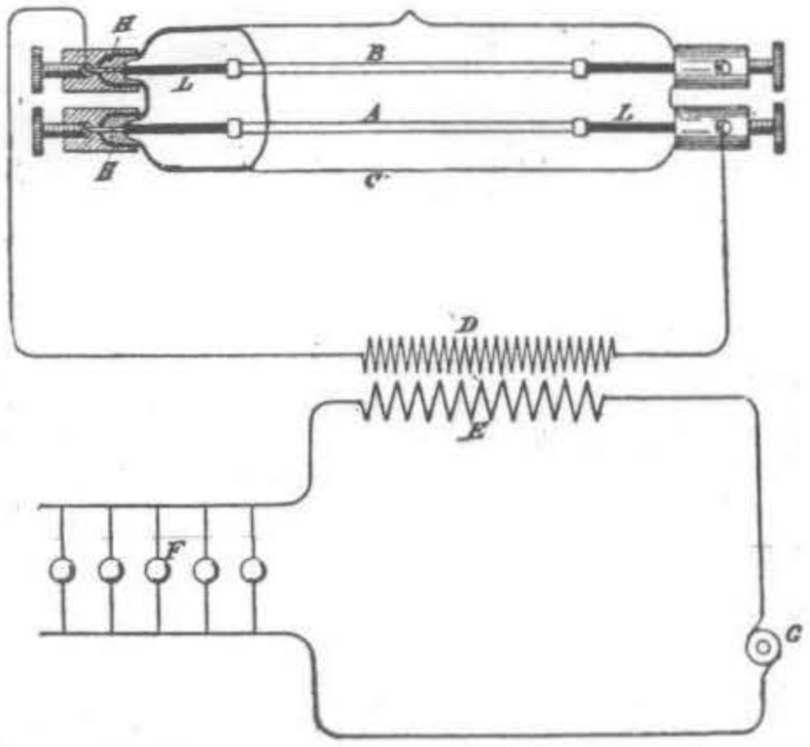
'Utilizing similar currents and mechanism, Mr. Tesla has demonstrated the fact that electric lamps and motors can not only be made to operate on one wire, instead of using a second wire on the ground to complete the circuit, but that we can operate them even by omitting the circuit. Our subway boards are to find their wires and occupations gone. Electric vibrations set up at any point of the earth may by resonance at any other spot serve for the transmission of either intelligence or power. With these impulses or wave discharges, Mr. Tesla also opens up an entirely new field of electric lighting. His lamps have no filaments as ordinarily known, but contain a straight fiber, a refractory button, or nothing but a gas. Tubes or bulbs of this kind, in which the imprisoned ether or air beats the crystal walls, when carried into the area or room through which these unsuspected currents are silently vibrating, burst into sudden light. If coated inwardly with phosphorescent substances, they glow in all the splendors of the sunset and the aurora."

The Tesla High-Potential Conductor.—In order to prevent loss by dissipation or interference by induction on line conductors carrying high-potential alternating currents, they have in some instances, such as at Deptford, London, been insulated and enclosed in a continuous conducting sheathing, which is connected with the ground by a good conducting path. The *Electrical Engineer* of New York states that, while conducing to the safety of the system, Mr. Tesla has found that the use of a conducting sheath or screen around the line conductors and well grounded, or even brought into proximity to external conductors or large bodies, is attended by an actual, and generally a serious, loss of energy, which is the greater the greater the number of alternations and the higher the potential. He therefore maintains the sheath entirely isolated or connected directly or inductively to the ground, through a path which will practically prevent the passage of currents over it. He has also found that when a continuous isolated sheath or screen is employed, there is greater liability to loss of energy by inductive action; for unless the sheath or screen be considerably shorter than the current waves passing in the conductor, E.M.F.'s will be set up between different points in the sheath, which will result in the passage between such points of induced currents. Mr. Tesla therefore divides up the sheath or screen into short lengths very much shorter than the wave lengths of the current used, so that the grounding of any one of such lengths or the approach thereto of a large body will result in an inappreciable loss, or at most a small local draining of the energy, while the tendency of currents to flow between different points in the sheath is effectually overcome. The function of the sheath as a static screen for preventing the dissipation of the electric energy, however, requires for its complete effectiveness an uninterrupted conducting partition or screen around the conductor. In the case of a sectional screen this is obtained by causing the ends of the insulated divisions or sections to overlap, and interposing insulating material between the overlapping portions. For transmitting currents of very high potential and very high frequency, Mr. Tesla provides between the sheath and the ground a path of very high ohmic resistance, or one containing a self-induction coil properly determined with respect to the existing conditions so that it will effect the desired result, or a condenser of very small capacity. In such cases the sheathing or screen for practical purposes may be regarded as isolated from the ground, since by the character of the connection employed no appreciable loss results from the passage of current from the sheath to the ground.

THE TESLA HIGH POTENTIAL CONDUCTOR.*

In order to prevent loss by dissipation or interference by induction on line conductors carrying high potential alternating currents they have in some instances, such as at Deptford, London, been insulated and inclosed in a continuous conducting sheathing which is connected with the ground by a good conducting path.

While conducing to the safety of the system, Mr. Tesla has found that the use of a conducting sheath or screen around the line conductors and well grounded, or even brought into proximity to external conductors or large bodies is attended by an actual, and generally a serious, loss of energy which is the greater, the greater the number of alternations and the higher the potential. He therefore maintains the sheath either entirely isolated or connected directly or inductively to the ground, through a path which will practically prevent the passage of currents over it. He has also found that when a continuous isolated sheath or screen is employed, there is greater liability to loss of energy by inductive action; for, unless the sheath or screen be considerably shorter than the current waves passing in the conductor, electromotive forces will be set up between different points in the sheath, which will result in the passage between such points of induced currents. Mr. Tesla, therefore, divides up the sheath or screen into short lengths, very much shorter than the wave lengths of the current used, so that the grounding of any one of such lengths or the approach thereto of a large body will result in an inappreciable loss, or at most a small local draining of the energy, while the tendency of currents to flow between different points in the sheath is effectually overcome. The function of the sheath as a static screen for preventing the dissipation of the electric energy, however, requires for its complete effectiveness an uninterrupted conducting partition or screen around the conductor. In the case of a sectional screen, this is obtained, by causing the ends of the insulated divisions or sections to overlap, and interposing insulating material between the overlapping portions.



Figs. 1 and 2.—The Tesla High Potential Conductor.

For transmitting currents of very high potential and very high frequency, Mr. Tesla provides between the sheath and the ground a path of very high ohmic resistance, or one containing a self-induction coil properly determined with respect to the existing conditions so that it will effect the desired result, or a condenser of very small capacity, as shown in fig 1. In such cases the sheathing or screen for practical purposes may be regarded as isolated from the ground, since by the character of the connection employed no appreciable loss results from the passage of current from the sheath to the ground. Fig. 2 shows the construction of an actual conductor of embodying the idea.

NOTES.

The Tesla Polyphase Patents.—An action has been brought by the Westinghouse Electric and Manufacturing Company against the General Electric Company for alleged infringement of the Tesla polyphase patents.

TESLA'S ALTERNATING CURRENT METER.

Tesla's Alternating Current Meter.

A novel meter for alternating currents, designed by Nikola Tesla, is illustrated in the accompanying diagram. The invention is based upon the fact that when a high tension discharge is made to pass from a conductor through rarefied gas, minute particles are thrown off from the conductor, the amount of detachment depending upon the strength of the current. In a suitable tube of glass are sealed platinum leading wires H coated inside the tube with insulating material. Sticks of carbon A, B are connected to these platinum terminals and the tube exhausted and sealed. The two carbon sticks A, B are electrically connected with the secondary of an induction coil, the primary of which is in series with the alternating circuit in which the current consumption is to be measured. For example, F represents a group of incandescent lamps, and E the primary of the induction coil. The difference of potential at the terminals of the secondary is proportionate to the primary current, and, therefore, to the current used by the lamps. The discharge from one conductor, A, to the other, as B, produces a detachment of infinitesimal particles along the entire length of the sticks, and after a period of service the latter increases in resistance. The amount of detachment is said to be proportional to the difference of potential between the two conductors. Hence, the increase of their resistance is in a definite proportion to the number of lamp hours. By measurements taken at the start and finish of any period of service the amount of energy used during such period of service may be computed. The action may be confined to confronting faces of the carbon sticks by coating the other faces with insulating material.

NIKOLA TESLA.

In another column we print a review and estimate of the work of Nikola Tesla from the pen of Lieut. Patten, whose own work, to some extent along similar lines, well qualifies him for the undertaking. While much has been written of Tesla and his achievements, it has been almost invariably from a popular standpoint, and, as far as we know, this is the first attempt to give a critical estimate. The great beauty of the Tesla experiments, the novelty of the subjects dealt with, the charming literary style and picturesque personality of the gifted inventor himself—all those have distracted attention from the technical and commercial features which, under ordinary circumstances, are the grounds upon which judgment is based. Perhaps another reason is that only recently has the opportunity been afforded, through an exhaustive compilation of Tesla's writings, patents and of other material, to take a comprehensive view instead of only the partial one hitherto possible. One is naturally disappointed that nothing practical has as yet proceeded from the magnificent experimental investigations with which Tesla has dazzled the world, and, what is still more disappointing, that they hold out no definite hope of the realization of the great promise they were supposed to contain. On the other hand, it should be borne in mind that Tesla is not working as a commercial experimenter with only a view to the speedy coining of his results into dollars and cents. His attitude is more that of Faraday, who felt that the world would obtain most benefit from his genius if devoted to pure physical research, knowing that his discoveries would eventually have a

practical fruition. The whole hope of modern science may be said to lie in molecular physics, and it is through work like that of Hertz and Tesla that we will, if ever, penetrate its mysteries. While therefore the popular conception of Tesla as one working like Edison to achieve only practical results is wrong, the popular estimation in which he is held has nevertheless a real justification in his valuable labors, though these may not lead directly to the marvels expected.

Nikola Tesla and His Work.

BY LIEUT. F. JARVIS PATTEN.

Mr. Nikola Tesla has been prominent in the electrical field for more than ten years, and the creations that have sprung from his brain have made his name familiar to the general public. His work, however, has been of such an advanced order of electrical application that comparatively few have a clear idea as to just what he has accomplished.

Within the past three months a book has been published which tells the story and which is indeed a rather exceptional contribution to the electrical literature of the day, presenting, as it does, an elaborate description of all that Mr. Tesla has thus far given to the public in his patents and lectures.* It includes not only descriptions of his numerous inventions, but his personal writings upon the lines of thought and experiment he has advanced, and so affords the opportunity for a brief review of what he has done.

From both a literary and typographical standpoint the book is an excellent addition to the electrical library. It is tastily gotten up, and evinces care and literary skill in the editing; the illustrations, which are profuse, are good, and this is equally true of the frontispiece portrait of Mr. Tesla, which to many will largely enhance the value of the book.

With the exception of a short biographical sketch, Part I., comprising twenty-four chapters, is devoted to a rather exhaustive treatment of the many forms of rotary field motors that Mr. Tesla has from time to time invented. One of these chapters, which will meet the requirement of the average reader, is an abridgment of Mr. Tesla's well remembered lecture before the American Institute of Electrical Engineers in May, 1888, in which he gave for the first time the rotary field motor invention to the public. Most of the remaining chapters of part I. are detailed descriptions of different modifications of the general multiphased motor system, such as would likely occur to an active inventor anxious to bar with a profusion of patents every access to a broad system naturally open to many variations. In fact, many of these chapters are little else than mere transcripts from patent specifications.

Part II. is devoted to high frequency phenomena, a field of investigation that seems to be peculiarly Mr. Tesla's own. It opens with an interesting chapter that seems to be from the editor's pen, in which he gives his own resume and estimate of the matter set forth in Mr. Tesla's three lectures upon high frequency effects, lectures given in succession before the American Institute of Electrical Engineers, the Royal Institution in London, and the Franklin Institute in Philadelphia. These three lectures, reproduced verbatim and making as many long chapters, constitute, in fact, the main part of the work.

Part III., comprising seven short chapters, describes quite a variety of inventions of relatively minor importance, so far as Mr. Tesla's work is generally known, and which would probably never have seen publication beyond the patent specifications, from which they are evidently drawn, had not the exhaustive design of this book rendered their inclusion excusable. The inventions here mentioned include an arc lighting system of earlier days, some suggestions of how a unipolar machine might be built, a pyromagnetic generator, a thermomagnetic motor, an anti-sparking dynamo brush, and a method of regulation for constant current. These chapters are interesting mainly as showing how much a professed inventor must do that is not in the line of great achievement.

A short but interesting chapter describing Mr. Tesla's personal exhibit of apparatus at the World's Fair, and a brief reference to his latest surprise, the "electro-magnetic

*"Inventions, Researches and Writings of Nikola Tesla." Edited by Thomas Commerford Martin. New York. 1894. Price, $4.00.

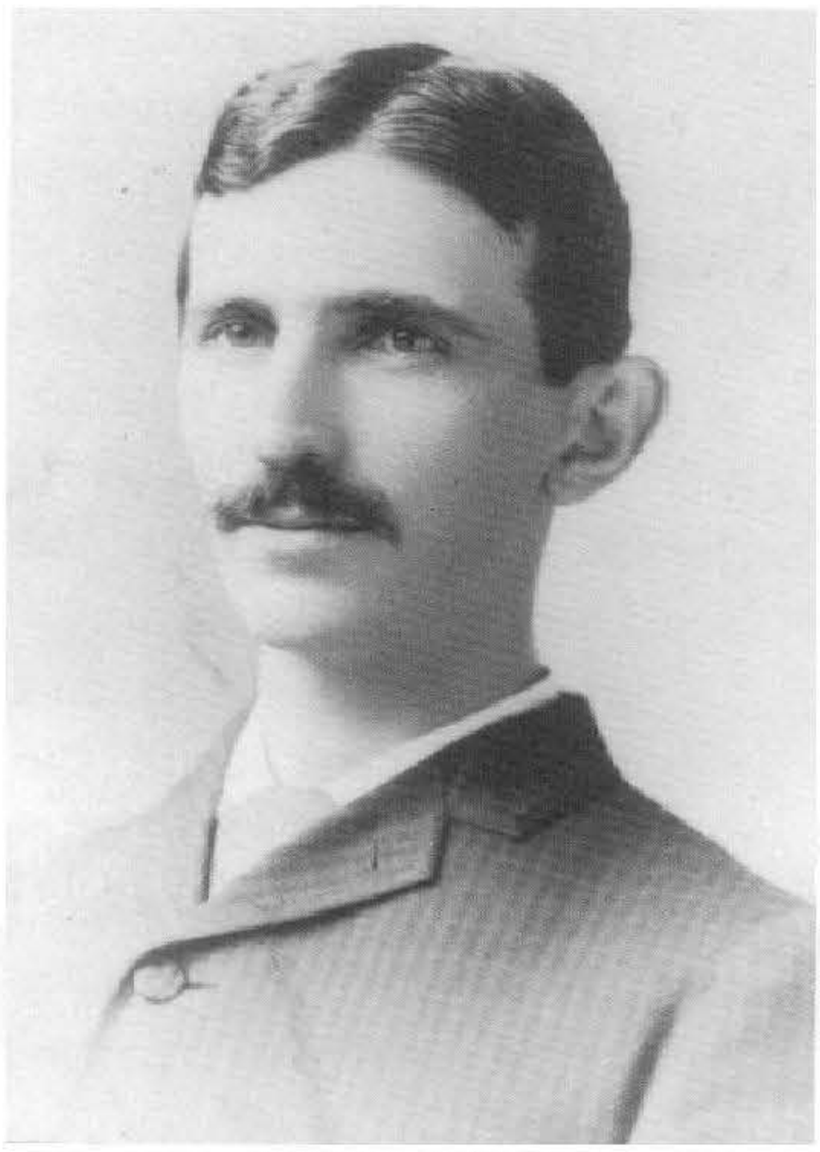
oscillator" for producing high frequency currents by mechanical means, ends the volume.

With the exception of a few chapters by the editor, the volume is a collection of Mr. Tesla's writings, and those who have followed his work closely will find in it little that is new. Much of the subject matter in Part I., devoted to polyphased currents, is taken in a sweeping manner from patent specifications, and as such will be new to some who little know, without such a review, how thoroughly Mr. Tesla looked after the possible variations of his broad invention. The various motors described are shown in their most elementary forms by mere diagrams of the operative circuits.

While these numerous variations of the same general idea are instructive as showing the growth of the invention in the inventor's mind, and the gradual development of the mere abstract idea to different practical forms, still, in all these descriptions there is little to be found that has any practical bearing or importance to-day. The engineer will find in these chapters little that he cares to remember for practical use or application, the advocate of controversy as to priority of invention will find ample data for reference, and the student of electrical science will find in them evidence of how little the most thoughtful inventor can foresee the features of his invention that will lead to most controversy and discussion, for nowhere in these earlier writings is any importance attached to the frequency of the alternating current used. Throughout the twenty-four chapters of Part I. the charming delusion prevails by inference that all these machines are as good at one frequency as at another. One might also draw the erroneous conclusion that polyphased currents were first discovered and used by Mr. Tesla; on the other hand, no one can doubt that the biphased and triphased rotary field machines were simultaneously worked out by him as early as 1887. He did not leave the triphased machine for a follower to invent.

Following the general treatment of multiphased machines come descriptions of various devices and makeshifts (no word seems more appropriate) for working these machines by a single alternating current. The rotary field motor operated by multiphased currents, as its every feature indicates it should be, is a unique and characteristic thing and should have been left to the field of operation that its inherent simplicity must sooner or later create for it. Its birth, however, was contemporaneous with that of single alternating current working, so the genius that first showed the rotary field machine in practice must pervert his invention to meet the requirements of a system to which it was entirely unsuited. The description of these many attempts adds but little to the value of the book.

In chapter XIV. is given a description of a single alternating current motor that does not depend upon the production of two currents from one, and another chapter shows a similar motor with a condenser in circuit, which points to Mr. Tesla as one of the earliest users of this device.



One cannot resist the conclusion, however, that this part of the work is a little padded with the only ostensible purpose of showing what a lot of inventions Mr. Tesla has made, and the reader is tempted to wish he had not invented so much.

In Part II., devoted to high frequency effects, we have to consider an entirely different order of work, which may be properly classed as pure science, for there is scarcely a practical effect described in the many pages given to the three lectures.

In this work the purpose in view has apparently been to establish by experimental process the identical character of light and some form of electrical manifestation of energy. In attempting this proof, Mr. Tesla has doubtless given new evidence in favor of the electro-magnetic theory of light, which theory, of course, preceded his work.

In his endeavor to obtain a very high frequency, Mr. Tesla doubtless started with the notion of setting matter into vibration at a rate approximating that of light, with the expectation that under such violent molecular agitation it would emit light. It is left to be inferred that so high a frequency is scarcely possible of attainment, while a much lower one under favorable conditions produces the desired effects. The investigation of these conditions constitutes a large part of the three lectures, which are sometimes tedious with exhaustive detail; though doubtless essential to a thorough investigation of the problem and invaluable as a guide to further work, these minutiae are not always interesting reading. This fact seems to be appreciated occasionally, and when it is we find a digression in the form of some purely speculative possibility—generally a suggested practical application of the effect under consideration. These are often so purely speculative in character as to be actually amusing.

Seriously speaking, the scientific world to-day believes in

NIKOLA TESLA.

the electro-magnetic theory of light which grows out of fundamental views enunciated by Faraday and elaborated in later years chiefly by Maxwell and Hertz. Mr. Tesla has not touched the mathematical side of this question, and so has added nothing to Maxwell's proof. Hertz established by experimental or physical demonstration the truth of Maxwell's deductions. So, if Mr. Tesla has added something to our scientific knowledge of this subject, it will consist in what he has added to the work of Hertz.

Broadly speaking, however, the Tesla experiments are the same in general results as those performed by Hertz, but are undertaken in a different and entirely original manner and are shown in far greater profusion and variety of effect. Indeed, Tesla's investigation of the electrostatic field, so far as variety of effect is concerned, would seem to leave but little to be desired. Tesla's labor in this direction was simply a long and painstaking investigation, the apparent purpose of which was really to determine what practical use, if any, can electrical science derive from the so-called Hertzian oscillations. If this question must be definitely answered by the Tesla experiments, we are compelled to say that no practical use for such phenomena has yet been shown.

The vacuum tube and light effects produced by rapid al-

ternations of an electro-magnetic or electrostatic field, and the transmission of energy along a single wire without a return lead, are beautiful, and mostly novel exhibitions of what can be done with electric energy under properly arranged conditions, but they are not of practical value in any use that has yet been made of them. They are simply advanced laboratory experiments of great scientific beauty and interest.

The introductory part of one lecture is given to a description of the apparatus used for producing the high frequency effects, and the precautions that must be taken in the arrangement of the parts are carefully pointed out with a view to help the experimenter who desires to follow this line of investigation.

Another is opened with a description of the best form of generator to be used, preference being given to a form of motor dynamo for transforming direct current into an alternating current of low voltage by a simple dynamo conversion. This low voltage alternating current is then changed to high tension by an ordinary converter, and this current, on being passed through the oscillatory transformer, has its frequency raised to something like a million a second.

Introducing another lecture, Mr. Tesla goes into a long digression upon the human eye that deals in nothing but generalities, having little or no bearing upon the subject.

The effects described in these three papers may be classed, for sake of arrangement, as phenomena produced by electrostatic force, dynamic electricity phenomena, and vacuum tube effects. We will consider some of these briefly.

Mr. Tesla claims that all electric and magnetic effects can be traced to the action of electrostatic molecular forces. In fact, he goes much further in one of his speculative digressions and refers everything among Nature's fanciful designs to the action of electrostatic force. His first claim finds some confirmation in a beautiful experiment he describes, in which he produces a veritable flame by the action of electrostatically charged molecules. A flame is thus produced by which, however, no material is consumed. He thinks this experiment gives us a further insight into the nature of an ordinary flame, which he attributes to the electrostatic effects produced by the chemical changes going on.

The experiments in which vacuum tubes are shown glowing brightly by simply being placed in a rapidly alternating electrostatic field are beautiful, but the practical application suggested—of lighting an apartment by simply creating an electrostatic field in the space between the walls and using detached vacuum tubes for lamps that will always be aglow when between the walls—is far from realization, and the reading public should not be left with the impression that anything of the sort has ever been accomplished.

Another very interesting experiment consists in the operation of lamps and motor devices by the discharge from condensers, and he points out methods of transforming or changing the voltage of direct as well as alternating currents by means of condensers, and expresses the hope in this connection of perfecting apparatus by which electricity of high tension may be obtained directly from heat energy itself. No suggestion is, however, given as to what the method is or how the transformation is to be effected. This hazy suggestiveness of great practical ends just in view but never reached becomes at times somewhat unsatisfactory.

Among the most beautiful of this array of experiments is one that illustrates the impedance of a rod or bar of practically no resistance when connected in a circuit to which a very high electromotive force and frequency is applied. Owing to the impedance the current may be shunted around it through a circuit of comparatively high resistance supplied with incandescent lamps that glow brilliantly when their terminals are connected to the bar at points only a few inches apart. It is further shown in this experiment that there are points or nodes on the bar, from which no current can be taken in the manner described, while others differently situated give a high difference of potential, and so marked is this distribution that the points can be readily selected by an ordinary voltmeter or by the lamp circuit itself.

The most surprising of the new facts elicited from these investigations is that the shock due to these very high potential and high frequency discharges can be supported by the person without serious inconvenience. This Mr. Tesla attributes to the fact that the body offers a large cross-section to the high frequency current, which distributes itself uniformly, so that the current density is small at any point of the path. The inference also follows that these currents pass through the human body in much the same manner as a direct current passes through a good conductor. The E. M. F. used in this experiment was about 2×10^5 volts and the frequency near a million a second. With this enormous potential literally in hand Tesla grasps one pole of the high tension transformer and approaches the other to the opposite pole, on nearing which a brush discharge having the appearance of a flame passes from his hand to the free pole. Enlarging upon this phenomenon in his usual style he estimates that with a frequency of four million and an E. M. F. of 3×10^6, his entire person would be enveloped in such a flame, but without danger.

In another beautiful experiment two straight wires are connected to the poles of the high tension transformer and stretched parallel to each other across the room, there being no cross connection between of any kind. When given the high tension current, these wires emit streams of light or brush discharges so profusely that light enough is produced to distinguish objects in the room. If these wires are bent into concentric circles, one inside the other in the same plane, the annular space between them is filled with streamers that make a sheet of light about a metre in area.

Perhaps the most interesting feature of these high frequency phenomena is their apparent capability of operating various sorts of electric devices—even motors of a certain description—and this with only a single wire leading to the source of energy. In one of these illustrations Mr. Tesla is led to say that he thinks it probable these experiments indicate the possibility of operating a motor at any point of the earth's surface from a central source with only an earth connection to the latter. This he hopes to accomplish by causing the electrical charge of the earth to oscillate and by the use of resonance a distant motor is made capable of picking out the current of different rate or frequency that is intended for its consumption or supply. It is probably suggestions of this character that have caused some readers to view Mr. Tesla's work as that of a visionary enthusiast.

It is more important, however, to determine just what Tesla has given in this discussion of high frequency phenomena that is of value—for its value is really quite independent of any views he may hold concerning the possible future applications of electricity.

He has built up a method of experimental investigation of physical phenomena, concerning which much remains to be learned. This method, with its vast array of beautiful experiment, is original and goes some steps beyond the point reached by previous work in this field, which may be defined as the experimental investigation of molecular physics. In all this there is little of practical interest to the electrical engineer. In going into this domain Mr. Tesla left what is commonly called electrical engineering behind and his work in this new field should therefore not be judged by its standards.

To the physicist Mr. Tesla stands a pioneer of a new and wide field of research.

To the electrical engineer he stands the inventor of the

rotary field machine, a brilliant and unique conception, which he soon left for the engineer to elaborate and figure out.

Before the general public he stands a phenomenal inventor from the Eastern World, from whom is expected little less than if he carried Aladdin's lamp in his hand, which, of course, is wrong, and an injustice both to the public and to Mr. Tesla.

Mr. Tesla is a hard and patient worker and has done enough for one decade in producing the rotary motor. He has doubtless much of importance in store for us, but the difference should never be lost sight of between the search for Nature's truths in the laboratory of the physicist and the reduction of the results attained, however great their promise, to a form suitable for commercial use.

PERSONAL

MR. NIKOLA TESLA has been awarded the Elliott-Cresson Medal by the Franklin Institute, of Philadelphia, for his Researches in High Frequency Phenomena.

NEW BOOKS.

Inventions, Researches, and Writings of Nikola Tesla. By THOMAS COMERFORD MARTIN. 8vo, 500 pp. The Electrical Engineer, New York, 1894.

This book for the first time affords the reader an opportunity to make a continuous and consecutive study of Mr. Tesla's work. Mr. Tesla has been more of a student and inventor than a writer and lecturer. He finds the laboratory more congenial than the lecture-room, and takes a much deeper interest in the prosecution of new lines of research and the development of new facts, than in the presentation to the public of the results of his work. As a consequence, Mr. Tesla's lectures and published papers have appeared at irregular and rather long intervals, and are scattered through the technical journals and in separate pamphlets.

Those interested in Mr. Tesla's work are greatly indebted to Mr. Martin for collecting as he has done into one volume all of Mr. Tesla's published papers, and especially for the connecting links and summaries that, as Mr. Tesla's intimate personal friend, he was so well qualified to supply.

The work begins with a brief biographical sketch, and we find that, as usual with great inventors, Mr. Tesla's fertile brain was even, while he was a student, developing new ideas, and it is interesting to note that the germ of the idea of the rotating field was conceived before the beginning of 1880.

Part I. deals with the rotating field apparatus, beginning with Mr. Tesla's paper read before the American Institute of Electrical Engineers in May, 1888. This paper was a revelation, to most of those present at that meeting, of an entirely new departure in alternating current work. The rotating field principle has since become familiar to electrical engineers through the published accounts of experiments conducted in this country and abroad, and numerous workers have entered the field. Simple as the principle seemed when first explained by Mr. Tesla, it was found when the attempt was made to apply it to the construction of large motors, that, contrary to the usual experience with continuous current machines,

the large motors were less efficient than the small ones, especially when operated at high frequencies. With the talent brought to bear upon the subject, sources of loss have been discovered and eliminated, and the motors improved until now they stand nearly on a par in efficiency with continuous current motors.

The chapters which follow in Part I. describe a great variety of forms of rotary field motors. In some the difference of phase is obtained on branches from a single circuit by the proper proportioning of resistance and self-induction. In others, a "magnetic lag" in peculiarly formed polar-projections serves to produce the rotary effort by the use of a single alternating current. Many of these forms could hardly be developed into efficient commercial machines, but they are curious examples of the working of alternating currents, and are especially interesting here as showing the extreme fertility of Mr. Tesla's mind.

Part II. relates to Mr. Tesla's high frequency experiments. In it are published in full Mr. Tesla's three lectures delivered respectively, at New York, May 20, 1891; at London and Paris, 1892; and at Philadelphia and St. Louis in 1893. The lectures are preceded by a review by Mr. Martin.

It is to be regretted that this review is not more discriminating. Instead of pointing out what properly belongs to Mr. Tesla, and what had already been done by other experimenters, he leaves the reader to infer that everything described is Mr. Tesla's work. The claim for novelty of the experiments seems, in some cases, to be unduly exaggerated. The operation of electrical devices by means of one wire is spoken of as though it were something before unheard of; and yet, how does it differ in principle from the old method of measuring the capacity of a condenser by charging it through a galvanometer? One wire from the battery passes through the galvanometer and terminates in the condenser. Close the key, and a current rushes through the galvanometer coil into the condenser and swings the needle. Substitute an alternating potential for the constant potential of the battery, and an alternating current would flow through the galvanometer coil.

The writer more than ten years ago showed that the needle of a galvanometer would be deflected by the rush of electricity into the coil when a glass rod charged by rubbing with a silk handkerchief was brought to one terminal, the other terminal having no connection with anything whatever. Deflection in the opposite direction was caused by charging the coil through the other terminal. Deflection was also produced by discharging the coil by one of its terminals. The coil used in this experiment was very thoroughly insulated, and held the charge given to it for some time. This was a case of an electrical device actuated through one

connection only, the generator being a glass rod and a silk handkerchief. The writer did not consider it anything wonderful; in fact, it was just what he expected would take place in a coil sufficiently well insulated, and having a sufficient number of convolutions.

How are we to understand the statement on page 120 that Mr. Tesla has demonstrated, that for the production of light-waves, "primarily," electrostatic effects must be brought into play? It does not appear that Mr. Tesla has produced light-waves *primarily*, in any way.

But the writer does not wish to be understood as finding nothing except for criticism in Mr. Martin's summary; far otherwise. The reader will find it an excellent *résumé* of the results portrayed in Mr. Tesla's lectures, and will find it very useful, even after having read the lectures themselves.

Referring to the experiments exhibited by Mr. Tesla in his three lectures, their novelty seems to the writer to consist more in the brilliancy and magnitude of the results than in the development of anything radically new. By this he does not mean in any way to belittle the value of Mr. Tesla's work. His experiments are no less a revelation if they only exhibit old phenomena in a new light, and demonstrate experimentally facts that were before only theoretically known. By means of a high frequency alternating machine, and still further by the extremely rapid Hertzian oscillations, the old induction coil is made to exhibit some wonderfully brilliant phenomena. Geissler tubes glow with unwonted brilliancy. In Crookes' tubes, in place of heating to redness only a tiny piece of platinum, a whole lamp filament or a block of carbon is rendered incandescent. In consequence of the high frequency, great differences in the phenomena are produced by exceedingly small changes in capacity, and many of the experiments strikingly illustrate this fact.

In the title to Mr. Tesla's New York lecture we find that he proposes to deal with high frequency phenomena "and their application to methods of artificial illumination." It is in this last that the practical engineer is specially interested; and the first question that occurs to him is, what is the efficiency of the methods hinted at by Mr. Tesla? [We do not find the methods more than hinted at in these lectures, and there is nowhere any light thrown upon the question of efficiency.] Knowing as we do the losses that accompany the use of high frequencies and high potentials, such as those due to disturbances in surrounding media, and currents in conductors due to their capacity, it would be interesting to learn what method Mr. Tesla may have in view for eliminating these. Mr. Tesla speaks of using an electrostatic screen for a conducting wire, and remarks that such a screen would have the same effect as removing all objects to an infinite distance. The writer does not know of any such screen.

A metallic sheath would serve as a screen only if its own potential were

maintained constant, and that could only be if it were in perfect conducting communication with the earth. The effect of any such sheath, whether connected to earth or not, would increase the capacity of the conductor.

The scheme of lighting by means of isolated vacuum tubes in a rapidly alternating electrostatic field is an attractive one, but the plates forming the boundaries of such a field would have considerable capacity. To charge them to a potential of a hundred thousand volts would require a considerable quantity of electricity, and if this charge were reversed many thousand times per second, the transfer of that quantity of electricity would mean a considerable current, and this current would be continually flowing whether any work were being done or not.

To be efficient it would be necessary that the capacity of the system when the lights were not in use should be extremely small, and should be largely increased by bringing them into action. Is it likely that such a relation could be achieved?

In the single wire distribution about which so much is said in the lectures, the result is only reached by a very accurate adjustment of frequency, potential, and capacity. Supposing the question of efficiency settled, would not such a system still be inapplicable for an extended distribution where lamps are to be turned on and off, on account of the nicety of the adjustments required? Would not the balance be destroyed with every lamp turned off or on. Is it not true that in any system involving the use of very high potentials and high frequencies capacity becomes a most important factor, and that small changes in capacity may interfere seriously with the working of the system?

In closing his London lecture Mr. Tesla tells us that his screened cables will not be made, "for ere long intelligence — transmitted without wires — will throb through the earth like a pulse through a living organism." But how many people could use the earth at once? Would not the telephone girls' frequent answer, "line in use," have to be accepted in that case as at least plausible?

In the Franklin Institute lecture a number of pages are given to the subject of resonance. The writer is not sure that he understands fully the statements and illustrations in that part of the lecture, and will only refer to one or two points.

The statement that "pure" resonance effects are impossible in nature evidently means simply that motion as we have to deal with it cannot be maintained without the constant consumption of energy. This is a fact perfectly well known, and is, of course, true of vibratory motion as well as of any other.

A body acted on by a force ceases to increase in velocity when the

resistances it meets with equal the force applied. A vibrating body kept in motion by successive small impulses derived from another body which vibrates in unison with it, which is all there is of resonance, ceases to increase in vibration when the resistances it meets with equal the impulses, or, in other words, when the loss of energy during each vibration is equal to the energy received during the same time. If the energy of the receiver is employed for some useful purpose, it must, of course, receive from the original vibrating body as much energy as is used; otherwise it will cease to vibrate.

When Mr. Tesla says that in "electrical vibration it is of enormous importance to arrange the conditions so that the vibration is effected with the greatest freedom," it is the same as saying that the waste of energy must be reduced to a minimum, and this is just as true when electrical energy is transferred in other ways.

It is also just as important that the transfer should be efficiently effected.

The case of the resonant tuning-forks, where one is sounded and imparts its vibrations to all the surrounding air, a small portion of which air imparts its vibration to the other fork, is an example of a very inefficient way of transferring energy. The energy of the first fork is mainly frittered away in imparting useless vibration to the surrounding air. If the energy of the first fork could be efficiently transferred, the vibration of the second might be maintained in mercury, and if agitation of the mercury were the object to be attained, it might be efficiently effected; and yet the means of transferring the energy from one fork to the other might be such that no effective vibration could be imparted unless the two forks were tuned to unison.

In short, when energy is to be transmitted by means of periodic motions, it may be desirable or convenient to use receivers having a definite vibration period of their own, in which case they must be adjusted to unison with the generator; but the use of such receivers does not increase or diminish the necessity of observing the other conditions of efficient transformation; viz. that as little energy as possible should be used outside of the receivers, and that in the receivers as little energy as possible should be consumed except for the useful purpose. In any case the use of resonant receivers introduces a new difficulty, that of adjusting them to unison, and maintaining unison under the varying demands for energy by the consumers.

Now it seems to the writer that in the transmission of energy electrically by means of high frequency and high potential currents the difficulties in preventing losses are greatly increased; and although, by the use of such high potentials, light may be obtained by means of discharges through

rarefied gases without the accompaniment of so large a proportion of energy in the form of dark heat, yet the losses in the use of electrical energy in this form, and applied in this way, seem to much more than counterbalance the efficiency of the luminous source itself.

As has been already said, Mr. Tesla has devised some wonderfully brilliant and striking experiments illustrative of the action of high potential and high frequency currents, but when it comes to the application of these to artificial illumination he is silent upon the all-important question of efficiency, and from such information as we have, it would seem that very little progress had been made toward any reasonable result in that direction.

Part III. treats of miscellaneous inventions. These are of interest as showing the diversified character of Mr. Tesla's work. Some of them show great ingenuity, but probably there are few of them to which Mr. Tesla would to-day attach any practical value.

Part IV. relates to Mr. Tesla's World's Fair exhibit, and to the oscillator, which was made the subject of the lecture before the members of the Electrical Congress.

The personal exhibit was itself a very interesting one, showing as it did, the progress of Mr. Tesla's work, especially in the development of the rotating field apparatus. The reader will be glad to find embodied here brief but excellent descriptions of the separate pieces of apparatus there exhibited.

The oscillators shown by Mr. Tesla at the Congress lecture were very ingeniously designed, and would no doubt give a fairly uniform vibration under varying loads; but the claim that the vibrations would be so uniform under all conditions, that a clock actuated by the apparatus "would keep absolutely correct time" is probably not intended to be taken literally. The apparatus appears to be an excellent one for the production of alternating currents whose frequency can be accurately known, and it may serve an excellent purpose in experiments and investigations, and perhaps for telegraphy, but the writer is unable to feel that confidence in the great future of this apparatus that he felt in that of the rotating field motors when they were first explained to him in Mr. Tesla's laboratory.

The chapter devoted to the oscillators in this volume is very brief, and does not describe very fully the oscillators themselves, or the apparatus used in connection with them.

The work of Mr. Tesla described in this volume covers a period of hardly eight years. In that time the rotating field principle was developed, and a multitude of different forms of motors embodying the principle were built. The high frequency alternators, induction coils, condensers, lamps, vacuum tubes, etc., etc., have all been developed through successive

experimental failures, and the immense variety of apparatus shown in successful operation on the occasion of the three lectures on high frequency phenomena are only a tithe of the instruments and apparatus built. All this shows not only Mr. Tesla's wonderful fertility, but his industry and perseverance as well. The writer understands that it is wholly his own work; the few assistants employed by him in his laboratory being only mechanics who could give him no help in the development of the apparatus. Few men can point to more work accomplished in so short a time.

WILLIAM A. ANTHONY.

Century Magazine May 1894

ZMAI IOVAN IOVANOVICH.

THE CHIEF SERVIAN POET.

HARDLY is there a nation which has met with a sadder fate than the Servian. From the height of its splendor, when the empire embraced almost the entire northern part of the Balkan peninsula and a large portion of the territory now belonging to Austria, the Servian nation was plunged into abject slavery, after the fatal battle of 1389 at the Kosovo Polje, against the overwhelming Asiatic hordes. Europe can never repay the great debt it owes to the Servians for checking, by the sacrifice of their own liberty, the barbarian influx. The Poles at Vienna, under Sobieski, finished what the Servians attempted, and were similarly rewarded for their service to civilization.

It was at the Kosovo Polje that Milosh Obilich, the noblest of Servian heroes, fell, after killing the sultan Murat II. in the very midst of his great army. Were it not that it is a historical fact, one would be apt to consider this episode a myth, evolved by contact with the Latin and Greek races. For in Milosh we see both Mucius and Leonidas, and, more than this, a martyr, for he does not die an easy death on the battle-field like the Greek, but pays for his daring deed with a death of fearful torture. It is not astonishing that the poetry of a nation capable of producing such heroes should be pervaded with a spirit of nobility and chivalry. Even the indomitable Marko Kraljevich, the later incarnation of Servian heroism, when vanquishing Musa, the Moslem chief, exclaims, "Woe unto me, for I have killed a better man than myself!"

From that fatal battle until a recent period, it has been black night for the Servians, with but a single star in the firmament — Montenegro. In this gloom there was no hope for science, commerce, art, or industry. What could they do, this brave people, save to keep up the weary fight against the oppressor? And this they did unceasingly, though the odds were twenty to one. Yet fighting merely satisfied their wilder instincts. There was one more thing they could do, and did: the noble feats of their ancestors, the brave deeds of those who fell in the struggle for liberty, they embodied in immortal song. Thus circumstances and innate qualities made the Servians a nation of thinkers and poets, and thus, gradually, were evolved their magnificent national poems, which were first collected by their most prolific writer, Vuk Stefanovich Karajich, who also compiled the first dictionary of the Servian tongue, containing more than 60,000 words. These national poems Goethe considered fit to match the finest productions of the Greeks and Romans. What would he have thought of them had he been a Servian?

While the Servians have been distinguished in national poetry, they have also had many individual poets who attained greatness. Of contemporaries, there is none who has grown so dear to the younger generation as Zmai Iovan Iovanovich. He was born in Novi Sad (Neusatz), a city at the southern border of Hungary, on November 24, 1833. He comes from an old and noble family, which is related to the Servian royal house. In his earliest childhood he showed a great desire to learn by heart the Servian national songs which were recited to him, and even as a child he began to compose poems. His father, who was a highly cultivated and wealthy gentleman, gave him his first education in his native city. After this he went to Budapest, Prague, and Vienna, and in these cities he finished his studies in law. This was the wish of his father, but his own inclinations prompted him to take up the study of medicine. He then returned to his native city, where a prominent official position was offered him, which he accepted, but so strong were his poetical instincts that a year later he abandoned the post to devote himself entirely to literary work.

His literary career began in 1849, his first poem being printed in 1852, in a journal called "Srbski Letopis" ("Servian Annual Review"); to this, and to other journals, notably "Neven" and "Sedmica," he contributed his early productions. From that period until 1870, besides his original poems, he made many beautiful translations from Petefy and Arany, the two greatest of the Hungarian poets, and from the Russian of Lermontof, as well as from German and other poets. In 1861 he edited the comic journal, "Komarac" ("The Mosquito"), and in the same year he started the literary journal, "Javor," and to these papers he contributed many beautiful poems. He had married in 1861, and during the few happy years that followed he produced his admirable series of lyrical poems called "Giulichi," which probably remain his masterpiece. In 1862, greatly to his regret, he discontinued his beloved jour-

nal, "Javor"—a sacrifice which was asked of him by the great Servian patriot, Miletich, who was then active on a political journal, in order to insure the success of the latter.

In 1863 he was elected director of an educational institution, called the Tekelianum, at Budapest. He now ardently renewed the study of medicine at the university, and took the degree of doctor of medicine. Meanwhile he did not relax his literary labors. Yet, for his countrymen, more valuable even than his splendid productions were his noble and unselfish efforts to nourish the enthusiasm of Servian youth. During his stay in Budapest he founded the literary society Preodnica, of which he was president, and to which he devoted a large portion of his energies.

In 1864 he started his famous satirical journal, "Zmai" ("The Dragon"), which was so popular that the name became a part of his own. In 1866 his comic play "Sharan" was given with great success. In 1872 he had the great pain of losing his wife and, shortly after, his only child. How much these misfortunes affected him is plainly perceptible from the deeply sad tone of the poems which immediately followed. In 1873 he started another comic journal, the "Ziza." During the year 1877 he began an illustrated chronicle of the Russo-Turkish war, and in 1878 appeared his popular comic journal, "Starmali." During all this period, he wrote not only poems, but much prose, including short novels, often under an assumed name. The best of these is probably "Vidosava Brankovicheva." In recent years he has published a great many charming little poems for children.

Since 1870 Zmai has pursued his profession as a physician. He is an earnest advocate of cremation, and has devoted much time to the furtherance of that cause. Until recently he was a resident of Vienna, but now he is domiciled in Belgrade. There he lives the life of a true poet, loving all and beloved by everybody. In recognition of his merit, the nation has voted him a subvention.

The poems of Zmai are so essentially Servian that to translate them into another tongue appears next to impossible. In keen satire free from Voltairian venom, in good-hearted and spontaneous humor, in delicacy and depth of expression, they are remarkable. Mr. Johnson has undertaken the task of versifying a few of the shorter ones after my literal and inadequate readings. Close translation being often out of the question, he has had to paraphrase, following as nearly as possible the original motives and ideas. In some instances he has expanded in order to complete a picture or to add a touch of his own. The four poems which follow will give some idea of the versatility of the Servian poet, but come far short of indicating his range.

Nikola Tesla

PARAPHRASES FROM THE SERVIAN.[1]

AFTER ZMAI IOVAN IOVANOVICH.

THE THREE GIAOURS.

IN the midst of the dark and stormy night
Feruz Pacha awakes in fright,
And springs from out his curtained bed.
The candle trembles as though it read
Upon his pallid face the theme
And terror of his nightly dream.

He calls to his startled favorite:
"The keys! the keys of the dungeon pit!
Cannot those cursèd Giaours stay
There in their own dark, rotting away,
Where I gave them leave three years ago?
Had I but buried their bones! — but, no!
They come at midnight to clatter and creep,
And haunt and threaten me in my sleep."

"Pacha, wait till the morning light!
Do not go down that fearful flight
Where every step is a dead man's moan!
Mujo to-morrow will gather each bone
And bury it deep. Let the Giaours freeze
If thy bed be warm."

"Nay, give me the keys.
Girl, you talk like a wrinkled dame
That shudders at whisper of a name.
When they were living, their curses made
A thousand cowards: was I afraid?
Now they are dead, shall my fear begin
With the Giaour's curse, or the skeleton's grin?
No, I must see them face to face
In the very midst of their dwelling-place;
And ask what need they have of me
That they call my name eternally."

As groping along to the stair he goes
The light of the shaking candle shows
A face like a white and faded rose;
But if this be fear, it is fear to stay,
For something urges him on his way —
Though the steps are cold and the echoes mock —
Till the right key screams in the rusted lock.

Ugh! what a blast from the dungeon dank! —
From the place where Hunger and Death were wed;
Whence even the snakes by instinct fled,
While the very lizards crouched and shrank
In a chill of terror. 'T is inky black,

[1] Copyright, 1894, by Robert Underwood Johnson. All rights reserved.

And icy cold, but he cannot go back,
For there, as though the darkness flowers —
There sit the skeletons of three Giaours
Ghost-white in the flickering candle-gleam! —
(Or is it the remnant of his dream?)
About a stone that is green with mold
They sit in a group, and their fingers hold
Full glasses, and as the glasses clink
The first Giaour beckons him to drink.

"Pacha, here is a glass for thee!
When last on me the sunlight shone
I had a wife who was dear to me.
She was alone — no, not alone;
The blade in her hand was her comrade true,
As she came to your castle, seeking you.

"And when she came to your castle gate
She dared you forth, but you would not go.
Fiend and coward, you could not wait
For a woman's wrath, but shot her, so.
Her heart fell down in a piteous flood.
This glass is filled with her precious blood.

"See how fine as I hold it up!
Drink, Feruz Pacha, the brimming cup!"

Spellbound the Pacha now draws nigh;
He empties the glass with a sudden cry:
The skeletons drink with a laugh and toss,
And they make the sign of the holy cross.

Then speaks the second of the dead:

"When to this darkness I was led,
My mother asked, 'What sum will give
Your prisoner back to the sun?' You said,
'Three measures of gold, and the dog shall live.'
Through pinching toil by noon and night
She saved and saved till her hope grew bright.

"But when she brought you the yellow hoard,
You mocked at the drops on her tired brow,
And said, 'Toward the pay for his wholesome board
Of good round stones I will this allow.'
She died while her face with toil was wet.
This glass is filled with her faithful sweat.

"See how fine as I hold it up!
Drink, Feruz Pacha, the brimming cup!"

Haggard the Pacha now stands by;
He drains the glass with a stifled cry:
Again they drink with a laugh and toss,
And the third one says, as his comrades cross:

"When this black shadow on me fell,
There sang within my mountain home
My one pale lad. Bethought him well
That he would to my rescue come;
But when he tried to lift the gun
He tottered till the tears would run.

"Though vengeance sped his weary feet,
Too late he came. Then back he crept,—
Forgot to drink, forgot to eat,—
And no slow moment went unwept.
He died of grief at his meager years —
This glass is laden with his tears.

"See how fine as I hold it up!
Drink, Feruz Pacha, the brimming cup!"

The Pacha staggers; he holds it high;
He drinks; he falls with a moan and cry:
They laugh, they cross, but they drink no more —
For the dead in the dungeon-cave are four.

THE GIPSY PRAISES HIS HORSE.

You 're admiring my horse, sir, I see.
He 's so light that you 'd think it 's a bird,
Say a swallow. Ah, me!
He 's a prize!
It 's absurd
To suppose you can take him all in as he passes
With the best pair of eyes,
Or the powerful aid
Of your best pair of glasses:
Take 'em off, and let 's trade.

What! "Is Selim as good as he seems?"
Never fear,
Uncle dear,
He 's as good as the best of your dreams,
And as sound as your sleep.
It 's only that kind that a gipsy would keep.
The emperor's stables can't furnish his mate.
But his grit and his gait,
And his wind and his ways,
A gipsy like me does n't know how to praise.
But (if truth must be told)
Although you should cover him over with gold
He 'd be worth one more sovereign still.

"Is he old?"
Oh, don't look at his teeth, my dear sir!
I never have seen 'em myself.
Age has nothing to do with an elf;
So it 's fair to infer
My fairy can never grow old.
Oh, don't look — (Here, my friend,
Will you do me the kindness to hold
For a moment these reins while I 'tend
To that fly on his shanks?) . . .
As I said — (Ah — now — thanks!)
The longer you drive
The better he 'll thrive.
He 'll never be laid on the shelf!
The older that colt is, the younger he 'll grow.
I 've tried him for years, and I know.

"Eat? Eat?" do you say?
Oh, that nag is n't nice
About eating! Whatever you have will suffice.
He takes everything raw —
Some oats or some hay,
Or a small wisp of straw,
If you have it. If not, never mind —
Selim won't even neigh.
What kind of a feeder is he? That 's the kind!

"Is he clever at jumping a fence?"
What a question to ask! He 's immense
At a leap!
How absurd!
Why, the trouble 's to keep
Such a Pegasus down to the ground.
He takes every fence at a bound
With the grace of a bird;
And so great is his strength,
And so keen is his sense,
He goes over a fence
Not across, but the way of its length!

"Under saddle?" No saddle for Selim!
Why, you 've only to mount him, and feel him
Fly level and steady, to see
What disgrace that would be.
No, you could n't more deeply insult him, unless
You attempted to guess
And pry into his pedigree.

Now why should you speak of his eyes?
Does he seem like a horse that would need
An eye-glass to add to his speed

Or, perchance, to look wise?
No, indeed.
Why, not only 's the night to that steed
Just the same as the day,
But he knows all that passes —
Both before and behind, either way.
Oh, he does n't need glasses!

"Has he any defect?" What a question, my friend!
That is why, my dear sir, I am willing to sell.
You know very well
It is only the horse that you give or you lend
That has glanders, or springhalt, or something to mend:
'T is because not a breath
Of defect or of death
Can be found on my Selim that he 's at your pleasure.
Alas! not for gipsies the care of such treasure.

And now about speed. "Is he fast?" I should say!
Just listen — I 'll tell you.

One equinox day,
Coming home from Erdout in the usual way,
A terrible storm overtook us. 'T was plain
There was nothing to do but to run for it. Rain,
Like the blackness of night, gave us chase. But that nag,
Though he 'd had a hard day, did n't tremble or sag.
Then the lightning would flash,
And the thunder would crash
With a terrible din.
They were eager to catch him; but he would just neigh,
Squint back to make sure, and then gallop away.
Well, this made the storm the more furious yet,
And we raced and we raced, but he was n't upset
And he would n't give in!
At last when we got to the foot of the hill
At the end of the trail,
By the stream where our white gipsy castle was set,
And the boys from the camp came a-waving their caps,
At a word he stood still,
To be hugged by the girls and be praised by the chaps.
We had beaten the gale,
And Selim was dry as a bone — well, perhaps,
Just a little bit damp on the tip of his tail.[1]

MYSTERIOUS LOVE.

INTO the air I breathed a sigh;
She, afar, another breathed —
Sighs that, like a butterfly,
Each went wandering low and high
Till the air with sighs was wreathed.

When each other long they sought,
On a star-o'er-twinkled hill
Jasmine, trembling with the thought,
Both within her chalice caught,
A lover's potion to distil.

Drank of this a nightingale,
Guided by the starlight wan —
Drank and sang from dale to dale,
Till every streamlet did exhale
Incense to the waking dawn.

Like the dawn, the maiden heard;
While, afar, I felt the fire
In the bosom of the bird;
Forth our sighs again were stirred
With a sevenfold desire.

These we followed till we learned
Where they trysted; there erelong
Their fond nightingale returned.
Deeper then our longings burned,
Deeper the delights of song.

Now, when at the wakening hour,
Sigh to sigh, we greet his lay,
Well we know its mystic power —
Feeling dawn and bird and flower
Pouring meaning into May.

Jasmine, perfume every grove!
Nightingale, forever sing
To the brightening dawn above
Of the mystery of love
In the mystery of spring!

TWO DREAMS.

DEEP on the bosom of Jeel-Begzad
(Darling daughter of stern Bidar)
Sleeps the rose of her lover lad.
It brings this word: When the zenith-star
Melts in the full moon's rising light,
Then shall her Giaour come — to-night.

What is the odor that fills her room?
Ah! 't is the dream of the sleeping rose:
To feel his lips near its velvet bloom
In the secret shadow no moonbeam knows,
Till the maiden passion within her breast
Kindles to flame where the kisses rest.

By the stealthy fingers of old Bidar
(Savage father of Jeel-Begzad)
Never bloodless in peace or war
Was a handjar sheathed; and each one had
Graved on its handle a Koran prayer —
He can feel it now, in his ambush there!

The moon rides pale in the quiet night;
It puts out the stars, but never the gleam
Of the waiting blade's foreboding light,
Astir in its sheath in a horrid dream
Of pain, of blood, and of gasping breath,
Of the thirst of vengeance drenched in death.

. . .

The dawn did the dream of the rose undo,
But the dream of the sleeping blade came true.

Robert Underwood Johnson.

[1] Readers will be reminded by this conclusion of Mark Twain's story of the fast horse as told to him by Oudinot, of the Sandwich Islands, and recorded in "The Galaxy" for April, 1871. In that veracious narrative it is related that not a single drop fell on the driver, but the dog was swimming behind the wagon all the way.

PERSONAL

MR. NIKOLA TESLA had the degree of LL.D. conferred upon him by Columbia College at the commencement exercises on June 13th. It will be remembered that it was at Columbia College, in 1891, before the American Institute of Electrical Engineers, that Mr. Tesla delivered the first of his brilliant series of lectures on his remarkable experiments with currents of high potential and high frequency.

NIKOLA TESLA AND HIS WORKS.

By Lieut. F. Jarvis Patten.

In this age of practical endeavor, when everything is turned to its immediate use with the least delay possible, a life like that of Tesla, devoted to scientific research for the love of it, stands out in peculiar and interesting prominence. Such a character, however, is the natural outcome of the rapid advance in all material investigation, which has become so broad, and goes into so many different fields of research, that few workers attain to general prominence.

The last decade pays tribute to two names that have added something to our knowledge and better comprehension of nature's methods. These names are Hertz and Tesla. Hertz gave promise of showing the ultimate law that connects matter separated by space. The work so well begun was ended by his untimely death. Maxwell had shown that all of nature's reacting forces can be expressed by methods of mathematical analysis, and clearly formulated by the terms of an equation. By purely empirical methods Hertz gave physical proof of the truth of Maxwell's theoretical deductions, and so connected pure theory to practical fact.

Out of both pure theory and physical research came the general conclusion, that all manifestations of energy are but the different tangible or apparent evidences of one and the same force; that all energy, whatever its form of manifestation, is simply molecular agitation of greater or less degree. If that be true, then heat and light are merely the results of molecular agitation, and could this agitation be set up by purely mechanical means, heat or light would result.

Tesla conceived the bold idea that, by causing matter to pass to the stage of luminous vibration, without remaining for any appreciable time in the stage of heat vibration, it would produce light without heat; and so near has he come to the practical accomplishment of this conception that he

has set the scientific minds of all Europe thinking, and placed his name beside that of Hertz.

Tesla comes from Herzegovina, near the Western borderland of Turkey, and in early youth was a pupil of the government schools where he lived. Later, he held government office as a collector of statistics. His twenty-third year found him in Paris, whither he had come to study engineering at the École Polytechnique. From this school he went to the Edison Station in Paris as an engineer, where his ability was quickly recognized, and he was soon persuaded to come to this country. Here a place was found for him in the celebrated Edison laboratory. He remained in this position a few years, but, having many ideas that he wished to develop independently, he left that employ, and has since conducted a laboratory of his own in New York City, which has been devoted purely to physical research and scientific investigation.

Thirteen years' residence in this country has not deprived Tesla of his cosmopolitan character and disposition. Master of five or six languages and a devotee to broad science, he is truly a citizen of the world, a genial host and charming companion. What first brought him into prominence and gave him the means to go further, was his discovery of the "Rotary Field Motor," an invention of marked originality and beauty, but not appreciated at its full value at the time of its discovery. Announced by him and commercially disposed of in 1888, it is now just coming into general use. Simple and beautiful as it seemed, our knowledge of electrical engineering was not then equal to the task of making the machine electrically right. European engineers, however, held to the work, and, following in their footsteps, we now understand the rotary field motor, and the largest electrical enterprise in the world, the fifty thousand horse-power plant for sending the power of Niagara to light Buffalo and other distant towns, will use the multiphase system that Tesla first gave to the engineering world six years ago.

An apt illustration of the difference between the purely theoretical or scientific mind, and the semi-practical mind

guided by scientific training, suggests itself here. Professor Ferraris, of Turin, independently discovered and announced the principle and operation of the rotary field motor at about the time that Tesla did the same thing in this country. The professor's announcement was in the form of a paper to a scientific society. Tesla made many forms of the machine, reduced his theory to a practical operative device, and, having protected his invention by many patents, he exhibited his machines to the American Institute of Electrical Engineers in May, 1888. Professor Ferraris's description, however, antedates Tesla's exhibition by some months. It is worthy of remark in passing, that three of the epoch making inventions in electrical advance are of Italian origin. I refer to the chemical element, or Volta's pile; the first direct current generator invented by Pacinotti, and left in obscurity for years; and last, but greatest of all for the coming era of long distance power transmission, the rotary field engine of Ferraris and Tesla.

Before considering Tesla's more recent work, it seems appropriate to describe briefly the salient features of this machine, which can be best done by comparing it with the ordinary type of electric motor. This, in general terms, is an engine having a fixed and a revolving part, of which the latter, turning about its spindle, communicates motion to other machinery. The moving part is always provided with commutating devices that constantly shift the magnetic axis backward, in the same measure and degree that the moving part turns forward. These devices are always intricate and complex. They are, in fact, the weak point of all electric engines. The Tesla rotary field machine, being entirely free from them, is a marvel of simplicity and ingenuity. To understand this machine, one must picture a circular iron ring, and conceive it to be magnetized along a vertical diameter, North Pole at the top; then, a moment later, along a horizontal diameter, with the North Pole at the right; again along the vertical diameter, but North Pole at the bottom; and lastly on the horizontal line again, with North Pole at the left, thus completing a revolution of the North Pole around

the ring. Such an effect is called a rotating magnetic field, and can be perfectly produced by the simultaneous use of two independent alternating currents, which follow each other periodically in such a way that one has always a maximum value or strength when the other is zero, and conversely. If now the iron ring is wound all around with a coil of wire closed on itself, and one such current be introduced to this winding at the extremities of a vertical diameter, while another is simultaneously introduced to the same winding at the extremities of a horizontal diameter, they will jointly produce a revolving magnetic field that turns continuously around the ring, while the latter remains fixed in space. We then have a fixed magnet, but the magnetism itself, or magnetic axis, is in motion. A compass or magnetic needle suspended freely inside the ring would spin around in its endeavor to follow the revolving magnetism or the shifting magnetic axis of the ring.

Tesla delights in surprises for the public. He generally brings a new line of development to fair completion before giving it any public exhibition. The rotary field motor was a genuine surprise to the world of electrical engineering in 1888. Nothing more was heard from him for two years, and his motor—talked of awhile as a sort of nine days' wonder—was practically forgotten, while he was at work on other problems, of which no hint was given until his celebrated lecture at Columbia College, in the spring of 1890. In this lecture he exhibited for the first time his wonderful "high frequency effects," and certainly gave the scientific world some promise of obtaining light without heat, although this accomplishment was far from fruition at the time, and I believe is now abandoned as hopeless on the lines attempted. Still, his researches developed many new and surprising effects, which, aside from their purely laboratory interest, may have a certain commercial value. In these researches, which constitute an investigation of what have now come to be known as "The Tesla Effects," it was his aim and purpose to establish by experimental process the identity of light and some form of electrical manifestation ot

energy, and he gave to science much evidence of the electro-magnetic theory of light that was new, though the theory, of course, had preceded his work, having been enunciated by Maxwell from purely theoretical deductions, and proven by Hertz by empirical methods.

Mr. Tesla started with the idea of setting matter into vibration at a rate approximating that of light (some two and a half millions a second), with the expectation that under such violent molecular agitation it would emit light. He has not as yet succeeded in obtaining so high a rate, but a much lower one produced some very surprising luminous effects. The general plan at first was this: To construct an alternating current dynamo that would produce this high rate of current alternation or pulsation. This current, now known as the "high frequency" current, will cause luminous effects in different media. Thus, in a darkened room, a bare copper wire conveying such a current will be seen to glow, and vacuum tubes will shine brightly, as a result of a molecular bombardment or agitation of the ether atoms, when such a current is sent through them under very high pressure—the very high electro-motive force of several hundred thousands of volts being used in most of his experiments of this character. The dynamo method for getting very high frequencies was soon abandoned as inadequate, and the oscillatory discharge of a Leyden jar or plate condensers was substituted. This answered much better, although the frequency was then an unknown quantity and quite beyond control; and this departure led to the discovery of some very beautiful electro-static effects, which are still being pushed by many investigators with the hope of arriving at some result of commercial value.

As soon as news of Tesla's first lecture, and the experiments there shown, reached the other side of the Atlantic, he was at once invited by various scientific societies of Europe to deliver his lecture and perform his experiments before them. This he soon did; and the scientific minds of Europe were quickly at work investigating the so-called Tesla effects, the result being that the electro-magnetic theory of light may

be regarded as proven, while it seems equally well-established that light without heat is not to be looked for as an outcome of the Tesla effects. A beautiful and startling exhibition of what can be done with electric energy, under properly arranged conditions, is that of causing vacuum tubes or partially exhausted bulbs to glow by merely holding them between two metallic plates (about four feet square, and two or three yards apart), which are made the terminal poles of a circuit conveying a high frequency and high voltage current. It was hoped that rooms could be lighted in this way by placing the plates in the walls, where such tubes would glow without any material connection whatever with the source of energy.

Mr. Tesla claims that all electric and magnetic effects are traceable to the action of electro-static molecular forces, and in confirmation of this theory he produces what appears to be a veritable flame by the action of electro-statically charged molecules of gas. A flame is actually shown issuing from the tip of a wand, or from the ends of his fingers, which flame is devoid of heat, and by it no material is consumed. Perhaps the most surprising of the new facts elicited from his investigations is that the shock due to these very high voltage and high frequency currents can be supported by a person without any serious inconvenience. He passes a current of two hundred thousand volts through his body with perfect impunity, whereas one of two thousand volts will produce almost certain death from even a momentary shock. In one experiment, two wires are stretched parallel to each other across the room. When given the high tension current they emit streams of light, or brush discharges so profusely that light enough is produced to distinguish objects in the room. If the wires are bent into concentric hoops, one inside the other in the same plane, the annular space between them is filled with streamers that make a sheet of flame a yard or more in area.

Mr. Tesla is viewed by some as an impractical inventor—a mere visionary enthusiast—but this is hardly fair to one who has built up an entirely novel method for the experimental investigation of physical phenomena. This method, with its vast array of beautiful experiments, is original, and goes

some steps beyond any point reached by previous work in the same line. There seems to be little of practical value in it for the electrical engineer. So we may say, that to the physicist Mr. Tesla stands as the pioneer of a new and wide field of research, while before the practical man of electricity he stands as the inventor of the "rotary field machine," a beautiful and unique conception, which he soon left for the practical man to figure out.

Before the general public he stands as a phenomenal inventor from the Eastern World, from whom is expected little less than if he carried Aladdin's lamp in his hand. This view of the matter, of course, is wrong, and is an injustice both to the public and the inventor. Mr. Tesla is a hard and patient worker, and did enough for one decade in producing the rotary motor. He has doubtless much yet in store for us, but the difference should never be lost sight of between the work of the empirical physicist searching for nature's truths, and the reduction of a single result to a form for commercial use.

College Notes.

YALE UNIVERSITY.

At the commencement exercises on June 27th, Yale Uuiversity conferred on Mr. Nikola Tesla the honorary degree of M.A. It will ba remembered that Columbia College made Mr. Tesla an LL.D. two weeks ago.

THE WORLD.

NEW YORK, SUNDAY, JULY 22, 1894.

OUR FOREMOST ELECTRICIAN

The Wonderful Discoveries and Daring Theories of Nikola Tesla, as Told by Him to The World.

GREATER EVEN THAN EDISON.

Hard at Work Experimenting with a New Kind of Light and Promises Wonders That Are Now Undreamed Of by Scientists.

THE ELECTRICITY OF THE FUTURE.

He Predicts It Will Be the Great Labor Saver—Picturesque Personality of a Man Who Is Toying with the Secrets of the Universe.

There is a small country in Europe called Lika, and in that country there is a village of forty houses, called Smiljan.

You have probably never heard of either, but you and many others will live to know about a baby that was born in the village of Smiljan in the country called Lika thirty-seven years ago.

It was probably the usual Slavonic baby, very dark, very nervous and doomed in advance to a dull and wasted life. Lika is really a part of Servia, and Servia had her day long ago. Her men gained fame by fighting and helping the Hungarians to keep Asia out of Europe. Huxley, who thinks seriously, and Oscar Wilde, who is foolish, can enjoy life and London now because those old fighters fought so hard.

Most of Servia's modern babies might as well have avoided the annoyance of birth for all they can ever do in the world, but this baby is an exception.

He was visible yesterday, in his grown-up condition, at Delmonico's. His name is Nikola Tesla. He is the best electrician living, if men who know about electricity may be believed. He is to the average electrician as Horace Greeley is to Bill Nye. He is serious, he is earnest, and in all ways he commands respect.

Every scientist knows his work and every foolish person included in the category of New York society knows his face. He dines at Delmonico's every day. He sits each night at a table near a window. When Ward McAllister, that strange contradiction of the theory that nature abhors a vacuum, wanders in, he sees Nikola Tesla with his head buried in an evening paper.

Every foolish young man who cares for the law of gravitation only because it interferes with jumping fences, every foolish young woman who thinks that there is something new about her two-cent love affair, has seen this serious, owl-faced Servian eating his dinner and thinking about electrical vibrations.

Nikola Tesla is almost the tallest, almost the thinnest and certainly the most serious man who goes to Delmonico's regularly.

VERY THIN, AND VERY TALL.

He has eyes set very far back in his head. They are rather light. I asked him how he could have such light eyes and be a Slav. He told me that his eyes were once much darker, but that using his mind a great deal had made them many shades lighter. I have often heard it said that using the brain makes the eyes lighter in color. Tesla's confirmation of the theory, through his personal experience is important.

He is very thin, is more than six feet tall and weighs less than a hundred and forty pounds. He has very big hands. Many able men do—Lincoln is one instance. His thumbs are remarkably big, even for such big hands. They are extraordinarily big. This is a good sign. The thumb is the intellectual part of the hand. The apes have very small thumbs. Study them and you will notice this.

Nikola Tesla has a head that spreads out at the top like a fan. His head is shaped like a wedge. His chin is as pointed as an ice-pick. His mouth is too small. His chin, though not weak, is not strong enough. His face cannot be studied and judged like the faces of other men, for he is not a worker in practical fields. He lives his life up in the top of his head, where ideas are born, and up there he has plenty of room. His hair is jet black and curly. He stoops—most men do when they have no peacock blood in them. He lives inside of himself. He takes a profound interest in his own work. He has that supply of self-love and self-confidence which usually goes with success. And he differs from most of the men who are written and talked about in the fact that he has something to tell.

WONDERS OF THE FLY.

It is most pleasing to hear this wise man talk about figures that tire the usual brain. Mr. Delmonico and an aged friend were talking to Mr. Tesla when I saw him night before last. Mr. Tesla having had his supper was discussing, by way of relaxation, the number of vibrations of the wing of a certain fly. The fly, of which Mr. Tesla did not know the name, is a fly that flies straight ahead so fast that you can't see him, and flies back in a straight line without any apparent effort.

"That," said Mr. Tesla, "is the strongest living animal, in proportion to his size. He moves his wings about twenty-five thousand times to the second." The aged man who had consented to take a drink with Mr. Delmonico mopped his forehead worriedly, for it was a hot night.

"And that is nothing, from the ordinary point of view," mused the distinguished Mr. Tesla. "You see, if you move your hand ten times in a second and then try to move it one hundred times to the second, it will take a hundred times as much strength to move it ten times as fast. The fly that moves its wings twenty-five times to the second requires twenty-five thousand multiplied by twenty-five thousand times as much force as he would to move them once in a second. That makes him use up about six hundred million times as much force as you might think to move his wings like that." Mr. Delmonico's aged friend said: "Don't talk of such exertion in this weather," and wearily mopped himself out of the place.

When the aged man had gone Mr. Tesla said he could go to sleep floating on the water, and Mr. Delmonico, who is a very handsome young man with a pointed black beard, said that he did not believe sharks ever ate any one up. Mr. Tesla said that was nonsense, for in the lower Danube pikes sometimes had seized men and dragged them beneath the surface. The pikes were four feet long, and became so dangerous that swimming about there was prevented. Mr. Delmonico said he was going to Sharon Springs, and started for the Springs at once.

Mr. Nikola Tesla then talked, at my urgent request, about electricity and the things that he hopes to do.

There is no intention here to give a technical account of Mr. Tesla's past achievements and future ambitions. It would be much too hard to write to begin with, and utterly incomprehensible to almost every one after being written. The idea is to discover the new great electrician thoroughly; to interest Americans in the Smiljan baby's personality, so that they may study his future achievements with proper care.

TESLA'S THEORY OF LIGHT.

Mr. Tesla's biggest undertaking at present—that to which he is devoting his most earnest efforts—is the production of light by the vibrations of the atmosphere. He has no intention of heating a bit of cinder red hot and letting it glow by incandescence. The present incandescent system, compared to the Tesla idea, is as primitive as an ox cart with two solid wooden wheels compared to modern railroading.

The light of the sun, according to Mr. Tesla, is the result of vibrations in 94,000,000 miles of ether which separate us from the centre of this solar system. Mr. Tesla's idea is to produce here on earth vibrations similar to those which cause the sunlight, and thus to give us a light as good as that of the sun, with no danger from clouds or other obstructions. Mr. Tesla has already achieved decided success in this line. He takes in his hand a long bar of glass, which, by vibration alone, lights up into most amazing brilliancy. He himself comes out of his experiments a most radiant creature, with light flaming at every pore of his skin, from the tips of his fingers and from the end of every hair on his head.

In explaining his experiments, Mr. Tesla uses figures calculated to pulverize an ordinary mind.

"It is difficult for me," he said, "to give you an idea that you will readily grasp about this question of vibration. In ordinary life our minds do not deal with the figures that come up in such investigations, but take a 5 and put after it fourteen zeroes; then you will have the number of vibrations which occur in the ether every second and which produce light."

I carried out Mr. Tesla's suggestion, with the following result—500,000,000,000,000.

"All I have to do," said Mr. Tesla, "to duplicate the sunlight is to get this number of vibrations to the second with my machinery on earth. I have succeeded up to a certain point, but am still at work on the task."

THE POWER OF VIBRATION.

I tried in various ways to present in cold writing some notion of what five hundred trillions of vibrations to the second might mean. I didn't succeed very well. The nearest I could was to mention, at Mr. Tesla's suggestion, the following fact: If a mass of metal as big as the Delmonico restaurant, in which we sat, possessing 10,000 times the resisting force of the most finely tempered steel, should be caused to vibrate with one millionth of the rapidity of the light-producing electric vibrations in ether, that mass of metal, 10,000 times harder than steel, would simply vanish into the air like smoke. It would disappear into separate atoms too small to be seen and would never be heard of again.

Electricity in its vibrations, according to Mr. Tesla, has a great advantage over all other things, such as flies' wings and other material bodies. Electricity has no weight, and therefore no opposition is offered to its moving backward and forward freely any number of times to the second.

"It is perfectly easy to prove that electricity weighs nothing," said Mr. Tesla. "I will load you so full of electricity that you can't hold any more and then put you on the finest weighing machine, and you will not find one-thousandth part of an ounce added to your weight."

I ventured to suggest to Mr. Tesla that as a vibrator electricity might meet with serious competition among modern statesmen, but his mind was so serious that he only said: "No statesman could vibrate fast enough to be of any value scientifically."

Before deciding to give Mr. Tesla unlimited space in the greatest newspaper that was ever heard of, I had heard from a dozen reliable sources that there was not the slightest doubt about his being a very great man. Authorities unite in declaring him the very greatest man living in the line of abstract electrical research.

One able electrician told me that there never was such a man for working out purely intellectual problems. Another said he could conceive of nothing more extraordinary than the devotion and admiration for Tesla entertained by all of the young electrical engineers. It is a pitiful thing for a morbidly conscientious writer to find himself booming one not altogether worthy of his periods and climaxes, but I am certain in the case of Mr. Tesla that it is safe to go ahead.

ONE OF HIS DISCOVERIES.

Mr. Tesla discovered the rotating magnetic field. That seems to me, next to his idea of getting light by vibration, the best thing he ever did. The rotating magnetic field is a thing which may be described but not understood. Everybody knows that a magnet will seize a piece of iron and hold it firmly; everybody knows that the magnet must use up force in holding that iron, but of course as long as it holds the iron perfectly still the force is wasted. The piece of iron if left alone would stand still. There is no use in getting a magnet to make it stand still. But Mr. Tesla found that he could get a magnet to use its force in such a way as to cause the piece of iron to spin violently round and round. He can make a wheel at a distance from the source of electro-magnetic force spin round with 10,000 horse-power. He expects to apply this principle in employing the strength of the Niagara Falls electric current. The fact may be mentioned that the Niagara Falls people who have relied upon Tesla to tell them how they may use their power at a distance have adopted his scheme.

This rotating magnetic field struck me as a most impressive discovery. I asked Mr. Tesla whether he didn't think it possible that the spinning, rotary motion of the earth and her fellow planets, commonly attributed to some unexplained primary propulsive force, might be due to the application on a grand scale of his rotating magnetic field idea. I suggested that the sun might be a great magnet, that the five hundred trillion vibrations per second which he spoke of showed considerable electrical power somewhere; that there was a great deal of iron and a powerful lot of electricity in the earth. Mr. Tesla observed that he thought it was dangerous to jump at such conclusions, but he treated my enthusiasm, born of complete ignorance, with a kind toleration, which did much to convince me of his true greatness.

THE SECRET OF ELECTRICITY.

Electricians in general think that Tesla's best work thus far is a machine which has industrial value as a new and more direct agent for producing electrical force. I didn't care much about that compared with the rotating magnetic field, but I asked Mr. Tesla to tell me in as few words as possible just how we get electricity, and why we get it when we do get it. Said Mr. Tesla:

"We get electricity by causing a wire to revolve near a magnet. The stronger the magnet the faster the revolutions of the wire, and the bigger the wire the more electricity.

"Why we get electricity in this way, and what electricity is, are different questions. Every electrician has his theory. I have one which I think I can demonstrate mathematically. There is no accepted explanation of the most extraordinary phenomenon in nature."

Mr. Tesla does not care to see in cold print an account of those things which he hopes to accomplish, or to see accomplished, by means of electricity.

"You would think me a dreamer and very far gone," he said, "if I should tell you what I really hope for. But I can tell you that I look forward with absolute confidence to sending messages through the earth without any wires. I have also great hopes of transmitting electric force in the same way without waste. Concerning the transmission of messages through the earth I have no hesitation in predicting success. I must first ascertain exactly how many vibrations to the second are caused by disturbing the mass of electricity which the earth contains. My machine for transmitting must vibrate as often to put itself in accord with the electricity in the earth."

TOOK 250,000 VOLTS HIMSELF.

Mr. Tesla is the interesting person who, in Philadelphia, before a large gathering, allowed a quarter of a million volts of electricity to go through his body. Having seen Carlyle Harris and one other unfortunate individual instantly killed by the application of less than 2,000 volts, I asked Mr. Tesla if he didn't feel a little worried about taking a current of a quarter of a million volts. Said he:

"I did at first feel apprehensive. I had reasoned the thing out absolutely, nevertheless there is always a certain doubt about the practical demonstration of a perfectly satisfactory theory. My idea of letting this current go through me was to demonstrate conclusively the folly of popular impressions concerning the alternating current. The experiment had no value for scientific men. A great deal of nonsense is talked and believed about 'volts,' &c. A million volts would not kill you or hurt you if the current vibrated quickly enough—say half a million times to the second. Under such conditions the nerves wouldn't respond quickly enough to feel pain."

"You see, voltage has nothing to do with the size and power of the current. It is simply the calculation of the force applied at a given point. It corresponds to the actual pressure per square inch at the end of a water pipe, whether the volume of the water be great or small. A million volts going through you doesn't mean much under proper conditions. Imagine a needle so small that the hole it would make in going through your body would not allow the blood to escape. Imagine it so small that you couldn't even feel it. If you had it put through your arm slowly, that would be, electrically speaking, a very small voltage. If you had it stuck through your arm with great rapidity, going, say, at the rate of a hundred miles a second, that would be very high voltage. Voltage is speed, pressure at a given point. It wouldn't do you any more harm to have a needle shot through your arm very rapidly—that is to say, with high voltage—than it would to put it through slowly. In fact, if it hurt you at all, the slow operation would probably hurt more than the other. The question of danger is simply the size of current, and yet if a big enough current should be turned against you and broken with sufficient rapidity—if it should, so to speak, jerk back and forth an inconceivable number of times to the second—it wouldn't kill you. Whereas, if applied continuously, it would simply burn you up."

ELECTRICITY OF THE FUTURE.

When Mr. Tesla talks about the electrical problems upon which he is really working he becomes a most fascinating person. Not a single word that he says can be understood. He divides time up into billionths of seconds, and supplies power enough from nothing apparently to do all the work in the United States. He believes that electricity will solve the labor problem. That is something for Mr. Debs to ponder while he languishes in his dungeon. It is certain, according to Mr. Tesla's theories, that the hard work of the future will be the pressing of electric buttons. A few centuries from now the criminal instead of working a treadmill or picking oakum will be sentenced to press fifteen electric buttons every day. His fellows, long since disused to work, will look upon his toil with pity and horror.

Mr. Nikola Tesla is to be envied. He owns one of those rare minds which do not absorb trivialities. A computation of the vibrations of a fly's wing is to him what croquet would be to Grover Cleveland—it is play. He can play when he wants to, but he doesn't do it very often.

Mr. Delmonico lowers his voice when he speaks of Mr. Tesla, as Boston cabdrivers used to lower their voices in speaking of John L. Sullivan. He said:

"That Tesla can do anything. We managed to make him play pool one night. He had never played, but he had watched us for a little while. He was very indignant when he found that we meant to give him fifteen points. But it didn't matter much, for he beat us all even and got all the money. There are just a few of us who play for 25 cents, so it wasn't the money we cared about, but the way he studied out pool in his head, and then beat us, after we had practised for years, surprised us."

I talked to this Mr. Tesla of Smiljan until all but one of the lights had gone out and until the feeble daylight found Mr. Delmonico's scrub-ladies scrubbing his marble floor. All that he said was interesting, both the electrical things and the others.

HARD WORK HIS PLEASURE.

He is very proud of his Slavonic race. He believes that the poetry of the Slavs written in Servian and Croatian would surprise the civilized world if it could be presented in widely known languages.

He says that the thin man relies constantly on the food which he eats at the moment. He looks upon good food as most important and feels the strengthening effects of it within twenty minutes. He believes that work never hurts, but that play does.

Nobody, he thinks, can work enough to hurt him.

He thinks that marriage and love interfere with success.

That suppers are very bad for one in New York, but all right in Paris.

He does not believe in telepathy, which is, according to its exponents, a sort of psychical electricity enabling one mind to communicate ideas to another without words. He considers that what is usually taken as an evidence of the existence of telepathy is mere coincidence. But the working of the human mind through observation and reason interests and amazes him, as it well may.

"Suppose I made up my mind to murder you," he said, "in a second you would know it. Now, isn't that wonderful? By what process does the mind get at all this?"

One wise man whom I knew used to say that the scientists with their jumble of laws governing the universe were ignoramuses, and that there weren't more than half a dozen fundamental laws all told. I asked Mr. Tesla what he thought about that.

"I think," said he, "that they could all be reduced to one."

TESLA AND THE REPORTER.

Nikola Tesla fell under the pen of Arthur Brisbane in last Sunday's New York *World*. Mr. Brisbane is a keen and astute observer and after admitting the uselessness of attempting to describe Tesla's work turned himself to the scarcely less easy task of critically analyzing the man. He assures his readers that he first satisfied himself that Tesla was worth "booming" and then proceeds to do it in characteristic fashion. Mr. Brisbane, who is a young man said to be deep in Joseph Pulitzer's confidence and esteem, is a first-class reporter and consequently sees things that other people miss. He is much given to describing character from anatomical indications and sizes up a man's worth from the color of his eyes, the contour of his chin, the size of his nose, the width of his mouth, the length of his thumbs. Tesla appears to Brisbane so:

He has eyes set very far back in his head. They are rather light. I asked him how he could have such light eyes and be a Slav. He told me that his eyes were once much darker, but that using his mind a great deal had made them many shades lighter. I have often heard it said that using the brain makes the eyes lighter in color. Tesla's confirmation of the theory through his personal experience is important.

He is very thin, is more than six feet tall and weighs less than 140 pounds. He has very big hands. Many able men do—Lincoln is one instance. His thumbs are remarkably big, even for such big hands. They are extraordinarily big. This is a good sign. The thumb is the intellectual part of the hand. The apes have very small thumbs. Study them and you will notice this.

Nikola Tesla has a head that spreads out at the top like a fan. His head is shaped like a wedge. His chin is as pointed as an ice-pick. His mouth is too small. His chin, though not weak, is not strong enough. His face cannot be studied and judged like the faces of other men, for he is not a worker in practical fields. He lives his life up in the top of his head, where ideas are born, and up there he has plenty of room. His hair is jet black and curly. He stoops—most men do when they have no peacock blood in them. He lives inside of himself. He takes a profound interest in his own work. He has that supply of self-love and self-confidence which usually goes with success. And he differs from most of the men who are written and talked about in the fact that he has something to tell.

Tesla has been written about by all sorts of writers, from heavy scientists to young and enthusiastic reporters for the electrical journals. But it doubtless gave him a new and unusual sensation to read Mr. Brisbane's critical and worldly analysis, the data for which he acquired in a conversation at Delmonico's where Tesla usually eats. It is a long jump from the scientifically accurate and tastefully written biography by Thomas Commerford Martin to the surgical dissection of Tesla by Arthur Brisbane. And yet both are interesting.

NIKOLA TESLA AND HIS WORK.*

By Nelson W. Perry, E. M.

IT is not often that it is in good taste to estimate the character of a man while he is living, or safe to weigh his works or to estimate their proper place in any science while it is still in an embryotic state. There are exceptions, however, as in the case of political and other celebrities who, by reason of their eminence, have become in a sense public characters, or whose work has already revolutionized the science in the interest of which it has been undertaken. Under both of these exceptions it seems altogether proper to speak of Mr. Nikola Tesla, for if a man by taking two continents by storm may be called a public character in the sense in which the expression is here used, Mr. Tesla is one, and if the discovery of a new system such as the rotary magnetic field which in a few years has largely revolutionized our methods of conversion of electrical into mechanical energy, and which has formed the basis of the greatest attempt at power-transmission ever made, partakes of the nature of a revolution of the science, then for this reason may Mr. Tesla's work be reviewed with propriety while their author is still in the flesh.

Mr. Tesla was born in 1857, and therefore is still quite a young man, but he has crowded within his thirty-seven years of life an experience that would be considered ripe for any one of a dozen other men if it were divided equally among them. While foreign-born (at Smiljan-Lika on the borderland of Austro-Hungary), he is an American by adoption. Though proud of his adopted country he is not so intensely American as some foreigners become who adopt this country as their home.

The one discovery of Mr. Tesla which among practical men stands out most prominently to-day, because of the practical results already obtained, is his discovery of what is generally known as the rotating magnetic field. The alternating current, as the name would imply, means a current which changes its direction periodically. It possesses many characteristics peculiar to itself. The distinct advantage of an alternat-

* In the publisher's announcement, some months ago, of a series of papers on "Electrical Science up to Date," was included the promise of a paper in this volume of THE ENGINEERING MAGAZINE, by Mr. Nikola Tesla, on "Electric-Lighting Without Heat." Only the unfortunate condition of the health of Mr. Tesla has postponed his compliance with his engagement in this connection. In order to keep faith, so far as possible, with the readers of the Magazine, there is presented herewith a paper by an electrical engineer who enjoys the acquaintance of Mr. Tesla, reviewing the discoveries of the latter gentleman which it was hoped that the inventor himself would be able to describe for us. The paper thus prepared has received the approval of Mr. Tesla, who, indeed, furnished personally some of the suggestions upon which it is based.—THE EDITOR.

ing or undulating current over a steady current such as heretofore used in arc-lighting is, that one is able to dispense with a large resistance in the dynamos and lamps which are necessary in order to obtain a steady light. This produces a greater economy in the circuit all along. For transmission purposes its advantages so far outweigh its disadvantages as to make it the method *par excellence*. Alternating-current motors enable us to obtain results which are not possible with motors heretofore used, namely: the motor may be made to run in perfect synchronism with the generators. In the ordinary motors the speed as is known falls below this increase, but not so in the motors just mentioned. But if one desires it is possible also to exactly imitate an ordinary direct-current motor and produce a machine which will have a great effort on the start.

Mr. Tesla conceived an idea which has entirely overcome the shortcomings of the alternating current as applied to motors. Every one knows—or at least is easy of demonstration—that if the north and south poles of a small horseshoe magnet be suspended over a bar of soft iron free to revolve in a horizontal plane, or be placed over an ordinary compass-needle, the latter will be attracted at either end by the poles of the magnet and take up a position parallel to a straight line drawn between the two poles of the magnet. Now if the latter be revolved through any angle the soft iron or needle will follow, being dragged around by the magnet, and if the magnet be caused to revolve regularly the iron will also revolve, being pulled around by the full force of the magnet. It was not feasible, however, to cause the magnet to revolve in this way, and Tesla's invention consisted in obviating this trouble and, in fact, in greatly simplifying the problem. He conceived the idea that if he took an iron ring and used two alternating currents, one of which had its maximum value at the instant that the other had a zero value—or, in other words, two currents whose periods were such that one waned as the other increased—he could produce in that iron ring by winding these circuits in alternate coils surfaces that without any mechanical movement of the parts would travel around that ring with a rapidity equal to the number of changes of direction of the currents employed. He thus had a ring, the north and south poles of which were rapidly revolving just as would the poles of the horseshoe magnet were it tied at its middle to a twisted string and allowed to revolve. A piece of iron pivoted at its middle placed concentric with this ring would therefore be dragged around by the changing poles of the ring. He had thus discovered what is somewhat awkwardly expressed by the expression, "the rotary magnetic field," and also the use of what have been termed "polyphased currents"—the one referring to the magnetism and the other

to the combination of currents by which this changing magnetism was produced. This discovery is undoubtedly one of the most important that has ever been made within the domain of alternating currents, and marks a most important step in applied electricity; in fact, it may be said to have been epoch-making, for without this method the experiment of transmitting 100 horse-power, 108 miles from Lauffen on the falls of the Neckar to the Frankfort Exposition grounds, in 1891, would have been impracticable.

If two separate currents are employed as Tesla employs them, we have what is called a "diphased" system; if three are employed it is called a "triphased" system; but in speaking of the employment of more than one current the generic term "polyphased" is used. Tesla's discovery is the basis of them all. The Frankfort-Lauffen experiment referred to was operated on the three-phased system. The great scheme of transmitting Niagara's power to distant points, which in magnitude far surpasses the former experiment, will employ the original Tesla diphased system.

His first successful experiment was in 1883, but the first practical motor that showed good efficiency was only obtained in 1887. Ferraris published a pamphlet bearing on the broad principles and some features of the discovery in May, 1888, but six months prior to this, that is in October, 1887, Tesla's first fundamental applications were filed in the Patent Office in Washington.

There is no conflict between Ferraris and Tesla, each according to the other full honor and credit for the work individually done.

As before stated, the discovery of the rotary field has nearly revolutionized the practice of tranmission of energy by alternating currents and the practical value of the invention is fully attested by the adoption by the most eminent experts in the world of the Tesla system for the Niagara electrical plant, by which it is proposed to transmit eventually at least 100,000 horse-power from the falls to various points along the Erie canal, as far as such transmission may prove economical. This invention at once attracted the eyes of the scientific world to Mr. Tesla, who was until then comparatively unknown. He has, however, been an indefatigable worker and has made many inventions which have attracted little attention, often only because of their lesser importance. Mr. T. Commerford Martin, in his exhaustive work on the "Inventions, Researches, and Writings of Nikola Tesla," catalogues 137 inventions or discoveries made by this man. There is not room here for even this catalogue and in discussing his work it will be necessary for me to confine myself strictly to a few of his accomplishments upon which his fame chiefly depends.

Mr. Tesla early turned his attention to phenomena of alternating

currents of high frequency and high potential. These brilliant effects which have so much interested scientific men are obtained in his experiments by a peculiar arrangement of condensers and coils, which enables him to obtain enormous potentials of a million volts or more which are alternated in direction many million times a second, if necessary. In the reports of his lectures his apparatus is minutely described, but limited space does not permit me to dwell upon it here. Others had experimented with currents of several thousand volts and as many reversals or more per minute. The phenomena thereby produced were so interesting as to lead Mr. Tesla to explore the field further. He employed currents of hundreds of thousands of volts and having more than 2,000,000 reversals per minute. With these elements at hand he possessed the key with which he unlocked entirely unexplored avenues and produced effects, especially of light, that literally dazzled the scientific world.

Maxwell had taught the world to believe that ordinary light was due to electromagnetic waves of the ether, having a frequency per second of 5 with 14 ciphers after it. He did not prove this, but arrived at his conclusions through mathematical logic. Later Heinrich Hertz proved the truth of these deductions experimentally. This meant that if, by any possible means, we could artificially produce ether waves of this frequency, we would have light without heat and a useful efficiency for the energy expended of about 99 per cent. instead of an efficiency of less than 1 per cent. as obtained in our best gas-burners. We can readily produce etheric waves of a frequency of some hundreds of thousands and even millions, but these fall far short of the requirements in the case, and there were practical obstacles in the way preventing the slightest hope of our ever being able to produce the required frequency or to transmit them if we could produce them. It was Tesla's idea that the desired results were possible of attainment by means of powerful electro-static effects which, by the way, he was able to produce by his peculiar methods and apparatus invented for this purpose and high potentials.

Of course the general bearing of these experiments is upon the problem of an efficient production of light, but in his lectures many scientific facts are pointed out, which contributed to a radical change in scientific opinion in regard to a number of phenomena. So for instance it was demonstrated that a gaseous medium like air, when electric stress of great intensity and frequency were made to act through it, becomes rigid. The agitation produced by the stress in the molecules of the air is such as to render the air luminous, and he produced in some experiments streams of light by merely charging the body. In fact it appears possible from some experiments that a flame might be produced which would appear to be ordinary gas-flame and yet it would be a solid. The phenomenon of the aurora borealis and of the electric storms are usually attributed to the changes of the potential of the sun. A very important fact was demonstrated that in an electrical condenser and in any insulating material, the air must be kept away. As long as this fact was not known it was not possible to properly insulate parts of high tension.

I give here a paragraph on this subject in his own words: *

> But powerful electro-static effects are a *sine qua non* of light-production on the lines indicated by theory. Electromagnetic effects are primarily unavailable, for the reason that to produce the required effects we would have to pass current impulses through a conductor, which, long before the required frequency of the impulses could be reached, would cease to transmit them. On the other hand, electromagnetic waves many times longer than those of light, and producible by sudden discharge of a condenser, could not be utilized. . . . . We could not affect by means of such waves the static molecular or atomic charges of a gas, cause them to vibrate and emit light.
>
> *To produce such luminous effects, straight electro-static thrusts are required; these, whatever be their frequency, may disturb the molecular charges and produce light.*

It is to be regretted that lack of space here prevents the elucidation of the terms used, but the fact will be well understood without this, that the production of light practically without heat is within the bounds of possibility. This was Tesla's grand discovery and it was this that dazzled the mental vision of the scientific world. It only remained for him to illustrate his theory by experiments that the physical vision of the world should also be dazzled. He further says:

> It has occurred to me, however, that electro-static effects are in many ways available for the production of light. For instance, we may place a body of some refractory material in a closed, and preferably more or less exhausted globe, connect it to a source of high, rapidly-alternating potential, causing the molecules of the gas to strike it many times a second at enormous speeds, and in this manner, with trillions of invisible hammers, pound it until it gets incandescent; or we may place a body in a very highly exhausted globe, in a non-striking vacuum, and by employing very high frequencies and potentials, transfer sufficient energy from it to other bodies in the vicinity, or in general to the surroundings, to maintain it at any degree of incandescence, or we may, by means of such rapidly alternating high potentials, disturb the ether carried by the molecules of a gas or their static charges, causing them to vibrate and to emit light.

Here are clearly enunciated three distinct methods of producing light by electro-static action, any one of which would have startled the scientific world if founded solely on hypothesis. Tesla's announcement was based on no such unstable basis as this, however; it was based on experimental data which he reproduced before his audiences. Some of these effects had in fact been produced in a feeble way by previous investigators in a somewhat different manner, but it remained for Tesla to bring them out in a far more brilliant way than any of his predecessors and thereby to call attention to their importance that they had not previously attracted. In regard to this, he says:

* Tesla's lecture before the American Institute of Electrical Engineers, delivered at the School of Mines, Columbia College, May 20, 1891.

But electro-static effects being dependent upon the potential *and* frequency, to produce the most powerful action it is desirable to increase both as far as practicable. [Tesla was the first to realize and practise this.] It may be possible to obtain quite fair results by keeping either of these factors small provided the other is sufficiently great; but we are limited in both directions. My experience demonstrates that we cannot go below a certain frequency, for, first the potential then becomes so great that it is dangerous; and secondly, the light production is less efficient.

Speaking of what has been termed the bombardment method (the first of the three above mentioned), he says:

There is no difficulty in reaching such high degrees of incandescence *that ordinary carbon is to all appearance melted and volatilized.* If the vacuum could be made absolutely perfect, such a lamp, although inoperative with apparatus ordinarily used, would, if operated with currents of the required character, afford an illuminant which would never be destroyed, and which would be far more efficient than an ordinary incandescent lamp.

In lamps constructed on this principle, the filament or button of refractory material was connected to but one terminal of the circuit instead of to both as necessary in present practice.

In regard to the second method, Mr. Tesla says:

The use of alternating currents of very high frequency makes it possible to transfer, by electro-static or electromagnetic induction through the glass of the lamp, sufficient energy to keep a filament at incandescence and *so do* away with the leading in wires. Many forms of lamps on this principle with continuous and broken filaments have been constructed by me and experimented upon.

Thus far he had used in the first case a single connection to the source of energy and in the second no connection at all, but in both cases some refractory material within the globe was brought to incandescence and served as the light-giving body. In the third method, however, he used neither connections nor filaments or buttons, but merely exhausted tubes having no electrodes whatever. Such tubes when grasped in the hands of the experimenter standing near an induction coil became luminous themselves. This seems to be a most remarkable phenomenon, as there is nothing from which the light can emanate. It would seem that the tubes were filled with a luminous substance which was light itself. Speaking of this phenomenon he says:

In all cases, then, when we excite luminosity in exhausted tubes by means of such a coil, the effect is due to the rapidly alternating electro-static potential and furthermore it must be attributed to the harmonic alternation produced by the machine and not to any superposed vibration which might be thought to exist.....In all the last-described experiments, tubes devoid of any electrodes may be used and there is no difficulty in producing by their means sufficient light to read by. The light effect is, however, considerably increased by the use of phosphorescent bodies such as yttria, uranium glass, etc.

But he caps the climax of this brilliant series of experiments by producing conditions whereby a vacuum tube without electrodes may be moved anywhere within the room and, with no connection whatever to the walls, still remain luminous. He says:

For this purpose I suspend a sheet of metal a distance from the ceiling on insulating cords and connect it to one terminal of the induction coil, the other terminal being preferably connected with the ground; or else I suspend two sheets, each being connected to one terminal of the coil, and their size being carefully determined. An exhausted tube may then be carried in the hand anywhere between the sheets or placed anywhere, even a certain distance beyond them; it remains always luminous.

During this lecture Mr. Tesla performed all of the experiments referred to and many more before his audience and then, summing up his own belief as to their value, he said:

How far the results here borne out are capable of practical applications will be decided in the future. As regards the production of light, some results already reached are encouraging and make me confident in asserting that the practical solution of the problem lies in the direction I have endeavored to indicate. Still, whatever may be the immediate outcome of these experiments I am hopeful that they will only prove a step in further development towards the ideal and final perfection. The possibilities which are opened by modern research are so vast that even the most reserved must feel sanguine of the future. Eminent scientists consider the problem of utilizing one kind of radiation without the others a rational one. In an apparatus designed for the production of light by conversion from any form of energy into that of light, such a result can never be reached, for no matter what the process of producing the required vibrations, be it electrical, chemical, or any other, it will not be possible to obtain the higher light vibrations without going through the lower heat vibrations. It is the problem of imparting to a body a certain velocity without passing through all lower velocities. But there is a possibility of obtaining energy not only in the form of light, but motive power, and energy of any other form, in some more direct way from the medium. The time will be when this will be accomplished, and the time has come when one may utter such words before an enlightened audience without being considered a visionary. We are whirling through endless space with an inconceivable speed; all around us everything is spinning, everything is moving, everywhere is energy. There *must* be some way of availing ourselves of this energy more directly. Then, with the light obtained from the medium, with the power derived from it, with every form of energy obtained without effort, from the store forever inexhaustible, humanity will advance with giant strides. The mere contemplation of these magnificent possibilities expands our minds, strengthens our hopes, and fills our hearts with supreme delight.

While none of these experiments on light have developed into practical processes, they constitute one of the most remarkable contributions to physical science since the days of Faraday. In the brilliancy of their conception and the beauty of the results obtained we are apt to lose sight of the great inventive genius that was required to devise and prepare apparatus suitable for their public production. Nowhere has the genius of Tesla been displayed to better advantage than in the production of suitable means to the desired ends, and the last public announcement he has made was a description of a mechanical and electrical oscillator by which his investigations of alternating currents would be facilitated.

His lecture of May 20, 1891, echoed around the world and attracted the attention of the gray-haired savants of Europe. He was at once besieged by invitations to repeat his lecture abroad and, on

February 3, 1892, he delivered his lecture with some additions before the most learned men of England, and received at their hands an ovation such as has perhaps never before been accorded to a scientific man. The last public appearance of Mr. Tesla was in a lecture during the Electrical Congress at the World's Fair, which was attended by the principal savants of Europe and America.

But Mr. Tesla is having the experience of all pioneers whose work does not show immediate practical results. One of the leading savants of Europe said to me after Tesla's last lecture: "His work is brilliant, but of what use is it? I would rather see him devote his energies to something more practical."

At this lecture Mr. Tesla exhibited and described a mechanical oscillator in which he had great confidence. He believed that its future possibilities in a practical way were great. He is still of that opinion and, notwithstanding the criticism just quoted, Mr. Tesla says that this invention contains the germ of the most practical work he has ever done. He probably knows best about this and we shall await the outcome with great interest. We are not at liberty to speak freely concerning this invention at this time, but when Mr. Tesla is ready to make an announcement we may hear something startling.

I believe that this sentiment finds considerable response among the scientists abroad. Faraday was constantly met with the question, *cui bono?* and Tesla cannot hope to escape the same experience. Faraday's minute electric spark obtained by electromagnetic induction was his baby. The question was reiterated, *cui bono?* That baby has now grown to man's estate and appears in the form of the 5000 horse-power Tesla generators now nearly completed for the great Niagara Falls transmission plant. The experiments in light, a few of which I have briefly referred to, are Tesla's babies. Who knows how they may appear in mature development?

My own estimate of Tesla is that his is one of the most vigorous and original minds the world has ever produced. Whether he will ever rank with Faraday, whom he resembles in many ways, I do not know, but there is no one in history whose work and character so closely resembles Faraday's to my mind as Tesla's. But Tesla's work is not finished. He is now engaged on something which he tells me he regards as the best work that he has ever done. What it may be the near future will disclose. It is unfair to write one's eulogium until his work is done. Tesla's work, perhaps, has only commenced.

NIKOLA TESLA AND HIS WORKS.

IN the *New Science Review* Lieut. F. Jarvis Patten gives a sketch of Nikola Tesla, together with a short account of what this distinguished young scientific investigator and inventor has accomplished. Before the advent of Tesla into the scientific field, we learn from Lieutenant Patten that out of both pure theory and physical research the general conclusion had been arrived at "that all manifestations of energy are but the different tangible or apparent evidences of one and the same force; that all energy, whatever its form of manifestation, is simply molecular agitation of greater or less degree." This being true, it follows that heat and light are merely the results of molecular agitation, and could this agitation be set up by purely mechanical means, heat or light would result. Tesla conceived the bold idea that by causing matter to pass to the stage of luminous vibration, without remaining for any appreciable time in the stage of heat vibration, it would produce light without heat; and, says Lieutenant Patten, "so near has he come to the practical acccomplishment of this conception that he has set the scientific minds of all Europe thinking, and placed his name beside that of Hertz."

HIS BEGINNINGS.

Tesla was born in Herzegovina, near the western borderland of Turkey, and in early youth was a pupil of the government schools where he lived. His twenty-third year found him in Paris, whither he had come to study engineering at the Ecole Polytechnique. From this school he went to the Edison Station in Paris as an engineer, and later to the celebrated laboratory near Orange, N. J. He remained with Mr. Edison for several years, but having many ideas that he wished to develop independently, he left that employ, and has since conducted a laboratory of his own in New York, which has been devoted purely to physical research and scientific investigation.

"Mr. Tesla started with the idea of setting matter into vibration at a rate approximating that of light (some two and a half millions a second), with the expectation that under such violent molecular agitation it would emit light. He has not as yet succeeded in obtaining so high a rate, but a much lower one produced some very surprising luminous effects. The general plan at first was this: To construct an alternating current dynamo that would produce this high rate of current alternation or pulsation. This current, now known as the 'high frequency' current, will cause luminous effects in different media. Thus, in a darkened room, a bare copper wire conveying such a current will be seen to glow, and vacuum tubes will shine brightly, as a result of a molecular bombardment or agitation of the ether atoms, when such a current is sent through them under very high pressure—the very high electro-motive force of several hundred thousands of volts being used in most of his experiments of this character. The dynamo method for getting very high frequencies was soon abandoned as inadequate, and the oscillatory discharge of a Leyden jar or plate condensers was substituted. This answered much better, although the frequency was then an unknown quantity and quite beyond control; and this departure led to the discovery of some very beautiful electro-static effects, which are still being pushed by many investigators with the hope of arriving at some result of commercial value."

HIS INVESTIGATIONS.

"Mr. Tesla claims that all electric and magnetic effects are traceable to the action of electro-static molecular forces, and in confirmation of this theory he produces what appears to be a veritable flame by the action of electro-statically charged molecules of gas. A flame is actually shown issuing from the tip of a wand, or from the ends of his fingers, which flame is devoid of heat, and by it no material is consumed. Perhaps the most surprising of the new facts elicited from his investigations is that the shock due to these very high voltage and high frequency currents can be supported by a person without any serious inconvenience. He passes a current of 200,000 volts through his body with perfect impunity, whereas one of 2,000 volts will produce almost certain death from even a momentary shock. In one experiment, two wires are stretched parallel to each other across the room. When given the high tension current they emit streams of light, or brush discharges so profusely that light enough is produced to distinguish objects in the room. If the wires are bent into concentric hoops, one inside the other in the same plane, the annular space between them is filled with streamers that make a sheet of flame a yard or more in area.

"Mr. Tesla is viewed by some as an impractical inventor—a mere visionary enthusiast—but this is hardly fair to one who has built up an entirely novel method for the experimental investigation of physical phenomena. This method, with its vast array of beautiful experiments, is original, and goes some steps beyond any point reached by previous work in the same line. There seems to be little of practical value in it for the electrical engineer."

To the practical man of electricity Mr. Tesla stands as the inventor of the rotary field motor, which he brought forth in 1888. Some idea of the importance of this discovery may be had when it is known that the largest electrical enterprise in the world, the 50,000 horse-power plant for sending the Niagara water power to Buffalo and other distant towns, will use the multiphase system that Tesla announced to the world through this motor.

Nikola Tesla.

The Sunday World of July 22 prints an interesting half-page article on Nikola Tesla, written by Mr. Arthur Brisbane, and accompanied by a portrait which we reproduce, without, however, the full caption which was as follows: "Nikola Tesla. Showing the Inventor in the Effulgent Glory of Myriad Tongues of Electric Flame After He Has Saturated Himself with Electricity." In deference to the well-known modesty of Mr. Tesla, we will not reproduce the newspaper writer's highly complimentary description of his personality and achievements, but confine ourselves to the following extracts, containing his remarks on the future of electricity and on the effects on the human body of high voltages coupled with high frequencies.

In answer to a question from the interviewer as to what he hoped to see accomplished by means of electricity, Mr. Tesla replied: "You would think me a dreamer and very far gone if I should tell you what I really hope for. But I can tell you that I look forward with absolute confidence to sending messages through the earth without any wires. I have also great hopes of transmitting electric force in the same way without waste. Concerning the transmission of messages through the earth, I have no hesitation in predicting success. I must first ascertain exactly how many vibrations to the second are caused by disturbing the mass of electricity which the earth contains. My machine for transmitting must vibrate as often to put itself in accord with the electricity in the earth."

When asked if he did not feel a little worried about taking a current of a quarter of a million volts, Mr. Tesla said, "I did at first feel apprehensive. I had reasoned the thing out absolutely; nevertheless, there is always a certain doubt about the practical demonstration of a perfectly satisfactory theory. My idea of letting this current go through me was to demonstrate conclusively the folly of popular impressions concerning the alternating current. The experiment had no value for scientific men. A great deal of nonsense is talked and believed about 'volts,' etc. A million volts would not kill you or hurt you if the current vibrated quickly enough—say half a million times to the second. Under such conditions the nerves wouldn't respond quickly enough to feel pain. You see, voltage has nothing to do with the size and power of the current. It is simply the calculation of the force applied at a given point. It corresponds to the actual pressure per square inch at the end of a water pipe, whether the volume of the water be great or small. A million volts going through you doesn't mean much under proper conditions. Imagine a needle so small that the hole it would make in going through your body would not allow the blood to escape. Imagine it so small that you couldn't even feel it. If you had it put through your arm slowly, that would be, electrically speaking, a very small voltage. If you had it stuck through your arm with great rapidity, going, say, at the rate of a hundred miles a second, that would be very high voltage. Voltage is speed pressure at a given point. It wouldn't do you any more harm to have a needle shot through your arm very rapidly—that is to say, with high voltage—than it would to put it through slowly. In fact, if it hurt you at all, the slow operation would probably hurt more than the other. The question of danger is simply the size of current, and yet if a big enough current should be turned against you and broken with sufficient rapidity—if it should, so to speak, jerk back and forth an inconceivable number of times to the second—it wouldn't kill you. Whereas, if applied continuously, it would simply burn you up."

NIKOLA TESLA.

NIKOLA TESLA AND HIS WORK.

LIEUT. F. JARVIS PATTEN contributes to *The New Science Review*, New York, July, an interesting account of the work of the young electrician Nikola Tesla, whose inventions have already been mentioned frequently in these columns. He says:

"Tesla conceived the bold idea that by causing matter to pass to the stage of luminous vibration without remaining for any appreciable time in the stage of heat vibration, it would produce light without heat; and so near has he come to the practical accomplishment of this conception that he has set the scientific minds of all Europe thinking. . . .

"What first brought him into prominence, and gave him the means to go farther, was his discovery of the 'Rotary-Field Motor,' an invention of marked originality and beauty, but not appreciated at its full value at the time of its discovery. Announced by him and commercially disposed of in 1888, it is now just coming into general use. Simple and beautiful as it seemed, our knowledge of electrical engineering was not then equal to the task of making the machine electrically right. European engineers, however, held to the work, and, following in their footsteps, we now understand the rotary-field motor; and the largest electrical enterprise in the world, the fifty thousand horse-power plant for sending the power of Niagara to light Buffalo and other distant towns, will use the multiphase system that Tesla first gave to the engineering world six years ago.

"An apt illustration of the difference between the purely theoretical or scientific mind and the semi-practical mind guided by scientific training suggests itself here. Professor Ferraris of Turin independently discovered and announced the principle and operation of the rotary-field motor at about the time that Tesla did the same thing in this country. The professor's announcement was in the form of a paper to a scientific society. Tesla made many forms of the machine, reduced his theory to a practical operative device, and having protected his invention by many patents he exhibited his machines to the American Institute of Electrical Engineers in May, 1888. Professor Ferraris' description, however, antedates Tesla's exhibition by some months. . . .

"Before considering Tesla's more recent work, it seems appropriate to describe briefly the salient features of this machine, which can be best done by comparing it with the ordinary type of electric motor. This in general terms is an engine having a fixed and a revolving part, of which the latter, turning about its spindle, communicates motion to other machinery. The moving part is always provided with commutating devices that constantly shift the magnetic axis backward, in the same measure and degree that the moving part turns forward. These devices are always intricate and complex. They are in fact the weak part of all electric engines. The Tesla rotary-field machine, being entirely free from them, is a marvel of simplicity and ingenuity. To understand this machine one must picture an iron-ring and conceive it to be magnetized along a vertical diameter, the North Pole being at the top; then a moment later along a horizontal diameter with the North Pole at the right; again along the vertical diameter but North Pole at the bottom, and lastly on the horizontal line again with North Pole at the left, thus completing a revolution of the North Pole around the ring. Such an effect is called a rotating magnetic field, and can be perfectly produced by the simultaneous use of two independent alternating currents, which follow each other periodically in such a way that one has always a maximum value or strength when the other is zero, and conversely. If now the iron ring is wound all around with a coil

of wire closed on itself, and one such current be introduced to this winding at the extremities of a vertical diameter, while another is simultaneously introduced to the same winding at the extremities of a horizontal diameter, they will jointly produce a revolving magnetic field that turns continuously around the ring, while the latter remains fixed in space. We then have a fixed magnet, but the magnetism itself, or magnetic axis, is in motion. A compass or magnetic needle suspended freely inside the ring would spin around in its endeavor to follow the revolving magnetism or the shifting magnetic axis of the ring. . . .

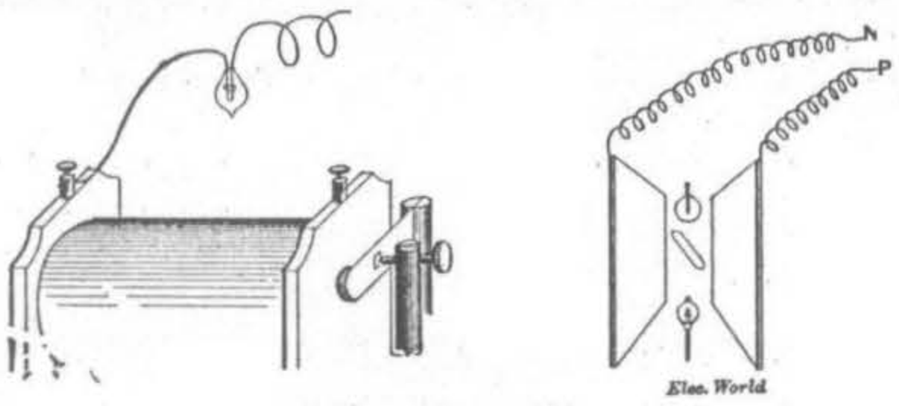
"Having disposed of his motor Mr. Tesla devoted himself to the establishment, by experimental process, of the identity of light and some form of electrical manifestation of energy. . . .

"Mr. Tesla started with the idea of setting matter into vibration at a rate approximating that of light (some two and a half millions a second) with the expectation that under such violent molecular agitation it would emit light. He has not yet succeeded in producing so high a rate, but a much lower one produced some very surprising luminous effects by currents of high frequency. In these experiments the dynamo was abandoned as inadequate and the Leyden-jar substituted. . . . The scientific minds of Europe were quickly at work investigating the so-called Tesla effects, the result being that the electromagnetic theory of light may be regarded as proven, while it seems equally well established that light without heat is not to be looked for as one of the Tesla effects.

"Mr. Tesla claims that all electric and magnetic effects are traceable to the action of electrostatic molecular forces, and in confirmation of this theory he produces what appears to be a veritable flame by the action of electrostatically charged molecules of gas. A flame is actually shown issuing from the tip of a wand, or from the ends of his fingers, which flame is devoid of heat, and by it no material is consumed. Perhaps the most surprising of the new facts elicited from his investigations is that the shock due to these very high voltage and high frequency currents can be supported by a person without any serious inconvenience. He passes a current of two hundred thousand volts through his body with perfect impunity, whereas one of two thousand volts will produce almost certain death from even a momentary shock. In one experiment, two wires are stretched parallel to each other across the room. When given the high tension current they emit streams of light, or brush discharges, so profusely that light enough is produced to distinguish objects in the room. If the wires are bent into concentric hoops, one inside the other in the same plane, the annular space between them is filled with streamers that make a sheet of flame a yard or more in area. . . .

"There seems to be little of practical value in this for the electrical engineer. So we may say that to the physicist Mr. Tesla stands as the pioneer of a new and wide field of research, while before the practical man of electricity he stands as the inventor of the 'rotary-field machine,' a beautiful and unique conception, which he soon left for the practical man to figure out."

Tesla Effects with Simple Apparatus.



BY H. M. MARTIN AND W. H. PALMER, JR.

All who visited the room in the Electricity Building at the World's Fair in which Mr. Tesla's high frequency apparatus was exhibited must have brought away with them a lively desire to repeat at their leisure the beautiful and interesting experiments there shown; but a recollection of the many expensive appliances used in obtaining the effects has doubtless deterred many from entering upon what must prove a valuable and absorbing line of study. It is the object of this paper to show that no one need fear failure in this field who has at his command the simple apparatus to be found in the most unpretentious laboratory; nor should it be thought that results are less instructive or of smaller scientific value when obtained in this way than when obtained by the use of more powerful apparatus.

Some years ago the writers, while testing a small Ruhmkorff coil, connected up a burnt-out miniature incandescent lamp between the secondary terminals. On closing the primary circuit the usual violent discharge was set up between the broken ends of the carbon. While the current was on one of the connections became unfastened, leaving the lamp joined to only one of the coil terminals, as in Fig. 1; and the discharge instead of being extinguished, changed to a soft glow that filled the whole interior of the lamp. This was, on a small scale, identical with the experiment performed so brilliantly by Mr. Tesla during his London lecture, when he lighted an exhausted bulb, having a sealed-in electrode, through a single lead from a source of high potential and frequency.

Although this experiment was often repeated, its significance was not realized until Mr. Tesla made known the results of the researches which have entitled him to rank among the foremost investigators of our times. But the published report of the lecture placed the previous experiment in its true light, and inspired a hope that other effects might be duplicated with the feeble apparatus at hand. The results have more than fulfilled our expectations.

The necessary potential and frequency were obtained from a small

FIGS. 1 AND 2.

Ruhmkorff coil capable of giving a quarter-inch spark when operated by three Bunsen cells.

Two insulated metallic plates 12"x12" in size were placed about three inches apart and connected with the terminals N and P (see Fig. 2). Exhausted bulbs, miniature incandescent lamps, Geissler tubes, etc., were then introduced between the plates, and glowed brightly without any direct connection with the plates or coil. Actual photometric measurements of the maximum light emitted by this arrangement show it to be greater than that obtainable by using the current directly in an incandescent lamp. This is significant as showing the poor economy of the present methods of electric lighting, and leads us to believe that molecular bombardment electrostatically sustained contains great possibilities in this connection.

A slight modification of this arrangement makes it possible to dispense with one of the two plates. In all these experiments the battery cells act as a species of reservoir or condenser, so that tubes and bulbs lying in their vicinity are often seen to glow brightly and fade, in proportion as the capacity of the apparatus is changed.

Incandescent lamps may be lighted through a single lead from one of the secondary terminals; this effect is greatly heightened if the hand or some other object of capacity is placed near the lamp bulb. The small 6 c. p. lamps are peculiarly adapted for use in these experiments, their shape seeming to concentrate the molecular bombardment upon the carbon filament.

If a good mercurial air-pump is not accessible, vacuum tubes that will serve for want of better may be obtained by heating mercury in a piece of tubing, and sealing the end after the mercury has reached the boiling point. A pretty experiment may be performed by holding the exhausted tube in one hand, with one end near the coil terminal, and then passing the other hand down the length of the tube, extinguishing the glow and giving the effect, as a friend expressed it, of "wiping the moonshine off."

Many other combinations will suggest themselves to the investigator, but there is one experiment which, since it depends upon a principle that has not, to the writer's knowledge, received as yet any published explanation, should be of special interest.

This phenomenon, a description of which has already appeared in

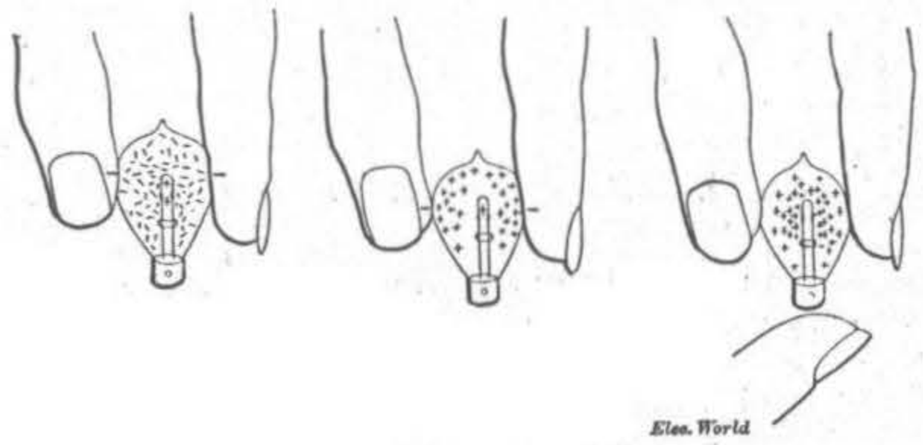


FIG. 3.

these columns,* may be satisfactorily observed with the small induction coil by proceeding as follows:

Holding the bulb of a miniature incandescent lamp in the hand, bring the leading-in wire into contact with the coil terminal; the bulb will be filled with the usual phosphorescent glow. If, now, the lamp is slowly withdrawn from contact with the terminal, this light will gradually fade, as the confines of the field are approached, and concentrate itself around the interior carbon. Soon a point will be reached beyond which the glow does not diminish through further removal from the coil. It is now quite self-sustained, and cutting the current off from the coil will not effect it in any perceptible way. This phenomenon we have called the "afterglow."

When obtained in this way, the afterglow will continue for from one to two minutes after the coil is shut off. The lamp may be carried glowing from room to room; if put down out of the hand the light becomes fainter, but is not extinguished. After some minutes, when the glow has faded quite away, a sudden flash may be observed if the leading-in wire is touched with the finger. Several of these flashes may sometimes be obtained before the bulb is entirely discharged.

It must not be supposed that this glow is due to heat remaining in the lamp carbon, the heating effect of so weak a coil being quite insignificant. A consideration of the accompanying figures will show the purely electrostatic nature of this phenomenon.

When the lamp is withdrawn from the alternating field, the interior electrode retains a charge differing in sign or intensity from that of the rarefied gas in the bulb and that induced in the fingers of the experimenter, Fig. 3. The natural consequences of this state of unequal charge are molecular bombardments and collisions more violent in the immediate neighborhood of the electrode, because of the small surface over which its charge is distributed. When electrical equilibrium has been established between the gas molecules and the electrode, this interchange of charge ceases, and the glow dies away. The condition of affairs at this moment is shown in Fig. 4.

Discharging the electrode will now cause a sudden rush of molecules toward it to re-establish equilibrium (see Fig. 5), giving rise to the momentary flash observed, and this may be repeated until no charge remains in the lamp.

This is, perhaps, the simplest arrangement ever devised for obtaining light from electricity, and it may not be extravagant to say that it embodies the fundamental principles of an economical system of artificial illumination.

*"The Afterglow in Exhausted Bulbs," The Electrical World, Jan. 20, 1894.

jars 16 cm. in diameter and 42 cm. high, three lamps could be made to glow, hung over each other, one a 65-volt lamp at the bottom, then a 16-volt lamp in the middle and a 2-volt lamp at the top.

If the middle of the glass bulb of such a lamp is filed off it will either not glow or glow very little. Tesla explains this by the different bombardment of the molecules of the glass in the bulb, while the author ascribes the result to the different heat conducting power of the air which entered.

If the incandescent body is a platinum wire of 0.05 to 0.1 mm. diameter, it will oscillate rapidly while glowing, taking the form of a zigzag line, not in a single plane like a stretched string, but in all possible planes, thus representing a model of a ray of natural light. A condition for the success of the experiments is the use of an interrupter which operates with certainty, as also in the use of a proper spark micrometer. He recommends the Foucault interrupter with tough zinc amalgam instead of mercury, covered with machine oil. The spheres of the micrometer are best made of zinc.

A Tesla transformer was constructed as follows: On a glass cylinder of 4 cm. diameter he wound 10 turns of a 4 mm. wire, with a distance between the windings of 1 cm., over which a thick glass cylinder, or better, a hard rubber cylinder of 6 mm. thickness, was placed, and on it were wound 200 windings of a 1 mm. wire. In order that the distance between the windings may be made 1 mm. two similar wires were wound next to each other, after which one of them was again unwound. The transformer was placed horizontally in an earthenware vessel filled with machine oil, and supported on hard rubber, and the secondary winding ended in two metallic balls on hard rubber pillars. The primary winding was connected with the Leyden jars in place of the above mentioned U form wire. When the interrupter is in action, brush discharges will appear at the knobs; if a conductor is placed near them, bright sparks will pass to it. Between two parallel wires connected to these knobs, a bright band of light of three to four metres in length will be formed.

If one pole is connected to earth and the other to a thin wire 15 to 20 cm. long which hangs freely suspended, it will begin to move and describe a cone-shaped figure which is distinctly visible in the dark on account of the brush discharges which take place from it.

If a person takes hold of one pole of such a coil, bundles of rays can be drawn out from any part of his body near which a conductor is approached. If the person is standing on a metallic plate a prickling sensation will be produced in the feet; in the dark, discharges will be seen to pass out of the shoes. If several persons are connected together the first taking hold of one pole of the transformer, while the last holds a Geissler tube with or without electrodes, this tube will be brightly illuminated, although none of the persons will feel the discharges.

If one pole is connected to earth and the other to a large metal sphere, 60 cm. in diameter, Geissler tubes will be brightly illuminated at distances of from three to four metres from this sphere.

An incandescent lamp connected with the pole which is not connected to earth shows only the pale light of a Geissler tube. But if a large metallic disc is connected to the glass bulb, the lamp will glow brightly. The filament will, in that case, oscillate so that it soon breaks. If a conductor be approached to the point of the lamp this point will be immediately pierced by the current and a continual bright stream of sparks will pass through the opening, and the filament will at once begin to glow until it is consumed.

In the second part of his paper the author states that a Tesla coil is quite different in its actions from an ordinary induction coil. A Geissler tube connected in any way with the pole of a Tesla coil shows cathode light at both electrodes, an anode light in the middle. A commutation of the primary current or a reversal of the pole has no effect. An electroscope is always charged positively when it is approached with a pole terminating in a point. Both poles produce only positive Lichtenberg figures, never negative.

Researches with different gases show that this preponderance of the positive discharges from the pole of a Tesla coil depends on the surrounding medium. Air or oxygen promote positive discharges; hydrogen, illuminating gas, nitrogen, carbonic acid gas and ammonia, promote negative discharges.

If two points are connected with one pole, one in air and the other in hydrogen, positive and negative electricity will be discharged simultaneously from the same pole, depending on the surrounding gas. If one of the points is in oxygen, and if gradually more and more nitrogen is added, an electroscope opposite the point will at first show a moderate positive charge; with increasing quantities of nitrogen this will increase; when the mixture corresponds to that of air the positive charge will reach a maximum; if the nitrogen is

Tesla Currents with Simple Apparatus.

Mr. F. Himstedt publishes in Wiedemann's Annalen, vol. 52, page 473, some interesting researches with Tesla currents, produced by means of rather simple apparatus. We give below a translation of an abstract of this paper as published in the Elektrotechnische Zeitschrift, July 12.

The reason why the researches of Tesla have not been reproduced in Germany is probably due to the fact that the apparatus which he used was not at hand. It is very interesting to note that the author succeeded in reproducing most of the results with exceedingly simple apparatus. He at first used Lecher's arrangement for the production of Hertzian waves, but afterward used still better known apparatus, namely, Leyden jars.

He connected the pole of a powerful Ruhmkorff coil (50 cm. long and 20 cm. diameter, using from 5 to 6 accumulators) with the inner coatings of two moderately large Leyden jars, insulated from each other by being placed on paraffine; he also used a spark micrometer. The outer coatings of the jars were connected with a 4 mm. wire, 150 cm. long and bent in the shape of a U. A 16-volt incandescent lamp connected in parallel to this wire was brought to a white heat by proper adjustment of the micrometer. By using

in excess the charge will be reversed and will become negative. The process is similar if it is begun with nitrogen and the oxygen gradually added. With an ordinary induction coil the charge of an electroscope will be reversed when the primary current is reversed.

DIGEST OF CURRENT TECHNICAL ELECTRICAL LITERATURE

COMPILED FROM PRINCIPAL FOREIGN ELECTRICAL JOURNALS

BY CARL HERING

ELECTRO-PHYSICS.

Researches with Tesla Currents.—An abstract of a paper by Mr. Himstedt, published in the *Elek. Zeit.*, July 12, will be found translated in full in another column of the present issue.

TESLA EFFECTS WITH SIMPLE APPARATUS.*

ALL who visited the room in the Electricity Building at the World's Fair in which Mr. Tesla's high-frequency apparatus was exhibited must have brought away with them a lively desire to repeat at their leisure the beautiful and interesting experiments there shown; but a recollection of the many expensive appliances used in obtaining the effects has doubtless deterred many from entering upon what must prove a valuable and absorbing line of study. It is the object of this paper to show that no one need fear failure in this field who has at his command the simple apparatus to be found in the most unpretentious laboratory; nor should it be thought that results are less instructive or of smaller scientific value when obtained in this way than when obtained by the use of more powerful apparatus.

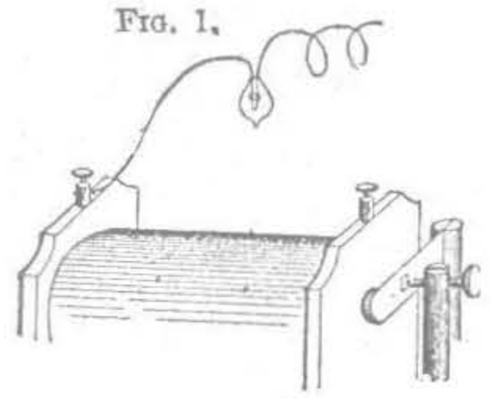
Some years ago the writers, while testing a small Ruhmkorff coil, connected up a burnt-out miniature incandescent lamp between the secondary terminals. On closing the primary circuit, the usual violent discharge was set up between the broken ends of the carbon. While the current was on one of the connections became unfastened, leaving the lamp joined to only one of the coil terminals, as in Fig. 1, and the discharge, instead of being extinguished, changed to a soft glow that filled the whole interior of the lamp. This was, on a small scale, identical with the experiment performed so brilliantly by Mr. Tesla during his London lecture, when he lighted an exhausted bulb, having a sealed-in electrode, through a single lead from a source of high potential and frequency.

Although this experiment was often repeated, its significance was not realised until Mr. Tesla made known the results of the researches which have entitled him to rank among the foremost investigators of our times. But the published report of the lecture placed the previous experiment in its true light, and inspired a hope that other effects might be duplicated with the feeble apparatus at hand. The results have more than fulfilled our expectations.

The necessary potential and frequency were obtained from a small Ruhmkorff coil capable of giving a ½in. spark when operated by three Bunsen cells.

Two insulated metal plates, 12in. by 12in. in size, were placed about 3in. apart and connected with the terminals N and P (see Fig. 2). Exhausted bulbs, miniature incandescent lamps, Geissler tubes, &c., were then introduced between the plates, and glowed brightly without any direct connection with the plates or coil. Actual photometric measurements of the maximum light emitted by this arrangement show it to be greater than that obtainable by using the current directly in an incandescent lamp.

Fig. 1.



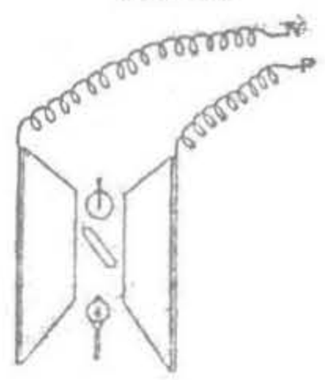


Fig. 2.

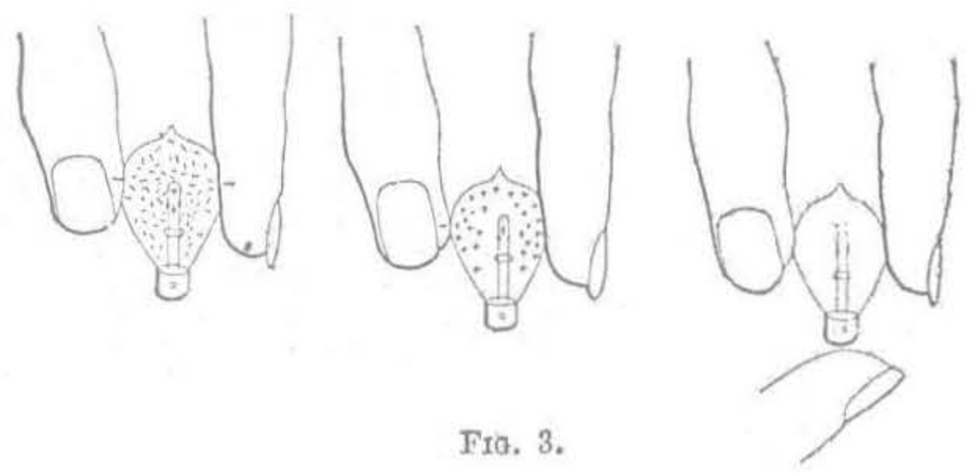

Fig. 3.

This is significant as showing the poor economy of the present methods of electric lighting, and leads us to believe that molecular bombardment electrostatically sustained contains great possibilities in this connection.

A slight modification of this arrangement makes it possible to dispense with one of the two plates. In all these experiments the battery cells act as a species of reservoir or condenser, so that tubes and bulbs lying in their vicinity are often seen to glow brightly and fade, in proportion as the capacity of the apparatus is changed.

Incandescent lamps may be lighted through a single lead from one of the secondary terminals. This effect is greatly heightened if the hand or some other object of capacity is placed near the lamp bulb. The small 6c.p. lamps are peculiarly adapted for use in these experiments, their shape seeming to concentrate the molecular bombardment upon the carbon filament.

If a good mercurial air-pump is not accessible, vacuum tubes that will serve for want of better may be obtained by heating mercury in a piece of tubing, and sealing the end after the mercury has reached the boiling point. A pretty experiment may be performed by holding the exhausted tube in one hand, with one end near the coil terminal, and then passing the other hand down the length of the tube, extinguishing the glow and giving the effect, as a friend expressed it, of "wiping the moonshine off."

Many other combinations will suggest themselves to the investigator; but there is one experiment which, since it depends upon a principle that has not, to the writer's knowledge, received, as yet, any published explanation, should be of special interest

* By H. M. Martin and W. H. Palmer, Jr., in the *Electrical World*, N.Y.

This phenomenon may be satisfactorily observed with the small induction coil by proceeding as follows:—

Holding the bulb of a miniature incandescent lamp in the hand, bring the leading-in wire into contact with the coil terminal; the bulb will be filled with the usual phosphorescent glow. If, now, the lamp is slowly withdrawn from contact with the terminal, this light will gradually fade as the confines of the field are approached, and concentrate itself around the interior carbon. Soon a point will be reached beyond which the glow does not diminish through further removal of the coil. It is now quite self-sustained, and cutting the current off from the coil will not affect it in any perceptible way. This phenomenon we have called the "afterglow."

When obtained in this way, the afterglow will continue for from one to two minutes after the coil is shut off. The lamp may be carried glowing from room to room. If put down out of the hand the light becomes fainter, but is not extinguished. After some minutes, when the glow has faded quite away, a sudden flash may be observed if the leading-in wire is touched with the finger. Several of these flashes may sometimes be obtained before the bulb is entirely discharged.

It must not be supposed that this glow is due to heat remaining in the lamp carbon, the heating effect of so weak a coil being quite insignificant. A consideration of the accompanying figures will show the purely electrostatic nature of this phenomenon.

When the lamp is withdrawn from the alternating field, the interior electrode retains a charge differing in sign or intensity from that of the rarefied gas in the bulb and that induced in the fingers of the experimenter, Fig. 3. The natural consequences of this state of unequal charge are molecular bombardments and collisions more violent in the immediate neighbourhood of the electrode, because of the small surface over which its charge is distributed. When electrical equilibrium has been established between the gas molecules and the electrode, this interchange of charge ceases, and the glow dies away. The condition of affairs at this moment is shown in Fig. 4. Discharging the electrode will now cause a sudden rush of molecules towards it to re-establish equilibrium (see Fig. 5), giving rise to the momentary flash observed, and this may be repeated until no charge remains in the lamp. This is, perhaps, the simplest arrangement ever devised for obtaining light from electricity, and it may not be extravagant to say that it embodies the fundamental principles of an economical system of artificial illumination.

NIKOLA TESLA AND HIS WORK

ADVANCING WITH CERTAINTY TO GREATEST TRIUMPHS.

Amazing Force Wasted in Making Electric Light—Economical Conversion of Available Energy—The Oscillator, Which Will Give to Most Machines the Value of Old Metal Only—Power of the Medium in Motion Around Us.

"Of the energy that goes to the making of electric light over 90 per cent. is wasted."

The statement is made on the authority of Nikola Tesla, and will be disputed by but few competent electricians. To explain the grounds on which it is made would be to elucidate some of the most elusive problems in physics, and to mark out the path of success for some of the most daring achievements of applied science. For, be it noted, it is electrical energy only of which Mr. Tesla speaks. No account is taken of the waste in combustion and in the many of the processes preceding the transformation of caloric into mechanical and mechanical into electrical energy.

Accepting Mr. Tesla's startling assertion in all its breadth, what a preposterous dissipation there must be of the energy stored in a lump of coal between its first liberation by combustion and its final appearance in its form of electric light! The waste of heat-

Nikola Tesla.

energy begins in the furnace, and is continued in every step of the process of generation, transmission, and conversion of the steam, so that it is one of the oldest and most stubborn commonplaces of mechanical engineering that a practical engine does not utilize more than 16 per cent. and sometimes not even as much as 5 per cent. of the heat energy employed to generate it. Besides, there is the loss by mechanical friction, in most cases equal to 35 per cent. on an average load of the engine, and the loss by belt friction, often equals 15 per cent. more—or 50 per cent. in all used up in the working of the engine itself, and in the transfer of the energy which it communicates to a piece of shafting. Even should that shaft be directly connected with an electric dynamo of good construction for conversion, there will be a further waste of certainly 20 per cent. in the dynamo itself. If the dynamo be worked in connection with an arc-lighting system, the loss will be high as 20 per cent., because of the unsteadiness of the electrical energy developed. And, between the dynamo and the carbon filament, or pencil, which is made the centre of an electric light, there ensues, as has been said, a loss of the potential energy conveyed to it of at least 90 per cent. To speak of the fluidity of scientific achievement in presence of waste on a scale like this is more than absurd.

Science and Invention to Save Energy.

In point of fact, science and her handmaid Invention are advancing by deliberate but perfectly confident strides toward a much more economical conversion of available energy. In the case of electric light, one may accept the correctness of the statement that it is not conceivable that the incandescent lamp can be much improved, and yet be forced to acknowledge that by a simple addition of purely mechanical application, the cost of producing the light may be reduced by one-half or even more. Suppose the steam engine and the electrical generator or dynamo, instead of being separate, should be combined in one. Suppose that the average 35 per cent. of loss by mechanical friction in the working of the engine should be saved, likewise the 15 per cent. of loss by belt friction and the 10 per cent. wasted in the dynamo, there would clearly be an addition of 60 per cent. to the available energy obtained from the steam for the purpose of producing electricity. Suppose, further, that the consolidated machine is much simpler, smaller, and lighter than the two which, which it is to replace; suppose it to be absolutely constant in its action, automatically regulated, and therefore available to the least possible amount of wear and tear, its advent would certainly mark a revolution, not only in the equipment of electric-light stations, but in many other fields of applied energy. These requirements Mr. Tesla seems to have met in the invention of the "oscillator." The essential characteristics of this very remarkable appliance may be briefly described to be the application of the pressure of steam to produce an extremely rapid vibration of a bar of steel or piston, which, in turn, is so adapted to a set of magnets that the mechanical energy of the vibrating bar is converted into electricity. Moreover, under certain conditions, the electrical vibration entirely governs the motion of the bar of piston, and, finally, by means of this appliance, the extraordinary result is reached that to all intents and purposes an absolutely constant vibration is established.

For reasons difficult to make plain without recourse to technical language, the great rapidity of this piston action admits of the use of steam at very high pressure, indeed, and lends itself to the development in this simply and economically constructed machine of power much in excess of that obtainable in the most costly expansion engines using a similar amount of steam. The primary purpose of the "oscillator" is to convert by a process as direct as possible the energy of steam into that of electricity. If the no rotary motion, because for its purpose rotary motion is not only unnecessary, but wasteful. If it be a question of generating electricity, for the production of light, all rotary motion in the mechanism is merely so much dissipation of energy. Dynamos and other reasons there can be no doubt about the impression which the "oscillator" will make in the lighting business. But if the machine does all that its inventor believes it can and will, it is also destined to have a very profound influence indeed on all the great branches of production and transportation. The fact is already recognized by all progressive men that the cheapest way of distributing power is by means of electricity. To say nothing about the enormous frictional losses due to the employment of extended systems of shafting and belting, account must be taken of the power wasted in moving long lines of shafting for the purpose of operating the small part which may be actually in use. When the transmission of power is made by electric energy, it is used only when and where it is needed.

Now, how it is recognized that it is most economical to convert the energy of the steam first into electricity, and then reconvert it into any form of motion that may be required, it is clear that the most successful signature of power production adapted to modern needs will be the one best fitted for the generation and economical generation of electricity. Mr. Tesla has done what may be called the core of a steam engine and the core of an electrical dynamo, given them a harmonious mechanical adjustment, and produced a machine which has in it the potentiality of reducing to a rate of waste of metal half the machinery at present moving on the face of the globe. It may come to do the work of the engines of an ocean steamship within a small part of the space they occupy and at a fraction of their cost, both of construction and operation. It will do the work, if all, without jar or pounding, and will reduce to a minimum the risk of derangement or breakage. There is nothing in the whole range of mechanical construction, from railway locomotives to stamp mills, which such an invention may not revolutionize.

Paradoxes in Tesla's Machine Involved.

It will be perceived that what has been outlined in regard to the construction of the "oscillator" involves some paradoxes in mechanics. If it is not to wear out, it must be destitute of friction, and must, therefore, present the anomaly of a steam cylinder and piston without packing, and yet admitting of no escape of steam. Still further, to bear out the claim of practical imperishability, the motion of the piston must be such as to produce molecular change in the metal calculated to weaken it, and the whole machine must be extremely simple in its adjustments and mode of operation in comparison with the highly complicated engines of to-day. There are engineers who will pronounce the attainment of these conditions to be impossible. But scientific men are becoming very cautious about the use of the word "impossible." It is less than twenty-five years since a man who had already won some reputation, then engaged in the construction of the present five-arch system of New-York, said to the writer that it would pay to use electricity as a motive power when we could get no feed steam boiler furnaces with piano frames. A steel rod vibrating without appreciable loss of energy, and without loss directly transforming the energy of its vibrations into electrical energy, may appear to be as much of a dream to the practical engineer of to-day, even on the eve of its realization, but when the genius of a scientific investigator of the first rank is combined with the genius of the inventor, humdrum people simply prepare to wait and watch.

They doubtless will be when Mr. Tesla's machine is sufficiently perfected to be introduced to the public, and it may surprise people who are hundreds of years in the future if this very beautiful piece of mechanical adaptation derives its chief value in the eyes of its inventor from the fact that it will enable him to pursue with new confidence some very far-reaching scientific investigations. It has given him a new tool, which promises to solve indispensable difficulties of certainty and uniformity of action hitherto lacking. This is by no means the only case in Tesla's scientific career in which he has demonstrated that practical achievements are simply the result of long speculative advance at the very outset of the path of investigation. He has already led him to a position of distinguished eminence, but even now the principle of the rotating magnetic field could be so applied as to reduce to a few hundred dollars the enormous and costly form of armature employed in the construction of motors. Scores of patents have been taken out by other men on inventions based on principles not his, which he has freely made for the guidance of his fellow-workers. But, brilliant as have been his practical achievements which directly or indirectly stand to Tesla's credit, he is only in the beginning of them, because he aims so extremely high. Electricians have an enormous respect for the man who applied the alternating current to motors, dispensed with brushes and commutators, and made an effective armature, formerly about as big as a cart wheel, not much larger than its hub. But these were relatively small things for the man whose goal of effort can be thus outlined: "We are whirling through space at an inconceivable speed all around us everything is spinning, everything is moving, everything is energy. There must be some way of availing ourselves of this energy directly. Then, with the light obtained from the medium, with the power derived from it, with every form of energy obtained without effort from the ever-flowing inexhaustible, humanity will advance with giant strides." This was said before the American Institute of Electrical Engineers at Columbia College in 1891. It was only the other day that Tesla repeated the same idea to the writer in a more confident form. "I expect to be able to set a machine in the middle of this room and move it by no other agency than the energy of the medium in motion around us." The three years which have elapsed since the delivery of this address have served only to deepen his conviction that the consummation hardly hoped for then is neither impracticable nor visionary.

Oscillator a Tool of Larger Problems.

When the key is found to the elimination of the chief waste of energy incidental to the production of electric light, then that consummation will not be far from our grasp. But, let it be noted that, however efficient the machine may be, it may prove impossible to be reducing the cost of generating the electricity that goes to the production of light, it marks only the first step toward the solution of greater problems in the working out of which it is to serve as a tool. The scientific as distinguished from the commercial value of the new machine, consists, as its inventor has pointed out, in its capacity for practically verifying theorizing currents of electricity whose frequency, i. e., rate of oscillation, whether high or low, is absolutely constant. Further progress in the direction whither Mr. Tesla's experiments are leading was all but impossible while the latter requirement was lacking. Some of the most perplexing problem which Tesla has set out to solve study popular fallacies, and even, indeed, almost transcend comprehension. But when it is stated that light is the result of etheric vibration of very high period and of a definite kind, much higher than the heat-producing vibrations, the same group of ideas that light production must be wasteful while it continues to be impossible to obtain the higher light vibrations without passing through the lower heat vibrations. No apparatus yet designed for the production of light, by any other form of energy, whether the process be electrical, chemical, or other has been able to avoid that necessity. Escape from it seems to be as impossible as from that of imparting to a body a certain velocity without passing through all lesser velocities.

But We Shall Not Be Able to Follow Very Far in the Path which the Advanced Guard of Modern Science Is Treading.

But we shall not be able to follow very far in the path which the advanced guard of modern science is treading if the laws of what we have been accustomed to call matter are regarded as the measure of the universe. Matter is a term whose significance science has greatly enlarged. It has become a scientific postulate that what is commonly called the void of space is filled with a medium which, though imperceptible to any human sense, has yet material properties. That is to say, the all-enveloping, all-pervading ether—the etheric ocean without a shore, in whose immensity suns and planets are but bubbles of varying size and hue—is the carrier and transmitter of all primary forms of energy, and perhaps is the material from which the tangible and visible universe has come. The question of the schoolbooks is relevant here: "If light is motion, what moves?" Beyond that which we call the earth's atmosphere, there are the depths of interplanetary space, through which must be communicated to us the form of energy known as light. But as the science primers again remark, "empty space can neither receive nor communicate motion." And we come to the only hypothesis that accords with the facts, that of the etheric ocean, namely, expectations to which that theory has given birth. The immensities of space, the ultra-tenuity of the universe's structure, is tossed about," as Tesla says, "in space eternally, a play to external influences, like a boat in a troubled sea." It moves, it vibrates, and that, too, with almost marvelous rapidity, and by the very necessity of its existence, as the postulate of the dead matter—quite an inconceivable thing, in spite of the popular impression to the contrary.

Possibilities in Appalling Figures.

Science says that light must travel at the rate of 186,000 miles a second; and that light is the product of an etheric vibration whose rate is about 500,000,000,000,000 a second, but science has hardly stopped to consider what profound possibilities there are in the forces which such appalling figures convey. Even now we know very little of what electricity is, but it has been one of the triumphs of modern investigation to identify electro-magnetic manifestations of energy with those of light and heat. Out of this identification has been born the demand which the world could be operated with one wire only, or without any connecting wire at all. The latter formula: "It is not necessary to have even a single connection between the motor and the generator, except, perhaps, through the ground; for not only is an insulated plate capable of giving off energy into space, but it is likewise capable of deriving it from an alternating electrostatic field, though in the latter case the available energy is much smaller." Now, from this demonstration of the possibility of working a motor without connecting wires by currents passed through the earth or by air, a dazzling possibility is revealed. For, "alternate currents, especially of high frequencies, pass with astonishing freedom through even slightly rarefied gases. To reach a number of miles into space requires the overcoming of difficulties of a merely mechanical nature. Once into space, there is little or otherw

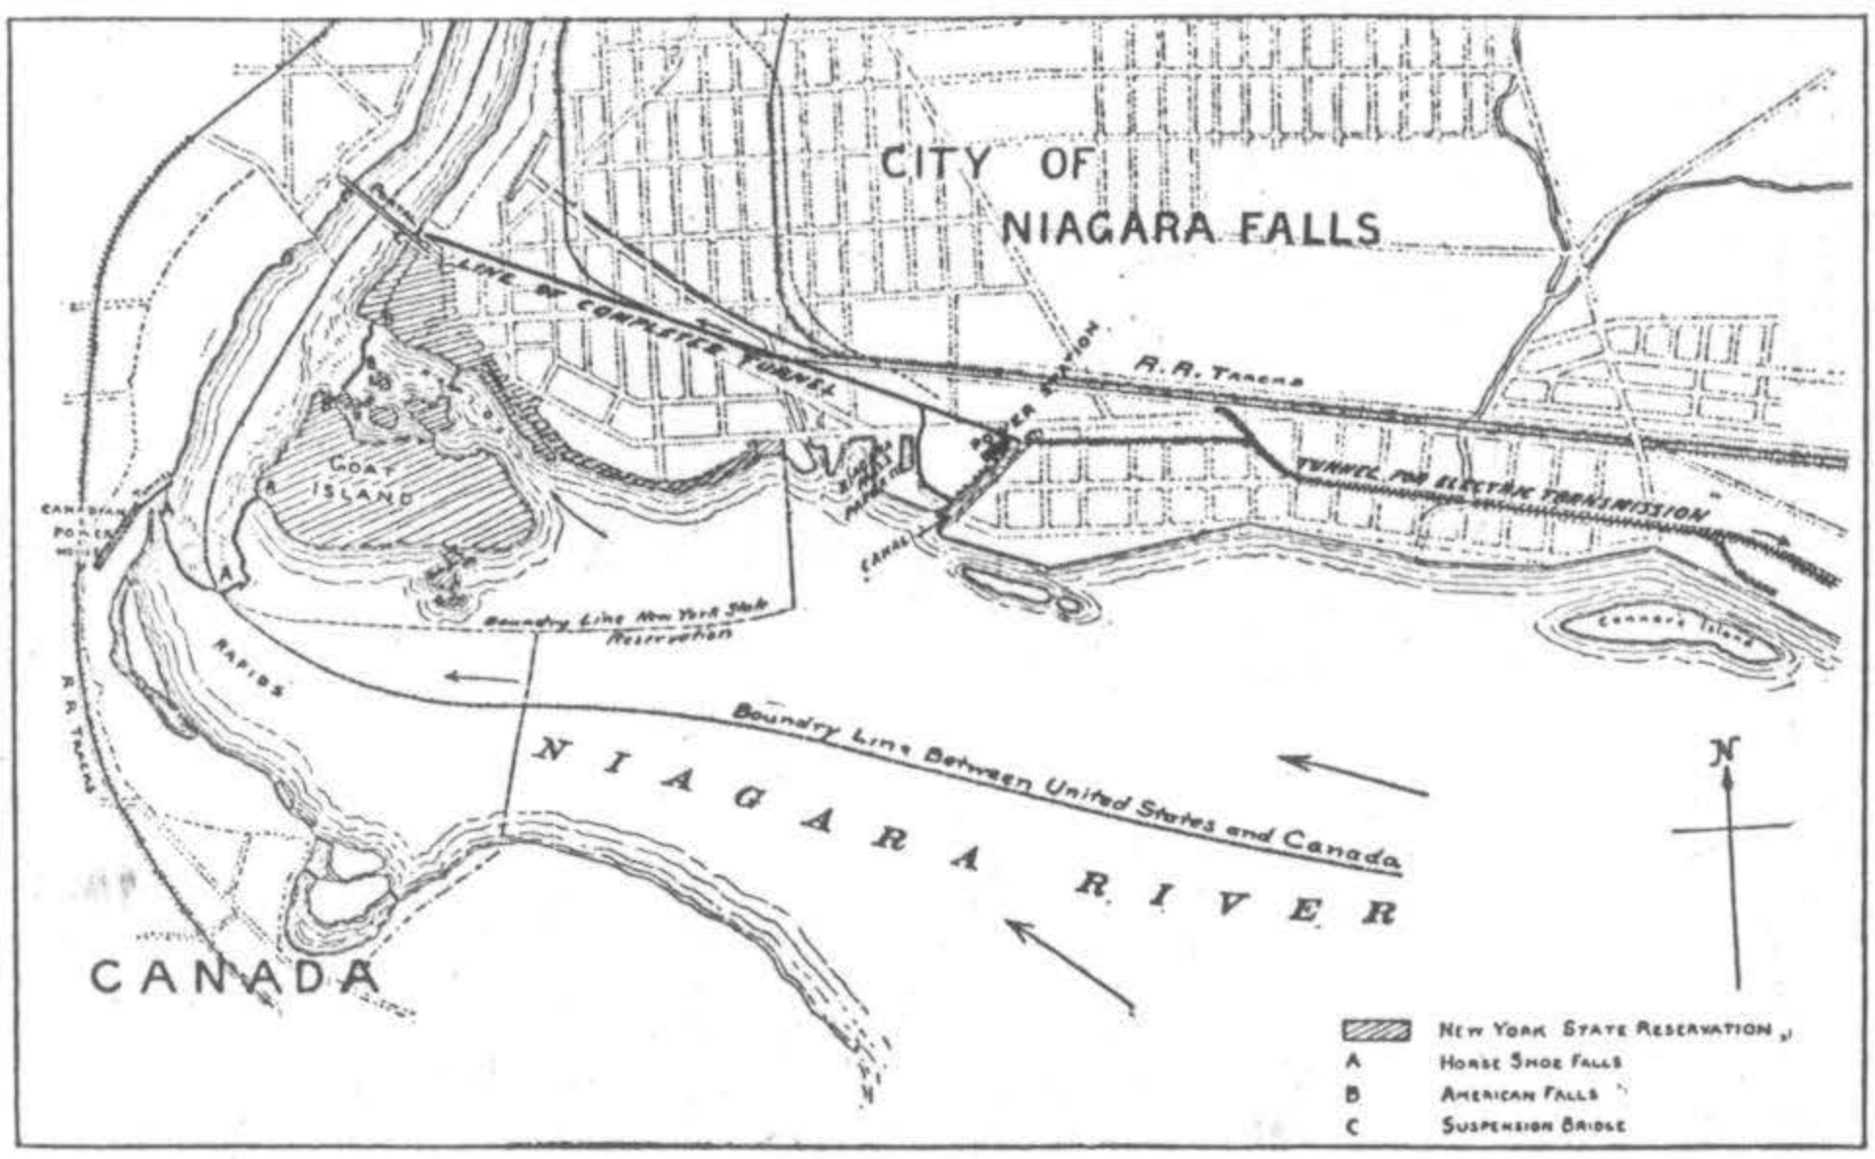
THE CAPTURE OF. NIAGARA.

By E. Jay Edwards.

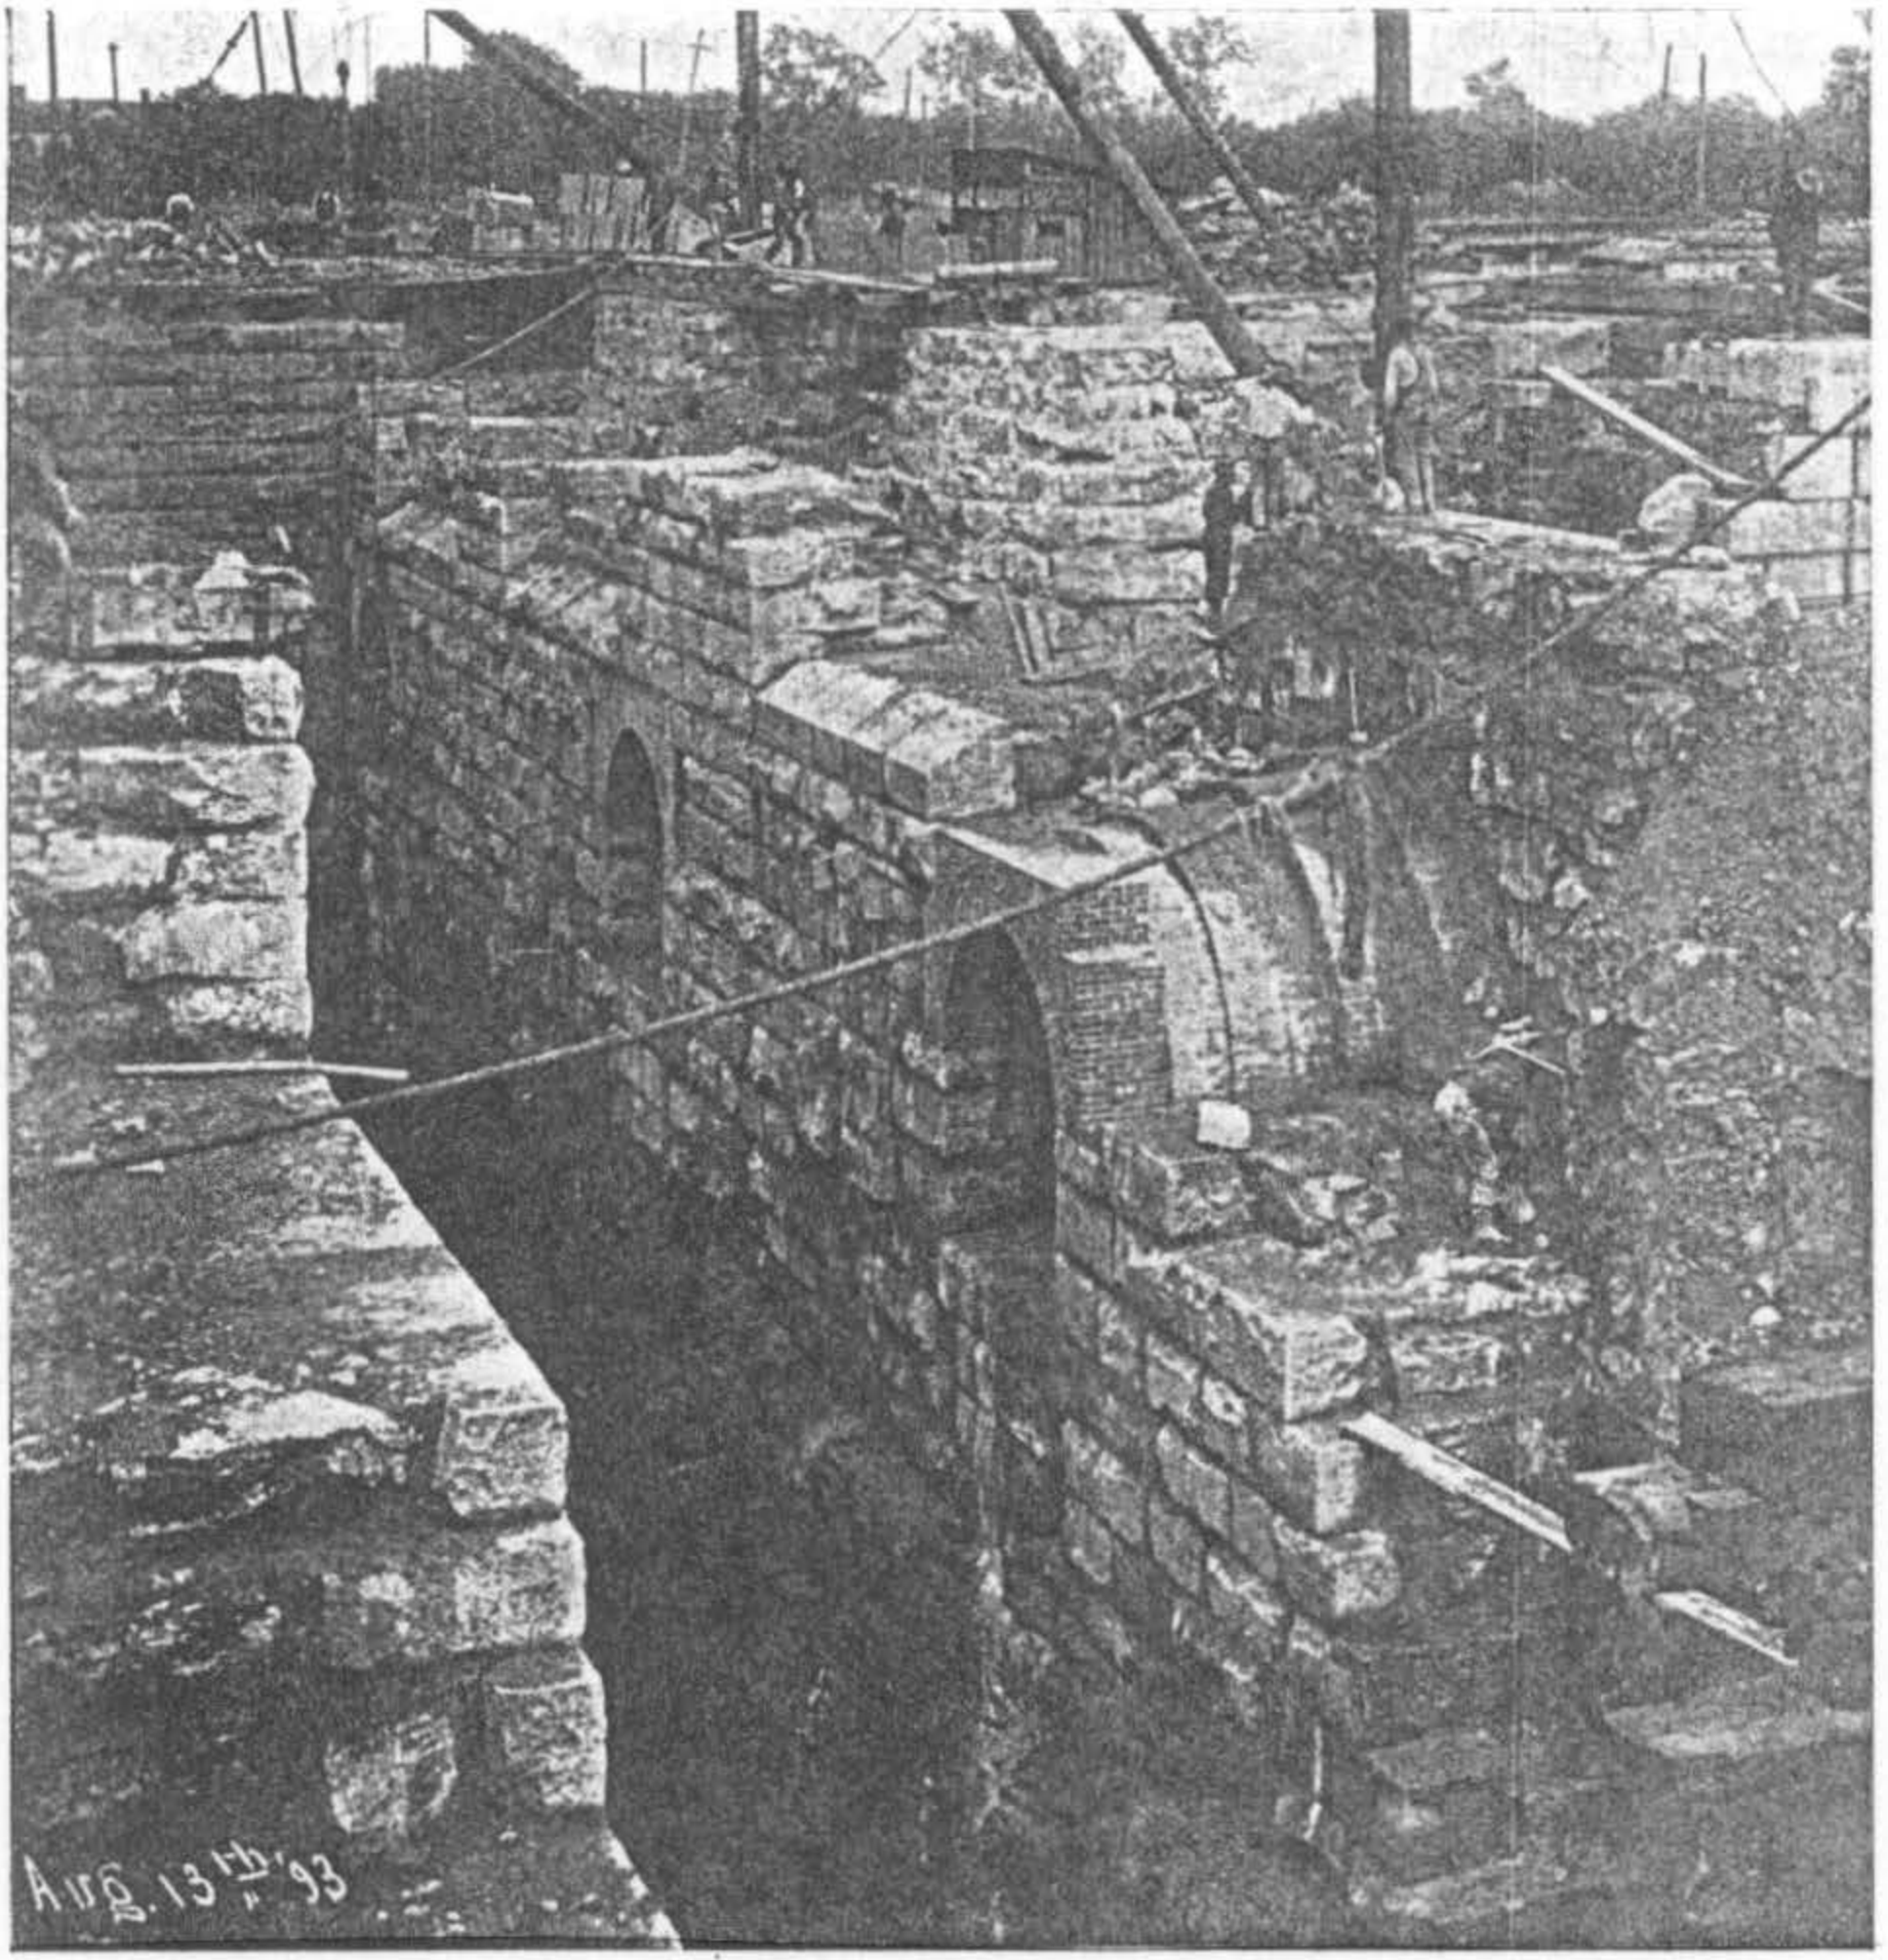
CAPITAL is not always timid, though such is the repute it bears. No finer display of business courage was ever made than that exhibited by Peter Cooper, Cyrus W. Field, and a few others, when they staked millions on the experiment of the first Atlantic cable. In a few weeks there will have been completed another enterprise having the commercial use of electricity as its end, which, involving the expenditure of a very great sum of money, furnishes a new illustration that capital can be courageous, at least on occasion; for that work which has been in progress alongside the Niagara waterfall for some four years is, after all, experimental, and the capitalists cannot know until the plant is finished, the tests are made, and the electric power is furnished, whether the undertaking is going to bring them profit, or whether they have paid dearly for their faith

THE PURPOSE OF THE PLANT.

The power-producing plant now near completion at Niagara Falls is an experiment, however, only as regards the commercial availability of the electric current to be generated. The use of some portion of the power captured from the Niagara cataract as a direct force brought to bear upon turbine wheels, so that they may move the machinery of immense mills, and as many mills as can be erected within the territory controlled by the company, is not experimental. None of the experts doubted the ability of the engineers, mechanical and hydrographic, to construct a plant that would furnish a water-power equivalent to all of the power used in the city of Buffalo for every commercial purpose. The driving of the greatest paper-making machine in the world by this water-power has not



SEAL OF THE CATARACT CONSTRUCTION COMPANY. PHOTOGRAPHED FROM THE ORIGINAL, WHICH WAS MODELLED IN CLAY BY McMONNIES.

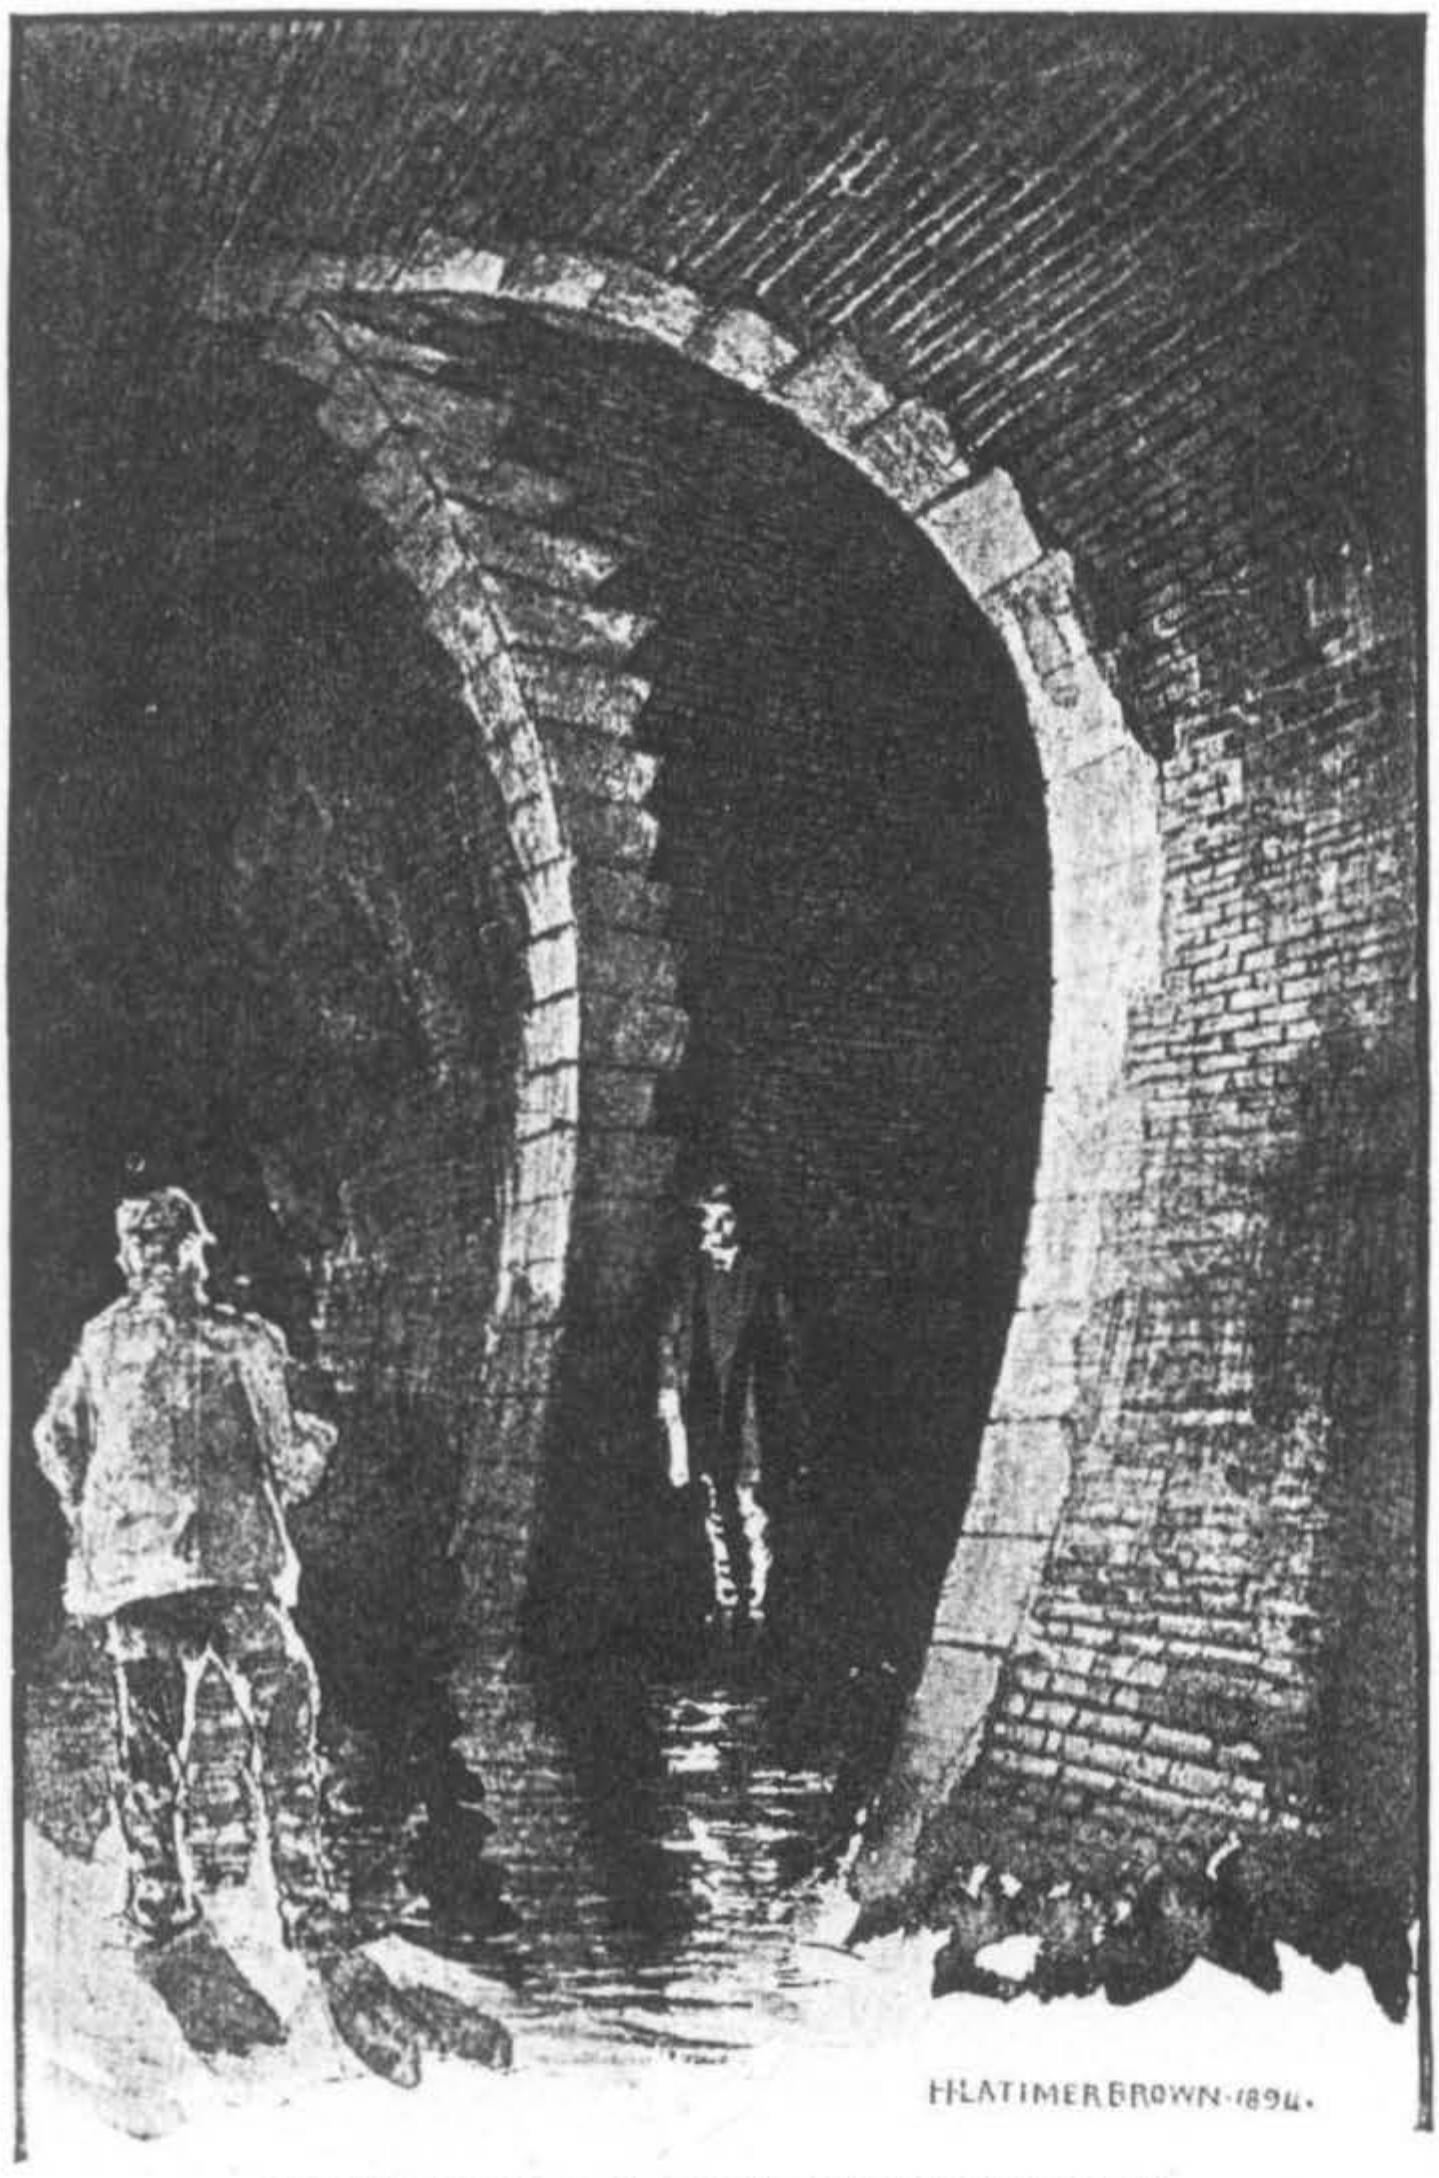


only been proved possible by practice, but it was proved possible even before the first stone was blasted from those rocky banks to make place for the foundations of the mill. To-day this colossal machine, dragon-like in its length and suggestion, the longest single piece of machinery in operation in any of the factories in the world, runs as smoothly, and delivers its finished product as perfectly, as the most exacting of mechanics or manufacturers could demand. To effect this only a little over three thousand horse-power is diverted from the Niagara current, and the amount of water is as inappreciable, almost, in its effect upon the Rapids, as would be the withdrawal of a hogshead of water from the ocean.

It is the design to secure perhaps as much as fifty thousand horse-power from the force of the Niagara current, by diverting it into turbine wheels for direct application. This of itself would create one of the greatest water-power plants in the world, and, if cost, transportation facilities, and other conveniences of manufacture are found to be satisfactory to the manufacturers, would be sure to rear upon the banks of the Niagara, before many years, a city rivalling Lowell, or Lawrence, or any of the great manufacturing towns in New England which have sprung into flourishing existence because water-power was near.

But it was not the development of water-power as a direct agent chiefly that led capitalists to put their money into the development of a power-producing plant. Their plan contemplated the conversion of some portion of the force of the Niagara current into electric power, and the delivery of that power to communities at least fifty, probably a hundred, and possibly five hundred miles or more away. Of course the mechanical engineers have long been aware that the power which goes to waste over

the Niagara precipice is sufficient to turn the wheels of probably every manufactory in the United States, if it could be communicated to them. For years a little of the Niagara force has been utilized at the Falls; paper-mills and other manufactories have long been established there. But the expense of utilizing the power on any large scale by the diversion of it to water wheels has been too great to tempt capitalists to make much of an investment for such purpose. Not until after the invention of dynamos and the development of electricity into a commercially available force, even when carried to some distance, did the capture of the Niagara River, and its subjection to honest labor on a large scale, command the serious thought of capitalists.

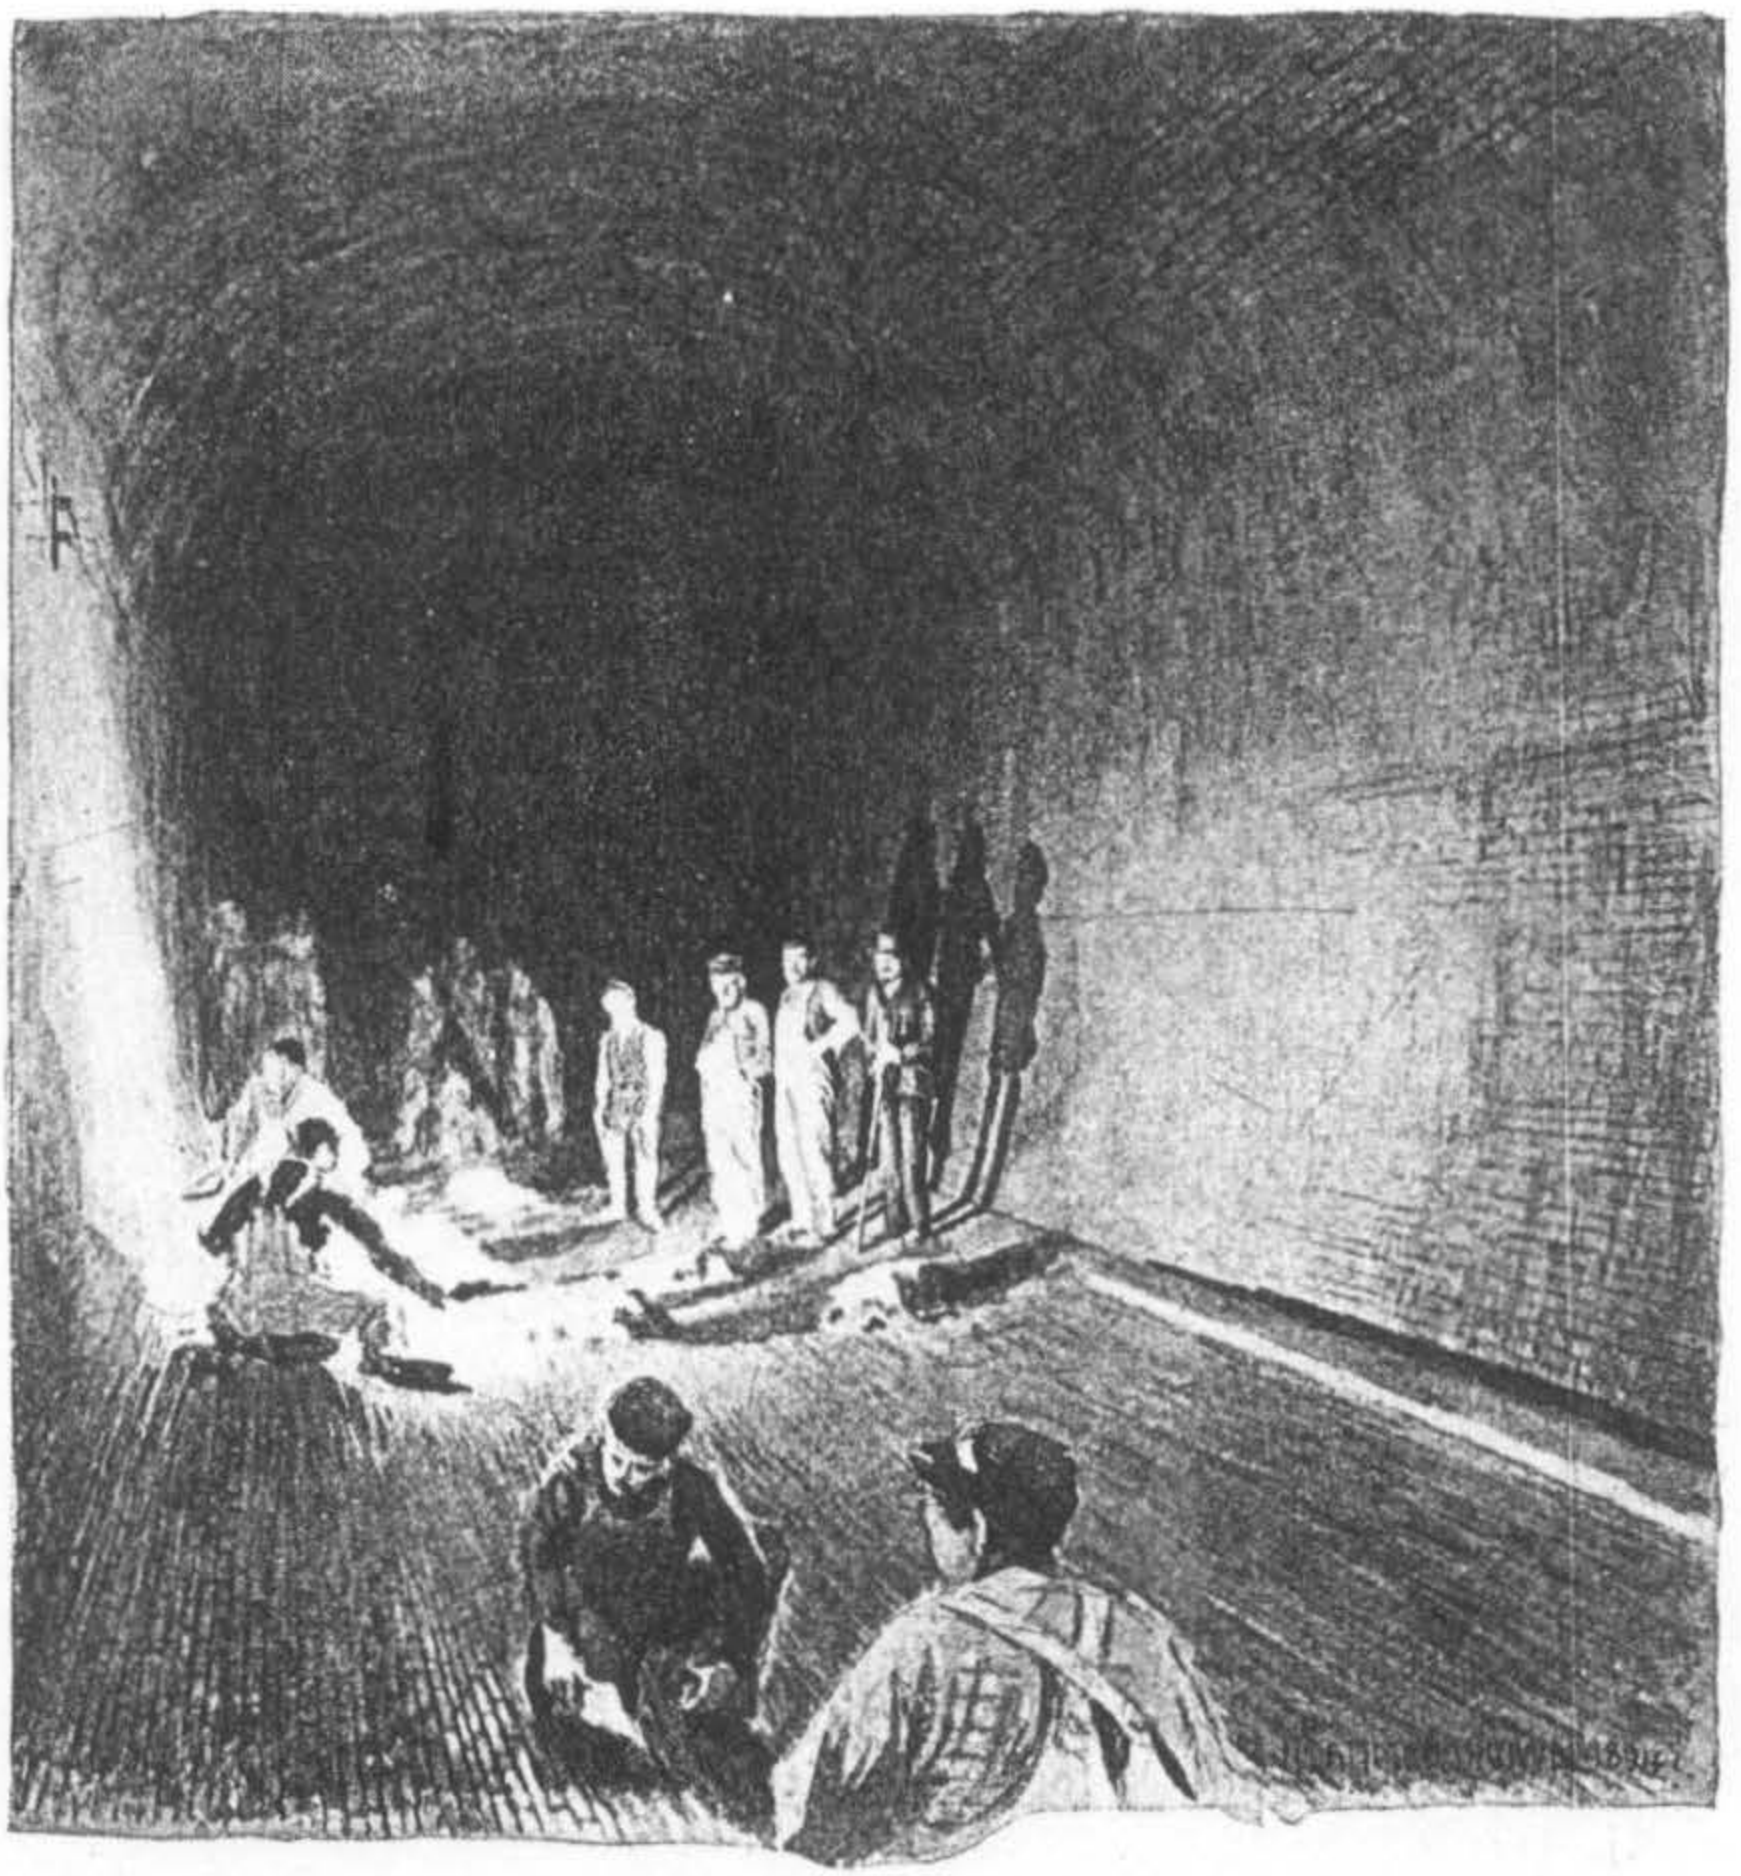


THE GREAT WHEEL-PITS IN COURSE OF CONSTRUCTION.

THE ORGANIZATION OF THE COMPANY.

It is now nearly five years since a few of the citizens of Niagara Falls determined to attempt the organization of a company to develop the Niagara water power and supply from it electrical power to near-by manufactories, and perhaps to the city of Buffalo. They met with the usual discouragements. The patience and aggressive faith of Mr. W. P. Rankine, a young lawyer of Niagara Falls, were all that stood between the original project and failure. Repulsed here and laughed at there, Mr. Rankine at last turned to Mr. Francis Lynde Stetson, a lawyer of New York City, who, having a large practice and intimate relations with some of the greater capitalists, might, Mr. Rankine thought, be disposed

to try and interest them, if he were once interested himself.

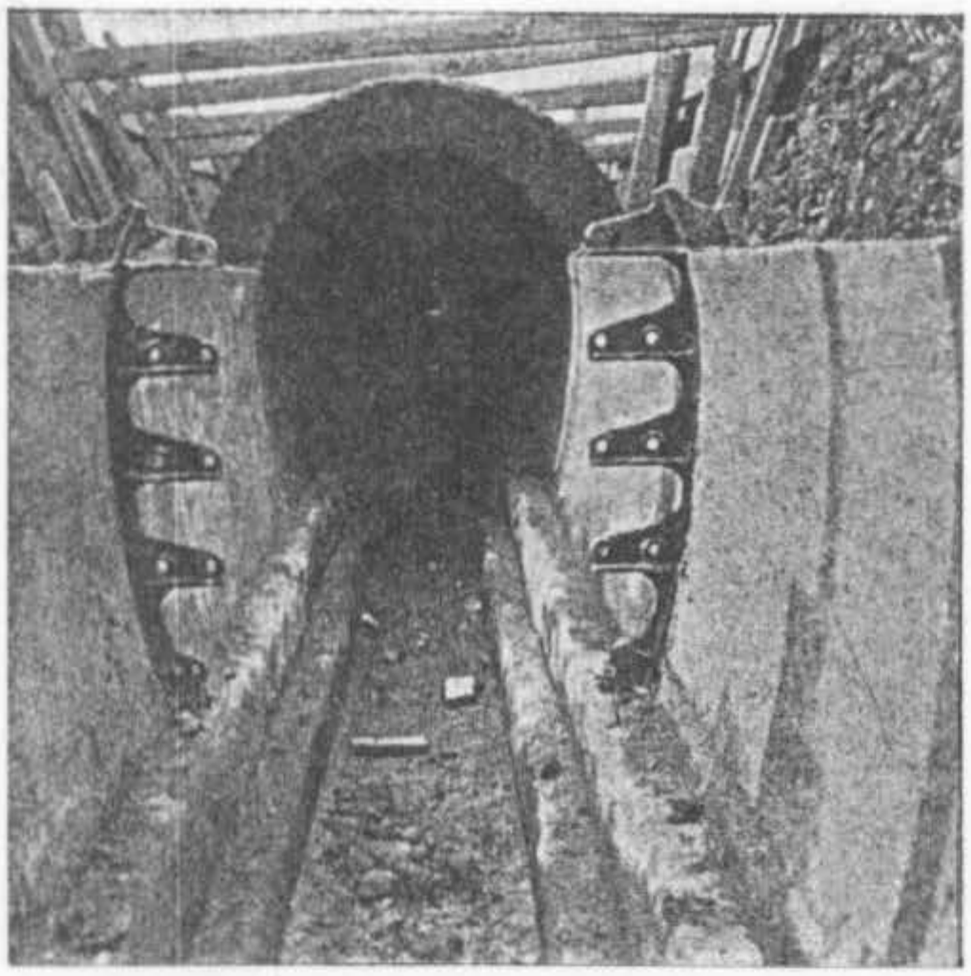


Mr. Stetson is a very busy lawyer. He is not a constructor, but a critic. It has not been his business to conceive and execute any of those plans which have developed into the greater business establishments of these years, but it has been his vocation to criticise, to view with the lawyer's eyes, to satisfy the statutes, and to show those who do plan what their rights and responsibilities are under the law. Therefore it was natural that, when the proposition to capture and control for the market some portion of Niagara's water power was made to him, he should be little disposed to listen. Perhaps, had the suggestion been made by one who was not an old and valued friend, he would have closed his ears to it entirely. As it was, it seemed to him too magnificent, almost too sublime, a scheme. However, he was at last persuaded, and upon his enlistment followed, under his influence, the enlistment of other important people. The company was organized, the needful money provided, the contracts given out, and upon a beautiful day in the spring of 1891, with appropriate and impressive ceremonies, the first spadeful of earth was turned.

JUNCTION OF THE MAIN TUNNEL AND THE WHEEL-PITS.

A WORK OF THE LARGEST DIFFICULTIES.

The enterprise so fraught with difficulties in the mere getting organized, involved in its execution yet more trying problems. It was necessary to determine not only the mechanical possibilities contained in the plan of construction, but also whether the expense entailed would be reasonable or would be so great as to make it prohibitive. And back of all others lay the ever-perplexing question whether the electric current, having been produced, could also be made available for delivery at considerable distances from the plant. On this the opinions of some engineers were discouraging. The reports of others had something of hope in them; but it was the splendid confidence of so great an engineer as Dr. Coleman Sellers, supplemented by that of Lord Kelvin, Mr. Clemmens Herschel, and one or two others, upon which the faith of the capitalists was based. The problem was, perhaps, not wholly solved in theoretical demonstration until Nicola Tesla, that illuminating wizard of electricity, persuaded these capitalists that he had discovered and, in great measure, perfected mechanical appliances which would make it possible to deliver the electric current, under complete control, and



INTERIOR OF THE MAIN TUNNEL.

without costly loss from waste, a long distance; certainly as far as Buffalo and Rochester, and, as he himself firmly believed, as far as Albany, three hundred miles away. Mr. Tesla also has faith that, with the improvements suggested by experience, it will be possible by and by to deliver the current at fairly competitive prices as far away as New York City on the east, and as Cleveland and other of the greater towns in Ohio on the west.

Whether Mr. Tesla's views are correct, is something that is yet to be tested. We cannot know, in fact, whether the electric current can be delivered with commercial profit to any considerable distance from the plant until (which will be a few weeks hence) the turbine wheels are actually started, their colossal power is delivered to the dynamos, and, after being by them converted into electricity, is conveyed thence to the testing points. The scientific world is awaiting these experimental tests as it awaited the first flashing of the message through the Atlantic cable; and the world of commerce and manufacture is awaiting them with no less interest. In Great Britain, lacking any colossal water power like Niagara, it is already proposed to set up sufficient plants at the coal mines for the local conversion of the coal into electricity, to be delivered all over England and Scotland; and this will surely be done if the Niagara enterprise succeeds.

THE FEEDING CANAL.

The power plant proper consists first of an inlet canal situated about a mile and a half up the river from the American Falls. This canal is really a great reservoir into which the water backs. The opening, or great, gates, are placed not at the upper but at the lower end, the end nearest the Falls. That was done because the engineers believed that the current would be too strong if the water was admitted directly from the river. It therefore goes in by

THE SUBWAY CONDUIT, WITH BRACKETS FOR CARRYING THE ELECTRIC WIRES. THE CONDUIT WAS ABANDONED ON ACCOUNT OF THE HEAVY COST OF CONSTRUCTION.

a back flow. The canal will always be full. No drought, no frost of winter, has ever occurred so severe as to interfere materially with the flow of water over Niagara's brink. Into the canal are cut gateways of massive masonry, each controlled by a heavy gate, and connected with enormous shafts, or penstocks, of iron and steel, some of them of a diameter as great as seven feet. Through each shaft may be delivered a continuous force of water equivalent to from two thousand to five thousand horse-power. Those that turn the turbine wheels which keep the massive machinery of the paper-mill in motion, deliver three thousand six hundred horse-power. The total capacity of the canal is one hundred thousand horse-power; and it will be possible to so increase the capacity of this and other plants controlled by the parent and allied companies that ultimately there may be captured from Niagara Falls as much as four hundred and fifty thousand horse-power.

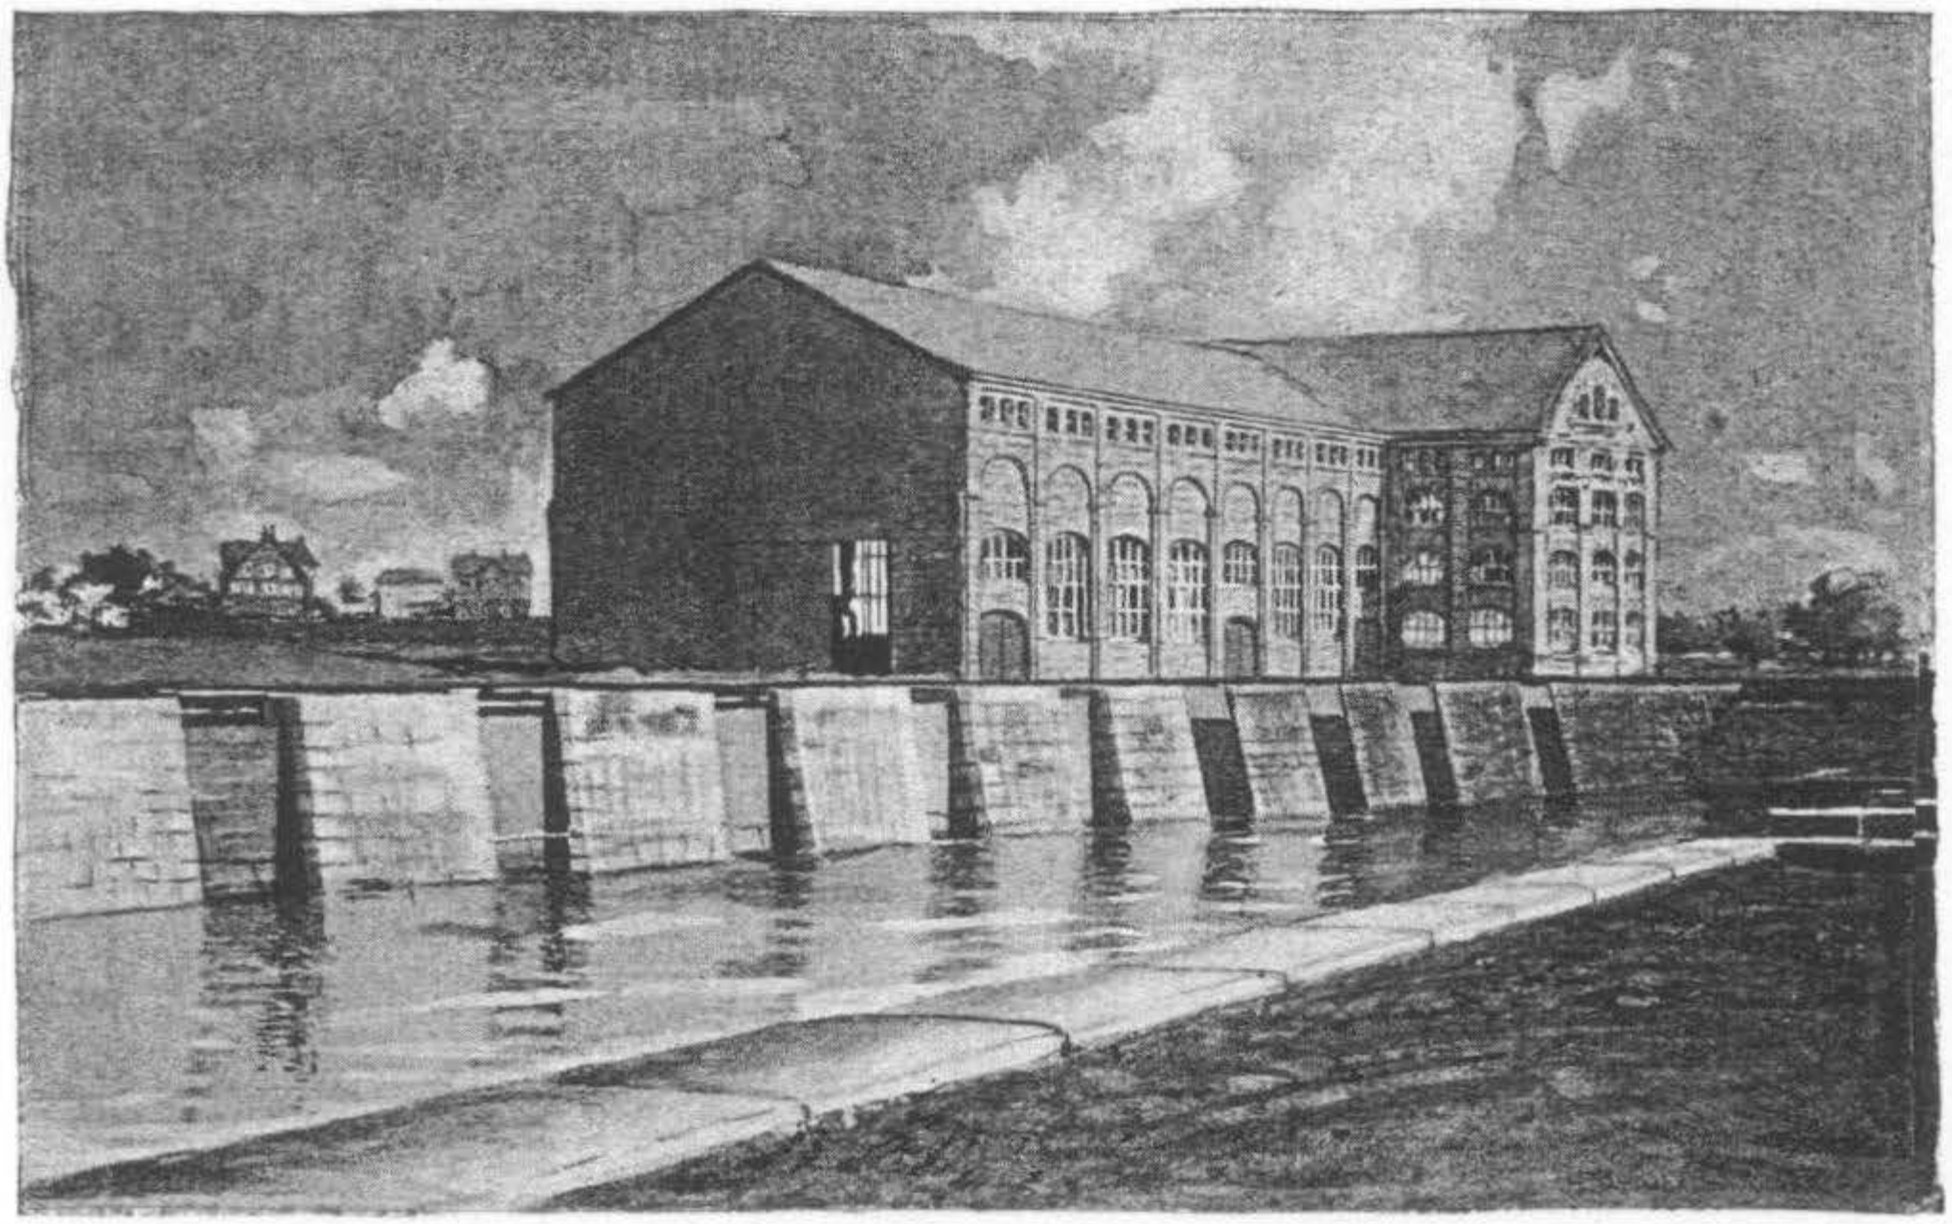
Some sense of the full significance of these figures can be had by bearing in mind that the city of Buffalo, one of the great manufacturing centres of the country, employs at present a force equivalent to only fifty thousand horse-power for all of its manufacturing plants. Four hundred and fifty thousand horse-power would serve to turn the wheels of every manufactory in central New York, to light and heat the cities and towns, and to provide propulsive power for the boats employed in traffic on the Erie canal. Yet even this is but a small fraction of the power which now goes to waste over the Niagara precipice. It has been estimated that when the plant is run to its full capacity, it will absorb only so much water from the river as would cause it to recede less than seven inches from its present mark upon the banks.

THE GREAT WHEEL-PITS.

Next to the canal or reservoir to be observed, are the great and gloomy pits at the bottom of which the turbine wheels are placed. Standing in the power-house of the paper-mill and looking down into the pit, it seems almost as though we were gazing into the mouth of the infernal regions. The workmen light a piece of tow saturated with oil, and when it has flamed up into a huge torch, let it down by a rope to the bottom of the pit. Then the visitor may see by the ghastly light of this torch the rushing of the water as it escapes from the wheel, and, coming up from the depths, he hears an infernal diapason. The force of the water is so great that if a man received it upon his body he would be crushed and shattered as though blown from the mouth of a cannon. The power is so great that turbine wheels of almost perfect resisting tensile strength have had to be made in order to receive the force with safety. Some of them are so large that it is possible for a man to stand between the blades, and one photograph has been taken in which Mr. Stetson and some of the officers of the company are pictured thus framed by these bronze blades. The pits are cut out of the solid rock, and the work was very expensive

THE MAIN TUNNEL WHILE UNDER CONSTRUCTION.

NIAGARA FALLS.

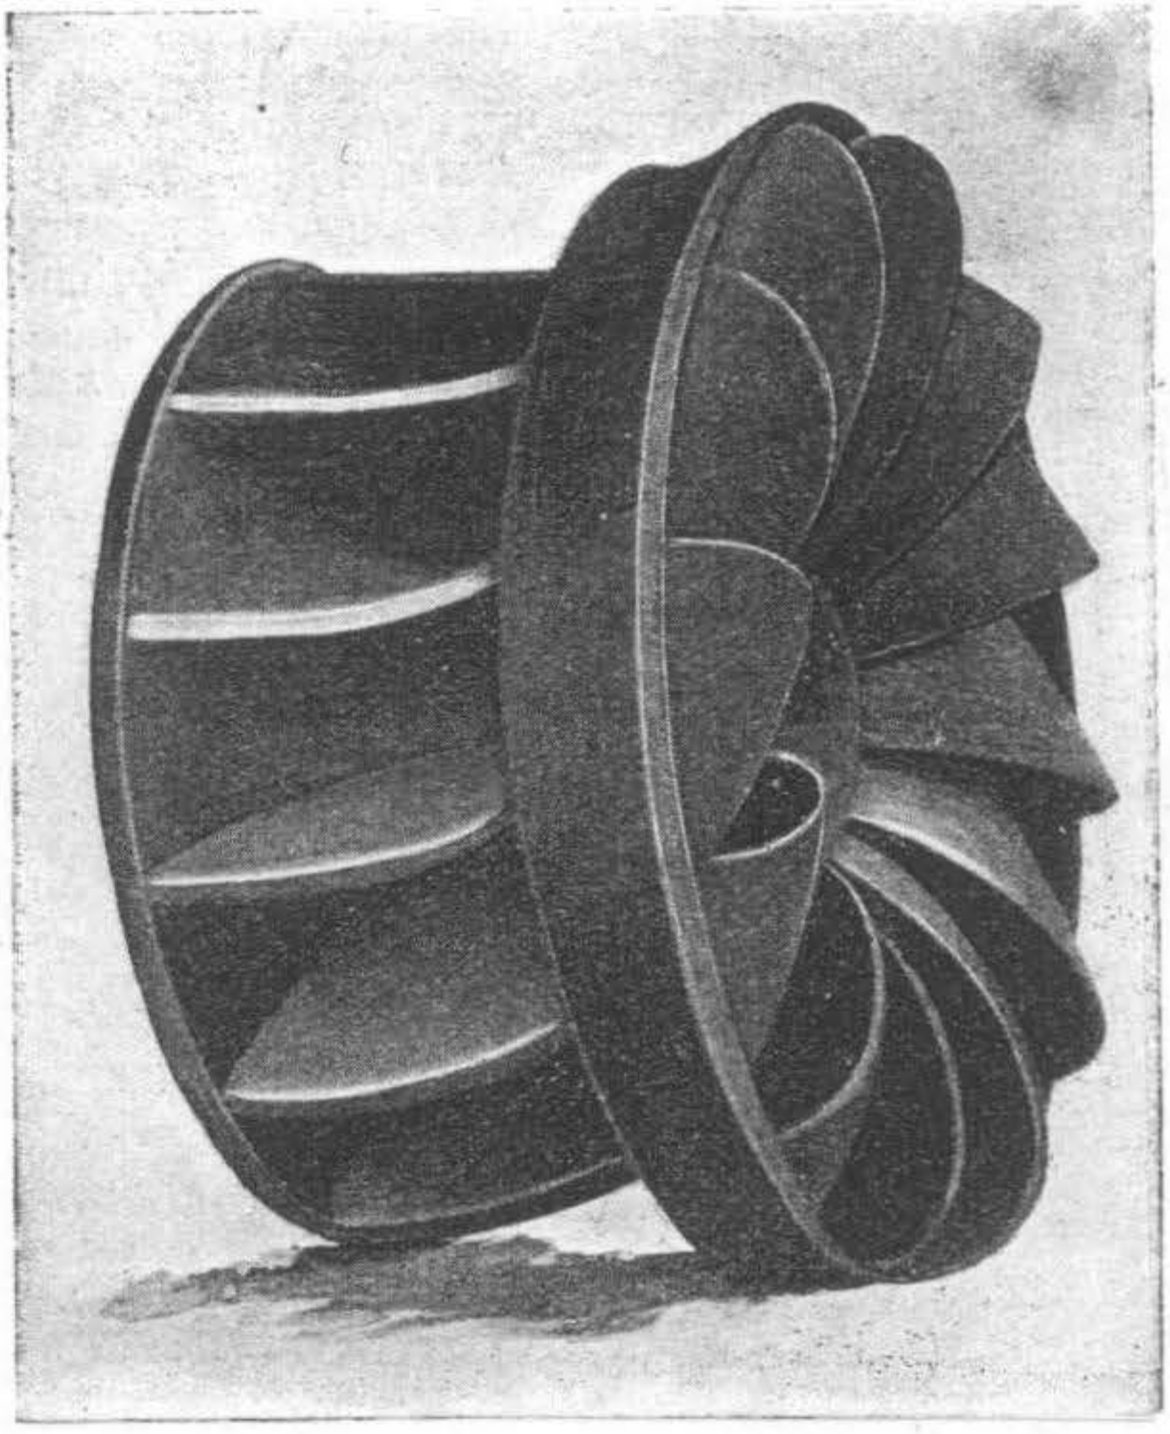


and difficult, consuming more time than the engineers had estimated it would.

THE ELECTRICAL POWER-HOUSE.

Over the greater of these pits is built the electrical power-house, a building designed by Stanford White, and suggesting in its unique and impressive architecture the enormous power to be generated within, and giving in itself some hint of the capacity of man to master the forces of nature. As it now stands it is one hundred and forty feet long, but the company designs ultimately to extend it three hundred feet. At the same time the main wheel-pit will be extended until it is large enough to contain ten turbine wheels, flying ten dynamos, each of five thousand horse-power. The water wheels at the bottom of the pit are connected by steel shafts to the dynamos, which are upon the main floor; so that the power of the water falling nearly two hundred feet upon the wheels is conveyed back to the surface and transformed by the dynamos into electricity. The dynamos are probably the finest and largest of all the mechanical implements now employed for the development of electrical power. They are built after the designs of the Westinghouse Company, and embody the very latest improvements in works of their class. For the present only enough of them are to be set up to produce electricity equivalent to fifteen thousand horse-power, and it is the design to deliver the greater part of this to the city of Buffalo.

THE GREAT TUNNEL.



The most difficult to construct, perhaps, and the most impressive to view, of the several parts of this huge piant, is an artificial waterway, cut through the solid rock, two hundred feet beneath the surface. It is seven thousand feet in length, and as smooth and perfect as the boring of a great war gun. This is the main tunnel. It has no other function than to receive and discharge the water which has served its purpose and spent its force upon the turbine wheels. One section of it is almost directly beneath the heart of the town of Niagara Falls. When the passenger alights

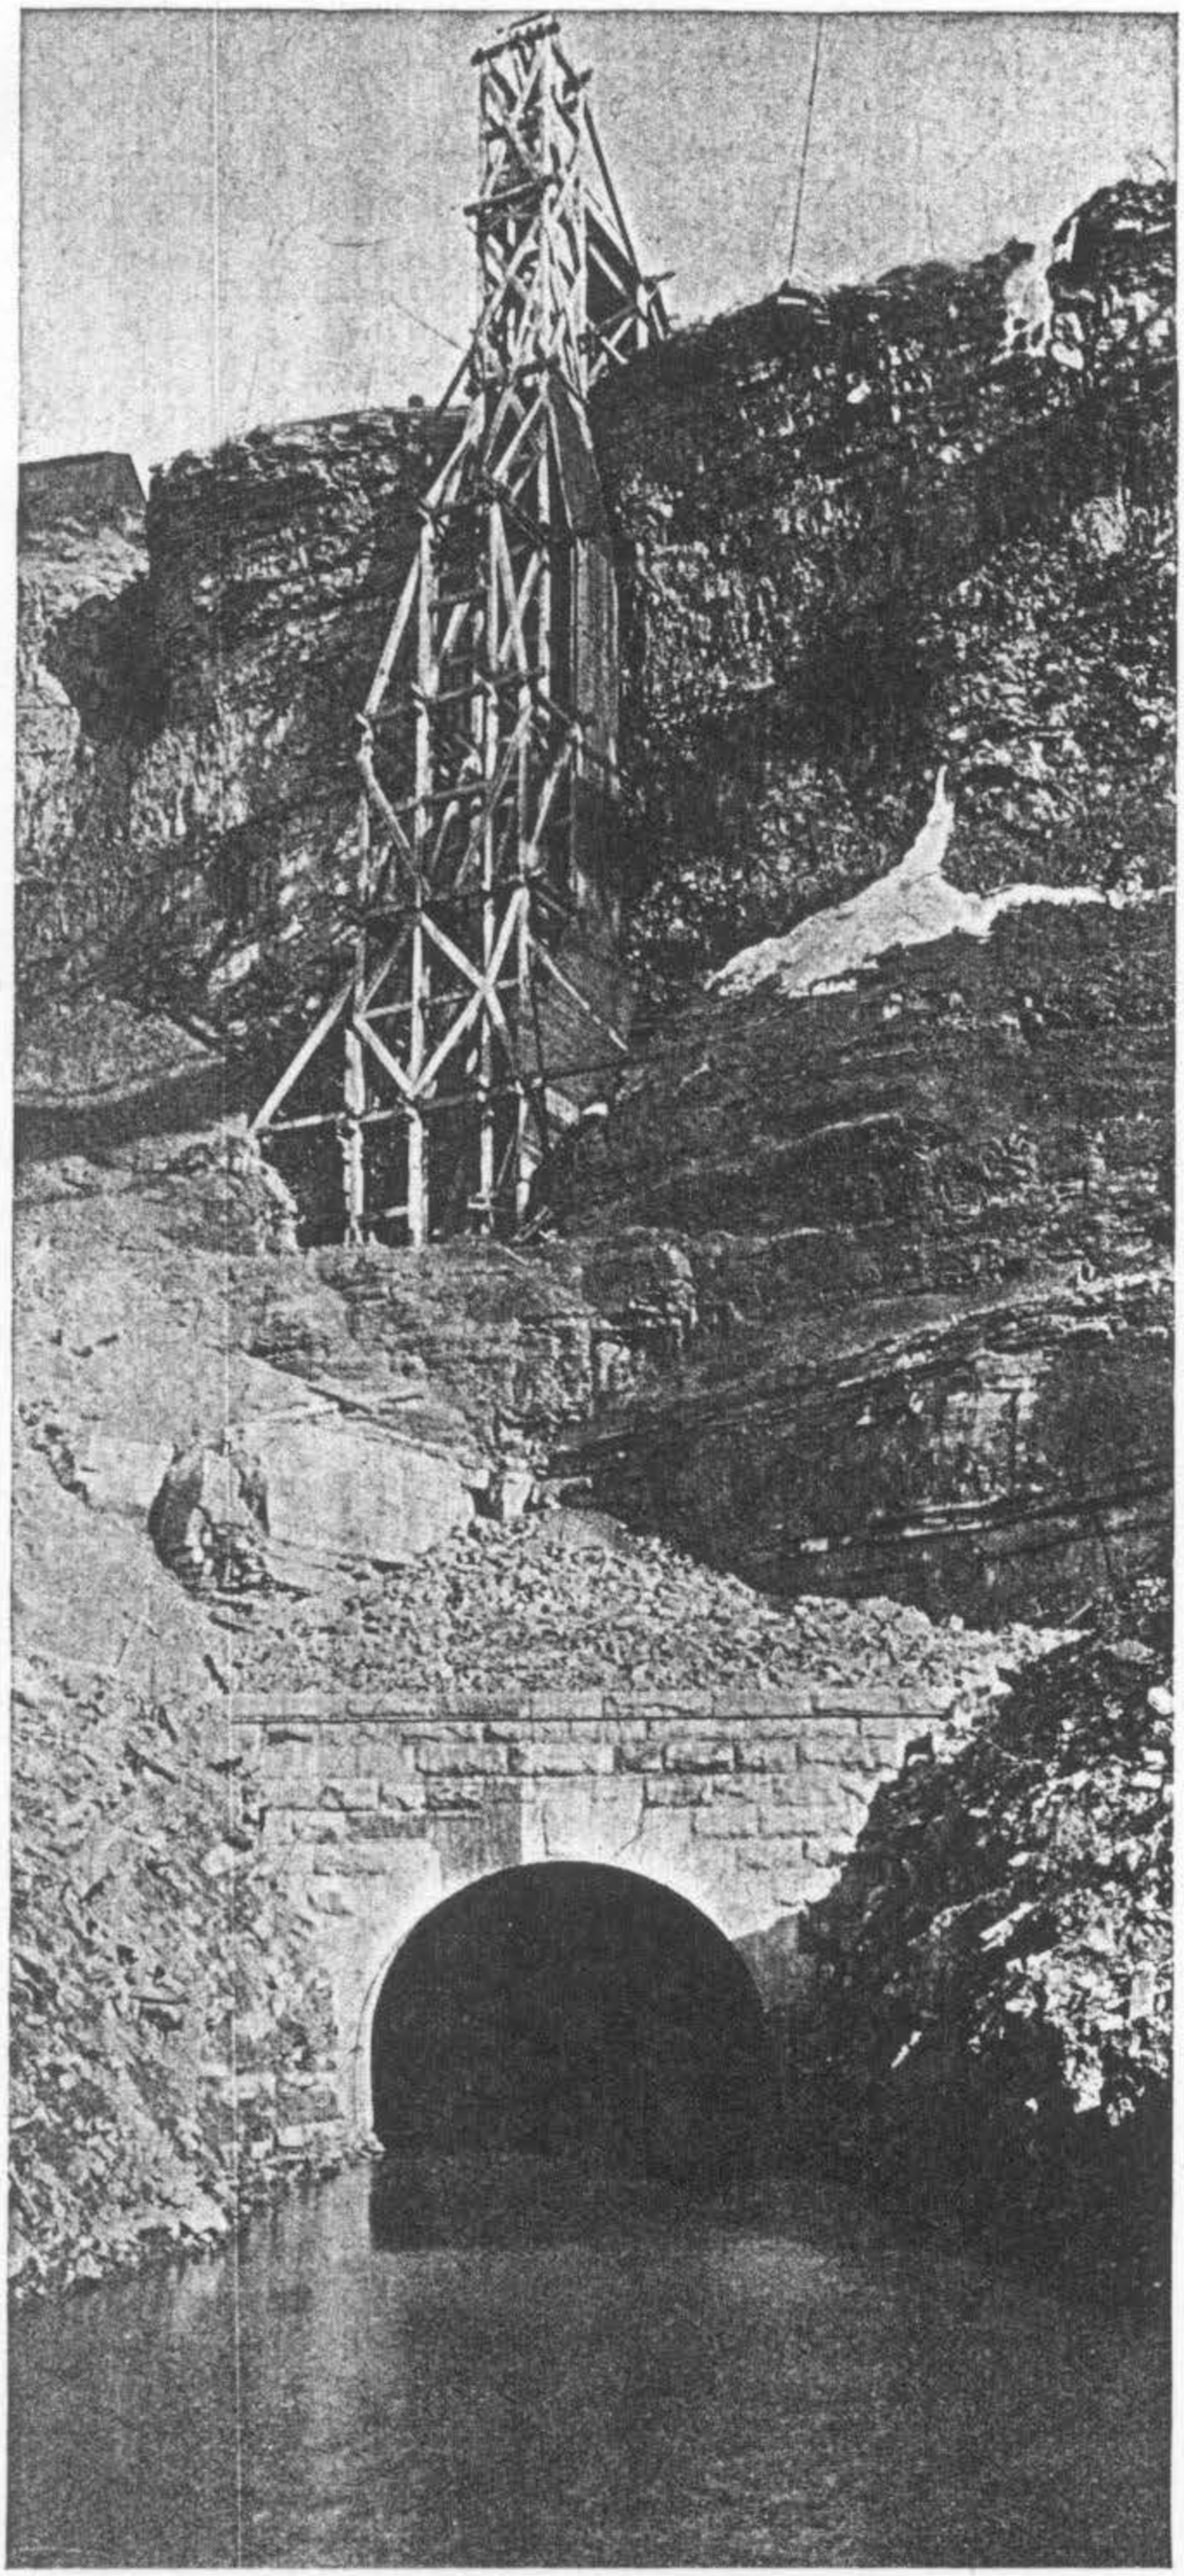
THE POWER-HOUSE AND THE FEEDING-CANAL.

at the railway station he stands just over it. It is probably the most perfect piece of continuous rock boring to be found anywhere in the world. It is large enough to drive through, being eighteen feet and ten inches wide at its greatest diameter and fourteen feet and five inches wide at the bottom, and twenty-one feet high. It has a grade of from four to seven feet to the thousand, or sufficient to carry off the water swiftly, and yet with the least friction possible. The great boring is shaped like a horseshoe. In order that it may more surely resist the action of the water, it is lined at the lower end with plates of the best steel, and for the rest of the distance it is lined with bricks burned with the particular view of enabling them to resist the friction of the water. Some idea of the amount of work necessary to bore this tunnel may be obtained from the fact that the rock excavated in making it was sufficient to fill in nearly twenty acres of land along the shore of the Niagara, thus reclaiming, or, rather, actually constructing, land which is estimated to be worth at least one hundred thousand dollars.

One of the most difficult of the problems that the engineers had to solve was the connection of the main tunnel with the wheel pits, for just there not only was the force of the water very great, but it was necessary to turn the tunnel almost at right angles. The

A TURBINE WATER WHEEL.

tunnel proper runs as straight as the arrow flies, and the outlet, situated about a quarter of a mile below the American Falls and almost exactly underneath the new suspension bridge, is of itself a very remarkable piece of engineering work, one that has been greatly discussed by engineers and in the scientific journals. It is probable that this outlet, and the inlet connecting the tunnel with the wheel-pits, made a larger demand on engineering skill, and required more of accurate and careful science, than did the entire tunnel between these two.



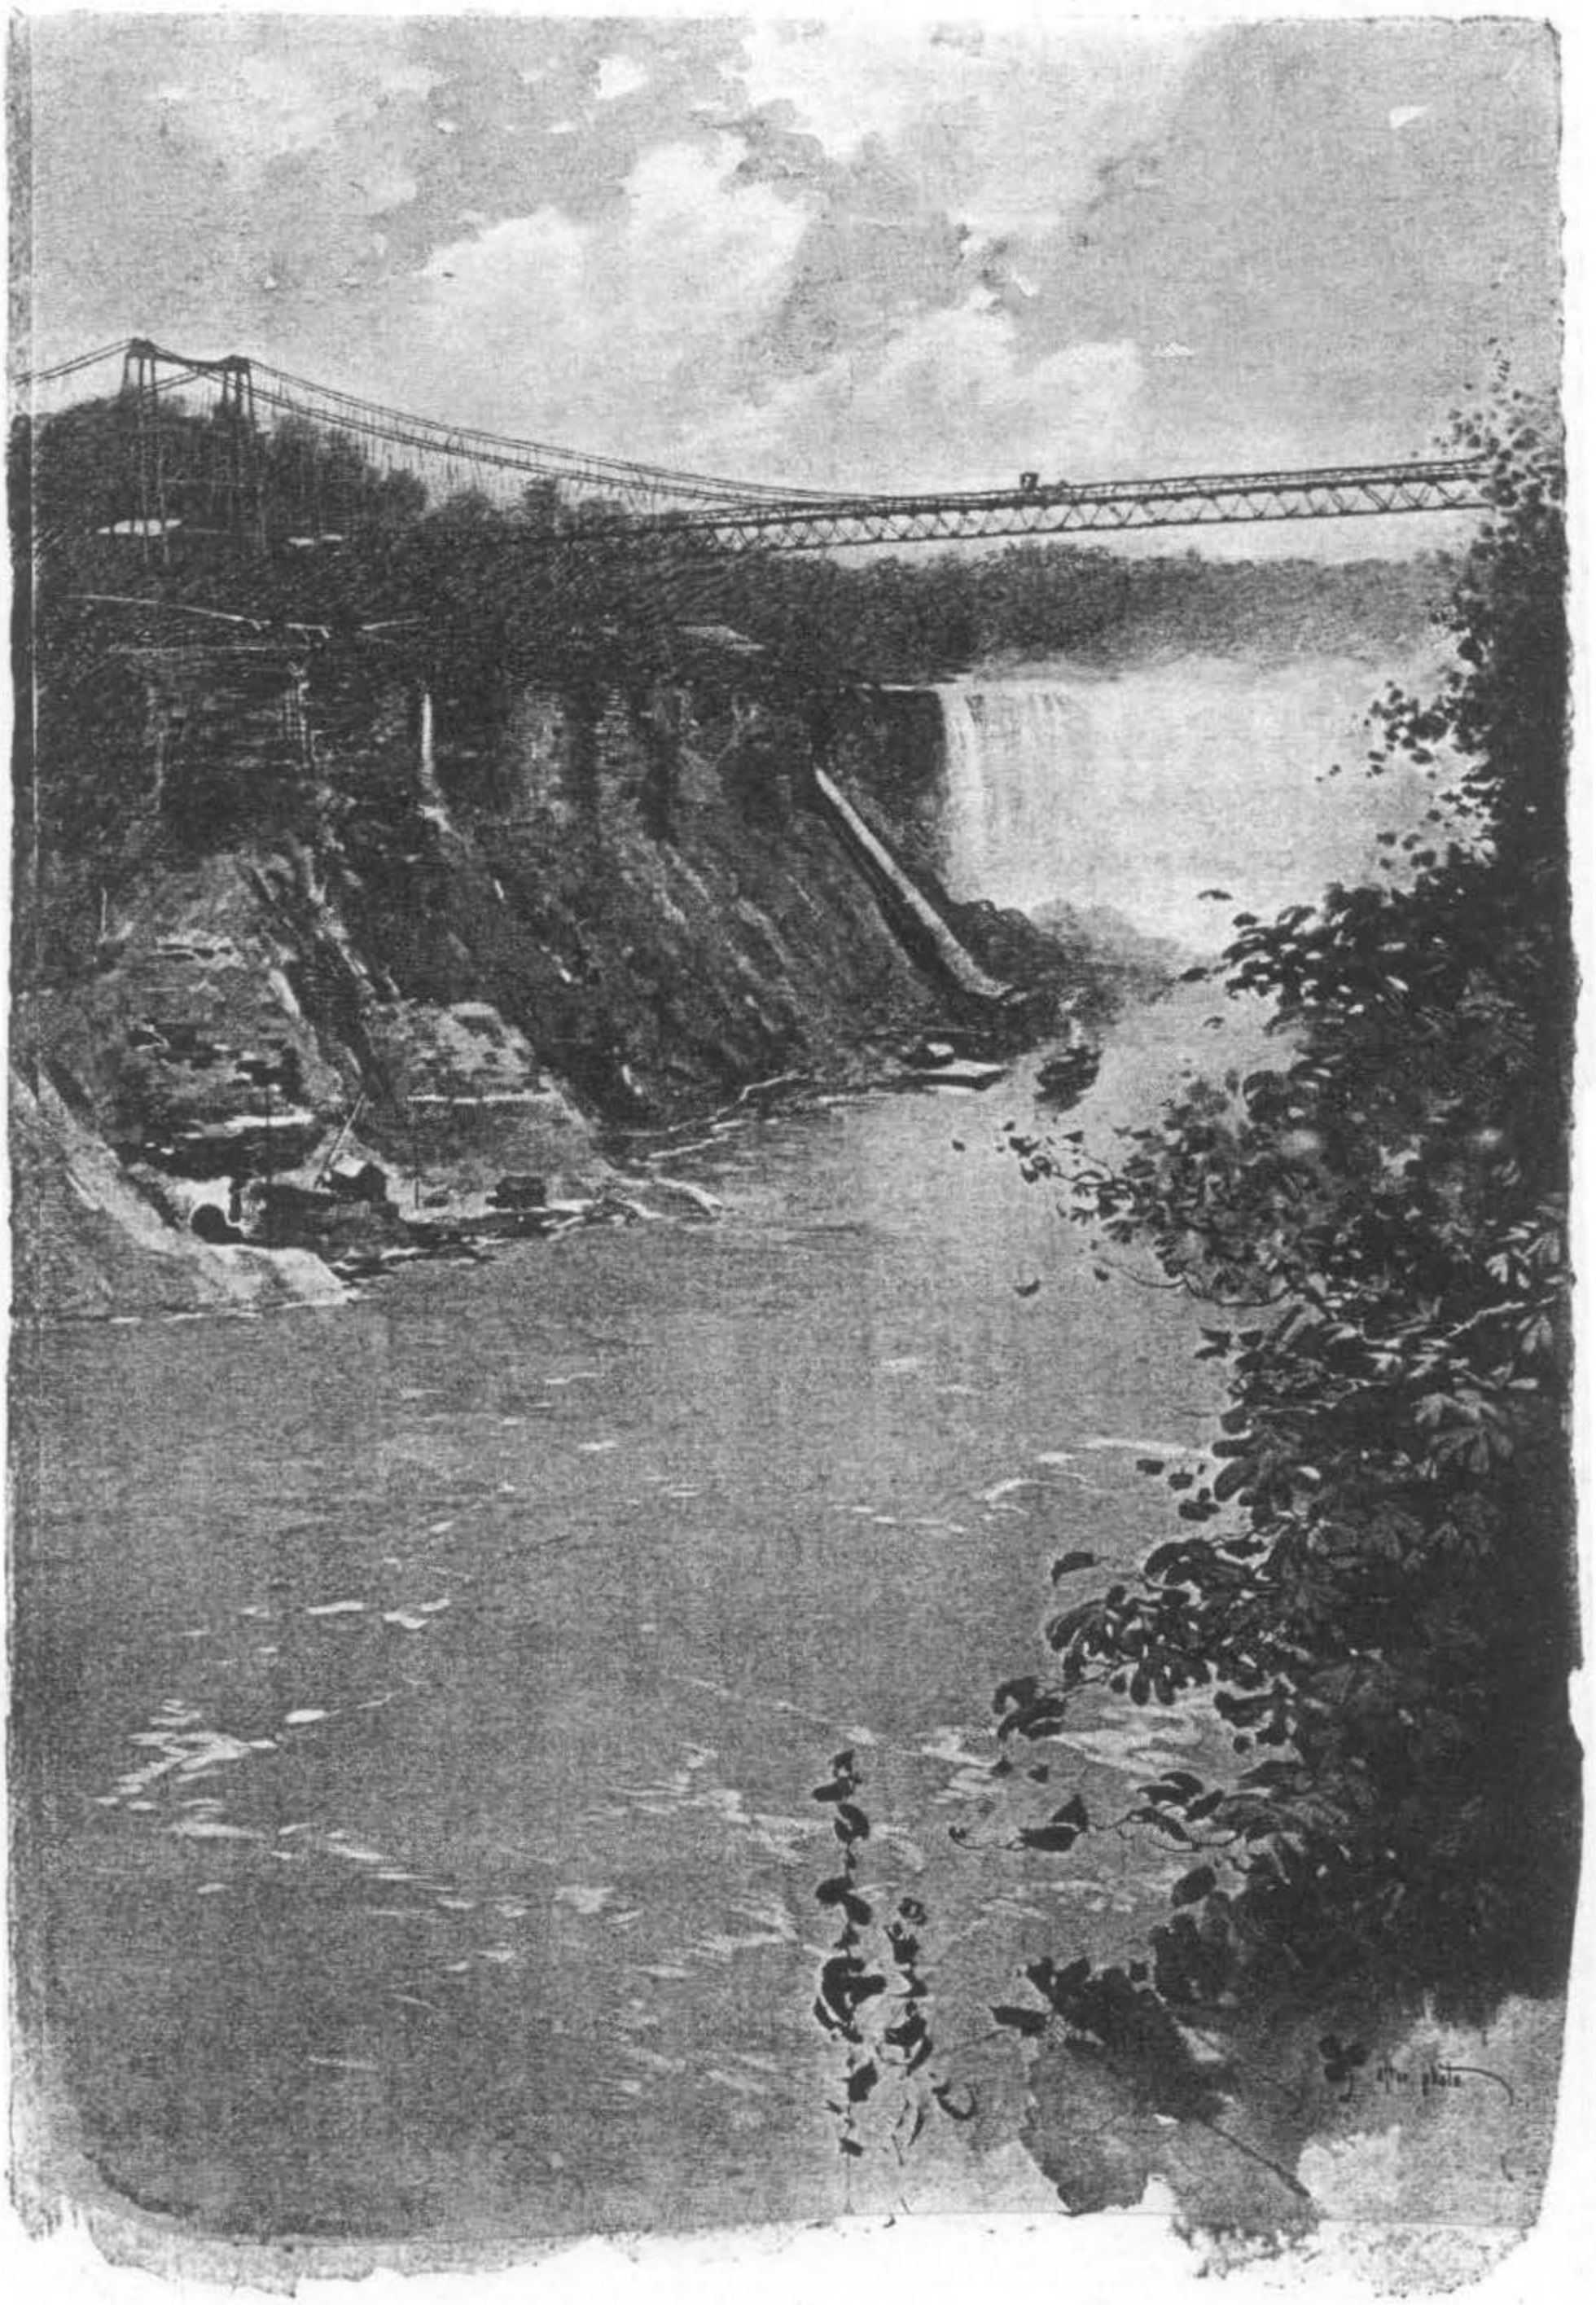
VIEW OF THE FALLS AND THE POWER-HOUSE.

THE WATER WHEELS.

The water wheels are not all of the same size. Those employed in the transmission of power to the machinery of the paper-mill were, when they were put in, the largest ever made. They were capable of generating as much as one thousand horse-power each. But they are mere pygmies in comparison with those which are to supply power to the great dynamos. Each of these has been built with the purpose of developing as much as five thousand horse-power, which is about the power required to drive an ordinary ocean steamship from twelve to fourteen knots an hour. There are to be three of these mammoth turbines, and their handmaids, the dynamos, are sympathetically colossal in their capacity to generate electricity.

THE COMMERCIAL PROBLEM.

Now that the plant itself is all finished and ready for the touching of the button which will send electricity over the wires, the next problem to be worked out in practice is the purely commercial one whether the

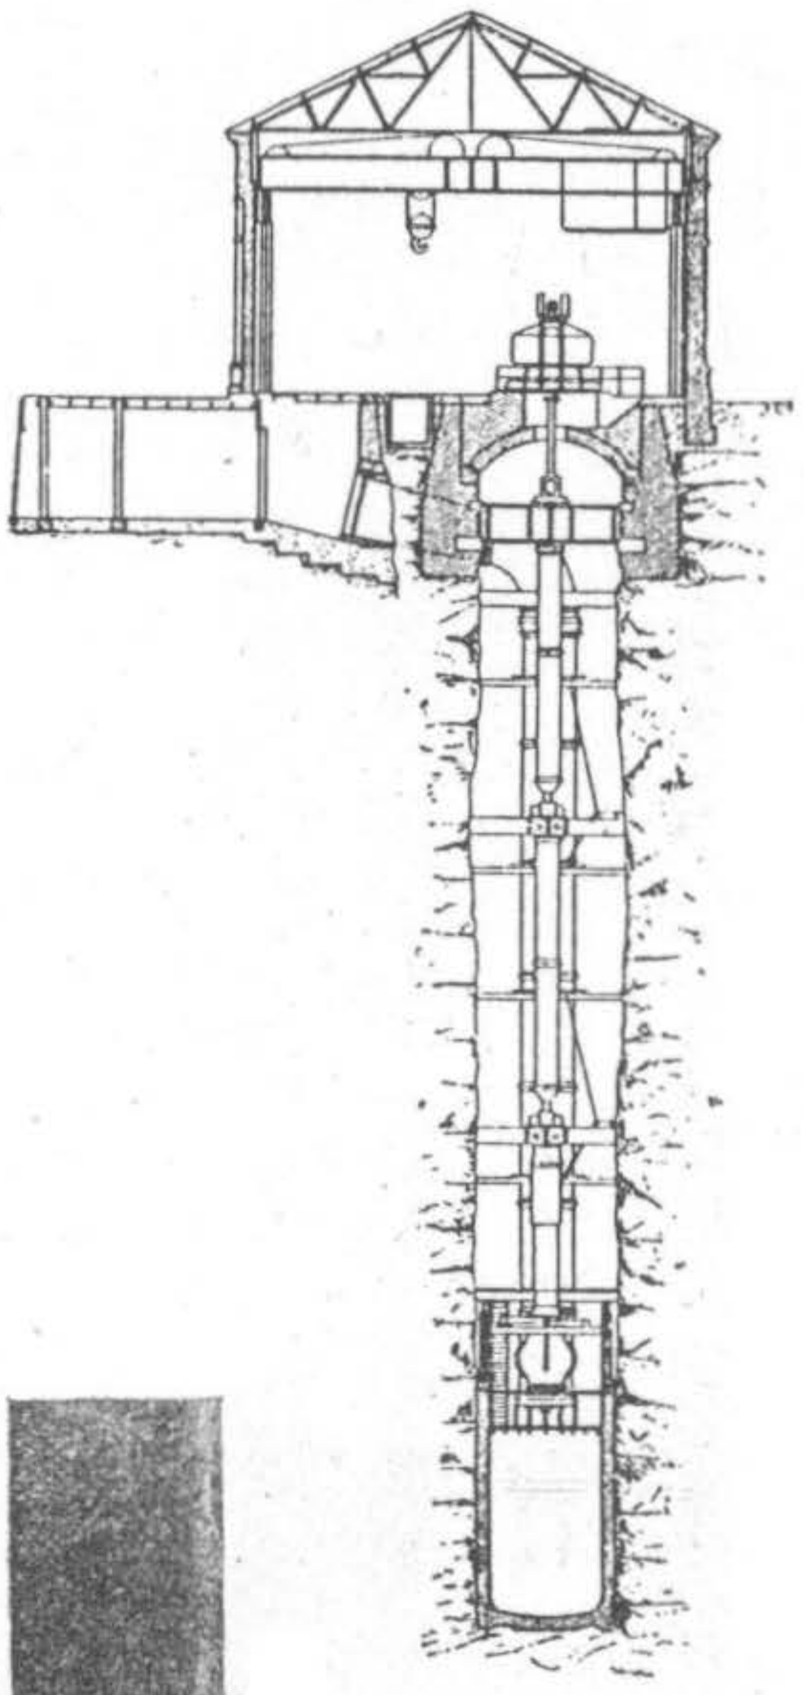


THE OUTLET OF THE TUNNEL BELOW THE FALLS.

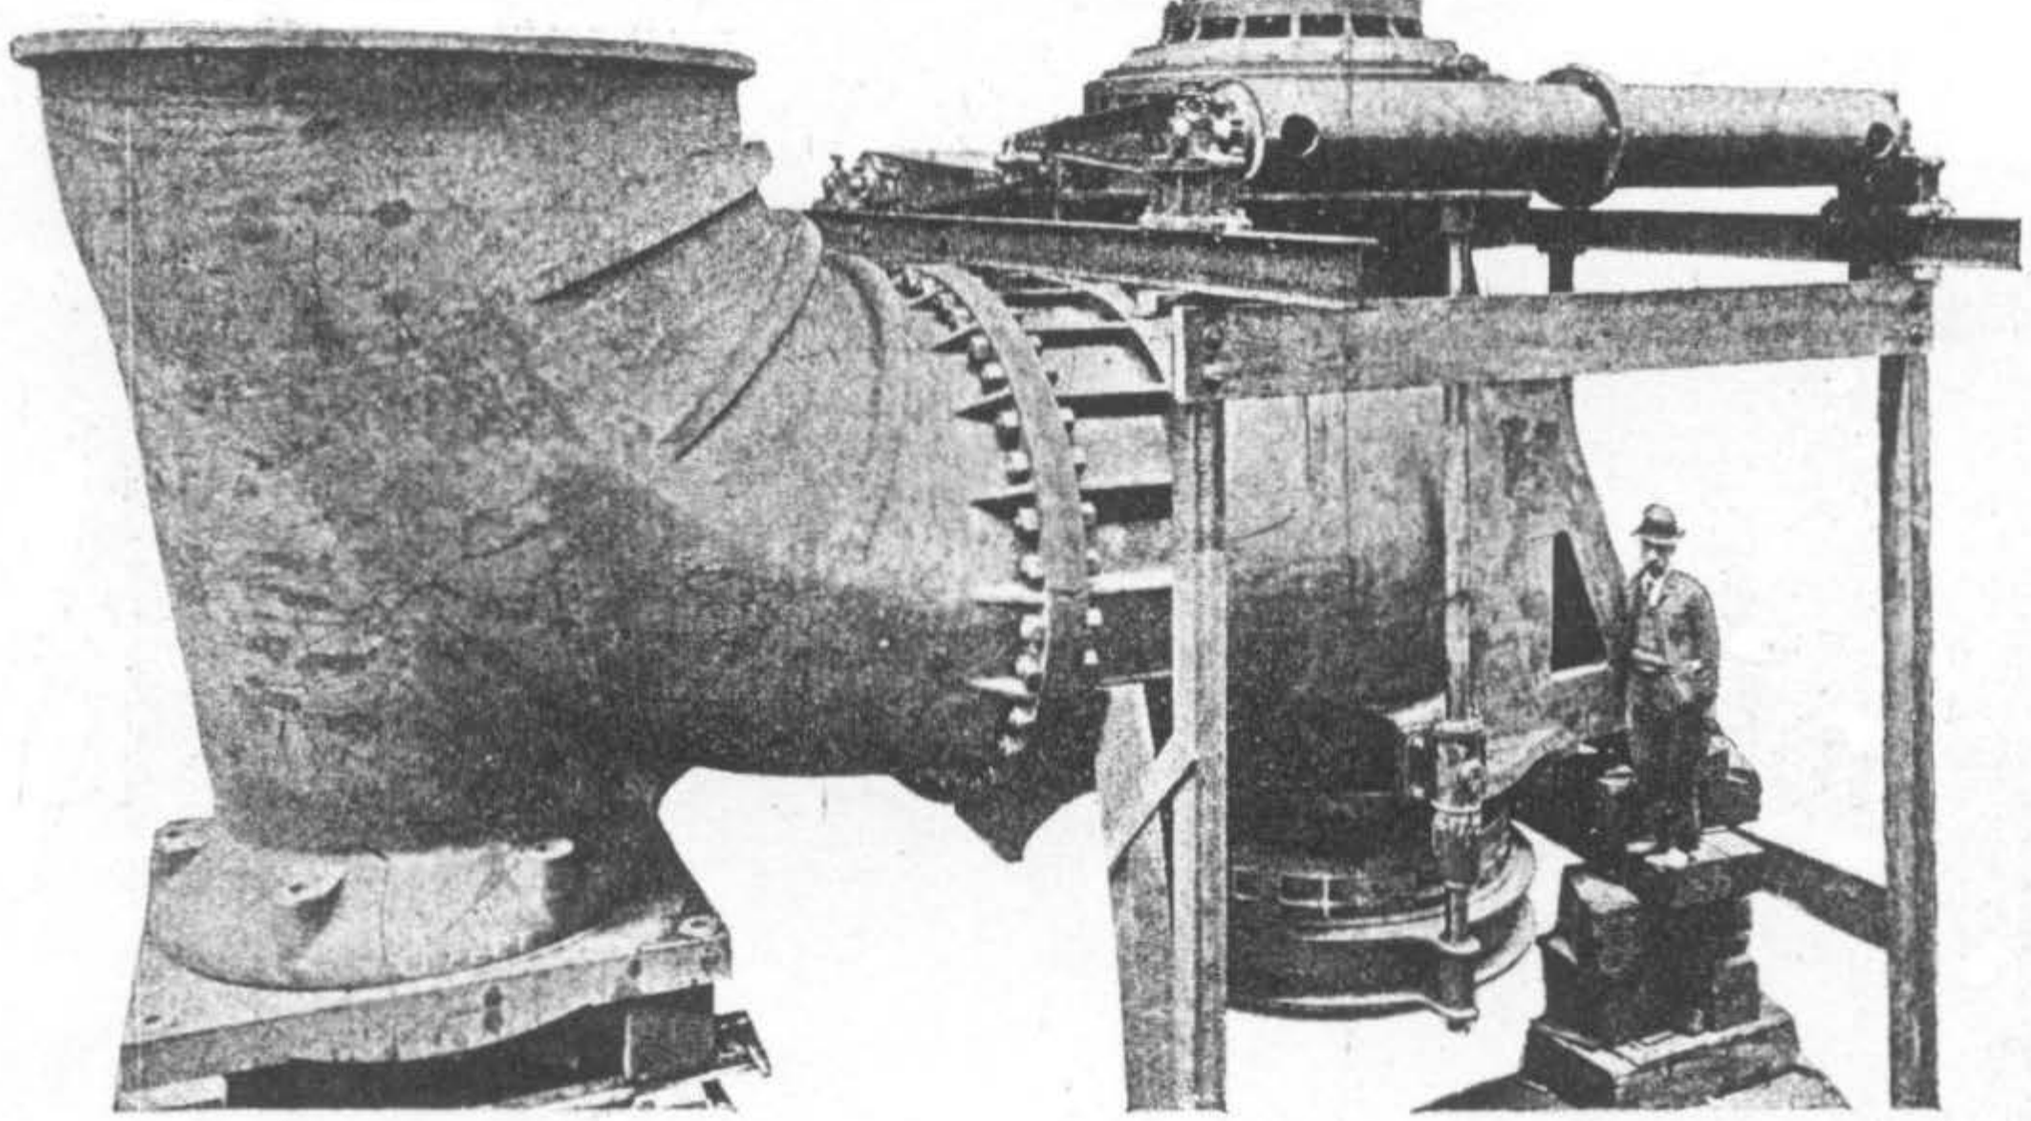
power can be furnished to manufacturers, especially those at a considerable distance, at a price profitable to them and the company. The company itself, of course, and the able engineers and scientists who are associated with it, have no theoretical doubts about the commercial success of the undertaking. And, if it is commercially successful, it is simply the beginning of a prodigious revolution in the manner of producing and delivering power. In that case the time is probably not far distant when all of the considerable mills, all of the lighting, much of the traction power of the region within three hundred or four hundred miles of Niagara Falls will be furnished with this living energy which has been captured from the Niagara cataract. There will be created a considerable city at Niagara Falls, and there will be a great development of Buffalo as a manufacturing centre. Then considerable water powers in other sections of the country will be utilized so that the force of them can be converted into an electric current and delivered for commercial purposes to the towns within a considerable radius.

THE TRANSMISSION OF THE ELECTRICITY.

It was the first intention of the engineers to carry the electric current from the power-house by means of wires stretched through a subway conduit, whose beginnings may now be seen at a point near the power-house. But it has been discovered that the construction of such a conduit will be too costly, and the electricity is to be transmitted by overhead wires. This is the part of the undertaking which Mr. Tesla has devoted much thought to for several years. He has assured the company that, by means of inventions and the scientific application of newly-discovered principles which he has



THE SUSPENSION BRIDGE, SHOWING THE OUTLET OF THE TUNNEL AT THE LEFT.



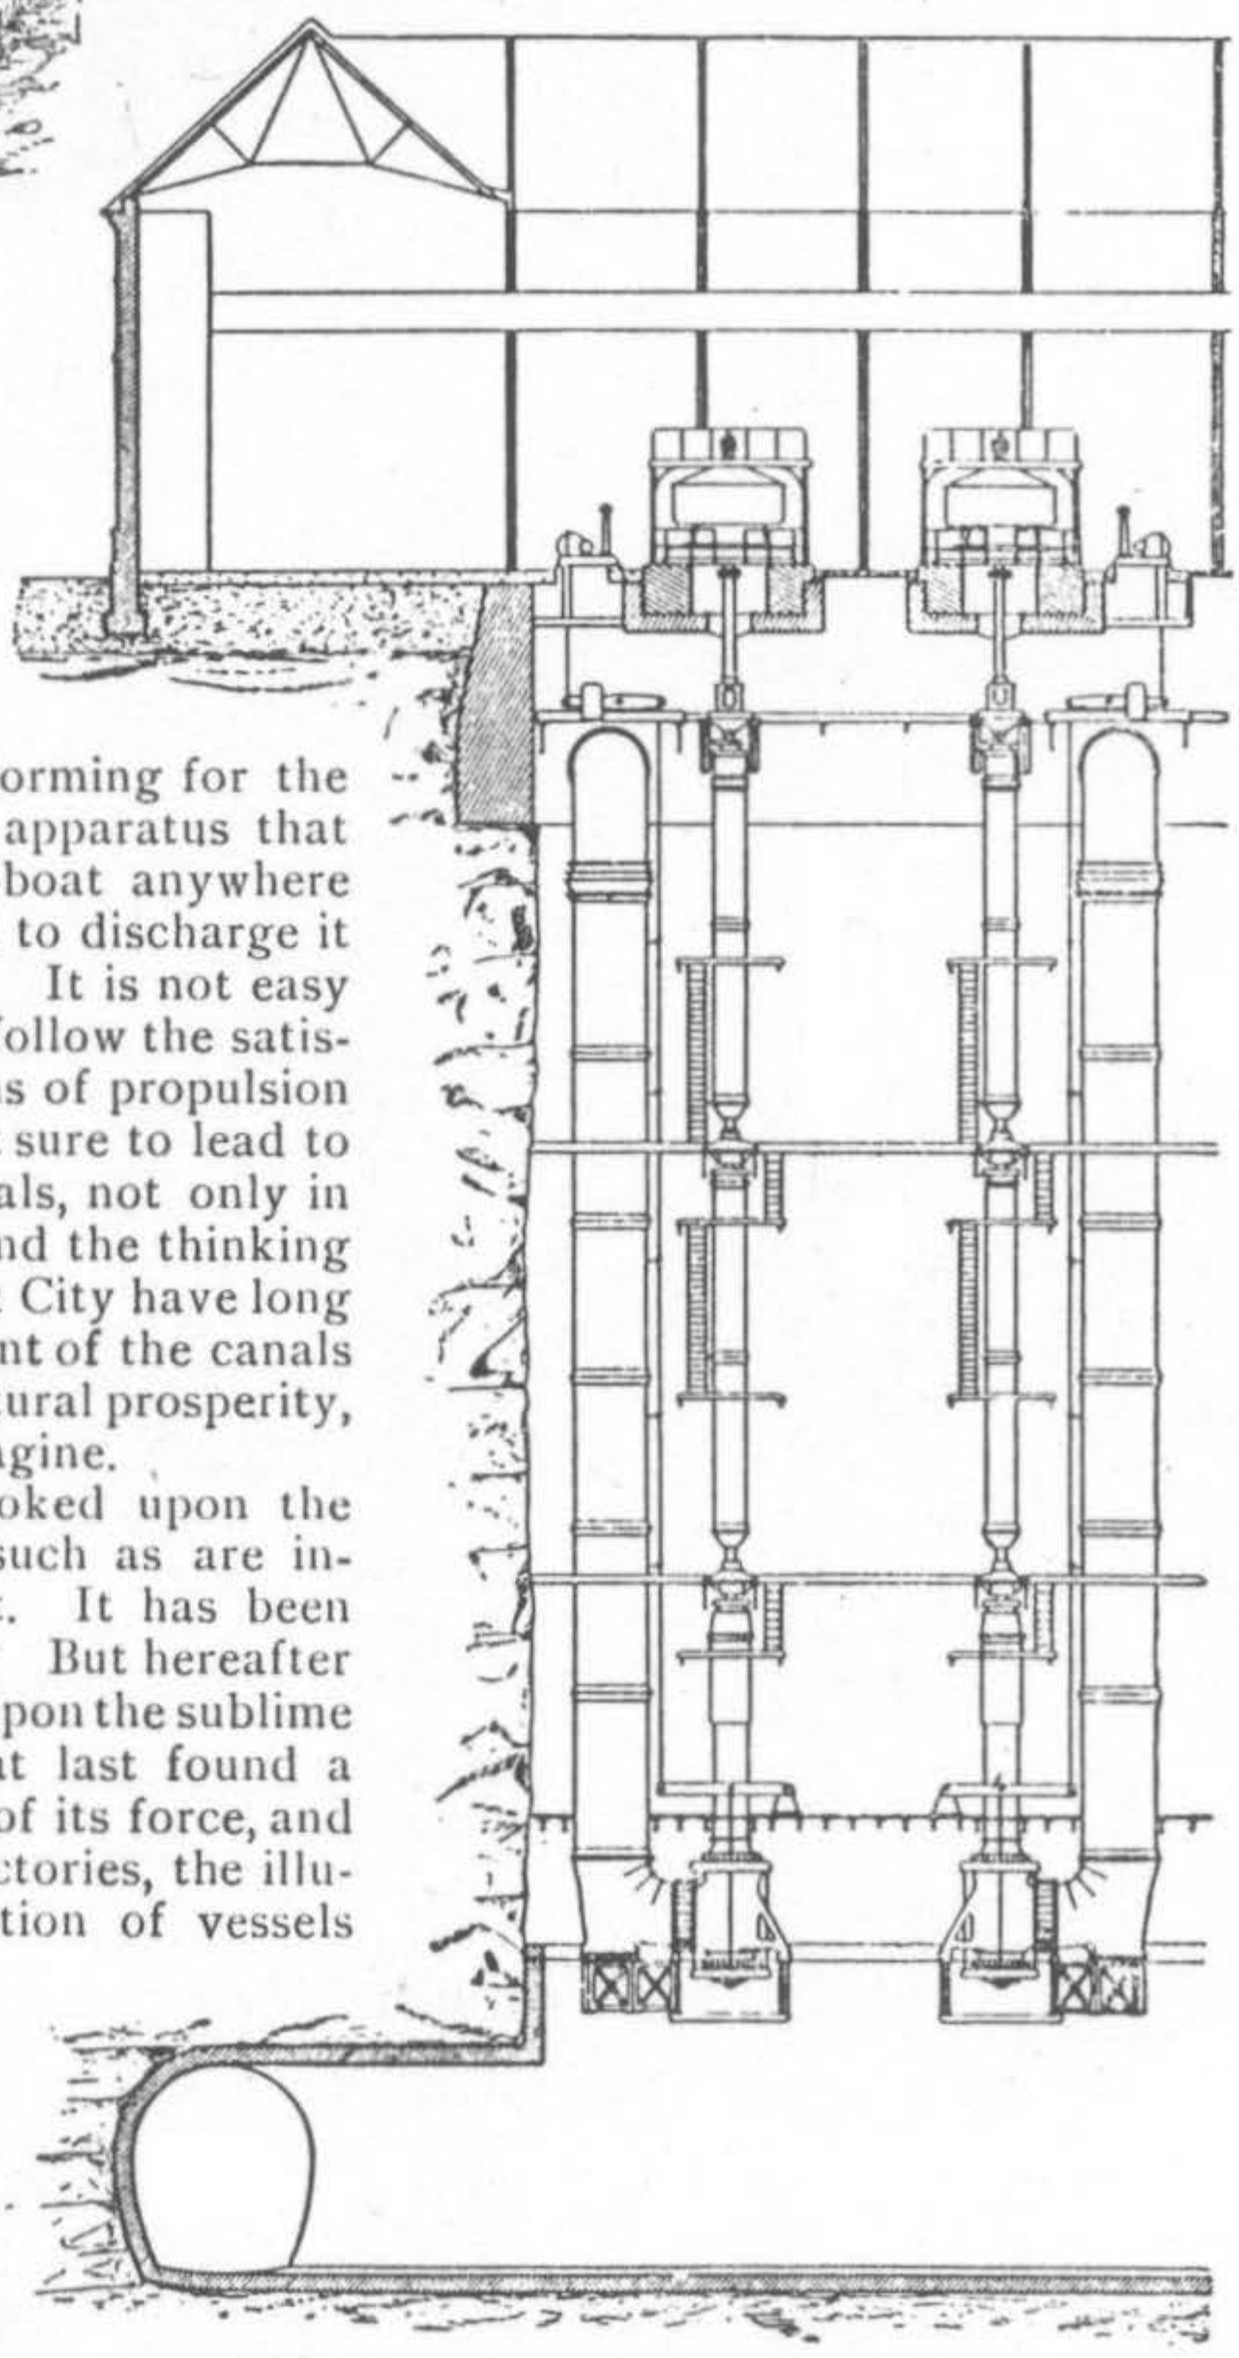
been able to make, it will be possible to convey the current without very great loss by induction or leakage, and under absolute control, by the use of certain transformers, as far east as Albany. It is Mr. Tesla's opinion that this current can be sufficiently utilized even to propel vessels from Albany to New York. The capitalists have faith in him. The scientists believe that he is right. The city of Buffalo is persuaded that it is so, and already contracts for the delivery of as much as ten thousand horse-power to that city have been made. In a general way it has been estimated that the power can be delivered to any town within a distance of three hundred miles, at a cost of about fourteen dollars a year per horse-power, and for twenty-four hours a day, while it is estimated that the cost to the city of Buffalo will be considerably less.

THE SEVERAL COMPANIES.

In the enterprise are several companies, each independent as a corporation, but all mutually dependent upon the parent company. There is the Niagara Construction Company, the Niagara Falls Power Company, the railway company (for they have built a railway some five miles in length), and the land company, which controls the new village of Echotah, a community which promises to be a model one. Then there are the Canadian companies, which will ultimately build two tunnels on the Canadian side, each of them representing a power-producing capacity of one hundred and twenty-five thousand horse-power, and work upon one of which is to be begun in a short time. It is also probable that in each of the towns in which electric power is furnished there will be organized

PENSTOCK AND SHAFTING. SIDE VIEW.

PENSTOCK AND CASING OF A FIVE THOUSAND HORSE-POWER TURBINE WATER WHEEL.



local companies for the control of it, independent in one respect, and yet practically controlled by the parent company.

One of the most important of the undertakings in contemplation is that of furnishing electricity for the propulsion of canal-boats. That the electric current can satisfactorily propel a heavily laden canal-boat was demonstrated by experiments made near Rochester last fall under the direction of Mr. Frank Hawley, who, while associated with the parent company indirectly, is more especially interested in the development of electric power for canal purposes. Already projects are forming for the equipment of the Erie canal with apparatus that will make it possible for a canal-boat anywhere to take up the electric current, and to discharge it again wherever the owner pleases. It is not easy to estimate the results that would follow the satisfactory use of electricity as a means of propulsion upon our water-ways. It is almost sure to lead to a greater development of the canals, not only in New York State, but elsewhere; and the thinking men of the exchanges in New York City have long said that with a greater development of the canals will come a commercial and agricultural prosperity, the limits of which no man can imagine.

A STREET IN THE NEW VILLAGE OF ECHOTAH.

Thousands of people have looked upon the Niagara cataract with emotions such as are inspired by no other natural object. It has been pronounced "nature's finest epic." But hereafter when the visitor who goes to look upon the sublime cataract discerns how men have at last found a way to take from it some portion of its force, and how the whirl of the wheels of factories, the illumination of cities, the steady motion of vessels upon the artificial waterways are all but responsive throbbings to the thunder of the cataract, perhaps he will consider that a yet finer epic has been written by the energy of those who have been engaged in subduing the forces of nature that they may serve mankind.

PENSTOCK AND SHAFTING—REAR VIEW.

McClures Magazine October 1894

NIAGARA.*

SINCE the first dawn, thro' vague and unknown ways,
  Between the icy north and where I fall,
  From lands beyond the pole, from where brooks call,
And sing responsive to the cold birds' lays,
I glide, I leap, I bound, thro' nights and days;
  I rush, I rave, I roar, and I appal—
  Ay! to the very heights of heaven's wall—
The hosts that reverential glances raise.

And puny men who walk the earth ne'er dream
  Of the great force beneath my glassy face;
    And, so, from my brown bed up to the sod,
I seem in all my majesty supreme
  Defying time and earth, and fate and space,
    To be the tumult of the tears of God!

AN EVENING IN TESLA'S LABORATORY.

WHILE the American Electro-Therapeutic Association was accorded a great honor in being the first body to receive an invitation to visit the Tesla Laboratory, and showed its appreciation by a large muster, it must be said that to engineers present the demonstrations made were even more interesting than to the physicians. The feature of the reception on Thursday evening was the exhibition of a recent form of Mr. Tesla's new machine, the oscillator, which was running beautifully and with which the experiments were performed. Some of these experiments were certainly quite remarkable. The oscillator was run at 350 pounds steam pressure, and in the course of his conversational remarks Mr. Tesla said that he did not anticipate any difficulty in running at much higher pressure with such a machine. There were two pistons in the machine vibrating in opposite phase 80 times a second. The vibrations of these pistons developed an electric current which was led to a bank of lamps, and some 50 incandescents were lit up by the current. Arc lights were also shown in operation, and Mr. Tesla pointed out the curious fact that when arcs were operated from this new type of machine, the oscillations of the pistons were but a fraction of the time of the oscillation of the carbon rod; and hence the lamps instead of pumping or jumping as they so often do when fed from the ordinary rotating machines, were as absolutely steady as though they were on a battery circuit. The ordinary rotating dynamo has inertia which requires time to respond, and hence considerable resistance, ohmic or inductive, must be provided in the ordinary arc armature; otherwise the amount of arc lights or variable load on the machine must be comparatively small in proportion to the steady load of incandescent lights.

Mr. Tesla repeated also what he said, as to another feature of advantage in the oscillator, at the time he first brought it to notice before the Chicago Electrical Congress, namely, the production of currents of constant period and the perfect maintenance of the regime once established. This enables him to perform experiments remarkable for the small amount of energy they take as compared with ordinary alternators. Mr. Tesla expressed the belief that by further perfecting such machines he will have at hand the means for transmitting intelligence to a distance without wires, as already pointed out in one of his recent lectures. He asserted that this problem depended solely on the perfection of this machine.

One of the very interesting and striking experiments shown was the following: Mr. Tesla had a circle or cylinder frame about 4 feet in diameter in a room about 40 feet by 80. This circle was composed of a number of turns of copper wire, and was entirely unconnected with anything and remote from anything, being in the centre of the open space. It was adjusted to the vibration of a current which passed through a wire stretched around the room; and vacuum tubes and small incandescent lamps were lighted by proper adjustments of the capacity of the circuit.

Another curious and suggestive experiment was the following. A small hoop or circle, about 3 feet in diameter was shown wound

with fine wire. Mr. Tesla explained that he had adjusted the wire to the ordinary average "capacity" of plain citizens, in such a way that the maximum current would flow through the wire. The ends of the wire were connected to two handles which could be grasped so as to allow the circle to be held out. The current induced in the wire sprang through the small air gap shunted by the handles, and powerful shocks were felt all around in the room, by means of this exploring instrument. When the area of the circle was compared with the area enclosed by the distant wire around the room, the effects were really remarkable.

Several motors were also on view, of the rotating field type, and single phase. There was one, of small dimensions, which served to count the oscillations, and which had been exhibited also at the World's Fair. Mr. Tesla touched incidentally on the advantages of the current curves employed in these machines, which are proportioned to the squares of the sines of the time. There are two such sine square curves superimposed in quadrature and Mr. Tesla commented on certain benefits obtained with such curves.

A great many other experiments were performed with static and electro dynamic induction, closing with the display of the vacuum tubes and phosphorescent bulbs lit up in the charged free spaces. Mr. Tesla frequently repeated the remark, which was obviously true to those who had seen his earlier experiments, that his oscillator is already proving of great value as a means of prosecuting further experiments and researches in the new field which he has opened up; while its promise of yielding great practical economy in the production of electricity is daily nearer realization. Among the advantages referred to were the ability of the machine to demonstrate the electro-magnetic theory of light, and its value as affording a crucial test of the Hertzian experiments and other investigations in that line. It may be added that besides the feature of running at almost any pressure, being, so to speak, frictionless, the most noteworthy fact to be appreciated by engineers is that when the piston vibrates at this great speed, and in spite of the high steam pressure, there is no packing on the piston whatever, and there is no leaking of the steam. As one watched the oscillator on Thursday evening, there was nothing to indicate that steam was present or was being used, except the steam gauge and its indication. The small boiler used by Mr. Tesla is one specially built for him by the Babcock & Wilcox Co., of their regular sectional type and tested up to 550 pounds. Mr. Tesla was really enthusiastic in praise of its working. The four arc lamps were of the Helios Company's make.

A MAN OF THE FUTURE.

A Genius Who Loves America and Has Added to Its Greatness.

How Nikola Tesla Looks at Work—The Day When We Can Telegraph Messages Without Wires—Niagara Power in New York—Electricity, Generated by Flying Atoms, Will be Pumped Out of the Earth for Use Anywhere. Tesla's Early Days and His Wonderful Experiments—His Latest Invention.

New York, Oct. 20.—It is a most difficult thing to interview Nikola Tesla, but to sit down and talk with him, man to man, ah, that is a different matter, and if one has had that privilege he will be glad to remember it in years to come, and to tell his grand-children about it, for it is quite likely that they will know very well who Nikola Tesla was.

This brilliant young electrician, who undoubtedly is the foremost thinker of the world in his chosen field is honestly and sincerely modest. No writer who has tried to get him to talk for publication has any doubts on that score. "It is an embarrassment to me," he says, "that my work has attracted much public attention, not only because I believe that an earnest man who loves science more than all should let his work speak for him if it will, but because I am afraid that some of the scientists whose friendship I value very much suspect me of encouraging newspaper notoriety." Mr. Tesla reverted to this matter several times in the course of two conversations and is evidently sensitive about it. Therefore, the portions of this article that come from him should be regarded as a spesial concession, particularly as he has never talked so freely before. Bogus interviews with him have been published of late, but this is genuine.

Nikola Tesla.

Mr. Tesla spends his days on the fourth floor of a machine shop at No. 33 South Fifth avenue. His name does not appear anywhere on the building, and there is nothing about the place to indicate that it is one of the world's centers of electrical interest. The whole floor is occupied by Mr. Tesla's laboratory, except that one corner is partitioned off into the plainest of little offices containing principally a modest desk for the inventor a more modest desk for his bookkeeper; a book case largely devoted to the "Official Gazette of the patent Office," and a small black board which hangs on the wall and bears evidence of hard usage. The black is worn from this board in several spots, and the rest of it is covered with figures and cabalistic signs. No doubt the science of electricity would have been notably poorer but for some of the problems worked out on that shabby black board, for when the inventor is puzzled he goes to it and works on it nervously with a stubby piece of chalk.

The laboratory itself looks commonplace to the uninitiated. It is filled with machinery and electrical appliances, and a stranger prowling about the building at will would surely mistake its fourth floor for a part of the machine shops below. One who is not an electrician would find in the Tesla workshop none of the marvels that make Edison's laboratory better than a circus for the sight-seer. An electrician, however, would find secrets there with which he could make and break colossal fortunes on the stock market, for the reasons that will appear further on.

But Mr. Telsa's half-dozen employes are tried and trusted men, and the would-be visitor would find it an extremely difficult matter to get into this laboratory. If he did get in he would be more than likely to find the inventor there, working over some bit of machinery, with a handkerchief tied about his throat in lieu of a collar, yet dressed in clothes of fashionable cut, and generally looking very neat and clean. Unlike Mr. Edison, the younger inventor has some regard for his personal appearance.

One rarely meets a man more free from affectations and self-consciousness than Nikola Tesla. He does not like to talk of himself, and when that subject comes up he is sure to steer away from it as quickly as possible. He has bachelor quarters at the Gerlach, on West Twenty-seventh street, but he can be found at Delmonico's nearly always at breakfast and dinner time.

With due apologies to Mr. Tesla for so much personality, it may be said that he has the same cast of countenance as Ignace Jan Paderewski—long and thin, with fine, clean-cut features, low forehead, and a certain gleam of the eye that denotes what might be called spirituality. He is an idealist and one who has created an ideal of him from the fame that he has won, will not be disappointed in him upon seeing him for the first time. He is fully 6 feet tall, very slender, very dark of complexion, nervous and wiry. Impressionable maidens would fall in love with him at sight, but he has no time to think of impressionable maidens. Day and night he is working away at deep problems that fascinate him, and any one who talks with him for even a few minuntes will get the impression that science is his only mistress and that he cares more for her than for money or fame.

Any one who has met Paderewski and has been able to speak German or French with sufficient fluency to enjoy a conversation with him, and who has also had the pleasure of a talk with Tesla across one of Delmonico's tables, will feel instinctively that the Polish pianist and the Servian electrican have much in common, and that it is a great pity they have never met. Some philanthropist could do both of them a service by bringing them together when Paderewski comes to this country again next December. They could at least find a common ground of interest in Slavic literature, with which both have a wide acquaintance.

Speaking of love for science, Mr. Tesla said the other day in one of the rare moments when he could be induced to talk of himself: "Wherever I am, I cannot help working at problems that present themselves to me and seem so important that I cannot help but try to solve them. I spend so many hours at my laboratory at times that my friends become alarmed and threaten to lock the place up and hide the key. Seriously," he continued, with earnest face and eyes fairly ablaze, "seriously, if they tried to do that I should shoot them. I would indeed. It makes no difference to a man's health how long he works as long as he loves his work, for his affection is like the oil in the lamp which keeps the wick burning without consuming the wick itself. When the oil is gone, then it is that the wick goes fast. If at any moment I lost my eagerness and enthusiasm, then very likely I would go to pieces.

"That was what would have happened to me if I had continued to be a journalist. You never knew that I was once a member of your profession? Well, I was. The trouble with me was that I wrote too carefully, and, as it seems to me, too thoughtfully. When I wrote an article of which I was particularly proud, my friends would say: 'Tesla, that was a masterpiece.' But the editor would say: 'Why don't you write something more lively? Not a half a dozen people would read that stuff.' No, journalism is the hardest work in the world for the man who wishes to be thoughtful. My heart was not in it, and it would have worn me out soon, like the wick without any oil. Even as it is now I get worn out sometimes, but it is a great comfort to be one's own master and to feel that there is nothing to prevent one's dropping all work at any moment and starting for Europe or elsewhere for as long a rest as one wants.

"I have noticed a queer thing about my mental operation, and that is that my mind seems to work in two halves, each independently of the other, so that when I talk, or even when I sleep, only one half of my mind appears to be thus engaged, the other half goes on steadily with whatever I have on my mind, or may be I ought to say with whatever it has on its mind. My friends say, 'You will kill yourself.' I say, 'Nonesense.' I used to be an athlete once and I recuperate very quickly. See me now." He held up his hands as if they were trustworthy indicators of his physical condition. They were long and thin and nervous. They trembled a little and the conclusion naturally to be drawn from them was that their possessor was a man whose tremendous energy, although under good control, was likely to use him up if run at such high pressure much longer.

Mr. Tesla is only 37 years old, and he looks even younger. He was born at a town called Smiljan in Servia, on the borderland of Austro-Hungary. His family was an old one, cultured and highly respected. His father was an eloquent preacher of the Greek church, and his mother was a woman of re markable ingenuity. He had an inherited taste for mechanics and it is her blood that made Tesla what he is. His father wanted him to enter the church, but he could not be kept away from experiments in magnetism and electricity, in which he was deeply interested by the time he was 16. He was finally permittd to go to a polytchnic school with the idea of becoming a professor of mathematics and physics. He was making inventions of improvements for the telephone before he was 25 years old. He secured employment in Paris as an electrical engineer and then came to America early in the80's, not because he had any definite employment in view, but because he became convinced that the United States was the best country in the world for an inventor, because new ideas were more quickly and highly appreciated here than anywhere else.

The day he arrived he e he went to work for Mr. Edison, for whom he had, and has yet, the strongest admiration. He left the wizard of Menelo park in order to join a company organized to sell some of his inventions in arc lighting.

Much of Mr. Tesla's spare time during his first five years in this country was devoted to experiment with what is known as the rotating field for use with the alternative current. In 1887 Prof. Anthony proved that the young electrician had produced an alternating current motor of an efficiency equal to that of direct current motors, yet dispensing with the brushes and commutators which had added materially to the cost and inconvenience of manufacturing electricity.

He pushed on eagerly in the field he had opened, experimenting with alternating currents of extraordinary high potentials and frequencies. The results of his experiments were laid before the public in a lecture delivered before the American Institute of Engineers in May, 1891. Before that time he had been known only to electricians. By the hour the reports of that lecture had found their way to the public, he was famous. The brilliant gathering of scientists before whom the lecture was delivered, was taken by storm with his theories and his remarkable experiments in verification of them. Soon after,

Those Little Worlds.

another lecture was delivered before the most notable body of electricians in Europe, the Institution of Electrical Engineers in London, and his reception by them was as enthusiastic as it had been in America. A day later, by special request, he repeated his experiments before the Royal Institution, and soon afterward responded to an urgent call from the two foremost societies of engineers in France. In 1893 he delivered lectures in Philadelphia and Europe, which served to intensify public interest in him. One of his experiments on these two occasions was spectacular in the extreme. Facing an audience of some 5,000 persons, he passed through his body a current of 200,000 volts, causing streams of light to pour from his body and break forth from his finger tips, whereas a current of a hundreth part of that energy would have killed him instantly, thus proving that the amount of electric energy that may be passed into the human body depends on the strength and frequency of the current, and that the higher these are the less harm they do the body. Mr. Tesla said that at the time that the only inconvenience he felt from thus making an electric light of himself was a slight pricking as of a needle, and a burning sensation at the finger tips.

The most important work on which Mr. Tesla is now engaged, and which bids fair to bring him more fame than anything he has done before this, is a machine by which a heretofore unheard of steam pressure can be applied to the generation of electricity, reducing the waste of the current, and what is of supreme importance, reducing the cost of electricity.

It is easy to see that any device by which the cost of electric power is brought below the cost of steam power will bring a revolution in the process of manufacturing more sudden and startling than was brought about by the introduction of steam. The economical transmission of electricity generated by water power, as at Niagara Falls, has already brought a promise of this revolution, and if Mr. Tesla's machine will bring a corresponding reduction in the cost of electricity to cities too far away to derive benefit from water power like that at Niagara, then, indeed, the revolution will be complete. Electric motors will everywhere

Experimenting.

take the place of costly and wasteful shafting in mills and factories, and the day when private houses will be lighted, heated and, to some extent, run by electricity, will be brought almost as near to other cities as it now is to Buffalo, which will receive its first installment of power from Niagara Falls in a few weeks at a price promised to be somewhere near a fourth cheaper than that now paid for the work done by steam.

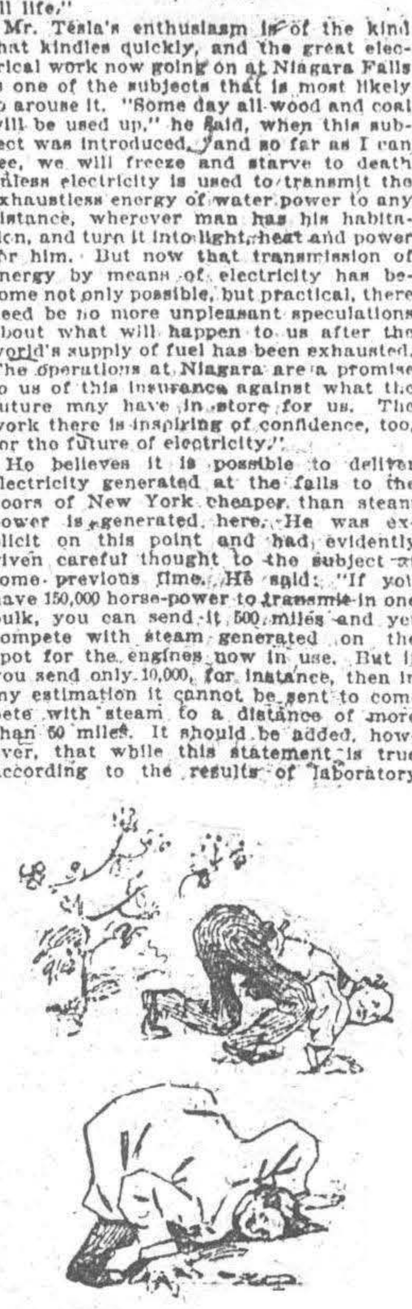
This much may be said positively, and the statement is here made to the public for the first time: If the wonderful machine on which Mr. Tesla is now putting the finishing touches works as well elsewhere as it has already worked in the Tesla laboratory, it will bring the extraordinary advantages suggested above. The inventor himself refuses to make any definite statement as to what his engine will do. "I know," he says, "that it will accomplish in my laboratory results that cannot but be considered important, and that certainly open up a new field for high-pressure boilers. It is now in operation and has succeeded absolutely, but of course I must not predict from laboratory results what a machine will accomplish when applied to public uses. It may take two or three years to prepare for placing it on the market. I have, of course, a pretty definite idea as to the reduction it will make in the cost of electricity, but there are many reasons why it would not be well to give the figures."

The young inventor endeavors to speak very conservatively of this new machine of his, but it is quite probable that he believes he has solved one of the most important practical problems within reach of the electrical science of the present day. Any one who is familiar with the mathematics of the steam engine will appreciate one phase of his device when it is stated that it is now run with a steam pressure of 375 pounds, the highest that was ever put to practical use. The pressure generally used is about 175 pounds. The boiler which supplies this steam pressure in the Tesla laboratory is said to be the most powerful ever constructed. It was built for the inventor by Babcock & Wilcox, and so far has responded to the amazng test to which it has been put. The machine to which this unprecedented pressure has been applied has to run almost without friction, that is the kernel of Mr. Tesla's discovery. He tells me that he would dare apply a steam pressure of 1,000 pounds to his machine, and would do so if he could get a boiler that could supply the pressure. Engineers who read this statement will conclude, unless they know Mr. Tesla personally, that he is crazy.

One technical value of this new discovery for utilising steam at high pressure is in the saving that it makes in the cost of heat for producing the steam, because it is a queer freak of nature that requires proportionately less heat to produce steam at high pressure than to produce it at low pressure. For instance, it takes an increase of only 56 degrees Fahrenheit to raise steam pressure from 125 pounds up to 250 pounds.

There are other electricians who say of Mr. Telsa that he is not a particularly great man as a practical, working electrician, and that his machines are not always as valuable in practice as they are in theory, but most of them admit willingly that he has no peer as a theorist and investigator, a dreamer of the dreams that will come true. His talk of the future is worth thinking about. He is very confident that great things are coming soon through the utilization of the electrostatic magnetic condition of the earth itself. "Sometime," he says, "electricity will be taken from all about us and used for light, heat and motive power. We will reach down to the earth and tap the current anywhere, getting all we want without expense. It is interesting to sit down somewhere, away from all interruption, and think out what that would mean. It seems hardly possible that these wonders can be far away, because the process by which they can be realized is so simple. Expressed roughly, all that would have to be done would be to set the earth's electricity to vibrating, and adjust a machine to these vibrations wherever the force was required. It is something as if the earth were a rubber bag. Shake it in one place and you feel the vibrations in another place. You and I could not feel the electrical vibrations, but I have in mind a machine that will. If nothing else is transmitted by these vibrations, intelligence surely will be. I have the best of reasons for predicting that messages will be transmitted through the earth in this way without wires, like a pulse through a human being. It seems surprising that this has not been done before.

"It is reasonable to suppose that the earth's electricity is generated by the atoms of which all things are composed. We and our world are not only whirling through space with terrific speed, but



The Incondescent Human Lamp.

every little atom in the world is whirling, too. Now there is good reason to believe that the molecules and their atoms are really little worlds that revolve and move in their orbits like the stars, causing the ether about them to spin with them, thus generating electricity, or affording the conditions suitable to its generation.

"While electricity could hardly be called the ether itself, it is probable that the effects of dynamic electricity and electromagnetism are the effects of ether in motion, and the effects of static electricity are the effects of ether under a strain. The discovery of a method of utilizing this practically exhaustless force that lies so close at hand, would uncover what are surely some of the greatest secrets of the universe. It would be the greatest discovery since the creation, and would bring about a total revolution in all life."

Mr. Tesla's enthusiasm is of the kind that kindles quickly, and the great electrical work now going on at Niagara Falls is one of the subjects that is most likely to arouse it. "Some day all wood and coal will be used up," he said, when this subject was introduced, "and so far as I can see, we will freeze and starve to death unless electricity is used to transmit the exhaustless energy of water power to any distance, wherever man has his habitation, and turn it into light, heat and power for him. But now that transmission of energy by means of electricity has become not only possible, but practical, there need be no more unpleasant speculations about what will happen to us after the world's supply of fuel has been exhausted. The operations at Niagara are a promise to us of this insurance against what the future may have in store for us. The work there is inspiring of confidence, too, for the future of electricity."

He believes it is possible to deliver electricity generated at the falls to the doors of New York cheaper than steam power is generated here. He was explicit on this point and had evidently given careful thought to the subject at some previous time. He said: "If you have 150,000 horse-power to transmit in one bulk, you can send it 500 miles and yet compete with steam generated on the spot for the engines now in use. But if you send only 10,000, for instance, then in my estimation it cannot be sent to compete with steam to a distance of more than 50 miles. It should be added, however, that while this statement is true, according to the results of laboratory

Listening for the First Telegraphic Message Sent Through the Earth.

practice, it may not apply exactly to the actual operation where all the differences of condition from those in the laboratory cannot be fully discounted beforehand."

A fellow-electrician who is in a positon to judge of Mr. Tesla with friendly impartiality gives this opinion of him—and it is an opinion that will probably be found to have the approval of most of the scientists who have come in contact with this wonderful young man: "He is a scientist who is in advance of his time, a seer, a genuine poet of electricity, a man whose eye is focused to the great things of science, and whose mind is fitted by nature to deal with them better than with the commonplace things that the most of us are obliged to busy ourselves with. He has been charged with being a visionary, but it seems to me that the charge is misleading, for though Tesla undoubtedly saw visions that other scientists had not seen, some of them were based on reasoning rather than on imagination unaided by facts, as was proved by the circumstance that the other scientists saw the same visions after Tesla had pointed out the way to look for them. They were visions that opened rich new fields for scientific exploration and that will bring practical benefits to every household. Tesla is young and strong and his head is not turned. He is as eager as ever, and there is no reason to suppose that the most brilliant and useful part of his life is not yet before him."

Mr. Tesla is gong to Europe very soon, but not to stay—not by any manner of means—he is too thorough-going an American for that. He believes the United States is the most progressive,

Power Generated from Niagra Falls.

enlightened and liberal land on earth, and of all the reasons he has for satisfaction with life he holds one of the greatest to be the decision that brought him to this country ten years ago.

I said to him a week ago, on bidding him goodby: "You're sure you are thoroughly Americanized now; that you'll never hunger after any other titles than that of a citizen of the United States." And this was the memorable saying with which he made an enthusiastic answer: "You bet."

Electric Motive Power.*

Relative Merits of Two-phase and Three-phase Currents.

BY ALBION T. SNELL.

Experts differ as to the relative merits of two a nd three phase currents. As regards the alternators and motors there is, perhaps, not much to choose between them. Machines designed for similar outputs, whether synchronous or non-synchronous, are found to have about the same efficiencies, starting torque, weight, and apparent watt consumption, the three-phase machines, however, being the better, according to experiments made by Mr. Kolbein, the chief engineer of the Oerlikon Works. As regards the winding details, perhaps the two-phase type is the simpler. The main difference between the two systems lies in the relative weight of copper required in the conductors for given conditions, and the ease with which the currents may be handled, regulated and controlled.

The first experiments with three-phase working brought to light difficulties in the regulation of pressure between the three mains at the points of supply, when the currents in the three circuits were not approximately the same, which though since overcome to some extent, are greater than those obtaining with two-phase currents—they lie chiefly with the design of alternators and transformers. Two-phase currents, if worked

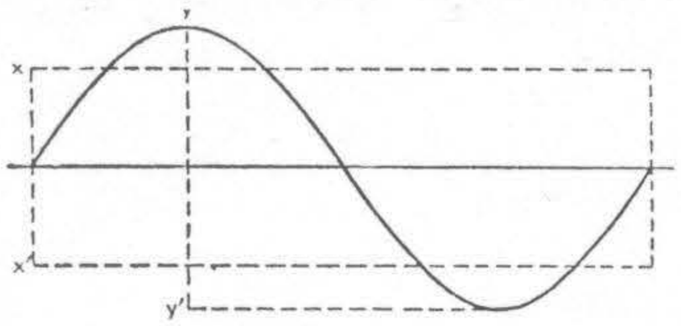

FIG. 1.

$x\,x'$ = Effective pressure of 3,550 volts.
$y\,y'$ = Maximum pressure of 5,000 volts.

with *two separate circuits* are as easily dealt with as single-phase currents, and serve readily most purposes to which single or poly phase currents are usually applied. They are specially convenient for distribution. It may be safely inferred that two-phase are better adapted for a combined service of light and power work; while the three-phase currents are specially useful for running with equally loaded circuits, and therefore are not generally so suitable for lighting work.

For simple transmission of power between two distant points, however, the requirements are different, and the three-phase current system is generally cheaper than either a continuous current or a one or two-phase current system.

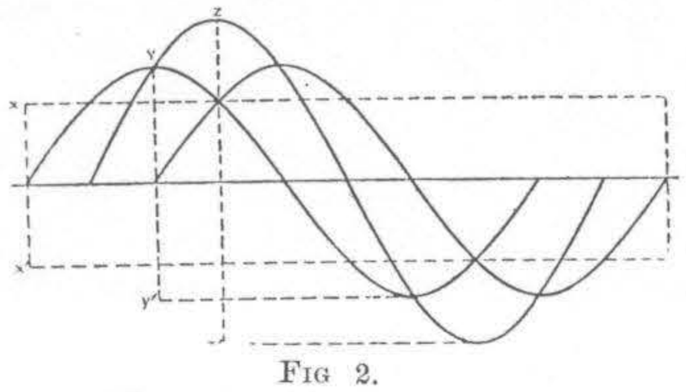

FIG 2.

$x\,x'$ = Effective working pressure of 3,550 volts.
$y\,y'$ = Maximum working pressure of 5,000 volts.
$z\,z'$ = Max'm component pressure of 7,100 volts.

This interesting and important problem may be considered from three points of view, each of practical value :

(1) On the basis of effective pressure at the distributing station (or motor terminals, perhaps).

(2) On the basis of maximum difference of pressure between conductors.

(3) When the economic law is considered.

The significance of the difference between effective and maximum pressure is at once apparent if Figs. 1, 2, 3 and 4 are examined.

In these figures the *electrical centre of gravity* is shown graphically. In any electrical circuit of good or bad insulation there is a datum pressure with reference to the variations of pressure in the circuit. For example, in a continuous current circuit the absolute pressure of the negative pole of the dynamo will have a constant ratio to that of the earth's surface at the particular site, and the difference of pressure between

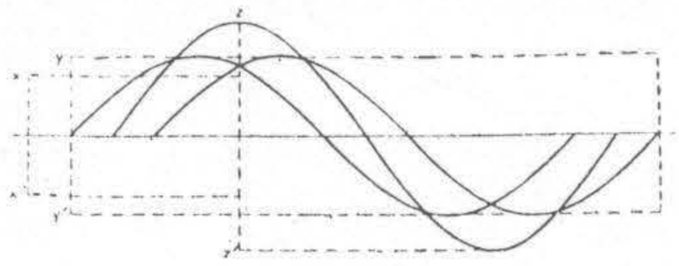

FIG. 3.

$x\,x'$ = Effective working pressure of 2,500 volts.
$y\,y'$ = Effective component pressure of 3,550 volts.
$z\,z'$ = Max'm component pressure of 5,000 volts.

it and the positive pole will simply affect the absolute pressure of the positive pole. And if the negative pole be grounded, the datum pressure will be that of the earth's surface.

Again, with an alternate circuit, with both poles insulated, the cyclical changes will alternately raise and lower the absolute pressure above and below zero pressure, which corresponds to that of the earth's surface. Thus in a circuit carrying a current of 5,000 effective volts pressure the maximum pressure between any two points of the circuit will be $5{,}000\ \sqrt{2} = 7{,}050$ volts, while the absolute pressure, i. e., that above the earth, will be only 3,525, positive or negative. The stress through the insulation to earth will, therefore, be only 3,525 volts.

But if the circuit be grounded, say, at one of the main terminals, the absolute pressure between the other terminal and earth will

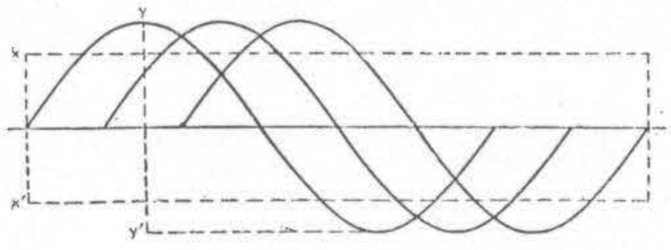

FIG. 4.

$x\,x'$ = Effective pressure of 3,550 volts.
$y\,y'$ = Maximum pressure of 5,000 volts.

be 7,050 volts, and therefore the insulation all over the high-pressure circuit will be subjected to this stress, although the effective working pressure will remain the same as before.

This possible change in the stress upon the insulation of a circuit carrying an alternate current has led to the general practice of earthing one of the primary mains, usually at both the generating and distributing circuits. The maximum stress is thus accepted and suitable precaution adopted to safeguard against accidents; and additional security is gained because a fault in the other main at any point at once blows the fuses and disconnects the faulty section.

With two-phase three-wire circuits it is permissible to earth the middle wire at the generating station, which then is at zero pressure. The same precaution is observed with the "star" coupled three-phase system. With the "triangle" three-phase system it is not permissible to earth either of the mains, since the earth would then form part of the circuit.

It appears then, from considerations affecting prime cost of line the three-phase system is cheaper for long-distance transmission than either single-phase or double-phase alternate currents. Continuous currents are the cheapest of all, but are not admissible for extra high pressures.

The selection of a system for a long distance transmission of power plant will mainly depend upon the maximum permissible pressure. If it be possible to work at such pressures as are feasible, in the engineer's judgment, for continuous-current dynamos (coupled in series or otherwise), then there can be no doubt from considerations affecting the line that this will be the cheapest and best system. But if extra high pressure be deemed advisable, then the three-phase system will generally prove the cheapest.*

In connection with this question it is important to notice that the engineers responsible for the electric transmission of power plant being laid down at Niagara, have finally, after mature consideration, decided upon a four-wire two-phase system. The reasons for their choice are given by Prof. G. Forbes, in a Paper entitled "The Electrical Transmission of Power from Niagara Falls," read before the Institution of Electrical Engineers on November 1, 1893. The details of the scheme have been strongly criticised by English experts, and the choice of the two-phase currents is open to doubt. When it is considered that Buffalo, the nearest large city, is fifteen miles distant, it is clear that the weight of copper will be a very important item in the cost of the whole plant, and in the author's judgment a three-phase system would prove more economical in first cost and give as good pressure regulation as the two-phase. For it must be recollected that there is a line difference of pressure of 20,000 volts, and hence step-down transformers will have to be used at every point from which power is taken. The *main line* drop will, therefore, be as difficult to regulate with two-phase as with three-phase currents; and variation of pressure of submains of the distributing systems can be as readily controlled by using *independent* secondary circuits from three-phase transformers as from *separate* secondary circuits of single or two phase transformers, Prof. Forbes's argument that two-phase currents are more easily *redressed* than three-phase currents is probably sound, but the fact that no form of alternate current has yet been made unidirectional in a practical manner cannot be ignored.

* The *Electrician*.

* The generating plant may perhaps be a two-phase one, with suitable step-up transformers, as proposed by Mr. Scott, of the Westinghouse Company. And it may also prove economical to transform the phase again at the receiving station. The ingenious proposals of Mr. Scott, however, have not yet been verified in practice; but there seems to be no doubt of their feasibility and usefulness.

Scientific Progress.

Tesla's Oscillator.

Tesla's latest invention, the "oscillator," is one of the most remarkable appliances of the age. It is described as being the core of a steam engine and the core of a dynamo combined, making a harmonious mechanical adjustment. This combination, says an enthusiastic admirer, constitutes a machine which has in it the potentiality of reducing to the rank of old bell metal half the machinery at present moving on the face of the globe. It may come to do the entire work of the engines of an ocean steamship within a small space they occupy and at a fraction of their cost, both of construction and operation. It will do this work without jar or pounding, and will reduce to a minimum the risk of derangement or breakage. There is nothing in the whole range of mechanical construction, from railway locomotives to stamp mills, which such an invention may not revolutionize. The essential characteristic of the machine is the application of the pressure of steam to produce an extremely rapid vibration of a bar of steel or piston, which, in turn, is so adapted to a set of magnets that the mechanical energy of the vibration is converted into electricity. The extraordinary result is that practically an absolutely constant vibration is established, and a power is obtained greatly beyond that obtainable in the most costly expansion engines using a similar amount of steam.

Besides saving in mechanical friction the 35 per cent of loss in the working of the engine, the 15 per cent of loss in belt friction, and the 10 per cent of loss wasted in the dynamo, making altogether an addition of 60 per cent to the available energy obtained from the steam for the purpose of producing electricity, it is simpler, lighter and smaller than the mechanism it is designed to replace, absolutely constant in its action, automatically regulated, and subject to the least possible amount of wear and tear. The utilization of this machine in any branch of industry would result in an appreciable lowering in the cost of production, and it is quite possible that its first general employment may be in electric lighting.

In the face of this marvelous invention a recent statement of Tesla seems hardly longer visionary. The young Montenegrin said: "I expect to live to be able to see a machine in the middle of this room and move it by no other agency than the energy of the medium in motion around us."

ON THE PRODUCTION OF ROTARY MAGNETIC FIELDS BY A SINGLE ALTERNATING CURRENT.

READ BEFORE THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS DECEMBER 19, 1894, BY LUDWIG GUTMANN.

Since the first announcements of Professor Ferraris and Mr. Tesla that rotation can be accomplished by employing two or more alternating currents of displaced phase, the question has been raised by many an engineer as to the possibility of producing a rotary magnetic field by the use of a single circuit, carrying the ordinary alternating current, instead of requiring three or more wires or several independent circuits. So far it has been necessary to construct a special generator armature, the windings of which were rotated in a field of constant polarity, to produce two or more currents lagging in phase behind each other. To use the currents generated for establishing a progressive or rotary field it was necessary to carry as many wires to the place of consumption as currents were employed differing in phase. Six years have passed, and quite rapid progress has been made in various directions. I wish now to bring to your notice a method of generating a rotary magnetic field by a single alternating current or its field without condensers or choking coils. This is accomplished by a device brought out by me some three years ago. Its fundamental principle is hardly as yet appreciated. However, the World's Fair exhibits, as well as literature of late, show that the device has attracted attention, and that several engineers have approached the principle involved.

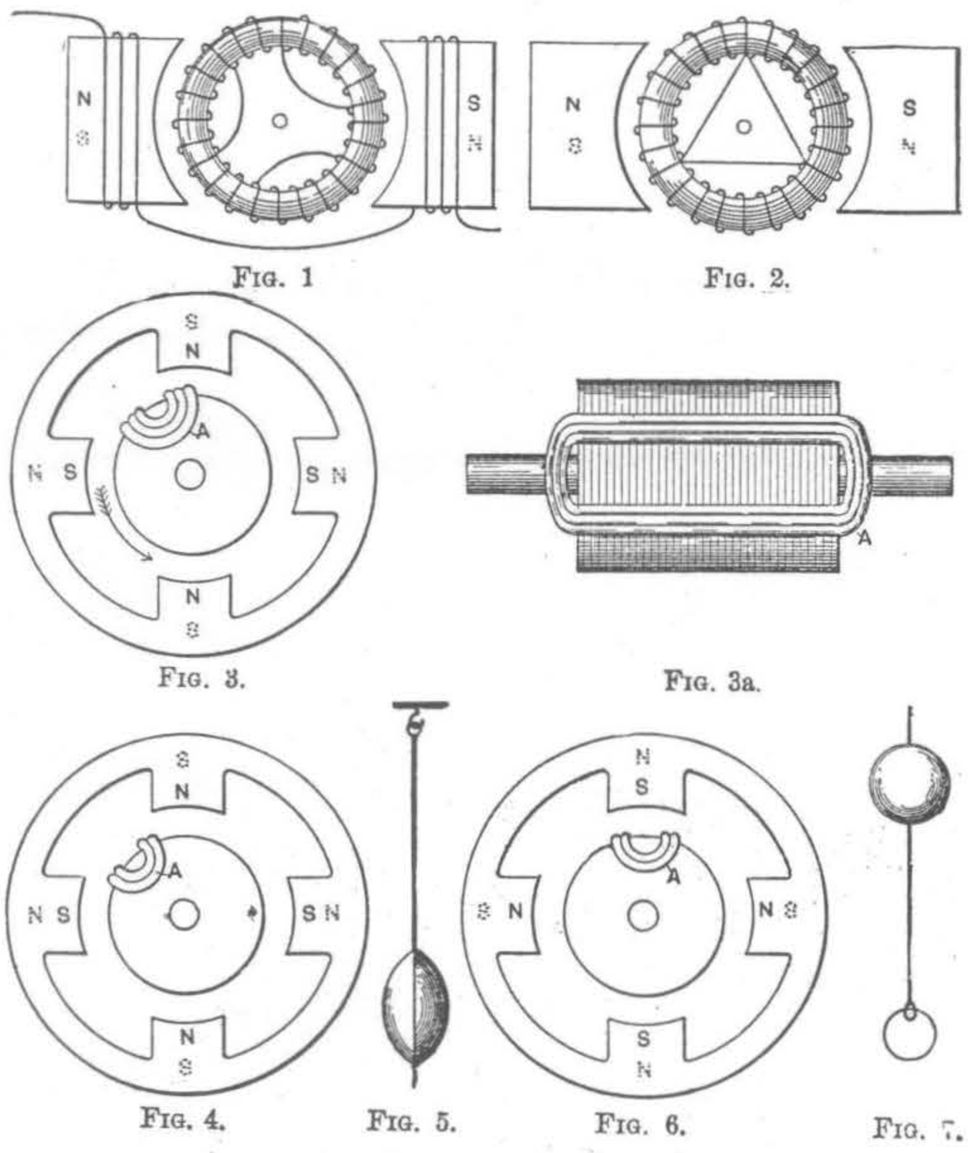

FIG. 1 FIG. 2. FIG. 3. FIG. 3a. FIG. 4. FIG. 5. FIG. 6. FIG. 7.

FIGS. 1–7.—ON THE PRODUCTION OF ROTARY MAGNETIC FIELDS BY A SINGLE ALTERNATING CURRENT.

I wish to refer to my motor and especially to its armature, described in 1891. Figs. 1 and 2 show the device. The former is principally used in the American patents, while the latter is given in the English patent of the same year. The novelty of the armature construction lies in a winding containing closed sub-circuits, and another point is that the closed circuits do not coincide in number with the poles of the field magnet. Before going into the action of this device I will mention two simple experiments which are essential in order to understand the operation of this rotary magnetic field system.

If we have a closed coil moving in an alternating magnetic field, or better, between the poles of a field magnet, as illustrated in Figs. 3 and 3*a*, energized by alternating currents, then the coil A will be repelled from the pole, owing to the secondary field which it establishes, so long as it cuts, or is threaded by the lines of the force of the field. The consequence is that it will rotate and place itself between the north and south pole, Fig. 4, where it reaches a stable magnetic equilibrium, as I like to term it, because in this position it acts like a pendulum properly suspended (Fig. 5). Any motion imparted causes the pendulum to make a few oscillations and come to rest, and similarly any attempt made to move the coil into an energized field will cause it to be repelled, and after a few oscillations it will remain at rest between the poles. It is repelled in either direction, because as soon as it approaches a strong magnetic flux, currents are induced in its windings and create an opposing field. The same coil can be in unstable magnetic equilibrium (Fig. 6), if it stands just in front of a pole, in which position it would act like a pendulum which is balanced with the weight above the point of the support (Fig. 7). Both are in unstable equilibrium; the least motion to the left or right imparted to either will cause them to accelerate in the direction of the impulse, and to assume a position of stability (Figs. 4 and 5). In this position, Fig 4, the coil is therefore currentless. This stable position is the natural position of synchronous motors in operation.

If such a synchronous motor is held behind the phase when rotating under load, a heavier current is induced in the spools which accelerate the armature and keep it in step. If, however, the motor runs in harmony, and suddenly a great deal of the load is taken off, then the armature has a tendency to go more quickly, but in this case opposing currents are generated in the windings, which retard the speed of the armature and keep it back, to remain in step or in stability.

Let us look into the device before us and consider first its quality as a motor. Returning to Figs. 1 or 2, preferably the latter, which is simpler and easier to explain, we find that if we send into the field magnet coil an alternating current, the armature will turn through a certain angle and stop. This motion depends upon the position of the three closed coils with respect to the two poles. This same device can itself be self-starting if we make the poles far enough apart and the energizing current sufficiently strong, so that at the initial speed the armature is repelled at a certain rate. This initial speed changes with the number of poles, closed circuits and alternations. Let us take the first case and examine it. If we try to rotate the armature (as I shall call it hereafter) in a field of alternating polarity, we induce currents in the closed circuits, which establish poles, but these poles are alternating in nature, and owing to the motion imparted, and owing further to the permanent connections in the winding, the poles move or travel with the latter. This accounts for the fact that if the field poles are close together the armature consumes power during its rotation through the alternating field; it acts as a dynamo and does not start from a state of rest. If we impart by mechanical means an impulse to the armature, currents are generated whose sum has a variable

and principally negative value. The armature makes a few revolutions and places itself in a stable magnetic equilibrium; viz., in such a position, symmetrical if possible, as not to generate any currents, and hence not to induce any reactionary* poles in the core. If, however, we impart to this armature a certain initial speed, which I shall call the critical speed, then it will continue to rotate, with a tendency to reach a certain fixed higher speed. This initial impulse may be given by mechanical or electrical means. I shall not state the results as yet, but prefer to explore the action first, so that the same may be before us in various diagrams, and enable us to make any deduction desirable. First, let us assume that the armature rotates synchronously: it is evident that in order to have an armature with three close-circuited coils, interconnected as shown, rotate in one direction, we must have currents induced whose sum has a positive value; viz., two of the coils must do work, in the same sense, while the third coil is either without a current, or has a smaller current in opposite direction, so that the value still remains positive. For true synchronism a close-circuited coil reaches within a half-period the opposite pole, and consequently our diagram for one revolution would look as follows: (See Fig. 8.)

The three diagrams, *a*, *b*, *c*, show the flow of currents and resultant poles. The close-circuited coil 2, diagram *a*, is at this moment generating opposing currents to the others; coil 1 is passing just in front of a pole. All three induced currents combined are developing poles as indicated, and rotating the armature in counter clockwise direction. The rotation being synchronous, diagram *b* shows the position of the armature when the polarity in the field has reversed; diagram *c* gives the position of the coils after the polarity has changed again. It will be noticed that the original position, as shown at *a*, has been reached again and that the cycle will repeat itself. Without explaining these diagrams at this point, I wish to bring before you several other conditions, all of which will assist in reaching definite conclusions. Looking at the armature we see that it has a symmetrical winding, and as long as these closed circuits do not coincide with the number of poles of the field magnet (contrary to all synchrous motors built heretofore), other working positions are possible. The operation will take place as long as the sum of the armature currents have a positive value, since as far as the rotation is concerned it is indifferent which of the coils are doing the work. Let us assume that the armature does not run at a synchronous rate, but at another fixed speed which may have a certain commensurable relation to the periods of the exciting field current, which speed I shall call the harmonic speed. Instead of showing the diagram with windings as in the first set, I have simplified them. In the following sets of diagrams, Fig. 9, I assume that the armature, on account of the load or other reasons, cannot reach synchronism, and that at each field reversal the position of the armature with respect to the field is the same, only the coils have changed places as indicated. You will notice that in this set of diagrams the armature, for each half-period, makes one-third of a revolution only; namely, coils 1, 3 and 2 exchange positions with the change of polarity. Let us step at once to another speed (Fig. 10), which you will no doubt admit as possible; viz., let us assume that coils 1, 2 and 3 cannot arrive at synchronous speed, and that coil 2 reaches the position which 1 ought to occupy, it will be seen that owing to the symmetrical position, it is quite indifferent which of these coils arrives at a given position required for harmonic operation. This will be clear to you by referring to the third set of diagrams, Fig. 10.

We are now enabled to compare three sets of diagrams, Figs. 8, 9 and 10. The first set shows for this new type of synchronous motor that at synchronous speed the pole positions in the armature are practically stationary relatively to the coils and core, and rotate with it. The second set shows that during a complete revolution of the armature, the field has reversed three times, that is, an odd number of times, hence, when the armature returns to its original position, after a complete revolution, it finds the field magnetization of reversed polarity. The magnetic field of the armature rotates in the opposite sense, one and a half times per revolution. In the third set, the armature makes but one-sixth of a revolution per half-period, and the magnetic field of the armature in a complete revolution rotates three times in the opposite direction. This statement may be startling, and my argument, so far, may not be entirely convincing, as on close inspection it will be found that the armature poles have to do considerable jumping. I will now explain the performance of the rotary magnetic field of this armature in a four-pole field, where the changes occur far more gradually, leaving no doubt whatever as to the assertion made. Fig. 11 shows diagrams illustrating synchronous speed. By the aid of these four diagrams we can more easily follow the pole position in the armature core, and find them stationary in it. Inspecting now Fig. 12, in which the armature speed is reduced, we are able to obtain a clear picture of the main subject under consideration.

In this set of five diagrams we see five positions, which coil 1, for instance, occupies before it has made one-third of a revolution. Nevertheless, if we now look at the changing pole positions we can readily detect that they are progressively shifting, and we also see that they have made one whole revolution and that in opposite direction to the mechanical rotation, or, in other words, the magnetic field would travel three times around the armature core during one revolution. In all armature diagrams described and to be described the resultant of the magneto-motive forces of the armature currents is given only. To complete the picture showing every one of the component magneto-motive forces acting, it becomes desirable to plot a diagram of force (Fig. 13). These components act like three variable concurrent forces, including an angle of 120 degrees with each other. These forces we may represent as equal, for the sake of convenience, as it does not influence the idea which we wish to illustrate. However, those two forces which are acting in the same direction are indicated by heavier lines.

FIG. 14.

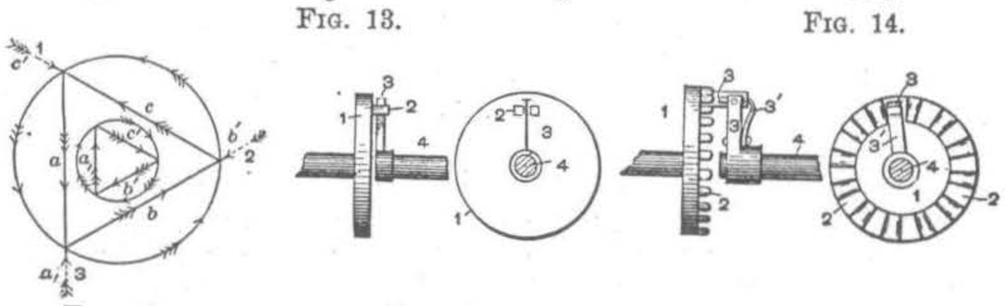

FIG. 15.

FIG. 15a.

FIG. 15b.

FIGS 8-15b.—ON THE PRODUCTION OF ROTARY MAGNETIC FIELDS BY A SINGLE ALTERNATING CURRENT.

Plotting the direction of the forces in order, as, for instance, in the last named set of diagrams (Fig. 12), where the coils act in the order 1, 2 against 3; 3, 1 against 2, and 2, 3 against 1, we obtain Fig. 13 for one cycle. The three figures marked *a*, *b* and *c* indicate the direction in which the three forces are acting in the three positions of one cycle or revolution.

By drawing the resultant diagram of force from the predominating forces of each position, we obtain the accompanying figure (Fig. 14). These forces form a triangle, and the rotation resulting may be seen from the direction of arrows on the circumference of the surrounding circle. However, the reactive forces should be considered and represented separately to obtain the true picture, and we have to add them to find the total force applied and the manner in which all the forces are acting. We therefore repeat the resultant diagram (Fig. 14), and add the opposing forces at their proper places. This diagram (Fig. 15) shows that the reactive forces, shown by dotted arrows, also have a common center, and that as regards time of maximum effect, they succeed each other in the direction of rotation of the armature, while they are acting in the opposite direction of the main force. If we now plot a diagram of these reactive forces alone, we obtain the smaller triangle shown (Fig. 15) inside the larger. It will be noticed that rotation is in the opposite direction; or, in other words, that in reality we have, with this disposition, to deal with two rotary magnetic fields in opposite direction; the useful work done will depend on the difference of the angular velocity of these two rotating fields and their relative intensity.

Looking now at the device as a generator (Fig. 12), we can account for the rotary magnetic field because we generate polyphased currents in the coils 1, 2 and 3. They operate together in the following order: 1, 2; 3, 1; 2, 3; 1, 2, etc. If rotated as shown the coils will distribute three-phased currents over the armature, and this will be understood when examining into the flow of currents of the close-circuiting conductors which are here provided with arrows. At this particular harmonic speed it will be further noticed that the simple alternating field of force has the identical qualities as a polyphase energizing field, as the poles in front of the close-circuited coil seem to be traveling (for the armature) in clockwise direction. This is indicated by the shading of the pole of the same sign in front of the coil most powerfully acted upon in the five positions, representing one revolution for the field. The currents displaced in phase cause the armature to rotate harmoniously with the alterations, and prevent the armature from being easily thrown out of step.

(To be concluded.)

*It is well to call the armature poles, due to the armature currents, reactionary poles. The other armature poles are induced directly by the field poles, and contribute nothing to the torque.

ON THE PRODUCTION OF ROTARY MAGNETIC FIELDS BY A SINGLE ALTERNATING CURRENT.

READ BEFORE THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS DECEMBER 19, 1894, BY LUDWIG GUTMANN.

(*Concluded from page 313.*)

Returning once more to the earlier diagrams, Figs. 9 and 10, we see that below synchronism there are two other speeds that are entitled to be called synchronous, because a certain fixed relation exists between the periods of field excitation and armature rotation.

It will be evident that the greater the number of closed circuits, the greater is the number of harmonic or synchronous speeds in which the armature can operate. If the armature contains ten closed circuits, and rotates in a two-pole field, it will be able to generate five currents, lagging 72 degrees behind one another in phase, and would have at least five speeds which are synchronous, and the armature, owing to its peculiar construction, can operate at a slower speed than the synchronous speed as interpreted heretofore.

Looking at the device from a general standpoint, it will be clear that this particular armature construction embodies all the weak points of a synchronous and all the strong points of a polyphase motor. The weak points are :

1. That the machine will not start from state of rest in the form shown, because in Figs. 1, 2 and 12, the coils act on one another differentially and have a variable and negative value ; they are in magnetic stability when at rest, hence no rotation can result.

2. The device has a small starting torque when rotated, owing to the differential action of the coils, which cause, with a small number of closed circuits, strongly oscillating or jumping poles until a harmonic speed is reached.

3. The device, when in rotation, is not reversible by simply changing circuit connections.

The strong points are :

1. That the motor develops polyphased currents in its own windings.

2. That, therefore, it is more difficult to pull it out of step, as it has the capacity to stand, what I would term, magnetic slippage.

Let us assume that a certain coil, which should reach a given point to run harmonically, remains behind owing to a slower motion of the armature; in this event the coil ahead has to perform the function at the expense of a heavier current. The loss of revolutions due to this action may be comparable to the slipping of a belt over a pulley. However, there is also a limit to the slipping. The armature should have some harmonic speed with respect to the alternations. Should it fall below the lowest harmonic speed, then it will come to a standstill just like any other overworked synchronous machine.

Synchronism in a motor means nothing more nor less than a magnetic flexible clutch, which may be represented mechanically as follows :

The old fashioned non-starting synchronous machine having equal armature coils and field poles, can be compared with the arrangement shown in Fig. 15*a*, giving side view and elevation. The disk 1 is provided with two projections; 2, imparts rotation to shaft 4 by means of the flexible arm, or spring 3, which enables the shaft 4 to be slightly behind or ahead of disk 1. However, if the work put on shaft 4 is in excess of the strength of spring 3, then it will break, and shaft 4 will speedily come to a standstill.

In contrast to this older form of synchronous motors stands the new one, which forms the subject of this paper and the machines operated by bi- or polyphased currents. The mechanism for showing magnetic coupling for these latter types may be represented by Fig. 15*b*. In this case, 1 represents a crown wheel the teeth marked 2 ; into these teeth meshes a catch 3 in a flexible manner, which catch is connected rigidly to shaft 4. Within the range of normal work, catch 3 would remain fixed between the two given teeth, but if the shaft 4 is overloaded, the flexibility of catch 3 will cause it to yield, and pull out of its position, drop in between some other two teeth, and continue to operate, but at a slower speed. The greater the excess of work the greater will be the slippage and the more

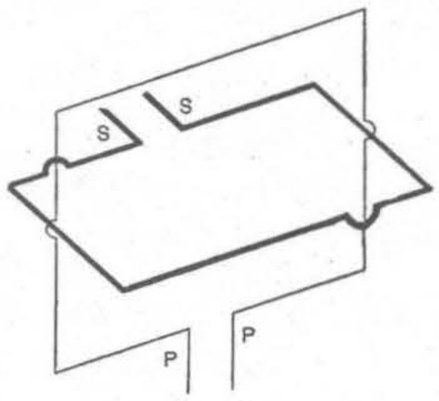

FIG. 16.

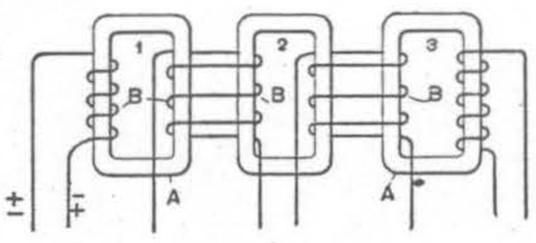

FIG. 17.

teeth will be jumped by the catch 3 in every revolution of disk 1. For the synchronous motor herein described, the overloading to the extent that it cannot reach the lowest harmonic speed would be equivalent to the breaking of spring 3^1.

It will be remembered that Prof. Ferraris obtained a rotary magnetic field and rotation by influencing one coil carrying a primary current, by another at right angles thereto carrying secondary currents. Here we have two phases from a single source, Fig. 16. To obtain a multiple of phases we may take two or three iron cores A and surround them with coils B, like the links of a chain, Fig. 17, so that the secondary coil of transformer 1 is the primary of transformer 3, and so on ; or we may design a special core for a transformer, and create a rotary magnetic field by applying to one coil a primary current from the line, and to another coil a secondary current from a transformer, whereupon by the rotary field obtained, polyphased currents may be taken through other coils on the transformer. These methods have, however, one drawback, and that is that the phase will change more or less in lag with difference in load, while for many purposes it is most essential that for efficient working the phase should remain at the same constant angle. This desideratum has been accomplished by the device under consideration, and any suitable number of currents lagging in phase may be obtained from a single alternating current.

To obtain a rotary magnetic field in or by a stationary body, at least two electric or electro-magnetic forces of definite phase relations, acting at an angle to one another and changing at periods harmoniously, are essential requirements.

If, however, we allow the body, or part of the same, to be movable, we may substitute mechanical rotation primarily as an adjuster of the periodicity and phase of one of the two forces ; the fundamental relation between the two forces must in this case also be the same as in the other ; namely, they must work in harmony and the periodicity and phase determines the periodicity and phase of the other of one force. If the second force is a current, it must be one of the same period or some harmonic of that period ; if it is rotation, it has also to be synchronous or harmonic. We can now clearly understand why, when rotating the armature, Figs. 1 and 2, in an ordinary alternating current field, we have no system of polyphased currents and no rotary field, simply because the armature rotation does not stand in any relationship whatever to the alternations ; but as soon as the speed does so, there are generated polyphased currents lagging in phase at a fixed angle, and a rotary magnetic field.

There is a difference whether the armature is influenced by a single alternating current, or by several, causing themselves a rotating energizing field. Nevertheless, in either condition the armature is in magnetic stability, and this state is the reason that it remains stationary in the first case and that it rotates in the second.

The reason that the motor starts in the second case is evidently because the inducing magnetic field is itself rotating in the stationary field magnet core. As said before, it is considered necessary for the proper operation of the armature for giving maximum torque, that if placed in an alternating current field of force the armature rotation should have a definite relation to the alternations. Up to the publication of this device, some three years ago, synchronous motors had as many armature coils as field coils, and hence to obtain the value of the synchronous speed, all that was necessary was to divide the alternations of the armature current n by the number of field poles p of the magnet employed. But if the number of armature coils are not the same as the field poles, then the speed may vary from this synchronous speed and

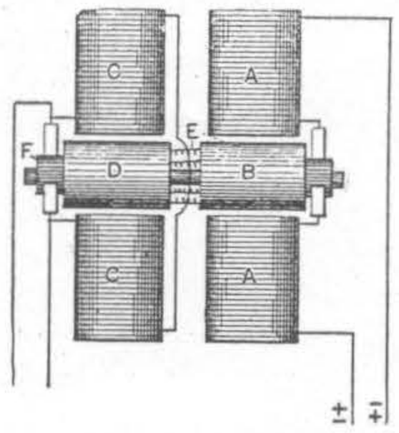

FIG. 18.

a modification is thought to be necessary. We would have to find the smallest common factor between the field poles p and armature coils p^1, with which we have to divide the number of alternations to obtain the value of the lowest synchronous speed, while the condition of slippage may allow for the lowest harmonic, the value $\frac{n}{p\,p^1}$.

It will now be clear that motors can be designed having any desired variation of speed and have defined synchronous speeds or approach the indifferent relation. I wish it understood that I do not intend to treat the subject in all its details, and I am especially reluctant on the ground of having carried on but few experiments.

The few diagrams presented do not disclose many conditions of those possible. They show only one or two facts of conditions which frequently are of a complex nature. Evidently the rotary magnetic fields in the device under consideration may have altogether different speeds from those shown in the diagrams; also, that the magnetic field may rotate with and ahead of the armature, and lastly, the speed of rotation of the rotary field of the armature may be synchronous, and opposite in direction to its rotation.

The device has been given in the form of a diagram, and as it has been described as not self-starting, I wish now to state that it becomes self-starting as a series, a shunt or an induction motor in a field of single phase or polyphased alternating currents. Fig. 18 represents one of the earliest forms, which have since been simplified to a considerable extent. The part A B represents here a simple series motor whose armature B may be any drum or ring type, open or closed coil winding ; the part C D may be similarly constructed. Both armature windings B and D are connected electrically by four wires E at points of equal distance, which number of conductors E may be reduced or increased, depending on the number of phase currents desired. Now send an alternating current into the series motor, part A B*, then the armature will start from state of rest and will send current impulses into the D part winding, which becomes the more regular the more the armature has approached synchronous speed, where biphase currents will be established therein ; these react on the field magnet core C, and for the purpose of maintaining the armature in this synchronous speed, the commutator F is applied to rectify the polyphase currents, which continuous current may be used to energize the magnet C.

The fundamental principle disclosed opens to us a very wide field for work. Not only are we enabled to construct motors almost as cheap and simple as continuous current motors, but there is in this principle involved the germ for the ideal distribution of power, inasmuch as we are enabled to collect the polyphased currents generated, or commutate them immediately at will.

Finally, I wish to call your attention to the fact that the last figure is in reality a motor-generator, and it is, therefore, evident that the electrical energy supplied need not all be transformed into mechanical power, but that a portion may be utilized in one of the modified forms named above.

Nikola Tesla as Viewed by a Layman.

A familiar figure at Delmonico's in the evening is that of a tall, well-knit, well-groomed man, swarthy, eagle-eyed, with a long nose, high cheek bones and a firm jaw, and with the air of being intensely interested in everything at which he looks. This is Nikola Tesla, man among men in the electrical world, a giant of discoverers, bold, original—a pathfinder whose every step is now being watched by all the scientific societies of the world. Where others have followed old theories and been hedged in by trammels of tradition, he has struck out at right angles, and startled the know-alls by showing that the laws of electrical force are still unwritten and unknown. His dynamo is radically different in construction and operation from any in use; his currents, while of vastly greater voltage, are innocuous; his system of lighting needs no filament of carbon or platinum, and gives out no heat; he can clothe himself in radiance like Phœbus, like Ajax; he can defy true thunderbolts, for he has tamed them while leaving their strength unshorn. All this and more has already been done, and yet the man has but little more than passed his thirtieth year, looks like a student, and has the unaffected simplicity of one whose thoughts never turn to self.—*Major Moses P. Handy in the "Mail and Express."*

DIGEST OF CURRENT TECHNICAL ELECTRICAL LITERATURE

COMPILED FROM PRINCIPAL FOREIGN ELECTRICAL JOURNALS

BY CARL HERING

ELECTRO-PHYSICS.

Tesla Effects With Influence Machine.—The first part of an abstract of a lecture by Dr. Toepler (inventor of the Toepler-Holtz machine) is published in the "Zeit. fuer Elek.," Dec. 1. He describes a number of experiments made with his multiple plate machines, and shows the advantages of using such a machine with 20 plates for making researches with high frequency currents; the machine itself is well known, but was improved slightly to increase the self-excitation and the intensity of the current for a very high voltage. He shows its application for produing some of the Hertz effects and states that it gives two different kinds of primary sparks. With this machine the fundamental experiments of Tesla can be demonstrated, although it consumes only 1-16 to 1-18-hp; better results were obtained with a 60-plate machine requiring ⅛-hp. The connections are the same as usual, the machine discharging through a spark-gap, the poles of which are connected to condensers whose outer coatings discharge through the primary of a transformer, the secondary current of which is used to produce the effects; with a large machine he obtains 100 sparks per second 3 mm. long; one of the chief advantages of using influence machines is that it gives the high tension and high frequency alternating currents directly; also that a better symmetry is obtained, for with an unsymmetrical system, discharges in one direction are obtained which are disturbing; no air-blast or magnetic field is in this case necessary to rupture the current in the spark-gap and to this he attributes, in part, the success of the results. A Geissler tube in this circuit shows the cathode light at both poles which proves that the current is an oscillating one, while with a Ruhmkorff coil the cathode light is produced at only one pole. The article is to be continued.

ELECTRO-PHYSICS AND MAGNETISM.

Tesla Effects With Influence Machines.—The conclusion of the lecture by Dr. Toepler (see Digest Dec. 29) is contained in the "Zeit. f. Elek.," Dec. 15. He showed the experiment in which an incandescent lamp was brilliantly illuminated, although shunted by a thick wire bent in the form of a loop, and to show that it was due to surface conduction he added a thin but wide sheet of metal bent like the wire and connected to it, which, therefore, greatly increased the surface but scarcely affected the cross section, the lamp in this case diminished greatly in candle power. With such high frequency currents iron has the opposite effects in a transformer than with the usual currents, which he showed with the aid of a lamp run from a high frequency transformer in which the iron could be introduced or withdrawn; a core of insulated copper wires produced no effect but a glass rod covered with tin foil almost extinguished the lamp. He gives the data for 4 coils and describes various experiments with them; he showed that there was a very appreciable repulsion between the coils of a transformer; by transforming the high frequency current to another of lower voltage and greater current, iron wires were melted and a sort of arc light consisting of a point of carbon resting on another could be lighted; other experiments were shown by transforming the high tension currents still higher. He performed the experiment of illuminating a Tesla single pole lamp, in which case, however, the glass opposite the filament soon became very hot; in one case the voltage was so high that the whole transformer was surrounded with light in the form of a brush discharge; he estimates that the voltage was 500,000; although of considerable intensity, these high tension currents give off comparatively little heat. Geissler tubes placed near two condensor plates, but not in contact, were so brightly illuminated that the experiment could readily be shown in daylight. In conclusion he states that almost all the Tesla experiments can be shown with his large 60 plate machine, but perhaps not on such a brilliant scale, the difference, however, is not as great as would appear from the difference in the amount of power used (concerning which, however, he unfortunately gives no data).

Tesla's Researches.—A lecture of Dr. Tuma on Tesla's researches is briefly abstracted in the "Elek. Zeit.," Dec. 20. According to Prof. Puluj there are two chief drawbacks against the use of this "light of the future," one being that with such high tension currents there is a generation of ozone which is as dangerous to breathe as chlorine gas; and the second is that a sufficiently durable insulation cannot be obtained; he also stated that Prof. Puluj showed similar lamps as early as 1880; they were run from a Ruhmkorff coil, and are said to have had a greater candle power than those of Tesla; references to the description are given; he states that long ago, in the eighties, Mr. Von Marxow showed experimentally that the physiological action of alternating currents is less, the higher the frequency.

Century Magazine February 1895

LUKA FILIPOV.

(AN INCIDENT OF THE MONTENEGRIN WAR OF 1874.)

PARAPHRASED FROM THE SERVIAN OF ZMAI IOVAN IOVANOVICH, AFTER LITERAL TRANSLATION BY NIKOLA TESLA.

ONE more hero to be part
Of the Servians' glory!
Lute to lute and heart to heart
Tell the homely story:
Let the Moslem hide for shame,
Trembling like the falcon's game,
Thinking on the falcon's name —
Luka Filipov.

When he fought with sword and gun
Doughty was he reckoned;
When *he* was the foremost, none
Blushed to be the second.
But he tired of the taint
Of the Turk's blood, learned restraint
From his sated sword — the quaint
Luka Filipov.

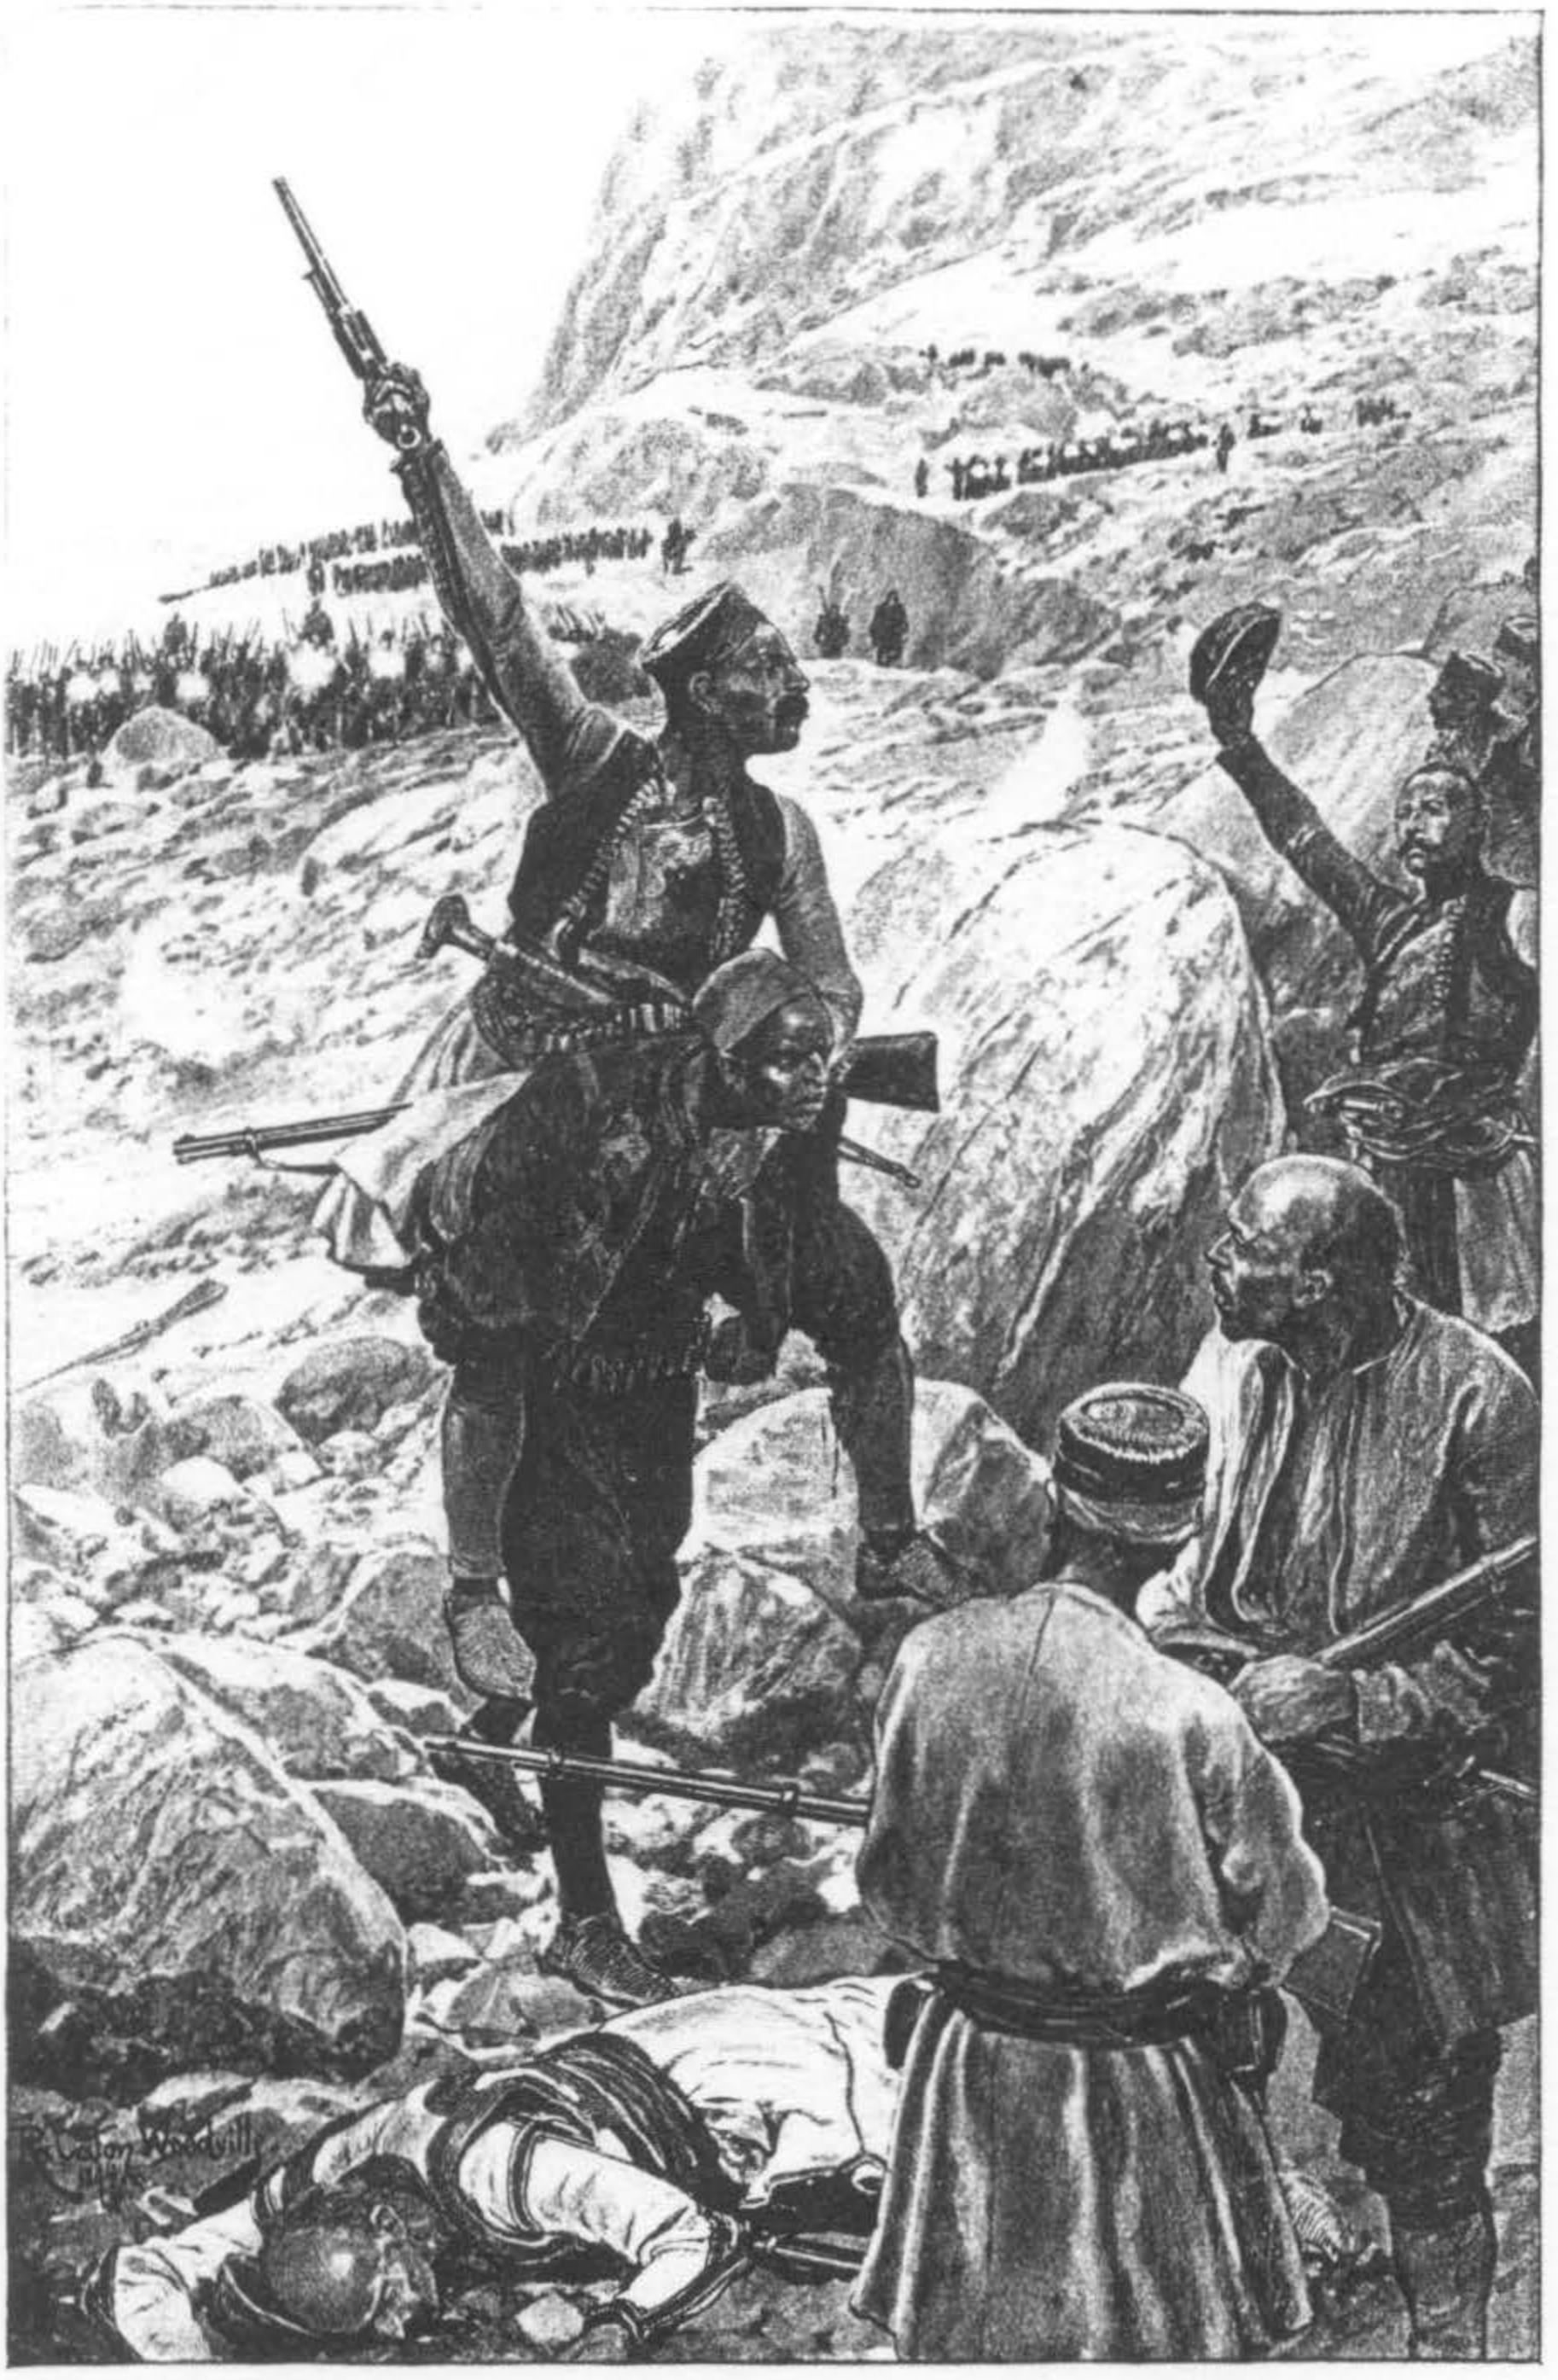
Thus he reasoned: Though they fall
Like the grass in mowing,
Yet the dead Turks, after all,
Make a sorry showing.
Foes that die remember not
How our Montenegrins bought
Our unbroken freedom — thought
Luka Filipov.

So, in last year's battle storm
Swooped our Servian falcon,
Chose the sleekest of the swarm
From beyond the Balkan:
Plucked a pasha from his horse,
Carried him away by force,
While we cheered along his course
"Luka!" "Filipov!"

To the Prince his prize he bore
Just as he had won him —
Laid him at the Prince's door,
Not a scratch upon him.
"Prince, a present! And for fear
He should find it lonely here,
I will fetch his mate," said queer
Luka Filipov.

Back into the fight he rushed
Where the Turks were flying,
Past his kinsmen boldly brushed,
Leaping dead and dying:
Seized a stalwart infidel,
Wrenched his gun and, like a spell,
Marched him back — him heeding well
Luka Filipov.

But the Moslems, catching breath
'Mid their helter-skelter,
Poured upon him hail of death
From a rocky shelter,
Till a devil-guided ball
Striking one yet wounded all:
For there staggered, nigh to fall,
Luka Filipov!



Paused the conflict — all intent
On the two before us;
And the Turkish regiment
Cheered in hideous chorus
As the prisoner, half afraid,
Turned and started up the glade,
Thinking — dullard! — to evade
Luka Filipov.

We 'd have fired, but Luka's hand
Rose in protestation,
While his pistol's mute command
Needed no translation:
For the Turk retraced his track,
Knelt, and took upon his back
(As a peddler lifts his pack)
Luka Filipov!

How we cheered him as he passed
Through the line, a-swinging
Gun and pistol — bleeding fast —
Grim — but loudly singing:
"Lucky me to find a steed
Fit to give the Prince for speed!
Rein or saddle ne'er shall need
Luka Filipov!"

So he urged him to the tent
Where the Prince was resting —
Brought his captive, shamed and spent,
To make true his jesting.
And as couriers came to say
That our friends had won the day,
Who should up and faint away?
Luka Filipov.

Robert Underwood Johnson.

DRAWN BY R. CATON WOODVILLE.

LUKA FILIPOV.

NIKOLA TESLA.

NIKOLA TESLA was born in 1857, at Smiljan, Lika, a region bordering on Austro-Hungary. His unquestionable genius was in part inherited from his mother, who took pleasure in constructing mechanical appliances, to be used in the household and for agricultural purposes. Having gone through the preparatory schools, he entered the polytechnic school at Gratz, where he began to prepare for the profestion of teacher in mathematics and physics. It was here that he saw a gramme dynamo, and although the instructor in charge stated that the commutator and brushes were absolutely necessary adjuncts, he saw a means whereby these could be dispensed with.

After this he conducted some experiments and became so fascinated by the work that he decided to take up the course in engineering. Having finished this he began to study languages, in order to be more fully fitted for the profession. He has undoubtedly found that this was a wise move, as it has often smoothed the way in his many dealings with foreigners.

During all this time he was constantly at work on his rotating field principle, and it was in 1882, when in Paris, while in the employ of one of the large illuminating companies, that he began in earnest to adopt it to commercial apparatus.

Believing America to have more field for inventors, he made up his mind to come, and fortunately secured a position in Mr. Edison's laboratory, which was then situated on Goerck street, New York city, in a building formerly known

as the Etna Iron Works. Here he endeared himself to all, both by the many instances of his genius and by his unostentatious manner.

But being influenced by the desire to advance his rotating field idea, he concluded it best to relinquish his position in the laboratory, although it was a very pleasant one. After joining a company for the manufacture and sale of arc-lighting apparatus, and this being successfully started, he began experiments with alternating currents and motors. In 1887 Mr. Tesla submitted to Prof. Anthony the results of his endeavors, and the ensuing test proved his motors to have a very high efficiency, as high in fact as those operated by direct current. This result was contrary to the expectations of the scientific world, as the alternating current had as yet won for itself but little confidence. Encouraged by these results, Mr. Tesla read a paper before the American Institute of Electrical Engineers in May, 1888, on high frequency and high potential currents, and exhibited his motors in operation, thereby demonstrating his first idea that a motor could be constructed without resorting to the use of complicated and expensive commutators and accessories.

Having opened up this new field in such a degree, he redoubled his efforts and obtained some very interesting results, which formed the basis of another lecture delivered by him in May, 1891, before the same Institute to which his first lecture was read. This decisively marked the beginning of a new era in the theory and practice of alternating currents. Three lectures followed, one in London, in 1892, and one in Philadelphia and St. Louis, respectively, in the subsequent year, each one being more advanced and treating of many beautiful things in the high-frequency and potential line.

The Tesla motor patents for the United States were secured by the Westinghouse company and have come largely into commercial use, and have proved to be very satisfactory from their simplicity. The Niagara Falls Power Company anticipate employing these motors, wound for the two-phase current, for the development of power in Buffalo and neighboring towns transmitted from Niagara.

In addition to Mr. Tesla's work in the foregoing subjects, he has been devoting himself recently to his "oscillator." Of late years the problem of generating electrical currents without passing from horizontal to rotary motion has been one of special interest to inventors. This had hitherto remained unsolved until Mr. Tesla brought out his oscillator, which is acknowledged to be a practical solution of the case in question. In this device the steam is let into a cylinder, the shaft of whose piston protrudes from one end in the early types, but, in the later forms, from both ends, sufficiently far to allow of field magnets being placed around it. This shaft is caused to vibrate very rapidly, producing currents in the surrounding coils, one hundred times a second being the number of vibrations obtained by an oscillator now used in Mr. Tesla's laboratory. The construction of the cylinder permits of using very high steam pressures, even as high as one thousand pounds to the square inch, and although there is no packing whatever, one is unable to hear or see the slightest trace of escaping steam. An unchanging frequency of vibration is established by means of an air spring, attached to the shaft, and should the pressure vary between wide limits, the number of vibrations per second remain unchanged, as any variation in pressure only causes a difference in amplitude, causing, however, a decrease in electrical power generated.

The capacity of these machines, then, depend, within reasonable limits, upon the steam pressure supplied, and as the cylinders may be made of very great strength, as stated above, a surprising amount of power may be produced from a machine occupying but comparatively little space.

Friction is conspicuous by its absence, there being but few bearings, thereby making the life of the apparatus one of unusual length, increasing efficiency and decreasing cost of maintenance as compared with the usual steam engine.

This mode of generation certainly bids fair to come into universal use, not only from the very nature of its simplicity and practicability, but from its high efficiency and cheapness.

Mr. Tesla is acknowledged to be one of the greatest living scientists, because of his ability in mathematics, physics and experimentation, his wonderful creative genius and his untiring application to his work.

The hope is sincerely felt by all that he may be spared to continue his labors which have been so favorably begun and have been productive of so much good.

ERNEST K. ADAMS.

Electrical Progress.

Tesla's "Oscillator."

Tesla's latest invention, the "Oscillator," is described as one of the most remarkable appliances of the age, consisting of "the core of a steam engine and the core of a dynamo combined, making a harmonious mechanical adjustment." This combination, says an enthusiastic admirer, constitutes a machine which has in it the potentiality of reducing to the rank of old bell metal half the machinery at present moving on the face of the globe. It may come to do the entire work of the engines of an ocean steamship within the small space they occupy and at a fraction of their cost, both of construction and operation. It will do this work without jar or pounding, and will reduce to a minimum the risk of derangement or breakage. There is nothing in the whole range of mechanical construction, from railway locomotives to stamp mills, which such an invention may not revolutionize. The essential characteristic of the machine is the application of the pressure of steam to produce the extremely rapid vibration of a bar of steel, or piston, which, in turn, is so adapted to a set of magnets that the mechanical energy of the vibration is converted into electricity. The extraordinary result is that practically an absolutely constant vibration is established, and a power is obtained greatly beyond that obtainable in the most costly expansion engines using a similar amount of steam.

Besides, it is said, saving in mechanical friction the thirty-five per cent of loss in the working of the engine, the fifteen per cent of loss in belt friction, and the ten per cent of loss wasted in the dynamo, making altogether an addition of sixty per cent to the available energy obtained from the steam for the purpose of producing electricity, it is simpler, lighter and smaller than the mechanism it is designed to replace, absolutely constant in its action, automatically regulated and subject to the least possible amount of wear and tear. The utilization of this machine in any branch of industry would, it is claimed, result in an appreciable lowering in the cost of production, and it is thought quite possible that its first general employment may be in electric lighting.

THIRD EDITION OF "THE INVENTIONS, RESEARCHES AND WRITINGS OF NIKOLA TESLA."

"The Inventions, Researches and Writings of Nikola Tesla," by Thomas Commerford Martin, published by THE ELECTRICAL ENGINEER, N. Y., has met with remarkable success. The first edition appeared during January, 1894, and the second was completely exhausted before the close of the year, several orders now being in hand for the third, which is expected this month. It is rarely that technical books have such a reception, The welcome accorded to the work abroad has also been most cordial. It har been favorably reviewed by the technical press of England, Gesmany, France, Russia, Italy and other countries; and an authorized German translation is now being brought out by the well known house of W. Knapp, of Halle. The book embraces all Mr. Tesla's inventions and researches made known up to date, and includes his oscillator, or new electrical generator, which he is rapidly bringing to a high pitch of efficiency and economy. The more important parts of the book have had the benefit of Mr. Tesla's personal revision.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

THE NIKOLA TESLA COMPANY.

The Nikola Tesla Company has been incorporated in New York City, to manufacture and sell machinery, generators, motors, electrical apparatus, &c., capital $5,000. The directors are Edward D. Adams, Ernest K. Adams, Alfred S. Brown and William B. Rankine of New York City, and Charles F. Coaney of Summit, N. J.

VIEWS, NEWS AND INTERVIEWS.

Mr. Nikola Tesla is generally regarded as an unusually modest man, and one who doesn't go in for ostentatious display. This was exemplified at the time the New York *World* printed an interview with him, written by Arthur Brisbane and accompanied by that truly marvelous picture of Tesla, showing him standing erect with lightning flashes glancing out from every portion of his body. Mr. Tesla had gone to a well-known health resort for a brief vacation a few days prior to the publication of the interview. He had been at the hotel just long enough to make a few acquaintances, and to become pretty well known himself. On the Sunday that the interview was published, the papers containing it reached the hotel at 10 o'clock. Mr. Tesla, in walking about the hotel lobby, observed many people who glanced at a paper in their hands, then looked up at him with an expression of awe, and finally put their heads together and discussed something in whispers. He finally discovered the cause to be that wonderful picture. At 11 o'clock Sunday morning Mr. Tesla was on the first train bound for New York.

Mechanical Progress.

Tesla's Steam Engine.

Much has appeared in technical journals concerning this engine, and considerable speculation has been indulged in regarding its practicability. The engine is a vibratory direct-generating one, or steam dynamo. The scheme is to produce electric current without rotary movement, friction or moving joints even, except of a steam piston, which directly vibrates or reciprocates—an armature between magnets. Mr. Tesla gives out the following particulars of his direct steam engine:

"I had gone considerably into the study of the practical aspects of the work which I was to present, and my notion was that I was touching upon something which would lay the foundations of a novel industry, perhaps of more than one industry. I dwelt chiefly on those features which possessed a purely scientific interest, my desire being to present the subject very modestly, as I was not quite sure of some of the questions involved. A prominent engineer came to me and said: 'Mr. Tesla, I want to tell you something, but I fear I may offend you.' I knew what was coming, and so I asked what it was. He said: 'Well, don't you work on steam engines. You have done some work in electricity. If you stick to it you will do some good work, but if you work on steam engines you are bound to fail.' Another, to whom I showed the advantage of doing away with complicated mechanism, and generating electricity directly, said, after he had watched it for a long time, 'Couldn't you apply this to rotating motion?'

"One of the first impulses which guided me was to produce an absolutely constant motion, which would be independent of any friction losses, or gravity, or temperature changes within very minute limits. I wanted to produce a positive motion, so that I might operate what I called a disruptive discharge coil. With a device which I invented, I was able to maintain a vibration with perfect constancy. The device consisted of a spring which required several tons of force to spring a certain distance, and which was constantly kept in vibration by steam pressure or air pressure. In the beginning I used springs of tempered steel. These steel springs would break, though they had a section of two or three square inches. So I resorted to air springs. The air springs would not break, but they had no constant resistance. Then I made the chambers of the air springs communicate with the outer air. This device yields a constant vibration; and as the force which is driving it is many tons, and the friction but a very small matter, it is unaffected by the pressure, so I have a constant vibration. This is the device which I believe will be used for many purposes—for instance, for governing all sorts of mechanisms, engines and so on. It contains much of interest for scientific men, because with it I am now able to produce currents of perfectly constant frequency.

"When we look at a steam engine, and inquire where the power comes from that drives the steam engine, we will always find that the power comes from a little box, a cylinder with a piston in it, and all the other appurtenances are really but to keep it going. My first idea was to apply the motion of the piston, which is freely movable, to a magnetic field, to move a magnet or coil in a magnetic field, and so generate currents by this direct motion. We can reduce the weight of the engine for the same pressure and the same piston speed to $\frac{1}{30}$ or $\frac{1}{40}$ if not $\frac{1}{50}$ of its weight. We do away with all mechanical frictions.

"The engine designed according to my ideas has a mechanical efficiency of 99¾ per cent. In my construction the dynamo may consist of a simple coil of the magnet and a simpler coil, which is all immersed in the magnetic field. There is no useless wire, consequently dynamo and engine, if they are reduced considerably in weight, increase in efficiency. There is only one engine that can equal it in output, and that is the turbine. With the steam turbine we can obtain an enormous output, and that is the reason why the steam turbine, in my opinion, may be found a valuable adaptation for driving dynamos. In reciprocating mechanisms we can expand the steam at an enormous rate. It is perfectly practicable in these mechanisms, which I have been working up to obtain, if you want, a speed of 100 metres a second; and while I do not contemplate producing such speeds, yet it is quite possible to do it. As I am enabled now to work without a packing, the expansion occurs at an enormous rate; and the engine being of such character that the exhaust can be readily reduced to pretty nearly the atmospheric pressure and the mechanical friction is reduced to such a small figure that we can raise the temperature of the steam very considerably.

"I am now preparing a boiler which will give me up to 350 pounds pressure. If we want to drive motors we must have a long stroke and a slow frequency; if we want to light lamps then we want a very short stroke and a very rapid motion. It is very important in this mechanism, in which the power depends on the square, to obtain as high a pressure as possible. It is more economical to produce rapid vibrations than low vibrations. But, so far as the economy of the dynamo and of the engine is concerned, it is better to produce a long stroke, because a long stroke means a high velocity. I think I am not mistaken in believing that we are going very shortly to have a means at hand of producing twice as much electricity from coal as we can produce at the present time. This is subject, of course, to a test, but I am quite confident it can be done."

ON EXPERIMENTS WITH TESLA CURRENTS.

BY F. HIMSTEDT IN "WIEDEMANN'S ANNALEN."

The author has succeeded in reproducing most of Tesla's experiments with very simple apparatus. He utilized at first the Lecher method of producing electrical oscillation, but later on used the still more common Leyden jar. The pole of a powerful Rubenkorff coil, 50 centimeters long and 20 centimeters in diameter, and used with five or six accumulator cells, was connected to the inner coatings of two medium-sized Leyden jars insulated from one another by standing on paraffine blocks, and also to a spark micrometer. The outer coatings of the jars were connected together by a copper wire four millimeters thick and 120 centimeters long, bent into U shape. A 16-volt glow lamp put in parallel with this wire was soon brought to incandescence when the spark micrometer was suitably adjusted. When jars 16 centimeters in diameter and 42 centimeters high were used, as many as three lamps could be made to glow —a 65-volt lamp below, a 16-volt lamp in the middle and a 2-volt lamp at the top. If the nipple of such a lamp be filed off it ceases almost entirely to glow. Tesla ascribes this fact to the alteration in the molecular bombardment in the lamp; but the author considers that it is due to the connection of heat by the air admitted.

If the incandescent body be a platinum of 0.05 to 0.1 millimeter diameter, it oscillates violently while glowing, not in one plane like a string under tension, but in every possible plane, becoming a model of a beam of natural light. It is essential to the success of this experiment to use a proper interruptor and a suitable spark micrometer. As interruptor the author used the Foucault form, with tough zinc amalgam in the place of mercury, and covered with machine oil. The balls of the micrometer are best made of zinc.

The Tesla transformer was made as follows: A glass tube of four centimeters diameter was taken, and on it were wound 10 turns, one centimeter apart, of a wire four millimeters thick. Over this was pushed an ebonite tube, six millimeters thick, on which were 200 turns of wire one millimeter thick and spaced with one millimeter between each. The whole transformer was placed in an earthenware container filled with machine oil, the secondary terminals being two metal balls on ebonite pillars. The primary was put in the place of the U-shaped wire, between the outsides of the Leyden jars. When the interruptor begins working, brush discharges start from these balls, and sparks spring to a conductor put near. Two parallel wires starting from the balls have between them a broad band of light three to four meters long. If one pole be put to earth, and to the other be connected a wire 15 to 20 centimeters long, hanging freely downwards, it begins to move when the interruptor is started and describes the surface of a cone, which is easily seen in a dark room by the brush discharge, which renders it luminous.

If anyone takes hold of the pole of such a transformer with the hand, rays of light start from any part of his body when a conductor is held near. If he stands on a metal plate he feels a pricking sensation in his feet, and in the dark the rays coming out of the soles of his shoes may easily be seen. If several persons form a chain, and the first touches one pole of the transformer, while the last holds in his hand a vacuum tube with or without electrodes, the tube glows brilliantly. None of the persons feel any symptom of the electrical phenomena.

If one pole of the transformer be earthed and the other connected to a metal sphere 60 centimeters in diameter, vacuum tubes glow brightly up to 15 feet away. A glow lamp connected to the unearthed pole glows faintly in a phosphorescent manner; but if a large metal reflector be placed over the lamp it glows brilliantly, while the filament oscillates so violently that it soon breaks. If a conductor be held near the point of the lamp, the glass is immediately punctured by the current, a continuous and brilliant stream of sparks passes through the opening, and the filament glows until it burns away.

In the second portion of the article the author remarks that a Tesla transformer differs in important particulars from an ordinary Ruhmkorff coil. A vacuum tube connected in any manner to the transformer shows kathode light at both electrodes, and evenly distributed anode light in the center. An alteration of direction of the primary current, or alteration of pole, has no effect in altering this phenomenon. An electroscope is always charged positively if held to either pole, and both poles give positive Lichtenberg figures only. It was found that this effect depended on the nature of the surrounding medium. Air and oxygen produce positive discharge; hydrogen, illuminating gas, nitrogen, carbon dioxide and ammonia give negative discharges. If a pole have two points immersed in air and hydrogen, respectively, positive and negative discharges take place simultaneously, according to the medium. If a pole be in oxygen, and nitrogen be gradually added; an electroscope shows first a positive charge, first increasing, reaching a maximum at the mixture corresponding to air, and then diminishing, and ultimately becoming negative. With a Ruhmkorff coil the charge in the electroscope changes sign if the primary current be reversed.

NIAGARA WILL DO IT.

Electricity from the Great Cataract May Supplant Engines, Cables and Locomotives.

STEAM WILL BE OBSOLETE.

Some of Bellamy's Brightest Dreams May Soon Be Realized in This City.

NEW YORK IS NOT TOO FAR.

Nicola Tesla Says the Problem of Long Distance Transmission Is Solved.

IN an article in the HERALD some time ago on electrical possibilities in New York I quoted the remark of Nicola Tesla that "the labor of the future will largely consist in pressing electric buttons." In a little talk I had with Mr. Tesla a few evenings ago he disclosed to me that he is now engaged upon important experiments looking toward a very material realization of his prophecy right here in New York city.

Mr. Tesla is now completing experiments, in which he has been engaged for the last four years, upon means of transmitting great electrical power long distances. Just the immediate means and mechanical devices which he has adopted for this purpose Mr. Tesla does not care at the present time to disclose. He, however, gave me a glimpse of his method. It is, in brief, that he believes that while it would probably be too expensive and too wasteful to attempt to transmit large electrical power by ordinary alternating currents, the feat may be achieved by means of what he terms "electrical waves." The phrase is one which an electrician will understand, but which would involve technical explanation of little interest to the lay reader.

What is more to the point is that the feasibility of utilizing Niagara Falls to do the mechanical work of New York city is not only now assured, but that the attempt will very shortly be made.

It is probable that within a month the actual work of construction looking toward this great end will have been begun.

A BIG PROBLEM SOLVED.

The officers of the Niagara Falls Power Company, which has in hand the great feat of "harnessing Niagara," are as yet reticent to speak upon the subject, inasmuch as their plans are not fully developed and the right of way has not yet been secured. When I saw him at his home, at No. 453 Madison avenue, yesterday, President Edward D. Adams said:—

"It has been the policy of this company to say nothing of what it is going to do and to speak only of what it has done. I must, therefore, decline to enter into any discussion of the company's plans. We might have a great many things in mind which another month would give an entirely different face to. We have been compelled to change our plans many times, at least in important details, and it would, therefore, be premature to attempt to speak now upon what the company has in mind with regard to bringing power to New York city."

Mr. Adams expressed himself, however, as firmly of the belief that the problem of long distance transmission has been practically solved. Upon this point he has the backing of most advanced electrical experts, in addition to Tesla.

Whatever doubts may have been entertained hitherto as to the possibility of successful transmission for long distances, it may be set down that the question is no longer open. For comparatively small distances, ranging from ten to fifty miles, the question has not only been solved, but the process is now being successfully employed at many points throughout the country.

Some time ago a company was formed for the purpose of utilizing the power of the beautiful Snoqualmie Falls, in the State of Washington. This famous cataract, the most imposing and most beautiful on the continent, except Niagara, lies about twenty-three miles directly east of the cities of Seattle and Tacoma, on Puget Sound. It is 268 feet in height, or more than one hundred feet higher than Niagara. Its total realizable energy is estimated at 51,000 horse power. What this means may be gathered from the fact that the total horse power employed in all the manufacturing enterprises of the industrial city of Buffalo, with a quarter of a million inhabitants, is only equivalent to about this single fall.

It is the design of the Snoqualmie Company to transmit the power acquired from the cataract and by electricity do all the mechanical work of Seattle and Tacoma.

Before undertaking the construction of their plan, the company looked carefully into similar enterprises now in operation. They found several successful examples. The San Antonio Electric Light Company of California transmits light and power thirty miles to San Bernardino, and recently tested its ability to employ a ninety mile circuit with perfect success. The Portland (Ore.) plant transmits power from the Willamette Falls to Portland, a distance of fifteen miles. A Mexican enterprise at the falls of Juanacatlan transmits power a distance of seventeen miles. In Montana, Idaho, California, Colorado and Utah plants are in operation successfully transmitting power all the way from four to thirteen miles. All of these have been in successful operation from two to five years.

MORE THAN MERE DREAMS.

It will be seen, therefore, that there is nothing particularly new or hazardous in the attempts of the Niagara Falls Company to turn the machinery of Buffalo by electricity from a distance of twenty-two miles. But this enterprise, great as it is, shrinks into insignificance before the definite dreams which this company has of practically furnishing energy for the whole machinery of New York State.

Several years ago it was officially estimated that the entire power employed to run all the machinery in New York State is equivalent to about 450,000 horse power.

The plans of the Niagara Company look to the generation of half a million horse power.

The question of transmission is practically the whole of the difficulty. Although the work of constructing a plant capable of generating this stupendous amount of energy has been a great one, it has practically been nothing more than a question of the application of capital and hard work along the lines of approved hydraulic engineering. The element of difficulty lies in the fact that electricity is of such an elusive character that, to speak untechnically, it leaks off the wires. Power that can be sold at a profit at Niagara Falls at $15 per year per horse power will at a certain distance reach a price equal to that of steam, owing to the loss from leakage and the expense of installation. Electricians are cautious about making predictions as to whether this distance is 100 miles or 1,000 miles. Dr. Coleman Sellers—no relative of Colonel Sellers—is president of the Niagara Falls Power Company, and a most conservative and experienced engineer. On this point he writes:—

It is absolutely certain, from what has already been done elsewhere, that profitable transmission to a distance of 150 miles is only within the existing practice of distributed power. This 150 miles from Niagara Falls, in a straight line, brings us to within ninety miles of the city of New York. And if we assume as probable economical transmission to a distance of 320 miles, we have an area including the very densest population. It would take in Columbus, Ohio, the cities of Washington, Philadelphia and New York; would include the whole of Pennsylvania, New York, two-thirds of Ohio, three-quarters of Michigan, besides reaching to Montreal, in Canada.

Thus the situation of Niagara Falls is phenomenal in its ability to distribute the power over an area that furnishes the most desirable market for its profitable development. If in the near future, as now seems entirely probable, Chicago can receive its power from Niagara Falls, then the whole of New England, as far as Maine, will come within the reach of this cyclops of energy.

This opinion of Dr. Sellers has the indorsement of no less a personage than Lord Kelvin, formerly Sir William Thompson, who ranks as the greatest electrical authority in the world.

TESLA'S BOLD DECLARATION.

The problem was, perhaps, not wholly solved in theoretical demonstration, however, until Nicola Tesla, that daring wizard of electricity, assured the company that he had discovered, and in great measure perfected, mechanical appliances which would make it possible to deliver the electrical current under complete control, and without costly loss from waste, at long distances. Mr. Tesla has faith that he has now devised the means to deliver the current, at fairly competitive prices, as far as New York city on the east, and as Cleveland and other great towns of Ohio on the west.

It yet remains to be seen whether Mr. Tesla's audacious views are entirely practicable. But no one who has watched the achievements of this wonderful genius can doubt for a moment that he is able to do everything that he promises. It was by a simple invention, of his alone, that it was possible to light the grounds of the World's Fair Exposition at Chicago in the dazzling fashion that made them almost as light as day. But for Mr. Tesla's invention the cost would have been absolutely prohibitive. It is this same simple device, too, that makes it possible to run a main current of electricity and tap it at a thousand points, exactly as we tap a water main. Before that each lamp had to have its separate current, and the use of electricity for house lighting, warming and a hundred other little purposes was economically impossible.

It was the first intention of the engineers to carry the electrical current from Niagara out over the country by means of wires stretched through a subway conduit. It was found however, that the cost would be very great. Mr. Tesla has therefore been engaged for some time in experimenting and devising means to bring the current by overhead wires. He has assured the company that, by invention and the scientific application of newly discovered principles, which he has made, it will be possible to convey the current without very great loss by induction or leakage, and under absolute control, by the use of certain transformance. Mr. Tesla believes not only that this current will be employed upon the Erie Canal, but even to propel vessels from Albany to New York.

PORTRAIT OF J. F. RAFFAELLI, THE PAINTER, BY HIS FRIEND, E. A. ABBEY.

WHAT WILL THE ELECTRICITY COST?

It yet remains to be seen whether the companies can bring electricity to New York city at a price sufficiently low to drive out steam, and practically abolish coal used for power purposes. In a general way, it has been estimated that the power can be delivered here at a cost of about fourteen dollars per year per horse power. If this can be done, it is safe to say that within one year after its introduction the use of coal will have very largely disappeared in New York city. We should have no more smoke and no more gas.

This means a great deal. Roughly speaking, New York pays out every year from $15,000,000 to $20,000,000 for gas alone. It spends upward of $30,000,000 a year for coal. In other words, if we could abolish coal and gas at a stroke, it would involve an item of from $40,000,000 to $50,000,000. Add to this the sums paid out for coal and gas in the additional area of greater New York and the neighboring cities of New Jersey, and this sum would be nearly doubled. The Niagara Company is therefore planning big things.

But even this does not begin to represent the actual saving that would be effected.

Take, for example. At the present time to run the big cable roads of this city there are required immense power houses, employing a large number of workmen, besides truckmen and horses used to transport the necessary coal to run the engines. If these roads were run by an underground trolley, all these power houses would be useless.

This fairly suggests the saving that would be effected all over the city. Steam engines would disappear, engineers would be out of employment and the number of truckmen and horses would be greatly reduced.

We are already dealing with an item of a hundred millions or so. But the prospect stretches still further. If electricity can be brought to New York, as Mr. Tesla declares, at such a price, we should have a Bellamyized metropolis. We should have no noisy, dirty elevated railroads, throwing clouds of hot cinders into the eyes of passengers or passers by upon the streets below. We should have no clumsy, unreliable cable which leaves us stranded half way from our destination about every third time we board a car.

REAL RAPID TRANSIT.

If the municipality under the lead of the Rapid Transit Commission constructs the underground railway, it will probably be from Niagara Falls that it will obtain the power required for the operation of the system. The elevated railroads are a demonstration of the costliness, noise, soot, smoke, gas, cinders, and every conceivable annoyance involved in the use of steam.

The elevated railroads, even if they could obtain cheap electrical power at about the figures indicated, could abolish their steam engines, operate their cars by electricity, make trains of one or two cars each, run them very much faster than they do now, and at a two or three cent fare, probably make as large a profit, if not larger, than they do at the present time. If a cheap, odorless, smokeless, non-heating motive power would be of advantage to the elevated railroads, it would be doubly so, in fact, almost a prerequisite, to the comfortable and successful operation of the underground lines. In the latter, traversing a long and slightly ventilated vault, the presence of smoke, soot and cinders, would be simply unbearable. It is the hope, too, of the projectors of the underground road to not only run the trains at such a speed, but to so reduce fares as to make it feasible for the workers of the downtown districts to have homes in the annexed districts, and still not lose more time going to and fro than they probably do now. This end could only be achieved through cheap electrical power.

HOW THE BIG PROJECT WAS BEGUN.

While the project of transmitting electricity a long distance has been of late years only the dream of daring innovators, yet its use as a motor power has been practically demonstrated for a considerable time. So it is rather strange than otherwise that the tremendous energy of Niagara should have so long remained unharnessed. The energy of the falls is so great that the mind can hardly grasp it. It is so great that the deflection of enough water to turn all the machinery for five hundred miles around—that is to say, to do all the mechanical work for New England and the Middle States—will not make an appreciable decrease in the volume of the water which goes over the falls.

Up to 1885 its enormous power remained practically unused. There were hundreds of engineers or men of a mechanical turn of mind who lay awake o' nights thinking of the fortunes that could be made by turning millwheels with this mighty stream. Finally one of them evolved a plan for a system of wheel pits a mile and a half above the falls, to which water would be carried by lateral canals and from which it would be taken to the river below the falls by a tunnel.

Capitalists were induced to take hold of the project, and the Niagara Falls Power Company was chartered in 1886. The first work was begun in October, 1890, four years ago. The main wheel pit was completed last year, and probably within another month the first of the giant dynamos will be ready. The work has cost, so far, some $4,000,000 and, incidentally, twenty-eight human lives. The device for applying the little portion of Niagara's strength which it is designed to utilize would be simple if one could see it on a small scale. From a point a mile and a half above the American Fall a broad, deep inlet leads back from the river. The heavy masonry with which it is lined at the upper end is pierced by a score of gateways, through which the inflowing water is admitted by short canals to pits, pouring down through huge steel pipes—engineers call them penstocks. The water strikes the bronze turbine wheels at the bottom and then whirls on through the subterranean passage ways that connect each pit with the main tunnel. This tunnel carries the water underneath the heart of the city to the portal just below what is known as the new Suspension Bridge.

A $1,250,000 TUNNEL.

The penstocks are brought down under the turbines and made to discharge upward into the wheels, an ingenious contrivance by which the pressure of the water is made to bear up the entire weight of the heavy wheels and 140 feet of shafting. Three of these turbines form practically an independent plant from which it is expected to cap 5,000 horse power. This will gradually be extended to a capacity of 50,000 horse power. In addition, another 50,000 horse power will be developed in various smaller pits adjacent. The tunnel which will carry away the water used in developing this 100,000 horse power is 1½ miles long, 21 feet high and shaped like a horseshoe. It was cut in a straight line through the rock 200 feet below the surface of the city. It cost $1,250,000, being lined its entire length with from four to six layers of hard brick.

The mouth of the tunnel is nearly 50 feet lower than the head, and the water tears through it at a furious rate. A marked piece of wood dropped in the water near the head of the tunnel is whisked out at the portal, 6,700 feet distant, exactly three minutes later.

Over the big pits is the power house, in which are the giant dynamos. Like almost everything else connected with this enterprise, the three dynamos in the central power station are far and away the most powerful ever constructed, each being expected to transform the 5,000 horse power received from its turbine shaft into an equivalent of electrical force. The most ambitious dynamos hitherto constructed sent out a little more than 2,000 horse power.

Some idea may be obtained of the force of the water in the big wheel pits when it is stated that if the stream injected into the turbines were directed at a man's body it would crush him like a triphammer. These big turbines, too, are so large that a man may stand between the blades.

When the company's entire plant is complete it will generate 450,000 horse power. In addition to this company, there is a second—the Niagara Falls Hydraulic Company—which, until the development of the more remarkable work up the river, possessed the largest water power plant in existence. While a much smaller enterprise than its great rival above, it still expects to compete with the latter in the generation and distribution of electrical power. It has the right of way for a canal 100 feet in width and has made arrangements to enlarge its plant at an early date.

THE CANADIAN ENTERPRISE.

Meanwhile, and in the face of these stupendous operations, a yet greater plant is under way on the Canadian side of the falls. Permission to build this plant was obtained from the Canadian government on condition that the work be begun by May 1, 1897. It is the intention to generate 250,000 horse power eventually on the Canadian side.

All the power generated on the Canadian side will be transformed into electricity and sent to a distance, as mills could not be built adjacent to the plant without disfiguring the scenery of the beautiful Victoria Park.

Those who have studied the question assure us that no one visiting Niagara Falls five or six years from now, when all these great enterprises are fully developed, will find any outward and visible sign of them except the mills along the hydraulic canal basin, which for years have formed a part of the view from Victoria Park.

There is little danger to the falls themselves. The vast mass of water speeding over the precipice will suffer but little diminution—not enough to even make it apparent to the naked eye. The official report of State Engineer Bogart in 1890 estimates that the diversion of enough water to produce a hundred thousand horse power would reduce the depth of the water at the crest of the American Fall about an inch and a half. So that the half a million horse power called for by the present plans of both companies will scarcely reduce the height of the falls three-quarters of a foot—hardly enough to make a noticeable difference in the appearance of this mighty cataract, whose sources of power come from half way across the continent, and whose strength, ceaselessly put forth, is more than twice as great as the combined energy of every steam engine in North America. Niagara will still be the monarch of waterfalls.

Nikola Tesla and the Electric Light of the Future

By Walter T. Stephenson

EXACTLY ten years ago Nikola Tesla, who, in June, 1894, received high honorary degrees from the Colleges of Yale and Columbia, came to this country, poor and unknown, to enter an Edison shop in New York City. For two years previous he had served as engineer in one of the new electric-lighting companies in Paris, and, having become an ardent and appreciative admirer of the splendid genius of Thomas A. Edison, whose fame in those days had only recently flashed throughout Europe, he was, naturally, eager to accept an opportunity of meeting the "wizard" face to face.

Tesla had already patented several minor inventions of his own, but, what was of more importance, his brain was then literally teeming with great ideas, as yet, perhaps, chaotic, but which must some day evolve into definite shape for revelation, and of all countries he firmly believed the United States offered the best encouragement to the inventor who could show practical results. Since New York has continued to be Mr. Tesla's home, we may reasonably infer that he has not been disappointed in his early expectations.

The young Servian electrician derived a fresh stimulus and lasting benefit from his association with Thomas A. Edison. Nevertheless, he soon realized that it would be far wiser for him to continue his special investigations alone, unhampered by other work. Therefore, after a few months of delightful intimacy, the two men of genius separated with mutual expressions of good will.

Nikola Tesla

Mr. Tesla now threw himself with redoubled ardor and energy into the study and analysis of alternating or polyphase currents, which had long been his chosen field of electrical investigation. In 1887 he exploited his wonderful invention of the rotating magnetic field for the economic transmission of power. This simple statement means that, after thirteen years of indomitable effort, embittered by sore disappointments and fierce controversies, a substantial success was at last assured, while scientists everywhere began now to await with keenest interest succeeding developments of the potentialities undoubtedly latent in these hitherto neglected alternating currents.

The majority of us probably are aware that the principal electricians of the world have long been struggling vainly towards the solution of a tremendous problem—the improvement of the electric light. When we are told, for one thing, that fully ninety-nine per cent. of energy is wasted every time such artificial illumination is produced under existing conditions, we begin to realize the crying need there is for a radical change in industrial methods. Now, the goal which some electricians declare to be already in sight means nothing less than the recovery of fully one-third of this wasted energy, thereby rendering possible an illumination many times brighter than at present and at a notable reduction of expense. The question is, which one of the few leaders in the race will outstrip the others and win an immortal name?

Rumors have reached the public ear with increasing frequency of late that Nikola Tesla was working slowly but surely in his own way towards the accomplishment of some such magnificent end.

We know that in May, 1891, Mr. Tesla emerged from the seclusion of his laboratory to deliver an address before the American Institute of Electrical Engineers, at Columbia College, on polyphase currents as applied to artificial illumination. Having in this lecture created a marked impression by the lucid exposition of his peculiar theories, he was soon urged by some of the prominent scientists of Europe to favor them in like manner. So it was that in February, 1892, he crossed the ocean and lectured before numerous audiences in England and on the Continent. It is not too much to say that the name of Nikola Tesla now commanded universal attention in the world of science, but still the man himself was beginning to chafe sadly already under his prolonged absence from the distant laboratory. In the fall of 1892, therefore, he gladly returned to New York to resume his interrupted labors in behalf of science.

In view of all this, even the hardiest of interviewers would be apt to think twice before intruding upon such an individual in his privacy. It will be enough, perhaps, for me to say that the forbearance and kindliness of Nikola Tesla are by no means his least distinguishing traits. Not very far from Washington Square, in the heart of that picturesque neighborhood known as the French quarter, teeming with cheap restaurants, wine-shops, and weather-beaten tenements, the observant passer-by will notice a huge yellowish brick building of some half-dozen stories apparently devoted to manufacturing purposes.

If such a one should undertake to explore the murky interior of this uninviting-looking pile, say to the extent of climbing three or four flights of stairs, and warily threading a signless path through successive mazes of vociferous machinery, his perseverance might be rewarded, as in my own case, by discovering the retreat of a modern wizard. While awaiting my opportunity in an anteroom, I caught glimpses through the adjoining office and library of the mystic laboratory itself, which, as I ascertained later, opened into an immense machine-room.

I may candidly state that I was a trifle shocked the first time I saw Nikola Tesla as he suddenly appeared before me in the library and sank into a chair seemingly in a state of utter dejection. Tall, straight, gaunt, and sinewy of frame like a true Slav, with clear blue eyes and small, mobile mouth fringed with a boyish mustache, he looked younger than his thirty-seven years. But what arrested my attention chiefly at the moment was the pallid, drawn, and haggard appearance of the face. While scanning it closely I plainly read a tale of overwork and of tremendous mental strain that must soon reach the limits of human endurance.

"I would like to talk with you, my dear sir," he said, "but I feel far from well to-day. I am completely worn out, in fact, and yet I cannot stop my work. These experiments of mine are so important, so beautiful, so fascinating, that I can hardly tear myself away from them to eat, and when I try to sleep I think about them constantly. I expect I shall go on until I break down altogether. So you would really like to see some of my experiments in electric lighting," he added. "I shall endeavor to accommodate you, my friend, if you will come with me into the laboratory. Be prepared, though, for a surprise or two."

Mr. Tesla then ushered me into a room some twenty-five feet square, lighted on one side by two broad windows, partially covered by heavy black curtains. Directly opposite was an open door leading into the machine-room, which seemed to be fairly alive with grimy figures flitting to and fro. The whole scene, to my unaccustomed eyes, suggested a veritable magician's den.

The laboratory was literally filled with curious mechanical appliances of every description. Wires innumerable, from the smallest size to cables three-quarters of an inch

thick, ran along the walls, ceiling, and even the floor. In the center was what appeared to be a large circular table covered with thick strips of black woolen cloth; snakelike cables running up underneath were connected at the other end with an adjacent dynamo, thereby establishing a possible center of electro-dynamic vibration. Between the table and the windows two large brownish globes, eighteen inches in diameter, depended from the ceiling by cords. These balls were composed of brass coated with two inches of wax to render them non-injurious, and served the purpose of spreading the electrostatic field.

So much for my surroundings as I glanced about in some bewilderment after hearing Mr. Tesla say that he had a surprise in store for me. Promptly suiting the action to the word, he called in several employees from the workshop and issued a succession of hurried orders which I followed but vaguely. Presently, however, the doors were shut and the curtains closely drawn until every chink or crevice for the admission of light was concealed, and the laboratory bathed in absolutely impenetrable gloom. I awaited developments with intense interest.

The next minute exquisitely beautiful luminous signs and devices of mystic origin began to flash about me with startling frequency. Sometimes they seemed iridescent, while again a dazzling white light prevailed.

"Take hold," said a voice, and I felt a sort of handle thrust into my hand. Then I was gently led forward and told to wave it. On complying, I spelled the word "Welcome" flaming before my eyes. Unfortunately, I was totally unable at the time to appreciate the kindly sentiment implied.

A hand approached mine ere I had quite recovered, and I felt the tips of my fingers lightly brushed. Fancy my dire dismay when I immediately experienced an acute tingling sensation, accompanied by a brief pyrotechnic display that was surprising, to say the least. When the daylight as well as my equanimity was in a measure restored, I learned something of the meaning of these wondrous experiments, which may be said to foreshadow in a way the electric light of the future. What impressed me most of all, perhaps, was the simple but cheerful fact that I remained unscathed while electrical bombardments were taking place on every side. Curiously enough, the polyphase currents of high frequency and high potential, of say 200,000 volts, have, as Mr. Tesla has demonstrated repeatedly on the platform, no harmful effect whatever on the human body, although a like energy exerted in indirect currents would prove instantaneously fatal.

Over two and a half years ago Mr. Tesla made this striking observation in one of his lectures: "The ideal way of lighting a hall or room would, however, be to produce such a condition in it that an illuminating device could be moved and put anywhere, and that it should be lighted no matter where it is put, and without being electrically connected to anything."

To return to my own experience in the darkened laboratory, it seems that the entire room was actually filled with electric vibrations through the agency of these same currents, styled alternating (that is, with direction perpetually changing). The strange devices I had seen were nothing more than nearly exhausted glass tubes bent into various shapes and analogous to lamps, excepting that they were devoid of filament or button.

These tubes being carried into the area where the electrical agitation was strongest, the remaining molecules of ether or air within all the while pressing against the crystal confines, a molecular bombardment followed, produced by the collision of two forces, and the bulbs simultaneously became luminous. Those which were made to glow with the colors of the rainbow were coated on the inside with phosphorescent substances.

I have attempted nothing more than a very imperfect outline of Mr. Tesla's novel and interesting scheme, which is to be regarded as still in a state of embryo. It cannot be denied, too, that there are many scientists to-day who shake their heads dubiously at the brilliant Servian's unequivocal attitude towards the electric light.

Meanwhile Mr. Tesla makes no boasts, but is willing to abide his time. Throughout the interview I was constantly impressed with the man's loftiness of purpose, innate modesty, and utter indifference to public applause. "I should much prefer not to be written about at all," he remarked; "but if it must be done, I trust you will take due pains to quote me correctly."

Speaking of the scientific status of the United States as compared with that of older nations, he said: "English scientists are the greatest in theory, perhaps, although, as far as practical results go, America may well claim to lead the world. That is why I like to stay here."

Mr. Tesla speaks our language with the idiomatic range and choice diction of a native who is also a scholar and a trained speaker, the guttural accent of the Slav, of course, being slightly noticeable. He told me that he felt equally at home in six languages, not to mention the same number of dialects.

Though simple, self-contained, and undemonstrative in manner, when he is especially pleased or absorbed in enthusiastic description of electrical wonders, the intellectual animation of his frank blue eyes, combined with a rarely winning smile, exercises a charm that is irresistible. I have noticed the same unconscious quality of personal magnetism in Mr. Edison, though in almost every other respect these two remarkable individuals are totally dissimilar.

Edison may be more truly the man of genius. He works out his intricate problems by intuition. He peers into the future like a seer of old, and receives, as it were, lightning flashes of inspiration to guide him to the goal. In a word, the illiterate train boy of thirty-odd years ago has come to be regarded as little less than a wizard; and yet, assuredly, he is neither a thinker nor a student in the true sense.

Now, how is it with the Servian, who has acquired fame much less rapidly? What was his life before he came among us? Let me say at the outset that eighteen years of exhaustive, patient study were accomplished before Nikola Tesla deemed himself adequately prepared to embark upon the career which he had planned from childhood.

Born in 1857 at Smiljan Lika, a remote village in Austro-Hungary, he is the descendant of a sturdy line of Servian patriots, who for centuries had taken a prominent part in the protracted struggle against the domineering Turk.

The young Nikola commenced his studies in the public school of Gospich when five years of age. Not long afterwards the marvels of electricity and magnetism began to dawn upon the boy's receptive soul. Fascinated and stirred until he scarcely thought of anything else, he resolved thenceforth to devote his life to research and investigation in this noble field of knowledge. In 1873, against the wishes of his father, who, being a clergyman in the Greek Church, had hoped that his son would discover a theological bent, Nikola entered the Polytechnic school at Gratz. It was at this institution, while puzzling over the complexities of a direct current Gramme machine, that his alert mind was led to conceive of a rotating magnetic field, which discovery was destined to deal the death-blow to those troublous contrivances the commutator and brushes. After completing the technical course at Gratz, Mr. Tesla removed to Vienna, where for several years he attended philosophical lectures, read omnivorously on many subjects, continued his special studies, and incidentally found time to master five or six languages. Verily, an intellectual training of this sort, in the face, too, of untold trials and difficulties, would have far exceeded the scope of any ordinary student.

Before I bade a regretful farewell to this kindly wizard of Washington Square he confided to me that he was engaged on several secret experiments of most abundant promise, but their nature cannot be hinted at here. However, I have Mr. Tesla's permission to say that some day he proposes to transmit electric vibrations through the earth; in other words, that it will be possible to send a message from an ocean steamer to a city, however distant, without the use of any wire.

To those who would gain a complete technical knowledge of the Servian's manifold labors since he came to the United

States I would recommend a careful study of the volume recently issued by Mr. T. C. Martin, of the "Electrical Engineer," entitled "The Inventions, Researches, and Writings of Nikola Tesla." How strange it is, indeed, that, though electricity has so long been partially controlled by mankind, yet we are utterly unable to define it! As Mr. Tesla has said: "The day when we know what electricity is will chronicle an event probably greater than any other recorded in the history of the human race."

A Mother of Bosnia

By Robert Underwood Johnson

From the Servian of Zmai, after Literal Translation by Nikola Tesla

I.

Three sons she has of Servian mold
  As balsam for her widow's grief,
While in her Danka all behold
  A treasure precious past belief.

Oh, lovely Danka! happy she,
  More fortunate than all beside,
To be the pride of brothers three,
  Themselves of Bosnia the pride!

In her they glory: she inspires
  To freedom's never-ending fight,
And in their hearts burn patriot fires,
  As stars upon the Turkish night.

And often at the mother's door
  Tears mingle with the words that bless:
"O gods of battle! guard my four—
  My falcons and my falconess."

II.

Her radiant beauty nothing hides—
  What wonder that the Turk has seen,
And as before her door he rides
  The Raven-Aga calls her queen!

For three nights has he lain awake—
  To call on Allah? Nay, till dawn
Calling on Danka, for whose sake
  His heart is sore, his brow is wan.

He gathers warriors ere the sun;
  They gallop quickly through the murk;
And Danka, at the signal gun,
  Cries, "Save me, brothers!—'tis the Turk!"

Now flash the rifles, speeds the fight,
  Till, shamed, the Raven-Aga flies.
Alas for Danka! in her sight
  One lion-hearted brother dies.

. . . . . .

Again the infidel appears,
  And at his heels ride forty guns;
But at the voice of Danka's fears
  Red many a Turkish stirrup runs.

But, oh, at vespers, when once more
  The baffled Raven back has fled,
Across the sill of Danka's door
  There lies another brother, dead.

. . . . . .

The Turkish devil once again
  Summons each savage wedding-guest,
And half a hundred to be slain
  Go forth at midnight toward the west.

Once more the stealthy Moslems ride,
  Once more the Servians gather fast,
As Danka summons to her side
  Her brother—and her last.

The fight grows fiercer, till the dead
  Fill the dim street from wall to wall.
Call on thy mother, Battle-wed,
  Thou hast no brother left to call!

The Raven seizes her and croaks:
  "At last thou art my bride, proud maid"
"Not thine—my yataghan's!" Two strong
  Her warm heart weds the loyal blade.

III.

Dark is the night as on the slopes
  Of that deserted battle-ground
The mother, crazed with sorrow, gropes
  Until her sons' three swords are found

And as she roams through Servian lands
  (Her mirth more piteous than her tears
She bears a blade in her thin hands
  To right the wrongs of many years.

And offering Danka's plighted knife
  Or one of those three patriot swords,
She calls the coldest rock to strife,—
  "Take, and repel the Turkish hordes

And as the rock no word replies,
  She asks, "Are you not Servian too?
Why are you silent then?" she cries;
  "Is there no living heart in you?"

She treads the dreary night alone;
There is no echo to her moan. . . .
Is every heart a heart of stone?

FRUITS OF GENIUS WERE SWEPT AWAY.

By a Fire the Noted Electrician, Nicola Tesla, Loses Mechanisms of Inestimable Value.

INVENTIONS IN THE RUINS.

The Workshop Where He Evolved Ideas That Startled Electricians Entirely Destroyed.

YEARS OF LABOR LOST.

Utterly disheartened and broken in spirit, Nicola Tesla, one of the world's greatest electricians, returned to his rooms in the Gerlach yesterday morning and took to his bed. He has not arisen since. He lies there, half sleeping, half waking. He is completely prostrated.

In a single night the fruits of ten years of toil and research were swept away. The web of a thousand wires which at his bidding thrilled with life had been twisted by fire into a tangled skein. Machines, to the perfection of which he gave all that was best of a master mind are now shapeless things, and vessels which contained the results of patient experiment are heaps of pot sherds.

By the fire which swept through the building at Nos. 33 and 35 South Fifth avenue in the early hours of yesterday morning one of the most valuable laboratories in the world was destroyed. It was that of Nicola Tesla, the Servian electrician. In those upper lofts were apparatus and appliances which meant a revolution in electrical science.

There were materials which he could shape to fetter the lightning and to call into action the most subtle of forces. Early and late he toiled there. He was on the eve of making known scientific discoveries which would have added new lustre to his name when all was swept away. He had worked day in and day out, and far into many a night over the work bench and the forge in those upper rooms.

THERE HE HAD TOILED.

Time spent in sleep he considered almost wasted. A man can never injure himself by working too much, was the maxim on which he shaped his life. He drove himself to tasks which would have seemed superhuman to the man of ordinary mind. He evolved theories upon which the power of Niagara was harnessed to work. He constructed mechanisms which converted simple materials into mighty electric currents.

In these lofts, above the dust and rattle of the elevated road and the din of the factory wheel, steam heaters were made. This man discovered principles in physics which have revised many a page in the great book of science.

Nicola Tesla came to this country about ten years ago from Servia. He was twenty-seven years old then, yet his name was already one of the foremost in the world of electrical research.

He was for a time associated with Thomas Edison. He and Mr. Edison parted after a few months and went their separate ways. They were friends, yet rivals.

The young Servian devoted all his best energies to the study of electrical phenomena. In addition to his work as controlling electrician for some of the largest companies using electrical power, he perfected several appliances for the production of electricity.

His discovery, in 1887, of the rotating magnetic field for the economic transmission of power, attracted the attention of the entire scientific world to him. His theory of the production of light by the vibration of the atmosphere, and his proposal to transmit messages without the use of wires, amazed the older scientists.

It was to perfect such theories as these that the young Servian toiled so unremittingly in his South Fifth avenue laboratory. The experiments which he has been carrying on there in the last few months were conducted with secrecy. He would say but little about them beyond the the fact that he hoped soon to solve a vexed electrical problem.

His strength was overtaxed by the strains placed upon it. For weeks those who knew him knew that he was bordering on a state of nervous exhaustion. Yet so firm was his will that few would have suspected how worn he was with toil.

"I am completely worn out," he said the other day to a friend, "yet I cannot stop my work. These experiments are so beautiful, so fascinating, so important, that I can hardly tear myself away from them to eat, and when I try to sleep I think about them constantly. I expect that I shall go on until I break down altogether."

THEN HE SUCCUMBED.

When the fire took away that which sustained him in spite of his exhaustion, the iron will was broken, and Nicola Tesla became as other men, whom work and care have worn.

The man who had, in the course of one of his experiments, withstood, under peculiar conditions, the polyphase currents of electricity to thousands of volts, is lying on his bed, clasping his nerveless hands and speaking no word.

The laboratory where he worked was situated over Gillis & Geoghegan's factory, in South Fifth avenue. The fire was discovered at half-past two o'clock yesterday morning. The building is now four cracked and blackened walls.

Hundreds of workmen were thrown out of employment, and the loss will be many thousands of dollars. It is easy to replace all that. Money will do it. But the loss which Nicola Tesla has sustained gold cannot make good.

The actual amount invested by him there was between $80,000 and $100,000. What he has lost and what the scientific world has lost cannot be estimated that way.

The New York Sun March 14, 1895

INVENTOR TESLA'S LOSS.

HIS LABORATORY AND WORK RUINED BY FIRE.

Gillis & Geoghegan Also Burned Out—The Six-story Building at 33 and 35 South Fifth Avenue Gutted—Years of Labor Gone for the Inventor—He Was Too Much Overcome by His Loss to Talk of It.

By a fire which almost completely gutted the six-story and basement building at 33 and 35 South Fifth avenue early yesterday morning Nicola Tesla, the electrician, lost all of the apparatus with which he has been carrying on his professional experiments. Among the things destroyed were several nearly completed inventions which were intended to revolutionize electric lighting.

Mr. Tesla occupied the entire fourth floor. When the floor gave way his apparatus fell to the second floor where it lies in unrecognizable ruin. It was not insured.

Gillis & Geoghegan, manufacturers of steam fitters' supplies, who occupied the rest of the building, lost their entire stock, valued at $63,000. They are insured for $60,000. The building, which belongs to Mrs. Matilda W. Bruce, was damaged to the extent of $40,000, which is also covered by insurance.

The fire was discovered at 2:30 o'clock. John Mahoney, the watchman employed by Gillis & Geoghegan, had left the office on the ground floor just before that hour to bank the fires in the subcellar, leaving a single gas jet burning. In about ten minutes he returned and found flames running along the floor and up the sides of the partition of the office. Mahoney yelled for a policeman.

Policeman Haggerty ran to the watchman's assistance. Mahoney had closed the office door and was pouring buckets of water on the flames. Seeing that this did no good he told the policeman to turn in an alarm. A moment later he was driven into the street by great tongues of flame which shot up through the floor.

Before Chief Reilly with Engine 33 reached the fire the flames had spread to the first and second floors, and were shooting to the top of the building through the stairways, airshaft, and elevator well. From top to bottom the building was saturated with machine oils, and this ignited with great rapidity. Chief Reilly at once sent in a third alarm. Chief Bonner was soon on the scene with about a dozen engines and trucks.

The Laurens lodging house stands next door at 37 South Fifth avenue. The firemen turned its 150 men occupants into the street and carried their hose to the roof of the building. The occupants of the Italian tenement houses in the vicinity were also turned out of their homes. The firemen fought the flames for fully three hours before they were under control. The Sixth avenue elevated road was blocked in the mean time, the firemen using its structure to work from.

It was not until 8 o'clock that the recall for the engines was sounded. The walls and framework of the building were still standing, but the north side of the structure was so badly cracked that the tenants of the nearest houses were ordered out again for fear that it would fall.

Inventor Tesla, who lives at the Gerlach Hotel, was almost prostrated when he heard the news, shortly before breakfast time. He has been for some time in a state of nervousness bordering on exhaustion because of overwork. He would not at first believe the messenger who brought the news. When convinced of its truth he slammed the door of his room shut and remained buried in thought for an hour. Then he dashed down stairs and went to the scene of the conflagration, where he gazed mournfully up at the fourth floor of the building. Later, in company with a fireman, he went up to the second floor and looked at the ruins of his work. He came out of the building much affected. He paid hardly any attention to the sympathy expressed by his fellow tenants, so absorbed was he in the thought of his loss.

After a light lunch at Delmonico's he retired to his apartments and denied himself to all callers, saying that he felt too bad to see anybody. The clerk would not even send up notes from the many friends of the inventor who called.

Tesla is a Servian. He came to this country ten years ago, and was associated for a short time with Thomas A. Edison. He has received honorary degrees from Yale and Columbia Colleges, and is the controlling electrical engineer to the Niagara Power Company and many other concerns.

Since he has been in the building in South Fifth avenue he has worked with about a dozen assistants in a very secretive manner. It was understood that he was working on inventions intended to save much of the energy now lost in electric lighting. It is well known to electricians that about 90 per cent. of the energy used to produce incandescent lights now goes to waste, and he has said that he hopes to save one-third of the loss.

The New York Sun March 14, 1895

The destruction of NIKOLA TESLA'S workshop, with its wonderful contents, is something more than a private calamity. It is a misfortune to the whole world. It is not in any degree an exaggeration to say that the men living at this time who are more important to the human race than this young gentleman, can be counted on the fingers of one hand; perhaps on the thumb of one hand.

MR. TESLA'S GREAT LOSS

All of the Electrician's Valuable Instruments Burned.

WORK OF HALF A LIFETIME GONE

Firemen Unable to Save His Laboratory in South Fifth Avenue—He Loses $50,000; Gillis & Geoghegan $80,000.

"I am in too much grief to talk. What can I say? The work of half my lifetime, very nearly; all my mechanical instruments and scientific apparatus, that it has taken years to perfect, swept away in a fire that lasted only an hour or two. How can I estimate the loss in mere dollars and cents? Everything is gone. I must begin over again."

That is all that Nikola Tesla, the renowned electrician, had to say about a fire that utterly wiped out his laboratory at 35 South Fifth Avenue yesterday and destroyed instruments on which he has made experiments in advanced electricity that have astonished the world. Tears were in his eyes when he spoke.

Nikola Tesla,
Whose Electric Works Were Burned Yesterday.

Ever since Mr. Tesla came to this country from Servia, about ten years ago and became for a time associated with Mr. Edison in his laboratory, at Menlo Park, N. J., his experiments have been watched with increasing solicitude by almost everybody interested in the progress of electrical science. He has attracted almost as much attention as "Wizard" Edison himself. The two men are scarcely rivals, for they conducted their investigations on substantially different lines. Personally, they are warm friends. Mr. Tesla never cared to talk much about his work. Few people knew what was going on in the rooms that were destroyed by fire yesterday. About fifteen men were at work there nearly every day, experimenting under Tesla's personal direction. He worked as hard as his men did. He had a little office with a roll-top desk and a rug but he seldom went near it except to talk to visitors. Most of his workaday hours were spent bustling about in his shirt sleeves among his instruments.

Outside of his shop he is something of a Sybarite. He dines at Delmonico's almost invariably, and lounges about the café during the evening. Habitués of the place know him well. He is very tall and very thin. His dark eyes are perhaps his most noticeable feature. They are large and brilliant, showing with the zeal of an enthusiast.

Lectures given by Mr. Tesla from time to time give the best idea of his hopes and aims. Of course, he does a great deal of practical work all the time, aside from his experiments. He is controlling engineer of the Niagara Power Company and consulting engineer to other corporations interested in electrical supply. But his experiments took up most of his time. One thing that Mr. Tesla was striving to accomplish was to prevent the enormous waste of force in the manufacture of electricity. He has contended that about 99 per cent. of the energy now goes to waste. His experiments have been devoted to saving at least one-third of the energy, which would make it possible to obtain a much greater illumination than can be procured at present, and at a great decrease in cost.

"The ideal way of lighting a room would be," he said in one of his lectures before a scientific society two years ago, "to produce such a condition in it that an illuminating device could be moved and put anywhere, and that it should be lighted no matter where put, without being electrically connected with anything."

Mr. Tesla has demonstrated in his experiments that the polyphase currents of high potency, even to 250,000 volts, have no hurtful effect on the human body. He allowed that number of volts to pass through his own body without harm. Through his discovery of the means of transmitting electricity without a wire, Mr. Tesla expected to produce a light as powerful as sunshine as soon as he had discovered how to care safely for the 8,000,000 volts necessary for the purpose.

Gillis & Geoghegan, manufacturers of steamfitters' supplies, occupied the lower floors of the building in which Mr. Tesla had his laboratory. Night Watchman Mahoney was employed to look after the building. He said that he was making his rounds as usual just before 3 o'clock yesterday morning when he discovered the fire. It had started on the ground floor, but from precisely what cause is not known. He tried in vain to put it out with pails of water.

The building was saturated with oils necessary in the manufacture of fittings, and it burned like a tinder-box. Before a line of hose could be put down it was evident that the place was doomed. Chief Bonner and his men could make little headway against the terrific heat. It was so intense that at one time the elevated railway structure caught fire. There was a box factory next door, filled with inflammable material, and every endeavor was made to keep that from going, too. It took three hours to get the flames under control. There are so many ramshackle buildings in that locality that if the box factory had once caught fire there is no telling where the fire would have ended.

Mr. Tesla's employes were dismayed when they appeared on the scene for work in the morning and found their occupation gone. Not one of them had the courage to go and tell their employer of his terrible loss. He appeared, as usual, about 10 o'clock, and found it out for himself. At first he was simply dazed.

"It cannot be true!" he exclaimed, pacing up and down before the ruins in hopeless despair. He told a fireman that he had no insurance, and that, so far as he knew, the money loss would probably represent $50,000. The loss to the building itself is estimated at $25,000, and the loss to Gillis & Geoghegan is estimated at $80,000. This is covered by insurance.

Mr. Tesla's Works Destroyed by Fire.—A Reuter's telegram, reproduced in yesterday's *Western Mail*, states that Mr. Tesla's works have been destroyed by fire. The whole of his extensive plant, and all his specially-designed apparatus for conducting experiments were destroyed. The damage is estimated at $100,000, but the greatest loss is the physical collapse of the inventor from the shock caused by the disaster.

TESLA AGAIN AT WORK.

He Says that a Million Dollars Would Not Pay for What Was Burned.

Nikola Tesla, the electrician, whose workrooms and apparatus were destroyed by fire on Wednesday morning, was at work again yesterday. Although not yet recovered from the shock occasioned by his loss, he spent several hours in drawing up the plans of a new invention. When seen at his apartment in the Gerlach Hotel Mr. Tesla was walking nervously up and down his room, dictating to a typewriter.

"Yes, I am at work again," said he, in reply to the reporter's question. "I have already begun work on a new set of plans. I shall now be obliged to work doubly hard to make up for the most unfortunate loss I have sustained."

When asked if he could give an estimate of his loss, Mr. Tesla said:

"No, that would be very difficult. In a case like this the loss cannot be estimated in dollars and cents. If it could be, I might say that a million of dollars would not pay for what has been destroyed."

"But you will doubtless be able to replace everything in time," said the reporter.

"I don't know," replied the inventor wearily. "Some things can never be replaced. A painter may have commenced a masterpiece which is destroyed while in process of completion. In that case the painter may begin all over again, inspired by his misfortune, as is sometimes the case. Nerved up by his loss, he may produce another masterpiece which will make him famous.

"In the case of an inventor it is different. When, at one blow, all his apparatus, his machinery, the work of months of careful study, are swept away, it is no easy matter to replace the loss. As I said before, I can give no estimate of my loss as most persons would reckon it. A man may spend $100,000 in fitting out a laboratory, which another man would not give $10,000 for. Some of my models," he continued, "were boxed up ready for shipment. There were a few which had already been sent away. The larger part of my work, however, was a total loss. I did not insure it, as no insurance could cover its true value."

Mr. Tesla said that his electrical apparatus, with which he hoped to improve the electric light had been destroyed with the rest. There were also other half-completed inventions of which he did not care to speak.

"All my friends have been very kind to me," said he. "I have received a letter from Mr. Edison offering me the use of his workshops in which to continue my experiments. He has shown me the greatest kindness and consideration. I do not think, however, that I will accept the offer. I shall probably within a short time secure other quarters in the city and begin my work anew. I have not as yet recovered sufficiently from the shock of my loss to make any definite plans.

"One thing in particular has cheered me up a good deal. It was the kind editorial which appeared about me in this morning's SUN. I am deeply grateful."

It is estimated that Mr. Tesla's loss, aside from the contingent damage, will amount to between $80,000 and $100,000, as much valuable apparatus and complicated machinery were destroyed.

THE destruction of Mr. Tesla's laboratory by a fire due to the carelessness of a lazy or stupid watchman is a very serious loss to the inventor and to the world; but it takes more than a fire to set back an inventor of such dauntless courage and such indefatigable originality.

DESTRUCTION OF THE TESLA LABORATORY BY FIRE.

By a fire which almost completely gutted the six-story and basement building at 33 and 35 South Fifth avenue, this city, on March 13, Mr. Nikola Tesla, the electrician, lost all of the apparatus with which he has been carrying on his professional experiments. He occupied the entire fourth floor. When the floor gave way his apparatus fell to the second story where it lay in unrecognizable ruin. It was not insured.

Gillis & Geoghegan, manufacturers of steam fitters' supplies, occupied the rest of the building. The fire was discovered at 2:30 a. m. John Mahoney, the watchman employed by Gillis & Geoghegan, had, he says, left the office on the ground floor just before that hour to bank the fires in the subcellar, leaving a single gas jet burning. In about ten minutes he returned and found flames running along the floor and up the sides of the partition of the office. Mahoney yelled for a policeman. Policeman Haggerty ran to the watchman's assistance. Mahoney had closed the office door and was pouring buckets of water on the flames. Seeing that this did no good he told the policeman to turn in an alarm. A moment later he was driven into the street by great tongues of flames which shot up from the floor.

Before Chief Reilly with Engine 33 reached the fire the flames had spread to the first and second floors, and were shooting to the top of the building through the stairways, airshaft and elevator well. From top to bottom the building was saturated with machine oils, used in cutting steam pipe, and this ignited with great rapidity. The firemen fought the flames for fully three hours before they were under control. The Sixth avenue elevated road was blocked in the mean time, the firemen using its structure to work from. It was not until 8 o'clock that the recall for the engines was sounded. The walls and framework of the building were still standing, but the north side of the structure was so badly cracked that the tenants of the nearest houses were ordered out again for fear that it would fall.

Mr. Tesla was at first very much affected by the news of his loss, but sustained the blow stoically, and within 6 hours was busily engaged making and giving out designs for the reconstruction of his latest type of oscillator, which has now been running successfully for some time past, lighting the laboratory and supplying current for a number of new and novel experiments. It is needless to add that Mr. Tesla has received innumerable expressions of sympathy and regret not only from friends and acquaintances but from total strangers.

TESLA'S LABORATORY BURNED.

THE DISTINGUISHED INVENTOR'S HEAVY LOSS BY FIRE OF APPARATUS AND RECORDS.

By a fire which almost completely destroyed the six-story and basement building at 33 and 35 South Fifth avenue, New York city, March 13, Nikola Tesla, the electrician, lost all of the apparatus with which he has been carrying on his professional experiments. Mr. Tesla occupied the entire fourth floor. When the floor gave way his apparatus fell to the second floor, where it remained in an unrecognizable ruin. It was not insured.

Mr. Tesla was naturally considerably affected by this sudden and most disastrous loss, but with true grit at once began preparations to resume his work elsewhere. In an interview he says :

I am congratulating myself all the time it is no worse. I begin all over again, but I have the knowledge and experience of what has gone before, and fortunately I was able to show with completed apparatus that my ideas and theories are correct. Had the fire occurred a few months ago, I should have been robbed of the opportunity of many highly successful demonstrations. Take my oscillator, for example, that combines the steam engine and dynamo. Last Fall, for example, I had there a gathering of medical and other professional men—perhaps 200—and they all saw the machine running, lighting up my laboratory with plenty of lights and furnishing current for a series of novel experiments. The machine is gone. But suppose the fire had happened before that or before others had seen it running? My statements about it would not have been half so convincing. Everything is destroyed—practically all—although, of course, where some of it has passed into commercial operation the interest in that part was of an historic and personal nature. I had a cabinet containing many of the earlier inventions, over which I have brooded and worked days and nights. To-day the ideas there embodied are utilized in the big 5,000 horse-power generators at Niagara and in kindred motors in a great many parts of the world ; but I prized the old models and trial apparatus, and would not have taken any money for them. Some of them were shown in the Electricity building at the World's Fair, where also some of the new principles I have discovered were illustrated by operative devices. These devices I had in my laboratory, and they have gone down in the wreck, too. Moreover, I had there some records, books and papers, such as every industrious experimenter is likely to get around him in time, and they have vanished. Happily, a good deal of my work has appeared in book form now, or in the technical journals, and that much is secure. The rest, he added, with just a little note of sadness in his voice, I shall try to jot down as soon as I can get time from more pressing matters. You know an inventor while making experiments often gets a few spare minutes between whiles, and I had been employing some of these spells lately in getting my data in better order. Part of that work has gone also.

I was engaged on four main lines of work and investigation. One of these was the oscillator, which I cannot but regard as a practically perfected machine, but which, of course, suggests many new lines of thought every day. Another was improved methods of electric lighting. Another was the transmission of intelligence any distance without wires. A fourth, which is an ever present problem for every thinking electrician, touches the nature of electricity. Each of these questions and many others I shall follow up, and somehow I cannot help feeling that this disaster will sharpen my intuition as to the best lines of work, so that good will come out of evil. With so much on my mind and hands I need not excuse myself for being brief with you. I have been overwhelmed with generosity and sympathy this week, and feel the kindness deeply, even if I can make no response. But I must carve my way through or over the mountain suddenly planted in front of me, and so you see me preoccupied. I am glad to add to-day that by last reports from the scene of the fire some of the debris is in better shape than I dared hope, and I may yet see some valuable salvage. But my men are meantime busy as though none of the old were left.

NIKOLA TESLA.

Tesla's loss by fire, while a serious one, has not prostrated the talented inventor, as the accounts in the daily press imply. Instead he goes to work with renewed vigor, replying to a friend, who suggested that he take a long rest before starting in again, that "I might have followed your advice and taken a rest if this had not occurred, but now I feel that it is about time to stop idling." Tesla never was an idler, and if he works any harder now than before, he will have to find the way to live without stopping to eat or sleep. The kindly tone of the great dailies in speaking of the young inventor's loss is particularly noticeable. We do not remember ever having seen a higher compliment paid anyone than the following from the *Sun* of this city, evidently by Mr. Chas. A. Dana:

> The destruction of Nikola Tesla's workshop, with its wonderful contents, is something more than a private calamity. It is a misfortune to the whole world. It is not in any degree an exaggeration to say that the men living at this time who are more important to the human race than this young gentleman can be counted on the fingers of one hand; perhaps on the thumb of one hand.

The ELECTRICAL REVIEW extends to Mr. Tesla its regrets over his most exasperating loss, but with everyone else interested in scientific progress is glad to note his resolution to at once take up his work so near completion. May health and strength and greater success and honor be his!

PUBLIC OPINION

A WEEKLY JOURNAL

Volume XVIII, Number 12 Thursday, 21 March, 1895

***The aim of this journal is to reflect public opinion. The utmost care is taken to treat each question upon which extracts are given in a perfectly fair, non-partisan and unbiased manner. The editors do not assume to determine the politics of any paper quoted, the political credits being taken from the publishers' own statements.

***Unless otherwise indicated, the condensed extracts printed in these columns are not rewritten, but are in the language of the original article.

The destruction of Nicola Tesla's electrical workshop in New York City is commented upon as a loss that distinctly sets back the hand upon the dial of progress in electrical discovery and invention, both theoretical and practical. It is hoped, however, that the lost apparatus may be replaced in the course of time, and that Mr. Tesla's genius and energy may yet produce the results delayed by this calamity.

Nicola Tesla's Loss

Baltimore *Herald*

A disposition prevails to view the destruction of Nicola Tesla's electrical laboratory in New York as a great calamity. The wizard himself is described as being very much cast down over the loss, which involves the fruits of a lifetime of labor, and particularly so because he thought he was on the eve of making discoveries which would have revolutionized electrical science. It is stated that delicate instruments and much intricate apparatus were ruined which could not be replaced. There seems to be no reason, however, for taking such a gloomy view, nor for viewing the loss incurred as irreparable. Mr. Tesla's capacity for technical research remains undiminished. He was said to be on the eve of mental breakdown previous to the fire on account of incessant pursuit of his experiments. By the time he fits up a new workshop he will have had an opportunity to recuperate, and can go to work with new strength. It ought not to be so very difficult, at least not impossible, to replace the apparatus. The brain that created it should be able to construct it anew. To Mr. Tesla the world already owes some wonderful inventions, and latterly he was pursuing a course of investigation which promised still more startling results. Transmission of electrical power over long distances, telegraphing without wires, light without heat, utilization of electricity for heating purposes, to the exclusion of coal, were some of the problems which engaged his attention. Several had already reached a partial solution, and it remained only to make them practical. A loss infinitely greater than the destruction of the workshop would have been the failure of the workman. As it is, we can afford to wait until the damage has been repaired.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 879.—Vol. XXXIV. FRIDAY, MARCH 22, 1895. PRICE FOURPENCE.
Annual Subscription (U.K.), 19/6

NOTES.

We are glad to learn by special cablegram that the somewhat sensational Reuter's despatch, which came to hand last week, announcing not only the burning out of Mr. Nikola Tesla's laboratory, but his mental collapse, was inaccurate in several respects. A fire began, it seems, early on Wednesday morning, the 13th inst., in the office of a steam-fitting concern situated on the ground-floor of the building in which Mr. Tesla carries on his work. The watchman reports that the mischief was started by a gas flame. Mr. Tesla's laboratory, on the fourth floor, was almost entirely destroyed. The contents included the whole of his polyphase models, most of his papers, the records of his experiments, the apparatus exhibited at Chicago, his original and latest form of oscillator, and all the apparatus with which he performed so many striking experiments when in London. None of the property was insured. Mr. Tesla, instead of being in a state of collapse as alleged, actively recommenced, on the very day of the fire, the building of a new oscillator. It is unnecessary to add that great sympathy has been expressed for this enthusiastic experimenter in the land of his adoption; an expression of feeling which we feel sure will find an echo in this country where he has made so many friends.

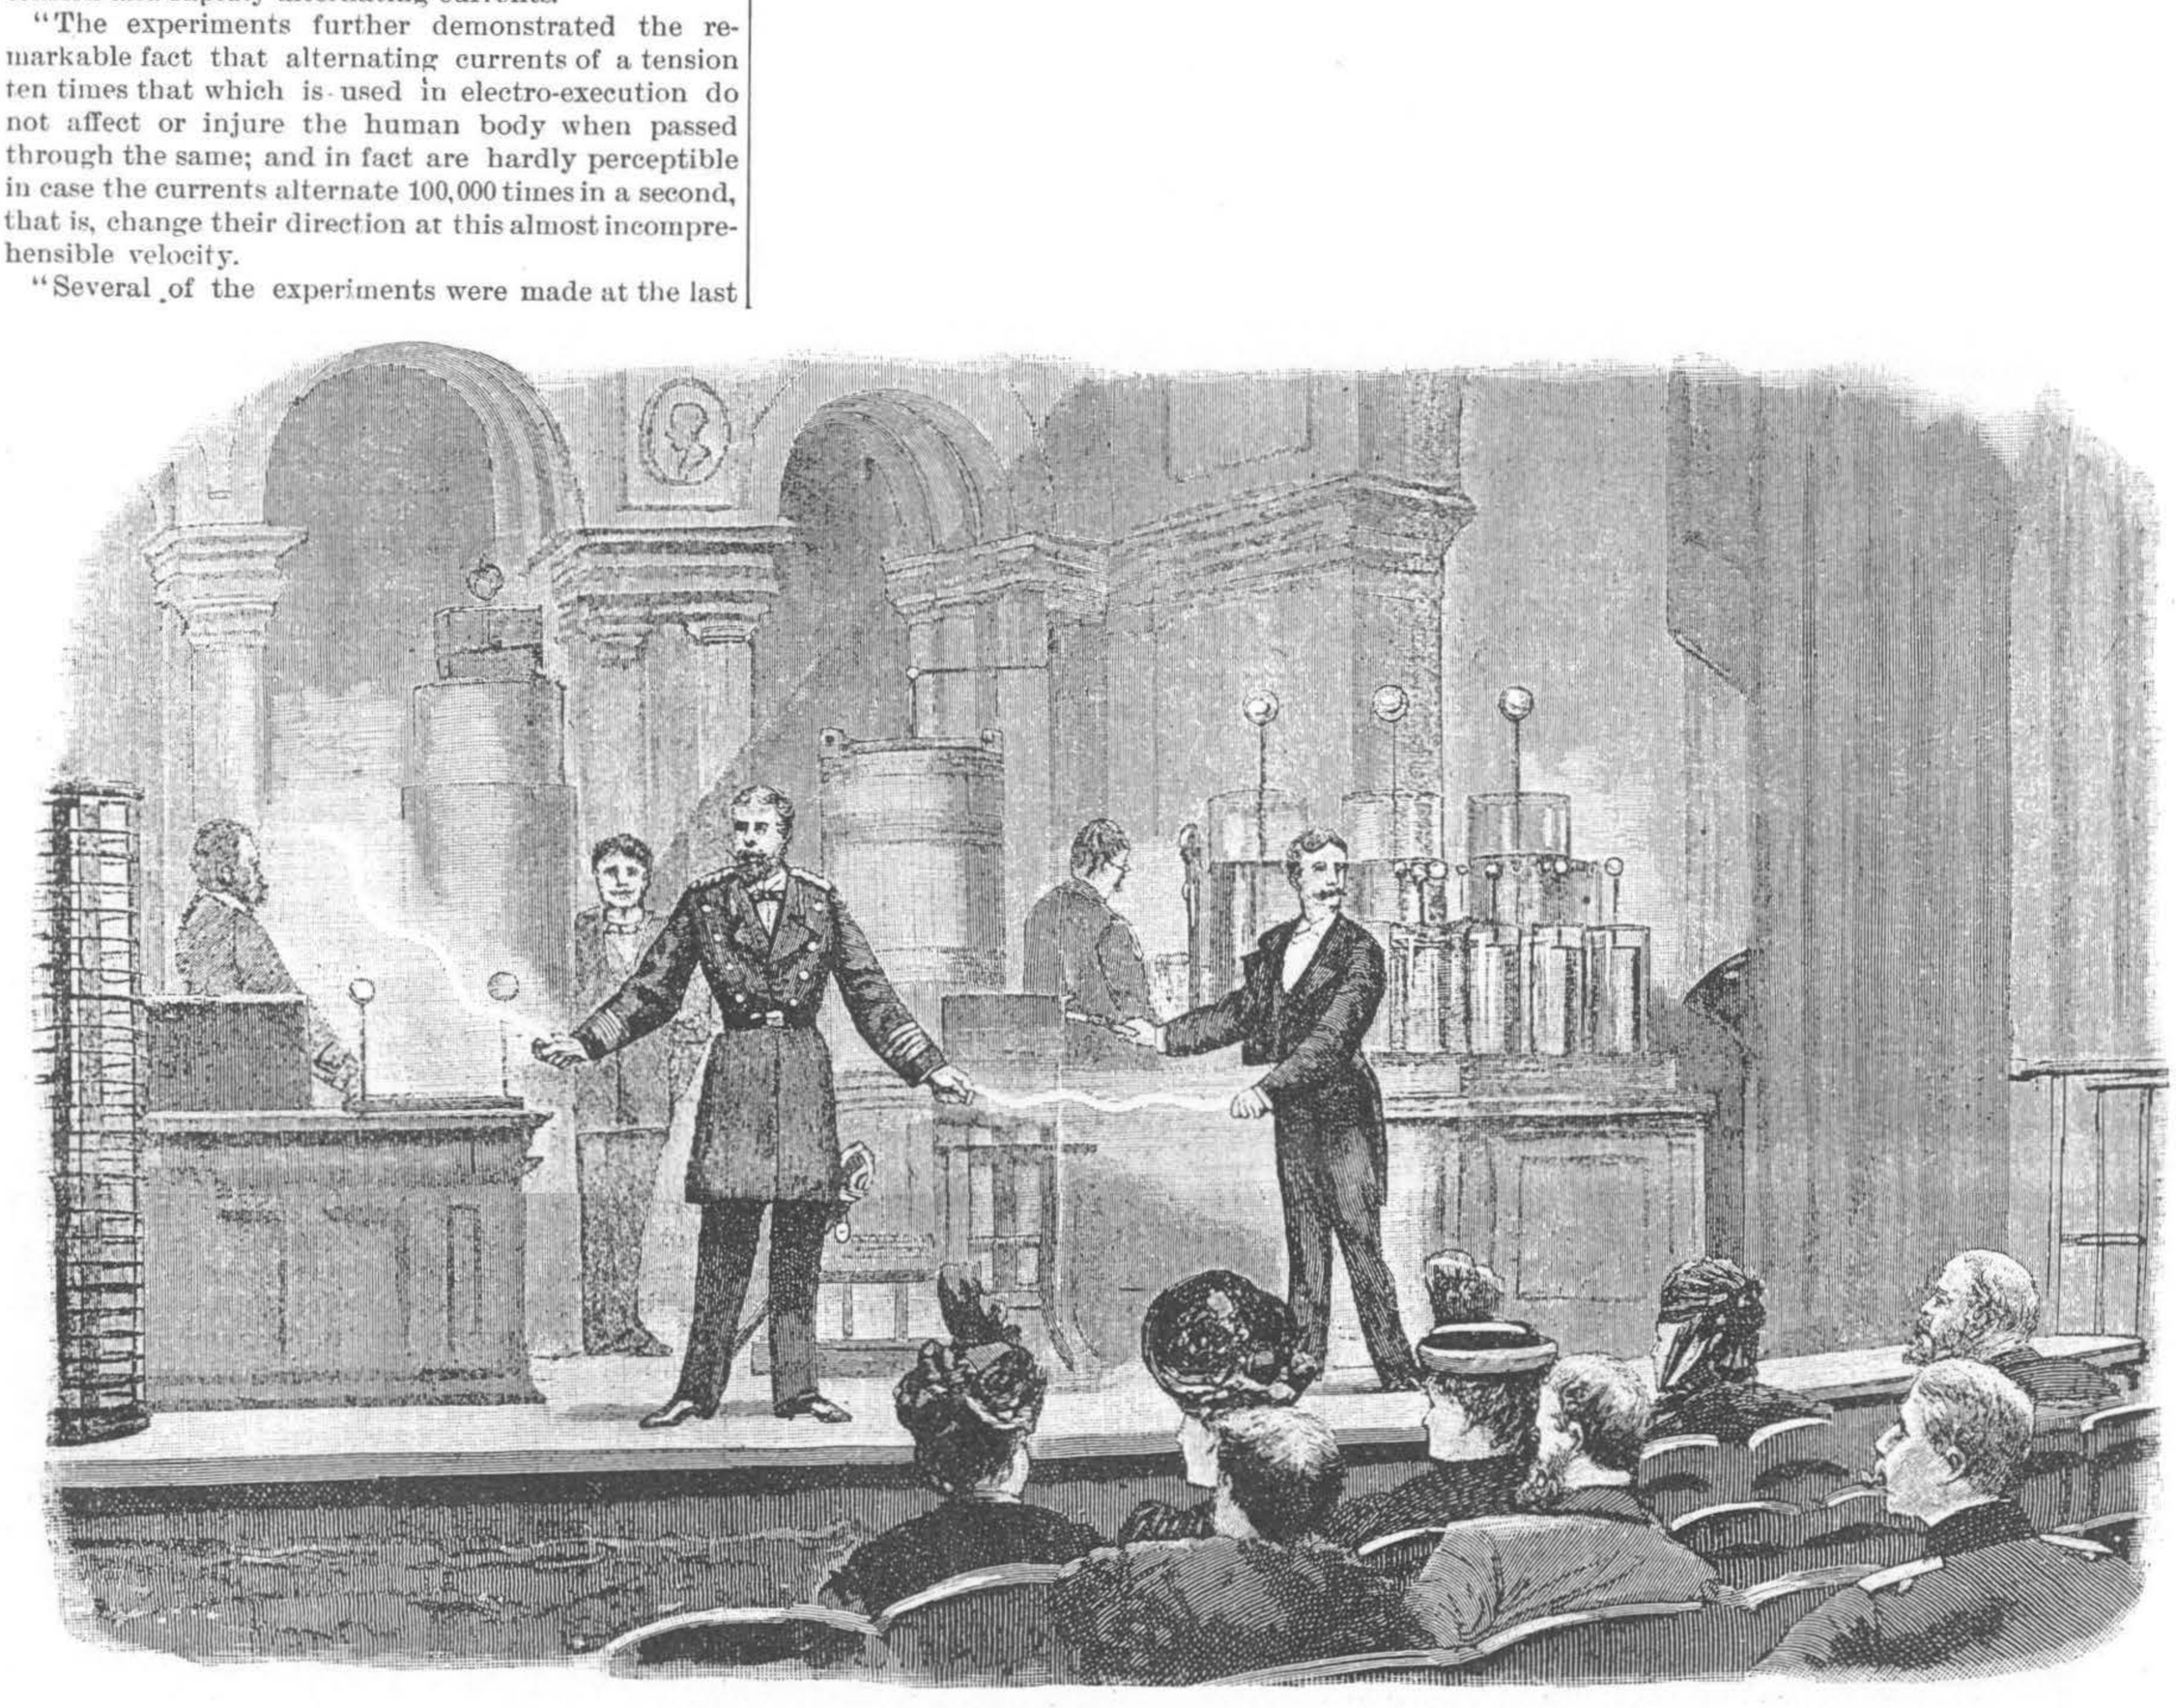
Tesla's Laboratory Destroyed.

A fire in the building at 35 South Fifth avenue on the morning of March 13 utterly destroyed the laboratory of Nikola Tesla, which occupied the two upper floors. The destruction was most complete, nothing having been saved from the wreck. Mr. Tesla had occupied this laboratory for several years and in it were gathered all of the results of his labors for years in many lines of work, notably in the utilization of electrical currents of high frequency and voltage. All of the magnificent apparatus which he used to illustrate his lectures on high frequency effects was destroyed, with the latest forms of his new type of dynamo, which was approaching commercial completion, besides scores of pieces of experimental apparatus employed by Mr. Tesla in researches, extending to every department of electrical science.

INVENTOR TESLA'S LOSS.

By a fire which occurred at 33 and 35 South Fifth Avenue, New York City, on the morning of March 13, Nikola Tesla, the inventor and scientist, sustained a severe loss in the total destruction of his laboratory, in which were several nearly completed inventions which, it is said, were intended to revolutionize electric lighting. The loss cannot unfortunately be reckoned in dollars, and it is feared may seriously affect Mr. Tesla's health, as for some time he has been in a state of nervousness bordering on exhaustion, on account of overwork occasioned by the approach to completion of some of his great inventions.

Dr. Tesla was for a time associated with Edison. The attention of the scientific world first centered upon Tesla in 1887 through his invention of the rotating magnetic field for the economic transmission of power. It is believed that Mr. Tesla's experiments were made with a view to saving at least one-third of the energy now wasted in electric lighting. He has been working in his laboratory with a number of assistants, and the results which he has actually obtained have been kept a profound secret. Mr. Tesla has lectured before scientific bodies, both in Europe and America, and he has recently received honorary degrees from Yale and Columbia Colleges. He is at present controlling electrical engineer of the Niagara Falls Power Company. Some of Mr. Tesla's remarkable experiments have been reproduced lately in Berlin. The Illustrirte Zeitung of recent date gives an engraving, which we copy, together with the following account:



'About twenty years have passed since Edison produced the incandescent lamps under the proud name of the 'light of the future,' and which lamps slightly modified are now the 'light of to-day.'

"A new 'light of the future,' is again promised from the United States, and should it materialize in practical form will have the great advantage over the incandescent and arc lamps that for its production no conducting wires are required, and which for this reason alone would be sufficient to produce a complete revolution in the electrical world.

"Nikola Tesla, the inventor of the new light, obtained by his experiments surprising results. In following up certain discoveries of Prof. Herz, of Bonn, relative to electrical waves, he succeeded in lighting a freely suspended incandescent lamp by the use of high tension and rapidly alternating currents.

"The experiments further demonstrated the remarkable fact that alternating currents of a tension ten times that which is used in electro-execution do not affect or injure the human body when passed through the same; and in fact are hardly perceptible in case the currents alternate 100,000 times in a second, that is, change their direction at this almost incomprehensible velocity.

"Several of the experiments were made at the last annual meeting of scientists in Vienna, but through Prof. Spies, one of the members of the Berlin 'Urania,' the experiments were made publicly, and were attended by the German Emperor's brother, Prince Henry, who, as the cut shows, served as a conductor for the high voltage currents. By reference to the illustration, it will be seen that the connection between two persons is made by Geissler tubes, which show the light produced by the currents. In another experiment a number of connected wires were arranged in the auditorium and connected with the electric current, whereby an electrical wave was produced in the room, and noticed by some of the audience through the lighting of Geissler tubes held in their hands, and without these persons being in direct connection with the wires."

RECENT TESLA EXPERIMENTS IN BERLIN.

Various Topics

New York Sun: The destruction of Nikola Tesla's workshop, with its wonderful contents, is something more than a private calamity. It is a misfortune to the whole world. It is not in any degree an exaggeration to say that the men living at this time who are more important to the human race than this young gentleman can be counted on the fingers of one hand; perhaps on the thumb of one hand.

NIKOLA TESLA.

His Discoveries in Electricity.

In a brief but pregnant comment on the destruction by fire of the workshop of Nikola Tesla, the New York "Sun" remarked: "It is not in any degree an exaggeration to say that the men living at this time who are more important to the human race than this young gentlemen can be counted on the fingers of one hand; perhaps on the thumb of one hand." There is perhaps no man now writing for newspapers whose culture is so many-sided and whose accomplishments range over so wide a field of human effort as those of the editor of the "Sun." The brevet rank of immortality conferred by an authority so competent challenges attention to the work of the man whom he deems worthy of placing on the pinnacle of fame. Reference to the practical aspect of that work has been made from time to time in these columns. But public curiosity about it has only begun to demand some intelligible exposition of its scope and purpose. Even among electricians it is but imperfectly understood, and there are the most widely divergent opinions as to its character and significance.

It is about ten to one that the mention of the name of Nikola Tesla in a company of ordinary intelligence will merely elicit the inquiry, "What has he done?" This question Mr. Thomas Commerford Martin essays to answer in the April number of the "Century," and brings to the task a felicity and accuracy of expository method well calculated to adorn and illumine the subject. Mr. Martin's richly illustrated and carefully digested study of Tesla will render it somewhat easier to put in popular language a reply to the popular question, but it suggests also the conclusion that for some time to come the greatest electrician of our time must continue to be an enigma to those whose only intelligible measure of achievement is that of tangible results and commercial valuation. The more distant an object is from the eye the more difficult is it to realize the rapidity of its movement, and the researches of Tesla are so far removed beyond the ken of most of us that we may watch him with a sensation such as that with which we regard bodies moving with prodigious velocity through interstellar pace, but whose apparent position remains unchanged.

Two years ago Mr. Tesla publicly declared that he was becoming daily more convinced of the practicability of transmitting intelligible signals or perhaps even power to any distance without the use of wires. He had already demonstrated that electric vibration might be transmitted through a single conductor, that is, that there was no necessity to employ a wire as a conductor of the return current. But if the earth may serve for one purpose, why not for both? Treating the earth in common with the air simply as a conductor of electrical vibration, and remembering the tremendous rapidity with which an electric disturbance may be propagated through the earth, there is nothing visionary in the claim that alternating currents might be passed through it from one source of electrical energy to another. The pendulous swing of the wave-like action of electricity might, in short, be indefinitely diffused by a series of sources of alternating currents working in perfect synchronism, that is, giving out electric energy of precisely the same period of vibration. This would be like moving a pendulum over a given arc of space by the application at either side of exactly the force needed to send it to the end of its swing on the other.

But if the earth, in addition to being a conductor of electricity, has itself a fixed electric charge, the possibility of using it as a vehicle for the transmission of electric energy becomes much more impressive and brilliant. For, as electricity behaves like an incompressible but elastic fluid, the slightest pressure applied to it at one point must be felt at all other points over which it is diffused. But pressure cannot be applied to the subtle and occult form of energy which we call electricity except by a similar phase of the same force. In other words, if the earth be an electrically charged body insulated in space, its charge can be disturbed only by an oppositely electrified system or known circuit whose period of vibration corresponds in some way with that of the charge of the earth. It is not enough to pump electricity into the earth to excite a reflex action in the electricity already there. The period of vibration of the energy pumped in must in certain essential respects correspond to the period of that with which the earth is charged to send the latter oscillating so as to produce in some perceptible degree what the electricians call "resonance."

This is the work to which Mr. Tesla has given most of the last few years of his life. The elusive difficulty of the task can be but imperfectly conceived even by those who know something of the scientific conditions of the problem. If the earth were a great tuning fork which would vibrate in unison with but one unknown note, it would be a comparatively simple problem to run up and down the gamut of tone to discover the precise combination of sound waves to which the globe would thrill in responsive music. But the gamut of electric vibration is so vast, and in the range of its period from low to high there is such an infinite series of combinations, that the attempt to find what may be called the fundamental note of the cosmic charge of electricity sounds like the effort of a dreamer. It has, nevertheless, been conducted in a very practical way, and has already begun to yield some highly practical results. If the true note has not yet been struck, some notes to which it is partially responsive have been. The electrical charge of the earth is no longer an inert force to human touch; under the wonder-working hands of Tesla it has moved and stirred, and in the purple streamers of lambent lightning which leaped at its impulse from the apex of the return wire in the now vanished laboratory there was the promise of such achievement as will cast into the shade all that science has yet accomplished for man.

Tesla is deeply impressed with the idea that all that man has yet done toward bending the forces of nature to his service is but feeble and tentative compared with what there is left for him to do. To have two electrical instruments move in unison though unconnected by wires and divided by half the globe, seems a marvellous not to say incredible achievement. But a much more marvellous thing than that is witnessed when simultaneously with the appearance of a white spot on the face of the sun there ensues a general disturbance of magnetic needles, and telegraphy is greatly interrupted by "earth currents" on this little globe of whose distances we make so much. If distance is an element in the problem, telegraphy without wires across an interval of ninety-two millions of miles must surely be less conceivable than a similar process over a distance of six thousand miles. To say that we cannot reduplicate the gigantic forces of nature is to beg the whole question, for all the scientific achievements of men have been merely the subjugation of the forces of nature to their service. An ordinary flame gives light and heat no less than the sun, and the light produced by both is equally the result of vibrations so inconceivably rapid that the force which they represent would, mechanically measured, be equivalent to a pressure of thousands of tons per square inch. Man can liberate by the simplest effort forces truly gigantic, but he is only beginning to learn how to employ them. Above all, he is only beginning to discover that his empire over nature is to be found in the co-ordination of forces in nature's own way.

It is in this direction that it will be reckoned the crowning glory of Tesla to have led his generation. A bolder or more original inquirer science has never numbered among her votaries; a man combining in a higher degree the patience of the investigator, the modesty of the student and the intuitive perception of genius the world has not seen. What other men have regarded as the limit of human attainment has been to him merely the beginning of a new domain of scientific conquest. Since he startled the electrical world with the principle of the rotating magnetic field his advance has been swift, continuous, irresistible. The world at large will better appreciate this when a scientific tool of his—the oscillator—invented in response to the necessity of producing electric vibrations of absolute constancy, becomes a commercial factor in cheapening by one-half the cost of light and increasing fourfold the effective energy of steam. But the interpretation of the secrets of nature which is destined to make his name immortal, will go on consuming years of a life dominated by an intensity of effort beyond that of which most men are capable, and people may go on asking, "what has he done?" forgetful how long may be the journey of one who has set his goal beyond the limit of achievement dreamed of by the most daring and farsighted of his contemporaries.

JOHN FOORD.

—*The Century* builded better than it knew when it engaged an article by T. C. Martin, editor of *The Electrical Engineer*, on "Tesla's Oscillator and Other Inventions," which will appear in its April number. Since this article was written, Mr. Tesla's laboratory, with all its contents, including machinery and records, was destroyed by fire, leaving the text and illustrations of Mr. Martin's paper absolutely the only record of some of the inventor's most important discoveries. Not the least interesting parts of this article are the reproductions of the first photographs taken by phosphorescent light, being portraits of Mark Twain, Joseph Jefferson and Marion Crawford.

[FROM THE OUTLOOK.]

NIKOLA TESLA AND THE ELECTRIC LIGHT OF THE FUTURE.

By WALTER T. STEPHENSON.

EXACTLY ten years ago Nikola Tesla, who, in June, 1894, received high honorary degrees from the colleges of Yale and Columbia, came to this country, poor and unknown, to enter an Edison shop in New York City. For two years previous he had served as engineer in one of the new electric lighting companies in Paris, and, having become an ardent and appreciative admirer of the splendid genius of Thomas A. Edison, whose fame in those days had only recently flashed throughout Europe, he was, naturally, eager to accept an opportunity of meeting the "wizard" face to face.

Tesla had already patented several minor inventions of his own, but, what was of more importance, his brain was then literally teeming with great ideas, as yet, perhaps, chaotic, but which must some day evolve into definite shape for revelation, and of all countries he firmly believed the United States offered the best encouragement to the inventor who could show practical results. Since New York has continued to be Mr. Tesla's home, we may reasonably infer that he has not been disappointed in his early expectations.

The young Servian electrician derived a fresh stimulus and lasting benefit from his association with Thomas A. Edison. Nevertheless, he soon realized that it would be far wiser for him to continue his special investigations alone, unhampered by other work. Therefore, after a few months of delightful intimacy, the two men of genius separated with mutual expressions of good will.

Mr. Tesla now threw himself with redoubled ardor and energy into the study and analysis of alternating or polyphase currents, which had long been his chosen field of electrical investigation. In 1887 he exploited his wonderful invention of the rotating magnetic field for the economic transmission of power. This simple statement means that, after thirteen years of indomitable effort, embittered by sore disappointments and fierce controversies, a substantial success was at last assured, while scientists everywhere began now to await with keenest interest succeeding developments of the potentialities undoubtedly latent in these hitherto neglected alternating currents.

The majority of us probably are aware that the principal electricians of the world have long been struggling vainly toward the solution of a tremendous problem—the improvement of the electric light. When we are told, for one thing, that fully ninety-nine per cent. of energy is wasted every time such artificial illumination is produced under existing conditions, we begin to realize the crying need there is for a radical change in industrial methods. Now, the goal which some electricians declare to be already in sight means nothing less than the recovery of fully one-third of this wasted energy, thereby rendering possible an illumination many times brighter than at present and at a notable reduction of expense. The question is, Which one of the few leaders in the race will outstrip the others and win an immortal name?

Rumors have reached the public ear with increasing frequency of late that Nikola Tesla was working slowly but surely in his own way toward the accomplishment of some such magnificent end.

We know that in May, 1891, Mr. Tesla emerged from the seclusion of his laboratory to deliver an address before the American Institute of Electrical Engineers, at Columbia College, on polyphase currents as applied to artificial illumination. Having in this lecture created a marked impression by the lucid exposition of his peculiar theories, he was soon urged by some of the prominent scientists of Europe to favor them in like manner. So it was that in February, 1892, he crossed the ocean and lectured before numerous audiences in England and on the Continent. It is not too much to say that the name of Nikola Tesla now commanded universal attention in the world of science, but still the man himself was beginning to chafe sadly already under his prolonged absence from the distant laboratory. In the fall of 1892, therefore, he gladly returned to New York to resume his interrupted labors in behalf of science.

In view of all this, even the hardiest of interviewers would be apt to think twice before intruding upon such an individual in his privacy. It will be enough, perhaps, for me to say that the forbearance and kindliness of Nikola Tesla are by no means his least distinguishing traits. Not very far from Washington Square, in the heart of that picturesque neighborhood known as the French quarter, teeming with cheap restaurants, wine shops, and weather-beaten tenements, the observant passer-by will notice a huge yellowish brick building of some half-dozen stories apparently devoted to manufacturing purposes.

If such a one should undertake to explore the murky interior of this uninviting looking pile, say to the extent of climbing three or four flights of stairs, and warily threading a signless path through successive mazes of vociferous machinery, his perserverance might be rewarded, as in my own case, by discovering the retreat of a modern wizard. While awaiting my opportunity in an anteroom, I caugh glimpses through the adjoining office and library of the mystic laboratory itself, which, as I ascertained later, opened into an immense machine room.

I may candidly state that I was a trifle shocked the first time I saw Nikola Tesla as he suddenly appeared before me in the library and sank into a chair seemingly in a state of utter dejection. Tall, straight, gaunt, and sinewy of frame like a true Slav, with clear blue eyes and small, mobile mouth fringed with a boyish mustache, he looked younger than his thirty-seven years. But what arrested my attention chiefly at the moment was the pallid, drawn and haggard appearance of the face. While scanning it closely I plainly read a tale of overwork and of tremendous mental strain that must soon reach the limits of human endurance.

"I would like to talk with you, my dear sir," he said, "but I feel far from well to-day. I am completely worn out, in fact, and yet I cannot stop my work. These experiments of mine are so important, so beautiful, so fascinating, that I can hardly tear myself away from them to eat, and when I try to sleep I think about them constantly. I expect I shall go on until I break down altogether. So you would really like to see some of my experiments in electric lighting," he added. "I shall endeavor to accommodate you, my friend, if you will come with me into the laboratory. Be prepared, though, for a surprise or two."

Mr. Tesla then ushered me into a room some twenty-five feet square, lighted on one side by two broad windows, partially covered by heavy black curtains. Directly opposite was an open door leading into the machine room, which seemed to be fairly alive with grimy figures flitting to and fro. The whole scene, to my unaccustomed eyes, suggested a veritable magician's den.

The laboratory was literally filled with curious mechanical appliances of every description. Wires innumerable, from the smallest size to cables three-quarters of an inch thick, ran along the walls, ceiling, and even the floor. In the center was what appeared to be a large circular table covered with thick strips of black woolen cloth; snakelike cables running up underneath were connected at the other end with an adjacent dynamo, thereby establishing a possible center of electro-dynamic vibration. Between the table and the windows two large brownish globes, eighteen inches in diameter, depended from the ceiling by cords. These balls were composed of brass, coated with two inches of wax to render them non-injurious, and served the purpose of spreading the electrostatic field.

So much for my surroundings, as I glanced about in some bewilderment after hearing Mr. Tesla say that he had a surprise in store for me. Promptly suiting the action to the word, he called in several employes from the workshop and issued a succession of hurried orders which I followed but vaguely. Presently, however, the doors were shut and the curtains closely drawn until every chink or crevice for the admission of light was concealed and the laboratory bathed in absolutely impenetrable gloom. I awaited developments with intense interest.

The next minute exquisitely beautiful luminous signs and devices of mystic origin began to flash about me with startling frequency. Sometimes they seemed iridescent, while again a dazzling white light prevailed.

"Take hold," said a voice, and I felt a sort of handle thrust into my hand. Then I was gently led forward and told to wave it. On complying, I spelled the word "Welcome" flaming before my eyes. Unfortunately, I was totally unable at the time to appreciate the kindly sentiment implied.

A hand approached mine ere I had quite recovered, and I felt the tips of my fingers lightly brushed. Fancy my dire dismay when I immediately experienced an acute tingling sensation, accompanied by a brief pyrotechnic display that was surprising, to say the least. When the daylight, as well as my equanimity, was in a measure restored, I learned something of the meaning of these wondrous experiments, which may be said to foreshadow in a way the electric light of the future. What impressed me most of all, perhaps, was the simple but cheerful fact that I remained unscathed while

electrical bombardments were taking place on every side. Curiously enough, the polyphase currents of high frequency and high potential, of say 200,000 volts, have, as Mr. Tesla has demonstrated repeatedly on the platform, no harmful effect whatever on the human body, although a like energy exerted in indirect currents would prove instantaneously fatal.

Over two and a half years ago Mr Tesla made this striking observation in one of his lectures: "The ideal way of lighting a hall or room would, however, be to produce such a condition in it that an illuminating device could be moved and put anywhere, and that it should be lighted no matter where it is put, and without being electrically connected to anything."

To return to my own experience in the darkened laboratory, it seems that the entire room was actually filled with electric vibrations through the agency of these same currents, styled alternating (that is, with direction perpetually changing). The strange devices I had seen were nothing more than nearly exhausted glass tubes bent into various shapes and analogous to lamps, excepting that they were devoid of filament or button.

These tubes being carried into the area where the electrical agitation was strongest, the remaining molecules of ether or air within all the while pressing against the crystal confines, a molecular bombardment followed, produced by the collision of two forces, and the bulbs simultaneously became luminous. Those which were made to glow with the colors of the rainbow were coated on the inside with phosphorescent substances.

I have attempted nothing more than a very imperfect outline of Mr. Tesla's novel and interesting scheme, which is to be regarded as still in a state of embryo. It cannot be denied too, that there are many scientists to-day who shake their heads dubiously at the brilliant Servian's unequivocal attitude toward the electric light.

Meanwhile Mr. Tesla makes no boasts, but is willing to abide his time. Throughout the interview I was constantly impressed with the man's loftiness of purpose, innate modesty and utter indifference to public applause. "I should much prefer not to be written about at all," he remarked; "but if it must be done, I trust you will take due pains to quote me correctly."

Speaking of the scientific status of the United States as compared with that of older nations, he said: "English scientists are the greatest in theory, perhaps, although, as far as practical results go, America may well claim to lead the world. That is why I like to stay here."

Mr. Tesla speaks our language with the idiomatic range and choice diction of a native who is also a scholar and a trained speaker, the guttural accent of the Slav, of course, being slightly noticeable. He told me that he felt equally at home in six languages, not to mention the same number of dialects.

Though simple, self-contained and undemonstrative in manner, when he is especially pleased or absorbed in enthusiastic description of electrical wonders, the intellectual animation of his frank blue eyes, combined with a rarely winning smile, exercises a charm that is irresistible. I have noticed the same unconscious quality of personal magnetism in Mr. Edison, though in almost every other respect these two remarkable individuals are totally dissimilar.

Edison may be more truly the man of genius. He works out his intricate problems by intuition. He peers into the future like a seer of old, and receives, as it were, lightning flashes of inspiration to guide him to the goal. In a word, the illiterate train boy of thirty-odd years ago has come to be regarded as little less than a wizard; and yet, assuredly, he is neither a thinker nor a student in the true sense.

Now, how is it with the Servian, who has acquired fame much less rapidly? What was his life before he came among us? Let me say, at the outset, that eighteen years of exhaustive, patient study were accomplished before Nikola Tesla deemed himself adequately prepared to embark upon the career which he had planned from childhood.

Born in 1857 at Smiljan Lika, a remote village in Austro-Hungary, he is the descendant of a sturdy line of Servian patriots, who for centuries had taken a prominent part in the protracted struggle against the domineering Turk.

The young Nikola commenced his studies in the public school of Gospich when five years of age. Not long afterward the marvels of electricity and magnetism began to dawn upon the boy's receptive soul. Fascinated and stirred until he scarcely thought of anything else, he resolved thenceforth to devote his life to research and investigation in this noble field of knowledge. In 1873, against the wishes of his father, who, being a clergyman in the Greek Church, had hoped that his son would discover a theological bent, Nikola entered the Polytechnic School at Gratz. It was at this institution, while puzzling over the complexities of a direct current Gramme machine, that his alert mind was led to conceive of a rotating magnetic field, which discovery was destined to deal the deathblow to those troublous contrivances the commutator and brushes. After completing the technical course at Gratz, Mr. Tesla removed to Vienna, where for several years he attended philosophical lectures, read omnivorously on many subjects, continued his special studies, and incidentally found time to master five or six languages. Verily, an intellectual training of this sort, in the face, too, of untold trials and difficulties, would have far exceeded the scope of any ordinary student.

Before I bade a regretful farewell to this kindly wizard of Washington Square he confided to me that he was engaged on several secret experiments of most abundant promise, but their nature cannot be hinted at here. However, I have Mr. Tesla's permission to say that some day he proposes to transmit electric vibrations through the earth; in other words, that it will be possible to send a message from an ocean steamer to a city, however distant, without the use of any wire.

To those who would gain a complete technical knowledge of the Servian's manifold labors since he came to the United States I would recommend a careful study of the volume recently issued by Mr. T. C. Martin, of the Electrical Engineer, entitled "The Inventions, Researches and Writings of Nikola Tesla." How strange it is, indeed, that, though electricity has so long been partially controlled by mankind, yet we are utterly unable to define it! As Mr. Tesla has said: "The day when we know what electricity is will chronicle an event probably greater than any other recorded in the history of the human race."

TESLA, MAN AND INVENTOR.

He Might be Called the Flower of a Mountaineering Clan.

HAS FACULTY OF RUSHING INTUITION

Achievements with the Neglected Alternating Current—A Man Who Dwells Apart—His Latest Problem Enormous.

Nicola Tesla is peculiarly fortunate to have taken up the cause and exploitation of the alternating current at a time when others cared to have little to do with it, when others scarcely appreciated its value and importance. Now that the rapid march of events in electrical development has

Recent Tesla Experiments in Berlin.

brought the art abreast of the times, Tesla finds himself lifted into prominence, not so much because of what he is to-day but because of the hard and now well-nigh unparalleled work that he has done during the last decade.

Tesla is a foreigner, but is not exceptional in that respect. It is curious how many of the great electricians who have made America the foremost country in electrical appliances have been born outside its borders. Bell, Thomson, and Weston were born under the English flag, and Edison himself hardly escaped being a Canadian; Sprague, the man who did more, perhaps, than any other to make the electrical railway an actuality, is of straight American blood, but Van Depoele and Daft, colaborers, were both aliens. It is not a matter of surprise, therefore, that Tesla, with so many others, should find a home and welcome and all the facilities for the fruition of his ideas on American soil.

There are many things to differentiate Tesla from his distinguished colleagues, and many which will make him a man apart to the end of the chapter. He is hardly the representative of any European nationality; perhaps he might be better spoken of as a flower of a mountaineering clan. Just as the Highlanders in Scotland have beaten back the tide of invasion, so his people, in the highlands of the Adriatic, have fought, cursed, and slaughtered the Turks ever since the turban invaded Europe.

His people are a rural people, and willing to be peaceful, but ever ready to turn their shepherds' crooks into spears and their scythes into bloody blades. They have been planted from time immemorial in the Adriatic mountains, but it was, perhaps, a happy caance that took thither in the turbulent First Napoleon days an officer of the victorious French legions, who intermarried and thus gave to the aboriginal stock the blood of which Tesla is the latest and best producer.

When Tesla, as a youth, found his tastes and inclinations turning to mechanics and electricity, expatriation became not a choice, but a necessity. Moreover, he had heard in those dim uplands, overshadowed by the Turkish mist of cruelty and oppression, the magic name of Edison, and he felt as though he could not live or die happily until he had found out for himself what the country was like that owned such men, and had there sought for himself an opportunity for his tastes and his genius. When Tesla came to this country he began, as almost every other emigrant does, at the "foot of the ladder."

He was willing to do so. No task that was given him was too heavy or difficult. But he soon found that it was easier and better to carry out some of his own seething and tumultuous schemes than to try to give shape to those of others, which he understood and solved even before the proposition was stated to him.

A notable faculty of Tesla's mind is that of rushing intuition. As with Edison, you begin to state a question or proposition to him, and before you have half formulated it he has suggested six ways of dealing with it and ten of getting around it.

Tesla said once to a friend: "If I were to try every crude idea when it first came into my mind I could bust two banks every day. That is the trouble with many inventors; they lack patience. They lack the willingness to work a thing out slowly and clearly and sharply in their mind, so that they can actually feel it work. They want to try their first idea right off; and the result is they use up lots of money and lots of good material, only to find eventually that they are working in the wrong direction. We all make mistakes, and it is better to make them before we begin."

As soon as Tesla began practical work he found that everybody in the electrical field of lighting and power was trying to work with the continuous current, which, with all its inherent advantages, has a great many drawbacks and complications. He felt that if electricity was to reach out into the fields awaiting it, it must have greater flexibility than could be secured with the continuous current, and he saw in the alternating current a means to a great many ends.

With that idea in his mind as a starting point, his career and his work may be regarded as a striking and sequential evolution. Even as a boy he thought it was necessary to abolish the commutator in electrical dynamos and motors, as that had always been the weakest part of these machines. In all his earlier work this idea haunted him, and, although he went through the usual experience in developing continuous current apparatus for incandescent and arc lighting, he felt that there was another goal to reach.

He startled the electrical public about eight years ago by bringing before the American Institute of Electrical Engineers a class of motors in which there were neither commutators nor brushes, and in which by the use of "phase" currents of shifting polarity, alternating currents are used in terms of the highest economy, flexibility, and range. From that moment may be said to begin the use of polyphase currents in this country and in Europe.

This is the chief line on which electrical work for light and power is advancing to-day. In this direction there has already been evolved what are known as single-phase, two-phase, tri-phase, and monocycle current apparatus, and it will readily be seen that these all can be grouped under the one idea of "polyphase currents," the nomenclature adopted by Mr. Tesla very early in his work.

It is impossible for the public to understand these things, even if they sit up all night for weeks; but, as illustrative of what Tesla polyphase system has been adopted for the enormous transmission of power at Niagara Falls.

All the twenty generators of 5,000 horse power each which are now being set up in the power house at Niagara are of the Tesla two-phase type. The radical advantage of this method is that it allows the power to be transmitted a long distance with small loss, and that it permits the employment at the consumption end of the line of devices which insure the best conditions of economy and efficiency.

It has been impossible to use the continuous current over long distances in any built, and it may be questioned whether any continuous current power transmission has ever exceeded 100 horse power over ten miles with the faintest success. The Rothschilds settled in France the transmission by high voltage continuous currents of less than 100 horse power between Paris and Creil, a distance of thirty-four miles, and the attempt was an ignominious failure.

But at Niagara Tesla has contemplated the transmission to Buffalo, a distance of over twenty miles, by the Tesla plan, of at least 50,000 horse power when the plant is in full operation.

Expert calculations show that the practical outcome of all this work is that power can be transmitted with economy at least 100 miles in every direction from Niagara Falls, while, if it were found expedient, it could easily be transmitted to New-York and Chicago. About this there is little question.

The condition that has to be met is whether it would not be cheaper to generate power in New-York from coal and in Chicago from natural gas, but this does not in any wise diminish the magnitude and brilliancy of the invention which renders such things feasible. Coal fields can be dug empty and gas fields even piped dry, but Niagara runs on forever.

Granted there are the coal fields in apparently inexhaustible abundance, Mr. Tesla has naturally felt that it would be well, incidentally, to get a little more power out of the coal than has been possible heretofore. To this conception is due his oscillator, in which he has endeavored to combine at one stroke the dynamo and the steam engine.

Even allowing for the natural and invincible optimism of an inventor, it is evident that if one can devise a dynamo reduced to its essential elements, and a steam engine which is governed by the dynamo, and not by its own cumbrous gear, one has an apparatus which should give up electrical current an output far above that which is now obtained from the dynamo as one unit and from the engine as another unit, each working, practically, on an independent basis, and each with its counteracting conditions that make against economy.

Mr. Tesla's latest oscillator was consumed in the fire the other day, and the few score who have visited the laboratory had the opportunity to see it in full operation, supplying a large number of incandescent lights, current for arc lights, and the means of conducting a large variety of curious and novel experiments demonstrative of entirely new phenomena.

This machine, which one could apparently pick up and walk away with comfortably under one's arm, was doing work which, under ordinary conditions, would require a machine that a cart and team of horses could with difficulty haul around town. The current was developed by a machine combining dynamo and steam engine which could stand on an office chair.

Among the experiments shown were those of lighting lamps in free space, the illumination of phosphorescent bulbs, the demonstration of the innocuous effects of currents of high potentiality and high frequency, and the ability of a plain, every-day mortal to take a million volts. All this apparatus was consumed in the fire; but the handful who saw it will never forget it.

They are only longing for a chance to see it again as soon as Tesla, with his indomitable courage and perseverance, has rebuilt it.

The man is an indefatigable, tireless worker. The day after the fire which wiped out his laboratory he worked until 3 in the morning, and at 9 o'clock he was up again and eager to get his men at work on reconstruction. Naturally, he felt his loss; but never was a sudden, staggering blow sustained with greater courage.

It is a curious and typical incident in the disaster that a few nights after, when he dropped, for sheer respite, into an up-town club, he found there a gathering of well-known actors, musicians, and artists. Some of these he knew well, for there is always a bon camaraderie among men of this stamp.

With quick and kind sympathy they immediately organized an impromptu "benefit concert," for his sole gratification, with an aggregation of talent that, had the public only known of it, would have given a substantial endowment for his new laboratory.

He seems to be a man who dwells apart. He has no kith or kin in this country, and only a few friends who share his confidences. Even in moments of closest social intercourse he will become abstracted, and never a time when he would not prefer his laboratory to any other spot on earth. One of his few recreations is billiards, another is literature.

He has taken not a little pride in endeavoring to introduce to the American literary public, with the assistance of Robert Underwood Johnson of The Century, the charming work of the national poet, Zmai Jovan, and it is not unlikely that the readers of this sketch will have noticed some admirable renderings from the Servian in that magazine, as well as in The Outlook, The Independent, and other periodicals.

An evening in Mr. Tesla's laboratory was something to remember. He rarely invited anybody there, but would sometimes yield to pressure, and once or twice entertained select and professional bodies with demonstrations that would be of interest and value. In the course of his experiments, Mr. Tesla had collected some very curious apparatus, and other novel pieces had been made to illustrate his lectures in this country and in England and France.

Much of this was glassware, in the shape of lamps and bulbs. Entering a wide, lofty room with these lamps or bulbs held in the hand, one would be surprised to see them light up brilliantly. Curious streams of luminosity would surge and twist in these empty glass tubes, milky white in glowing turbidity.

These tubes were of different lengths and dimneters, the larger ones as long as a broomstick and as thick, the smaller ones, as thin as wheat straws and as long. Whether held singly or in sheaves, their illumination was equally brilliant and pure.

In some lamps Mr. Tesla had placed substances that phosphoresced, under the stimulation of the currents reaching them across many feet of space, and the light was red or blue or yellow, according to the ingredients. Other lamps or tubes had been twisted into odd and interesting shapes.

One, for instance, was like a veritable handful of lightning, when the streams of luminescent ether rushed through its strange zags. Many were shown for their novelty and beauty, but Mr. Tesla had a great variety of phenomena to explain with their help, and, seeing them, it was impossible not to believe that the era of practical phosphorescent lighting is very close.

Mr. Tesla has lectured once in New-York, once in Philadelphia, once in St. Louis, twice in London, and twice in Paris. He is not a successful elocutionist, and is prone to forget himself in the pleasure of demonstrating one novel phenomenon after another, regardless of his audience; but experts have never found his addresses long enough.

The experience in St. Louis in 1893 was rather disturbing. The National Electric Light Association was meeting in the city, and had indeed made Tesla's show it what might be expected among developments in the near future. Somehow it got hinted around the city that the effects would be novel and strange, as well as of technical interest, and the local committee was swamped with applications for tickets.

Finally, the great hall in the Exhibition Building was taken, somewhat reluctantly; but on the night of the lecture the rush was so great that people had to fight for admission, and Tesla, to his dismay, found himself facing a jammed house of probably 5,000 auditors. He had expected a little gathering of expert electricians, and, though he went through the ordeal bravely, no power on earth would induce him to try anything like it again.

After the lecture was over the crowd insisted on meeting at close quarters the man who had dazzled and puzzled them, and thronged to an offhand reception, from which there was no escaping.

It was a funny episode, also, of the World's Fair, that while Mr. Tesla was attending the Electrical Congress, by special invitation, to explain the principle of his oscillator, a shrewd Westerner, who had seen the exhibit of Tesla's apparatus in Electricity Building, hunted him up and nearly killed him with ceaseless propositions for a long lecturing tour at rates that would make a modern prima donna die of envy. But Tesla does not lecture for pay.

The way in which Tesla does his work is rather interesting. Unlike most inventors, he has practically no associates, so that he is not subject to such a sharp controversy as arose between Morse and Vail as to the origin of certain features of the telegraph.

He has an intelligent staff of workmen, who carry out his orders implicitly; but beyond that the directing brain power of his laboratory is solely and wholly his own. He begins work early in the day, and will very often work until late into the night, after which he can sometimes be found eating his dinner at Delmonico's at the time when people are dropping in from the theatre.

His thoughts are given entirely to his own work; but his growing fame has brought around him a persecuting host of small fry inventors and men with schemes, who want him to work out impossibilities for them and make millions in the feat. His judgment is remarkably quick and sound on all kinds of engineering, with which he has the most intimate acquaintance; but he rarely can be invited out of his way to express his opinion about it. In short, he is intensely absorbed with the problems which he has set himself, and which deal with the fundamental conditions of being upon this little planet.

More than this: It is not generally known that of late Mr. Tesla has carried his ideas and work to a height of audacity which can only be spoken of as unparalleled. It has generally been supposed and assumed that this earth has a natural electrical charge of its own.

Accepting this theory as true, Mr. Tesla argued that it should be within the power of mankind, with suitable apparatus, to disturb this electrical contrast, and in some of his later inventions he has directed his energies to that enormous problem, which, if successfully solved, would represent in science the material conquest of the world by a Napoleon or a Cæsar.

Mr. Tesla now thinks he has succeeded in his object, and has, with his own eyes, seen the electricity of the earth reach out its arms of ethereal and vocal flame to heaven. This, seems incredible; but Mr. Tesla is one of the most secretive and cautious of men, and has not yet been known to speak of a thing as being possible until he had already accomplished it in his laboratory.

Of course, this achievement, which is among his latest, has many bearings and aspects. With suitable mechanism, properly adjusted, it will be possible to talk from one part of this earth to another without wires. But this is a detail. If this earth has an electrical charge, and all the other heavenly bodies have, as they undoubtedly have, an electrical charge, we have at once facilities of interplanetary communication, should there be beings who have yearnings across the chasms of space.

GEORGE HELI GUY.

TESLA'S OSCILLATOR AND OTHER INVENTIONS.

AN AUTHORITATIVE ACCOUNT OF SOME OF HIS RECENT ELECTRICAL WORK.[1]

SKOBELEFF, the great Russian general, once said of the political conditions in Central Asia, that they changed every moment; hence the necessity for vigilance, no less the price of empire than of liberty. Thus changeful, also, is the aspect of that vast new electrical domain which the thought and invention of our age have subdued. They who would inform themselves expertly about it, in whatever respect, must ever keep up an attitude of strained attention. Its theoretical problems assume novel phases daily. Its old appliances ceaselessly give way to successors. Its methods of production, distribution, and utilization vary from year to year. Its influence on the times is ever deeper, yet one can never be quite sure into what part of the social or industrial system it is next to thrust a revolutionary force. Its fanciful dreams of yesterday are the magnificent triumphs of to-morrow, and its advance toward domination in the twentieth century is as irresistible as that of steam in the nineteenth.

Throughout this change there has prevailed a consistency of purpose: a steady aim has been leveled at definite goals; while useful arts in multitude attest the solidity of the work done. If, therefore, we find a tremendous outburst of activity at the very moment when, after twenty-five years of superlative productiveness, electricians were ready, with the reforming English statesman, to rest and be thankful, we may safely assume that electricity has reached another of those crucial points at which it becomes worth the while of the casual outside observer to glance at what is going on. To the timid and the conservative, even to many initiated, these new departures have indeed become exasperating. They demand the unlearning of established facts, and insist on right-about-faces that disregard philosophical dignity. The sensations of a dog attempting to drink sea-water after a lifetime spent on inland lakes are feeble compared with those of men who discover that electricity is quite other than the fluid which they have believed it to be from their youth up, and that actually there is no such thing as electricity or an electric current.

Electricity has, indeed, taken distinctively new ground of late years; and its present state of unrest — unsurpassed, perhaps, in other regions of research — is due to recent theory and practice, blended in a striking manner in the discoveries of Mr. Nikola Tesla,[2] who, though not altogether alone, has come to be a foremost and typical figure of the era now begun. He invites attention to-day, whether for profound investigations into the nature of electricity, or for beautiful inventions in which is offered a concrete embodiment of the latest means for attaining the ends most sought after in the distribution of light, heat, and power, and in the distant communication of intelli-

[1] The photographs reproduced in this article were taken, under the special direction of the inventor, by Tonnele & Co.

[2] A biographical sketch of Mr. Tesla, by the present writer, with portrait, appeared in THE CENTURY for February, 1894.—EDITOR.

gence. Any one desirous of understanding the trend and scope of modern electrical advance will find many clues in the work of this inventor. The present article discloses a few of the more important results which he has attained, some of the methods and apparatus which he employs, and one or two of the theories to which he resorts for an explanation of what is accomplished.

By a brief preliminary survey, we may determine our historical longitude and latitude, and thus ascertain a little more precisely where we are. It is necessary to recapitulate facts known and accepted. Let it, then, be remarked that aside from the theories and interpretations that have beset the science, electricity as an art has for three hundred years been directed chiefly to securing an abundant, cheap, efficient, and economical supply of the protean agency, be it what it may. Frictional machine, Leyden jar, coil, battery, magnet, dynamo, oscillator,— these are but the steps in a process as regular and well-defined as those which take us from the aboriginal cradling of gold out of river sands up to the refining of ore with all the appliances of modern mechanism and chemistry. Each stage in electrical evolution has seen the conquest of some hitherto unknown art — electrotherapy, telegraphy, telephony, electric lighting, electric heating, power transmission; yet each has had limitations set on it by the conditions prevailing. With a mere battery much can be done; with a magnet, still more; with a dynamo, we touch possibilities of all kinds, for we compel the streams, the coal-fields, and the winds to do us service: but with Mr. Tesla's new oscillator we may enlist even the ether-waves, and turn our wayward recruits into resistless trained forces, sweeping across continents of unimagined opportunity.

The dynamo, slowly perfected these fifty years, has rendered enormous benefits, and is destined to much further usefulness. But all that we learn now about it of any intrinsic value is to build it bigger, or to specialize it; and the moment a device reaches that condition of development, the human intellect casts about for something else in which the elements are to be subtler and less gross. Based upon currents furnished by modern dynamo-electric machines, the arc-light and the trolley-car seek to monopolize street illumination and transportation, while the incandescent lamp has pre-empted for exclusive occupancy the interiors of our halls and homes. Yet the abandonment of gas, horses, and sails is slow, because the dynamo and its auxiliaries have narrow boundaries, trespassing which, they cease to offer any advantage. We can all remember the high hopes with which, for example, incandescent lighting was introduced some fifteen years ago. Even the most cynical detractor of it will admit that its adoption has been quick and widespread; but as a simple matter of fact, to-day, all the lamps and all the lighting dynamos in the country would barely meet the needs of New York and Chicago if the two cities were to use no other illuminant than electricity. In all England there are only 1,750,000 incandescent lamps contesting for supremacy with probably 75,000,000 gas-burners, and the rate of increase is small, if indeed it exceeds that of gas. Evidently, some factor is wanting, and a new point of departure, even in mere commercial work, is to be sought, so that with longer circuits, better current-generating apparatus, and lamps that will not burn out, the popular demand for a pure and perfect light can be met. In power transmission, also, unsatisfied problems of equal magnitude crop up. "Is there any load that water cannot lift?" asked Emerson. "If there be, try steam; or if not that, try electricity. Is there any exhausting of these means?" None, provided that our mechanics be right.

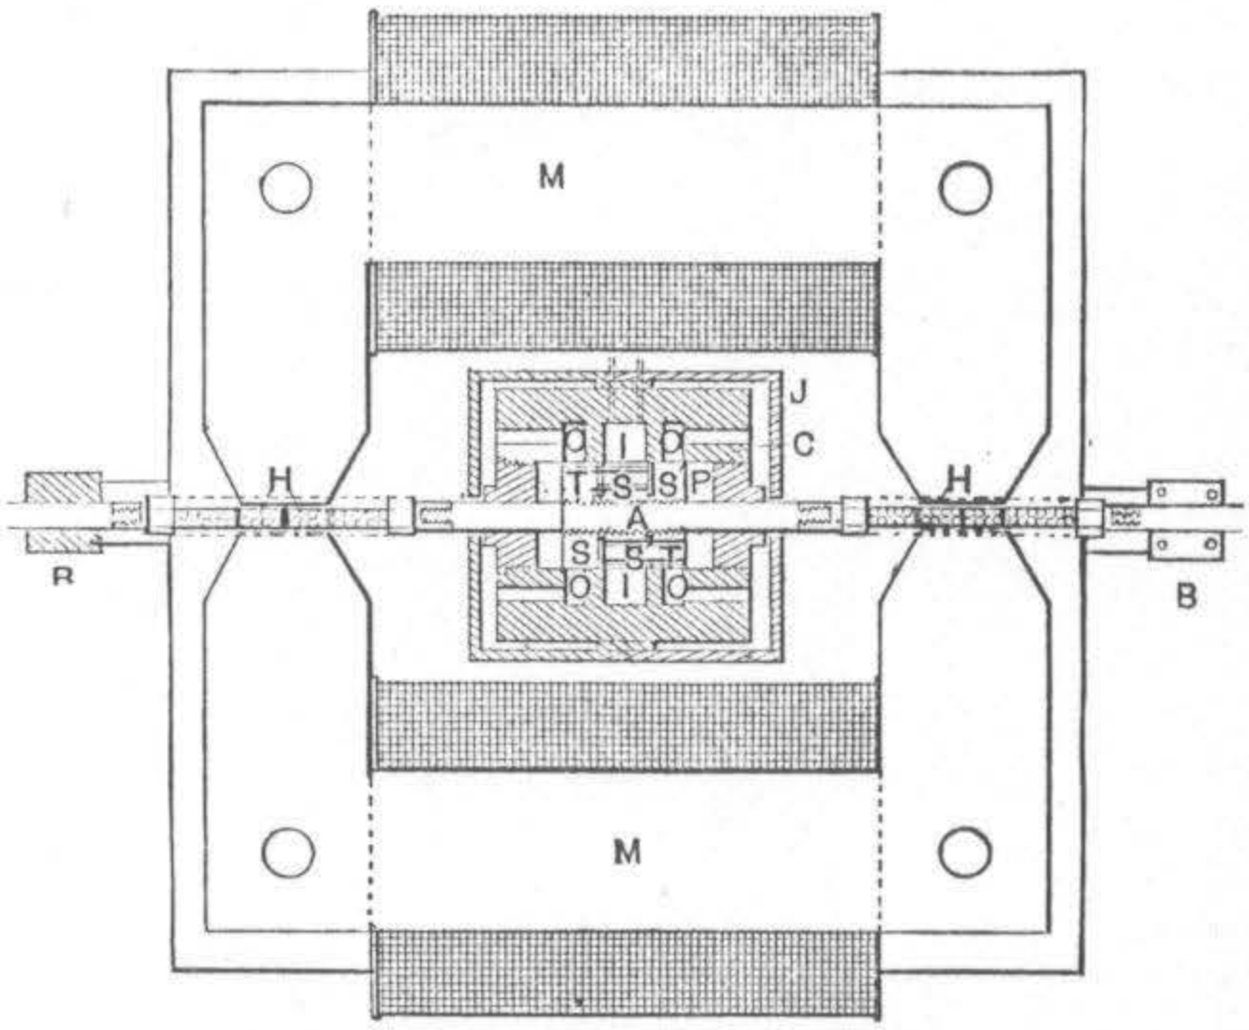
It must not be supposed that the new electricity is iconoclastic. In the minds of a great many people of culture the idea prevails that invention is as largely a process of pulling down as of building up; and electricity, in spreading from one branch of industry to another, encounters the prejudice that always rebuffs the innovator. The assumption is false. It may be true that in the gladiatorial arena where the principles of science contend, one party or the other always succumbs and drags out its dead; but in the arts long survival is the law for all the appliances that have been found of any notable utility. It simply becomes a question of the contracting sphere within which the old apparatus is hedged by the advent of the new; and that relation once established by processes complex and long continued, capable even of mathematical determination, the two go on together, complementary in their adjustment to specific human needs. In its latest outgrowths, electrical application exemplifies this. After many years' use of dynamo-electric machinery giving what is known as a "continuous current," the art has reached the conclusion that only with the "alternating current" can it fulfil the later duties laid upon it, and accomplish the earlier tasks that remain untouched. With the continuous current we have learned the rudiments of lighting and power distribution. With the alternating current, manipulated and coaxed to yield its highest efficiency, we may solve the problems of aërial and marine navigation by electricity, operate large railway systems, transmit the energy of Niagara hundreds of miles, and, in Mr. Tesla's own phrase, "hook our machinery directly to that of Nature."

THE GENERATION OF CURRENT.

LET us see wherein lies the difference between these two kinds of currents. In all dynamos the generation of what we call electric current is effected by the whirling of coils of wire in front of magnets, or conversely. The wires that lead away from the machine and back to it to complete the necessary circuit, may be compared to a circle of troughs or to a pipe-line; the coils and magnets are comparable to pump mechanism; and the lamps or motors driven by the current, to fountains or faucets spaced out on the trough circle. This comparison is crudity itself, but it gives a fairly exact idea. The current travels along the surface of the wire rather than inside, its magnetic or ether whorls resembling rubber bands sliding along a lead-pencil. A machine that produces continuous current, dipping its wire coils or buckets into the magnetic field of force, has all its jets, as they come around to discharge themselves, headed one way, and complicated devices called "commutators" have been unavoidable for the purpose of "rectifying" them. A machine that produces alternating currents, on the contrary, has its jets thrown first into one end of the trough system, and then into the other, and therefore dispenses with the rectifying or commutating valves. On the other hand, it requires peculiar adjustment of its fountains and faucets to the streams rushing in either way. It is an inherent disadvantage of the continuous-current system that it cannot deliver energy successfully at any great distance at high pressure, and that therefore the pipe-line must be relatively as bulky as were the hollow wooden logs which were once employed for water-conduits in New York. The advantage of the alternating current is that it can be delivered at exceedingly high pressures over very slender wires, and used either at that pressure or at lower or higher ones, obtained by means of a "transformer," which, according to its use, answers both to the idea of a magnetic reducing valve, and to that of a spring-board accelerating the rapidity of motion of any object alighting on it. Obviously a transformer cannot return more than is put into it, so that it gives out the current received with less pressure but in greater volume, or raised in pressure but diminished in the volume of the stream. In some like manner a regiment of soldiers may be brought by express to any wharf, and transferred, Indian file, to a sailing barge or an ocean liner indifferently; but throughout the trip the soldiers will constitute the same regiment, and when picked up by another train across the ferry, the body, though there be loss by desertion and sickness, will retain its identity, even if the ranks are broken in filling the cars, and are reformed four abreast at the end of the journey.

ALTERNATING CURRENTS.

LET us, still recapitulating familiar facts, make the next step in our review of what is involved in the resort to alternating currents. It was stated above that the current-consuming devices such as motors, likened to fountains, needed peculiar adjustments to the inflow first from one side and then from the other. Not to put it at all too strongly, they would not work, and have largely remained inoperative to the present time. Lamps would burn, but motors would not run, and this fact limited seriously the adoption and range of the otherwise flexible and useful alternating current until Mr. Tesla discovered a beautiful and unsuspected solution of the problem, and thus embarked on one part of the work now revealing grander possibilities every day. The transmission of the power of Niagara has become possible since the discovery of the method. In his so-called "rotating magnetic field," a pulley mounted upon a shaft is perpetually running after a magnetic "pole" without ever being able to catch it. The fundamental idea is to produce magnetism shifting circularly, in contrast with the old and known phenomenon of magnetism in a fixed position. Those who have seen the patient animal inside the treadmill wheel of the well at Carisbrooke Castle can form an idea of the ingenuity of Mr. Tesla's plan.



Ordinarily, alternating-current generators, such as are now in common use, have a great number of projecting poles to cause the alternations of current, and hence their "frequency" is high — that is, the current makes a great many to-and-fro motions per second, and each ebb-and-flow in the circuit is termed the "period" or "frequency," one alternation being the rise from zero to maximum value and down to nothing again, and the other the same thing backward. If we ruled a horizontal straight line, and then drew a round-bellied Hogarth curve of beauty across it, the half of the curve above the line would be illustrative of the positive flow, the lower half of the negative flow; the top of one oval and the bottom of the other oval would be the positive and negative maxima respectively; and the point where the curve crossed the straight line would mark the instant when the current changes its direction. A swinging pendulum is an analogy favored by scientists in their endeavors to illustrate popularly the process of the generation of the alternating current. Each time the copper wire in the coils on the dynamo armature is rotated past the pole of the dynamo field, the currents in each coil follow this rise and fall; so that the number

of the magnets and coils determines the period or frequency, as stated. The more numerous the magnets, and the faster the rotation of the coils, the quicker will be the ebbs and flows of current. But the character of the work to be done, and existing conditions, govern the rate at which the current is thus to be set vibrating; and no small amount of skill and knowledge enters here. The men who can predicate the right thing to do are still few and far between. The field has as yet been little explored. Moreover, in one of the deepest problems now engaging the thought of electrical engineers,—namely, the production of cheap light and cheap power by these new means,—opposite conditions pull different ways. Mr. Tesla made up his mind some time ago that for motor work it was better to have few frequencies; and the whole drift of power transmission is on that path, the frequency adopted for the work at Niagara being only twenty-five. But, as was natural, he ran through the whole scale of low and high frequencies, and soon discovered that for obtaining light, one great secret lay in the utilization of currents of high frequency and high potential. Some years ago, after dealing with the power problem as above described, Mr. Tesla attacked the light problem by building a number of novel alternating-current generators for the purpose, and attained with them alternations up to 30,000 per second. These machines transcended anything theretofore known in the art, and their currents were further raised in pressure by "step up" transformers and condensers. But these dynamos had their shortcomings. The number of the poles and coils could not be indefinitely increased, and there was a limit to the speed. To go to the higher frequencies, therefore, Mr. Tesla next invented his "disruptive discharge coil," which permitted him to reach remarkably high frequency and high pressure, and, what is more, to obtain these qualities from any ordinary current, whether alternating or continuous. With this apparatus he surprised the scientists both of this country and of Europe in a series of most interesting demonstrations. It is not too much to say that these experiments marked an epoch in electricity, yielding results which lie at the root of his later work with the oscillator in an inconceivably wider range of phenomena.

THE TESLA OSCILLATOR.

Up to this point we have been considering both continuous-current and alternating-current dynamos as driven by the ordinary steam-engine. Perhaps nine tenths of all the hundreds of thousands of dynamos in the world to-day are so operated, the remainder being driven by water-wheels, gas-engines, and compressed air. Now, each step from consuming the coal under the boilers that deliver steam to the engines, up to the glow of the filament in an incandescent lamp, is attended with loss. As in every other cycle that has to do with heat transformation, the energy is more or less frittered away, just as in July the load in an iceman's cart crumbles and melts in transit along the street. Actual tests prove that the energy manifesting itself as light in an incandescent lamp is barely five per cent. of that received as current. In the luminosity of a gas flame the efficiency is even smaller. Professor Tyndall puts the useful light-waves of a gas flame at less than one per cent. of all the waves caused by the combustion going on in it. If we were dealing with a corrupt city government, such wretched waste and inefficiency would not be tolerated; and in sad reality the extravagance is but on a par with the wanton destruction of whole forests for the sake of a few sticks of lumber. Armies of inventors have flung themselves on the difficulties involved in these barbaric losses occurring at every stage of the calorific, mechanical, and electric processes; and it is indeed likely that many lines of improvement have already been compelled to yield their utmost, reaching terminal forms. A moment's thought will show that one main object must be the elimination of certain steps in the transfer of the energy; and obviously, if engine and dynamo both have large losses, it will be a gain to merge the two pieces of apparatus. The old-fashioned electric-light station or street-railway power-house is a giddy maze of belts and shafting; in the later plants engine and dynamo are coupled directly together on one base. This is a notable stride, but it still leaves us with a dynamo in which some part of the wire wound on it is not utilized at every instant, and with an engine of complicated mechanism. The steam-cylinder, with its piston, is the only thing actually doing work, and all the rest of the imposing collection of fly-wheel, governor-balls, eccentrics, valves, and what not, is for the purpose of control and regulation.

In his oscillator Mr. Tesla, to begin with, has stripped the engine of all this governing mechanism. By giving also to the coils in which the current is created as they cut the "lines of force" of the magnets, a to-and-fro or reciprocating motion, so that the influence on them is equal in every direction, he has overcome the loss of the idle part of the wire experienced in rotating armatures; and, moreover, greatest achievement of all, he has made the currents regulate the mechanical motions. No matter how close the governing of the engine that drives the ordinary dynamo, with revolving armature, there is some irregularity in the generation of current. In the Tesla oscillator, if its inventor and the evidence of one's eyes may be

This form of oscillator has been used for experimental purposes, with air as the propelling force. It illustrates the principle of operation further developed in the machine shown in perspective in Fig. 2, in which steam is used as the propelling force. Outermost of all is seen the magnetic frame M M, built up of thin sheet-iron. This frame is wound with energizing coils of wire (indicated in hatchwork), as in ordinary electromagnets, and thus an intense magnetic "field of force" is concentrated on each side in the vicinity of H H, where are seen in dotted line two pairs of armature coils moving between the jaws of the inclosing electromagnets formed by M M. These armature coils, at H H, are supported on the shaft A, which runs through the piston P, and they, with the shaft, have additional bearings in the boxes B B at each end of the mechanism. The piston P is fitted into the hollow of the cylinder C, which in turn is inclosed by a jacket J, the latter serving chiefly to deaden the sound caused in working. The piston P is provided with channel-ports O O and I, which extend all around its inside surface. I is the inlet for the propelling compressed air, and O O are the outlets for the expanded air after its work is done at each stroke. In the piston P there are also two slots S S', while tubes T T are screwed into holes drilled in the piston. These tubes T T establish communication between the slots S S' and the chambers seen on each side of the piston, each chamber being thus connected with the slot which is remote from it. Now, the compressed air being brought through a delivery-pipe to the inlet I, with the piston P in the position it occupies in the diagram, and the shaft A being slightly touched so as to slide it a little to the left, the compressed air rushes through the slot S' and its communicating tube T, out into the chamber on the left of the piston. The pressure thus encountered by the piston on the left, from the expanding air, drives it back toward the right. Owing to its inertia, the piston thus impelled overshoots the position of equilibrium, allowing in this way the next supply of compressed air to rush from the inlet I into slot S and its tube T, and from them into the chamber on the right of the piston. Meantime the communication to the left-hand chamber is cut off, and the now expanded air there, having instantly done its work, escapes through the channel-port outlet O. As the piston now travels back from the right on the return stroke, a precisely similar operation takes place on the right-hand side of it, due to the expanding of the compressed air there and its subsequent quick escape as exhaust. In this manner, so long as compressed air is supplied, oscillation of the piston P is maintained at a very high rate, and with highest accuracy. The coils of fine wire mounted on shaft A, to which the piston P is firmly attached, are thus rapidly thrust to and fro by the shaft across the faces of, and in the space inclosed by, the jaws of the electromagnets at H H. In this manner they cut the so-called "lines" of the intense "field of force" at those two points, and currents are thus engendered in them, which are led off to the exterior circuit for use. These currents are "alternating" in their character, and are of high regularity. The maintenance of constancy of oscillation on the part of the piston P is also due to the reaction and steadying effect of this electromagnetic part of the combination. The "fitting-boxes" at the ends of the cylinder C inclosing the piston project a carefully determined distance into the cylinder, thus setting limits to the length of the stroke. It will be obvious to those familiar with such matters that steam could also be used in this type of oscillator, with slight adjustments.

FIG. 1. DIAGRAM OF WORKING PARTS OF EARLY FORM OF TESLA OSCILLATOR, AS IF SEEN FROM ABOVE, IN SECTION. (FROM "THE ELECTRICAL ENGINEER," BY PERMISSION.)

believed, the vibrations of the current are absolutely steady and uniform, so that one could keep the time o' day with the machine about as well as with a clock. It was this superlative steadiness of the vibration or frequency that Mr. Tesla aimed at, for one thing. The variations caused by the older apparatus might be slight, but minute errors multiplied by high rates of occurrence soon become perceptible, and militate against desirable uniformity and precision of action. Back of the tendencies to irregularity in the old-fashioned electrical apparatus were the equal or greater tendencies in the steam-engine; and over and above all were the frightful losses due to the inefficient conversion in both of the power released from the fuel under the boiler generating the steam.

Gain in one direction with a radical innovation usually means gain in many others, through a growing series. I confess I do not know which of the advantages of the oscillator to place first; and I doubt whether its inventor has yet been able to sit down and sum up all the realities and possibilities to which it is a key. One thing he does: he presses forward. Our illustration, Fig. 2, shows one of his latest forms of oscillator in perspective, while the diagram, Fig. 1, exhibits the internal mechanism of one of the early forms. Fig. 2 will serve as a text for the subsequent heads of discourse. The steam-chest is situated on the bed-plate between the two electromagnetic systems, each of which consists of field coils between which is to move the armature or coil of wire. There are two pistons to receive the impetus of the incoming steam in the chest, and in the present instance steam is supplied at a pressure of 350 pounds, although as low as 80 is also used in like oscillators, where steam of the higher pressure is not obtainable. We note immediately the absence of all the governing appliances of the ordinary engine. They are non-existent. The steam-chest *is* the engine, bared to the skin like a prize-fighter, with every ounce counting. Besides easily utilizing steam at a remarkably high pressure, the oscillator holds it under no less remarkable control, and, strangest of all, needs no packing to prevent leak. It is a fair inference, too, that, denuded in this way of superfluous weight and driven at high pressure, the engine must have an economy far beyond the common. With an absence of friction due to the automatic cushioning of the light working parts, it is also practically indestructible. Moreover, for the same pressure and the same piston speed the engine has about one thirtieth or one fortieth of the usual weight, and occupies a proportionately smaller space. This diminution of bulk and area is equally true of the electrical part. The engine-pistons carry at their ends the armature coils, and these they thrust reciprocatively in and out of the magnetic field of the field coils, thus generating current by their action.

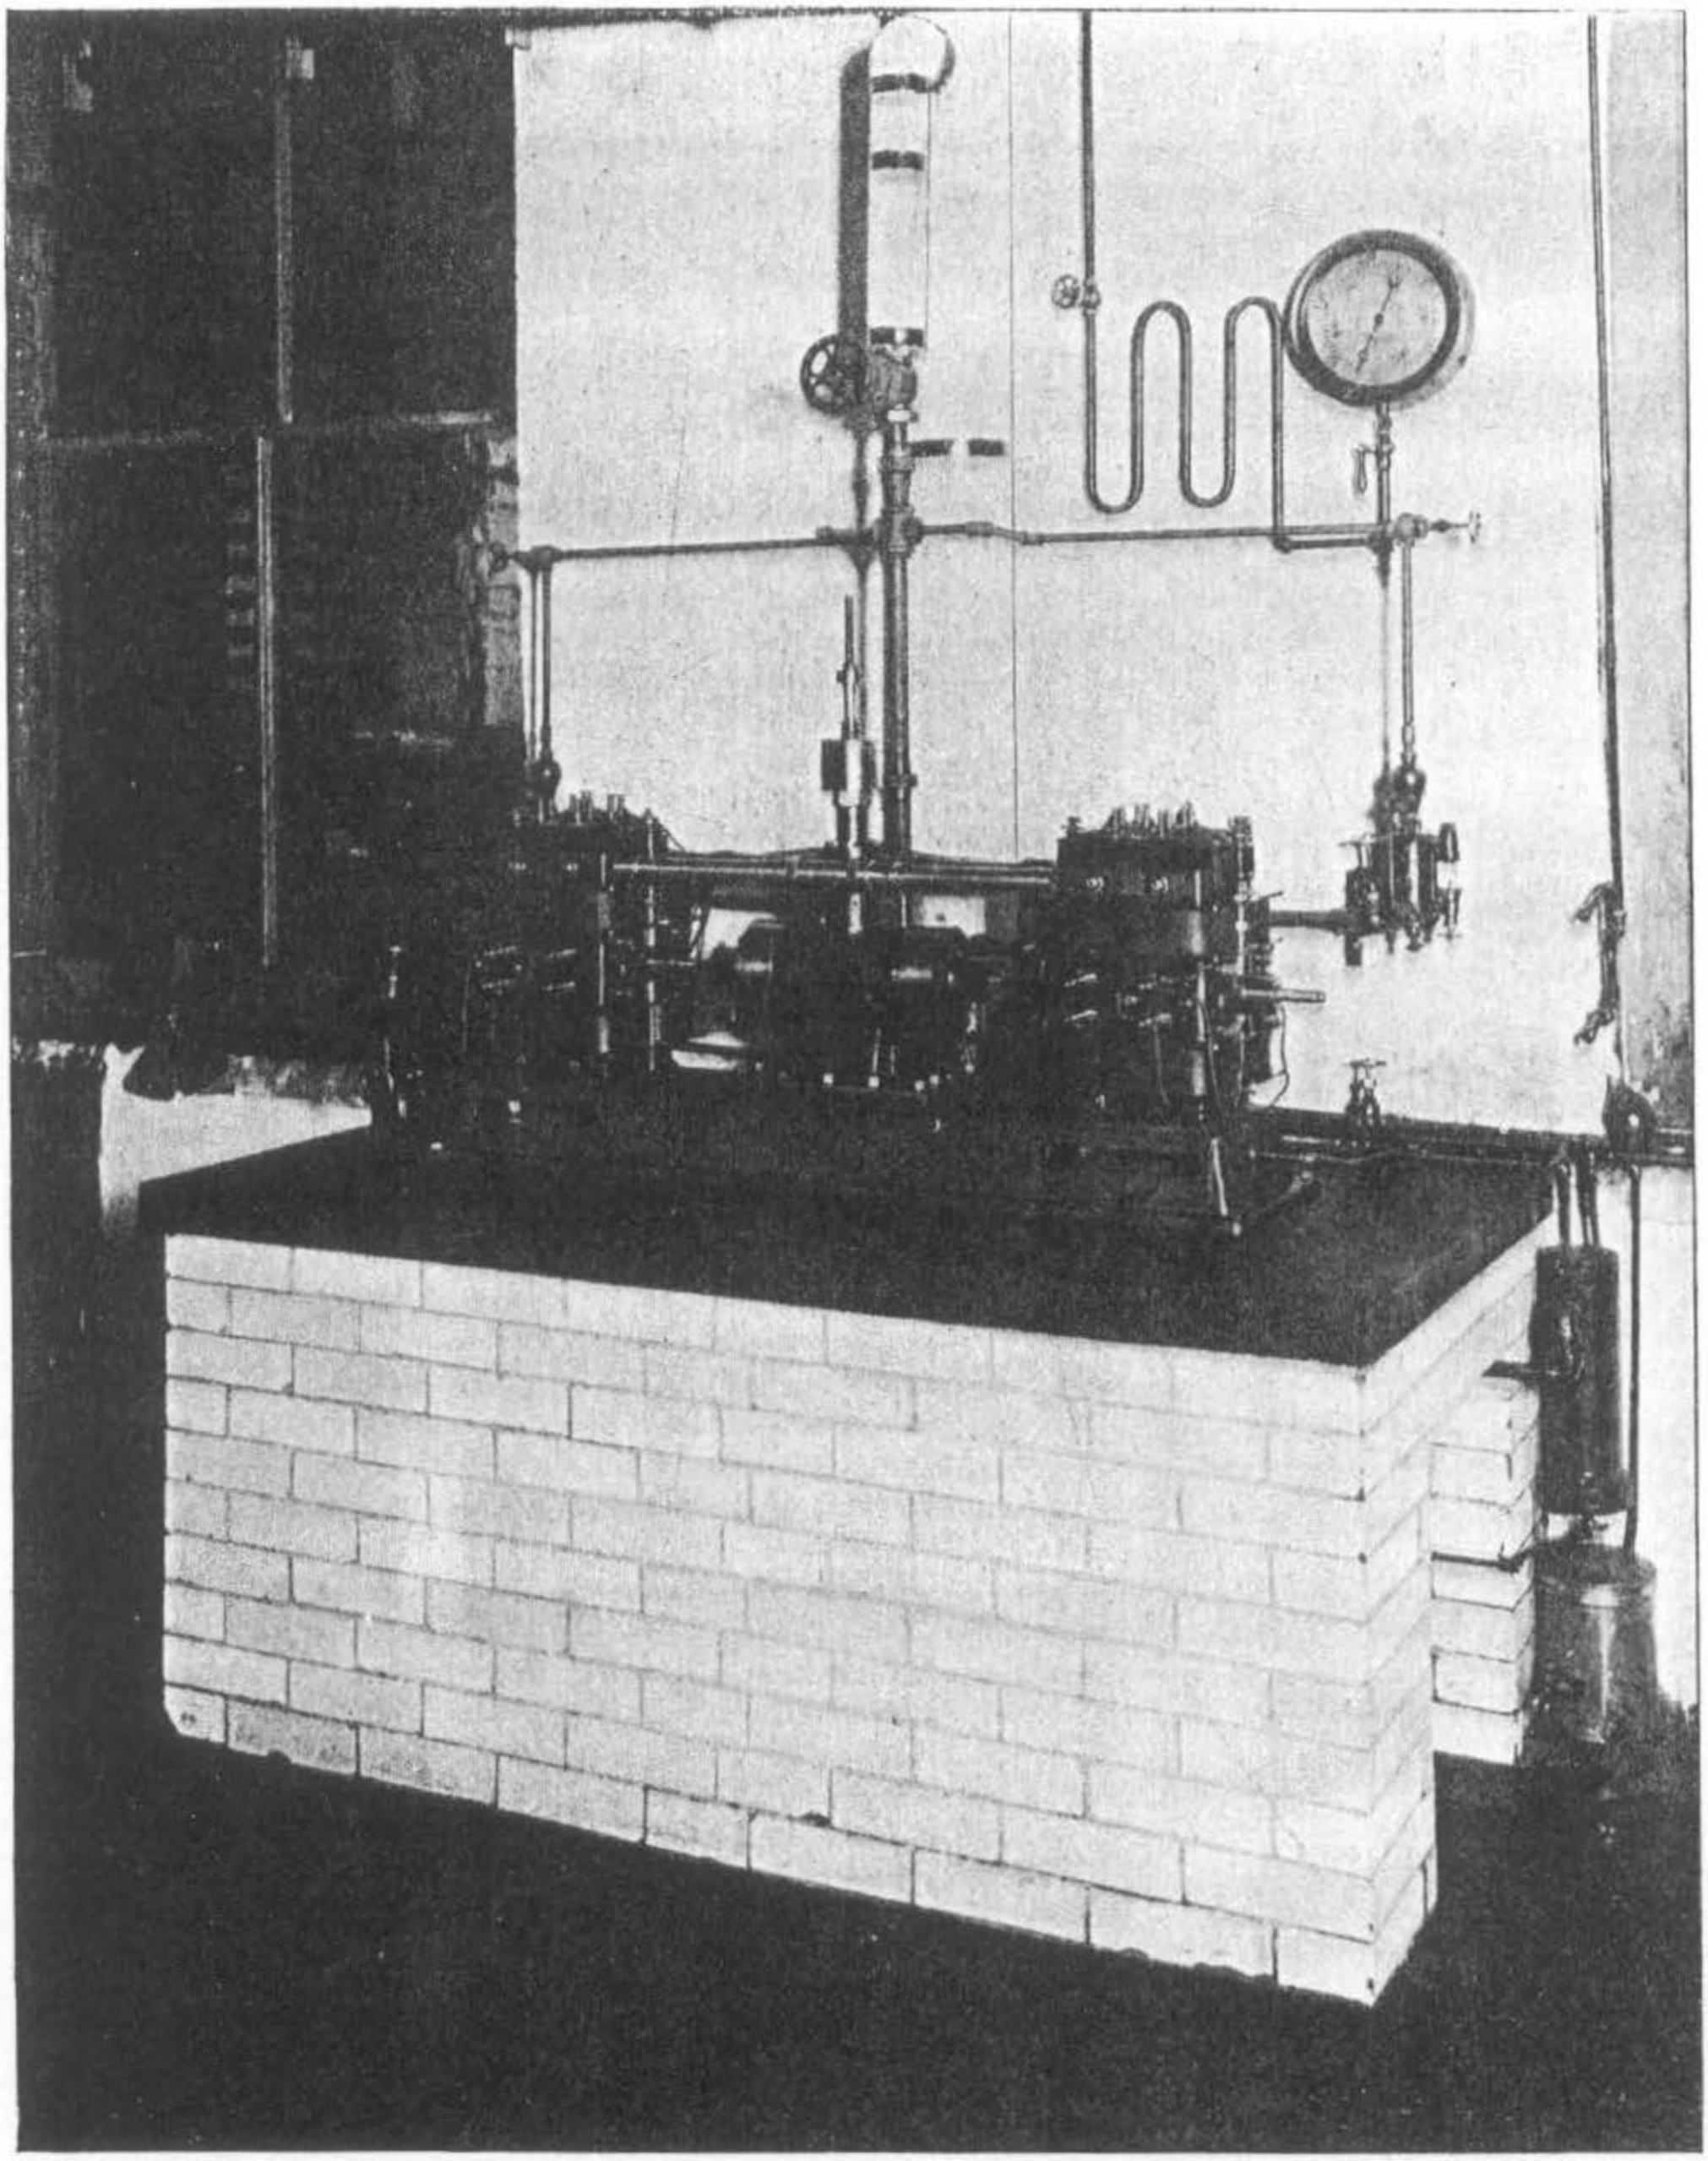


FIG. 2. LATEST FORM OF TESLA OSCILLATOR, COMBINING IN ONE MECHANISM DYNAMO AND STEAM-ENGINE.

If one watches any dynamo, it will be seen that the coils constituting the "armature" are swung around in front of magnets, very much as a turnstile revolves inside the barricading posts; and the current that goes out to do work on the line circuit is generated inductively in the coils, because they cut lines of influence emanating from the ends of the magnets, and forming what has been known since Faraday's time as the "field of force." In the Tesla oscillator, the rotary motion of the coils is entirely abandoned, and they are simply darted to and fro at a high speed in front of the magnets, thus cutting the lines of the "field of force" by shooting in and out of them very rapidly, shuttle-fashion. The great object of cutting as many lines of an intense field of force as swiftly, smoothly, regularly, and economically as possible is thus accomplished in a new and, Mr. Tesla believes, altogether better way. The following description of remarkable new phenomena in electricity will justify him in regard-

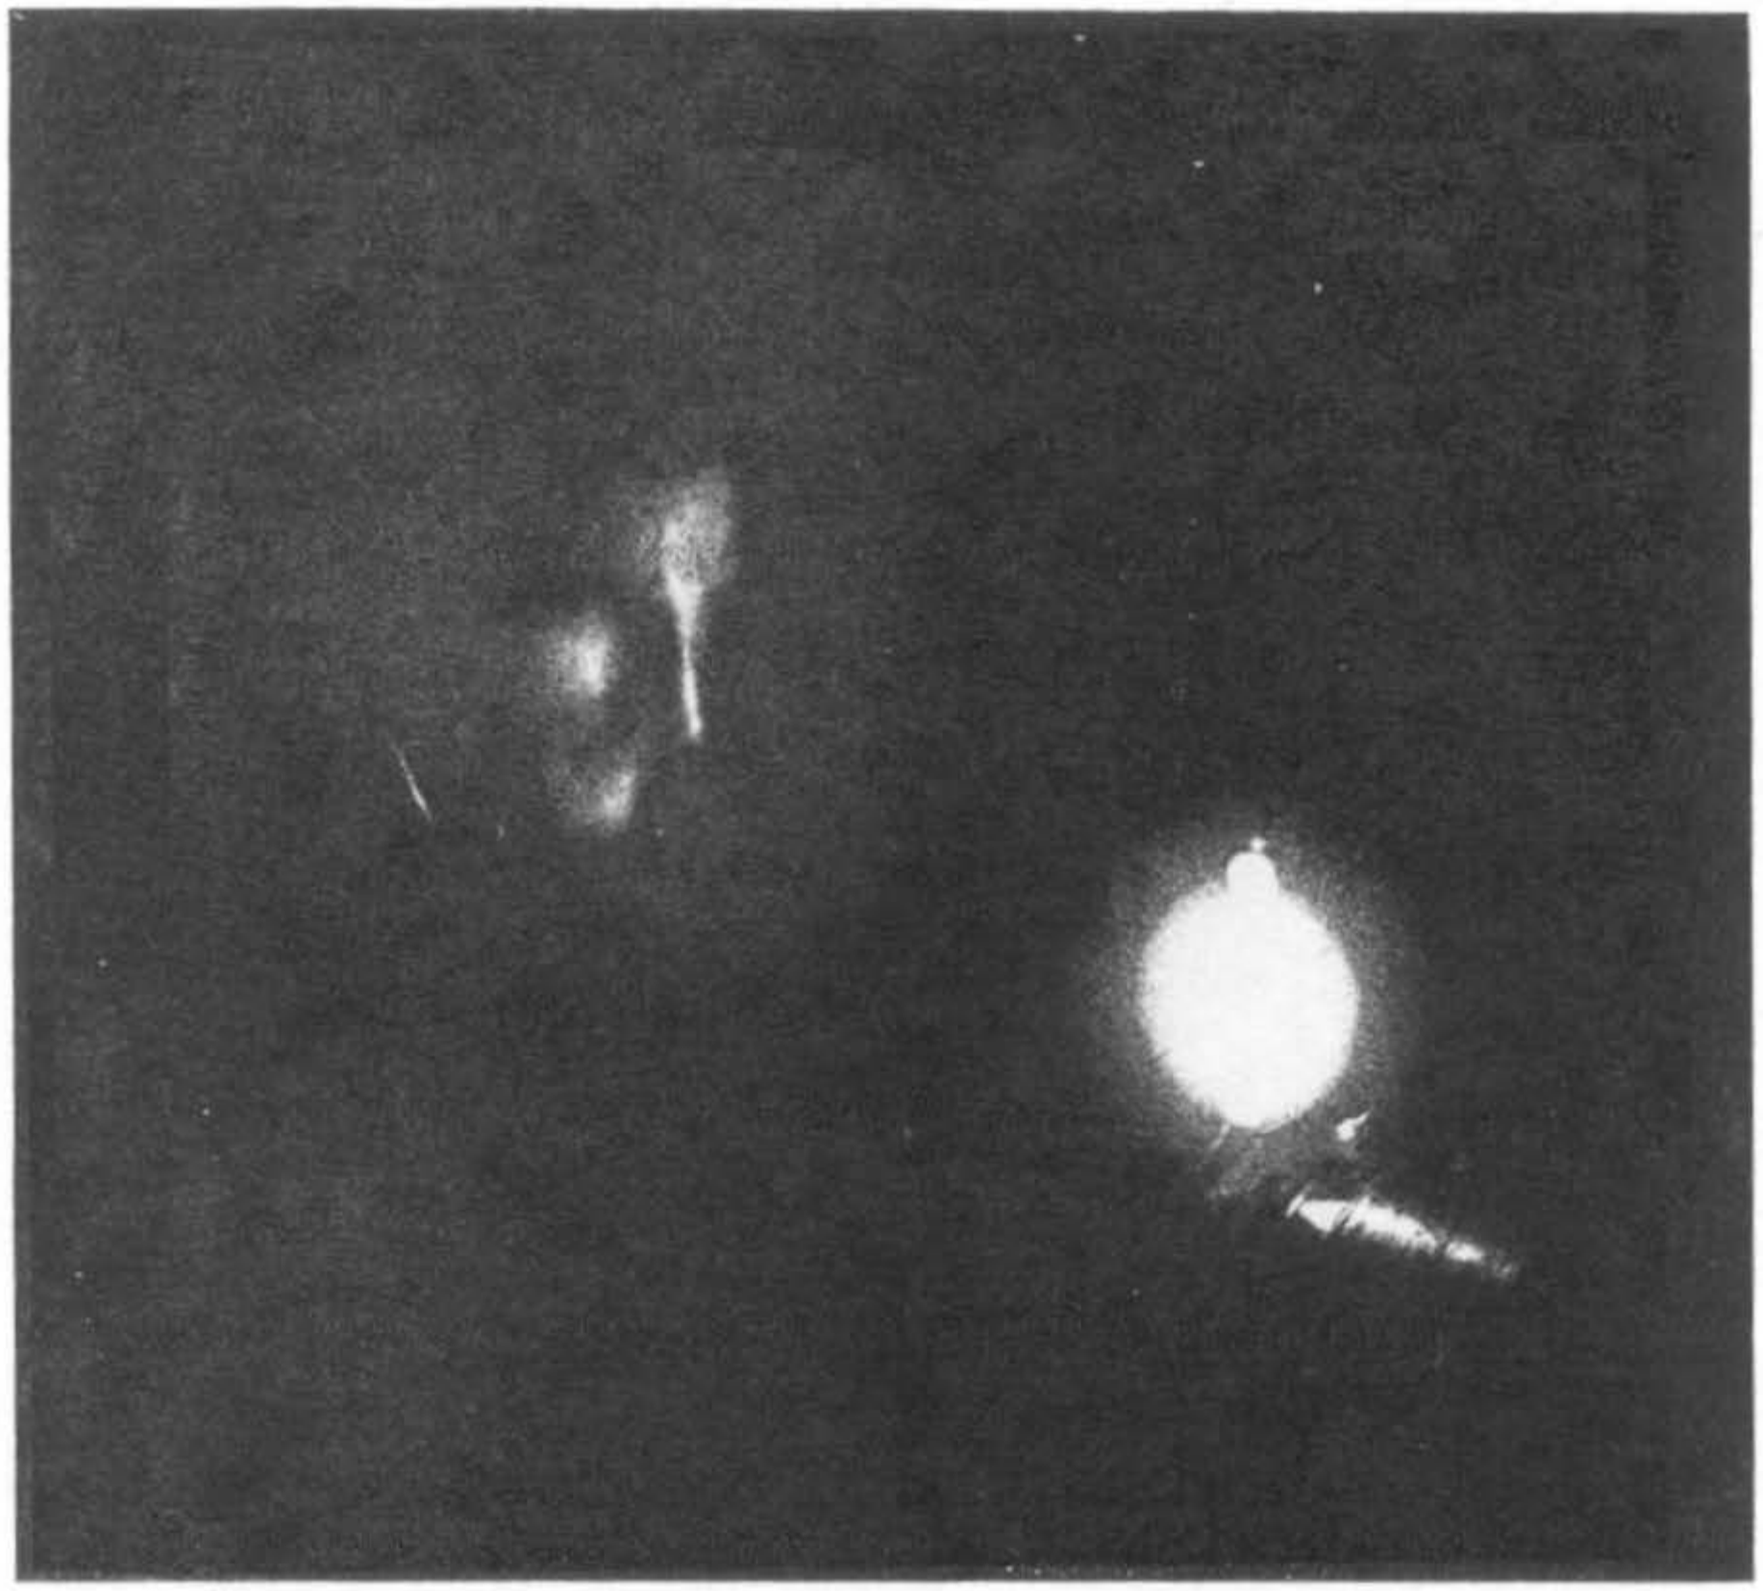

FIG. 3. FIRST PHOTOGRAPH EVER TAKEN BY PHOSPHORESCENT LIGHT. THE FACE IS THAT OF MR. TESLA, AND THE SOURCE OF LIGHT IS ONE OF HIS PHOSPHORESCENT BULBS. TIME OF EXPOSURE, EIGHT MINUTES. DATE OF PHOTOGRAPH JANUARY, 1894.

ing the oscillator as an extremely valuable instrument of research, while time will demonstrate its various commercial and industrial benefits.

Incidentally it may be remarked that the crude idea of obtaining currents by means of a coil or a magnetic core attached to the piston of a reciprocating steam-engine, is not in itself an entire novelty. It may also be noted that steam-turbines of extremely high rotative velocity are sometimes used instead of slow-moving engines to drive dynamos. But in the first class of long-abandoned experiments no practical result of any kind was ever reached before by any sort of device; and in the second class there is the objection that the turbine is driven by means of isolated shocks that cannot be overcome by any design of the blades, and which frustrate any attempts to perform work of the kind now under survey. What we are dealing with here is a dual, interacting machine, half mechanical, half electrical, of smallest bulk, extremely simple, utilizing steam under conditions unquestionably of the highest efficiency, its vibrations independent of load and pressure, delivering currents of the greatest regularity ever known for practical work or research. That such a combination should produce electricity for half the consumption of steam previously necessary with familiar apparatus in equivalent results, need not surprise us; yet think how much a saving of that kind would mean in well-nigh every industry consuming power!

THE OSCILLATOR AND THE PRODUCTION OF LIGHT.

HAVING obtained with the oscillator currents of high potential, high frequency, and high regularity, what shall be done with them? Mr. Tesla having already grappled successfully with the great difficulties of long distance power transmission, as narrated above, has first answered that question by boldly assailing the problem of the production of light in a manner nearer, perhaps, to that which gives us sunshine than was ever attempted before. Between us and the sun stretches the tenuous, sensitive ether, and every sensation of light that the eye experiences is caused by the effect of five hundred trillions of waves every second impressed on the ether by the molecular energy of the sun traveling along it rhythmically. If

the waves have a lower frequency than this 500,000,000,000,000, they will chiefly engender heat. In our artificial methods of getting light we imitatively agitate the ether so poorly that the waves our bonfires set up rarely get above the rate at which they become sensible to us in heat, and only a few waves attain the right pitch or rapidity to cause the sensation of light. At the upper end of the keyboard of vibration of the ether is a high, shrill, and yet inaudible out energy-waves on the ether, which will be conveyed to us through the glass of the bulb by the ether as light rather than as heat. The glass is as unconfining to the ether as a coarse sieve is to water.

Now Mr. Tesla takes his currents of high frequency and high potential, subjects the incandescent lamp to them, and, skipping some of those intermediate wasteful heat stages of lower wave vibration experienced in the old

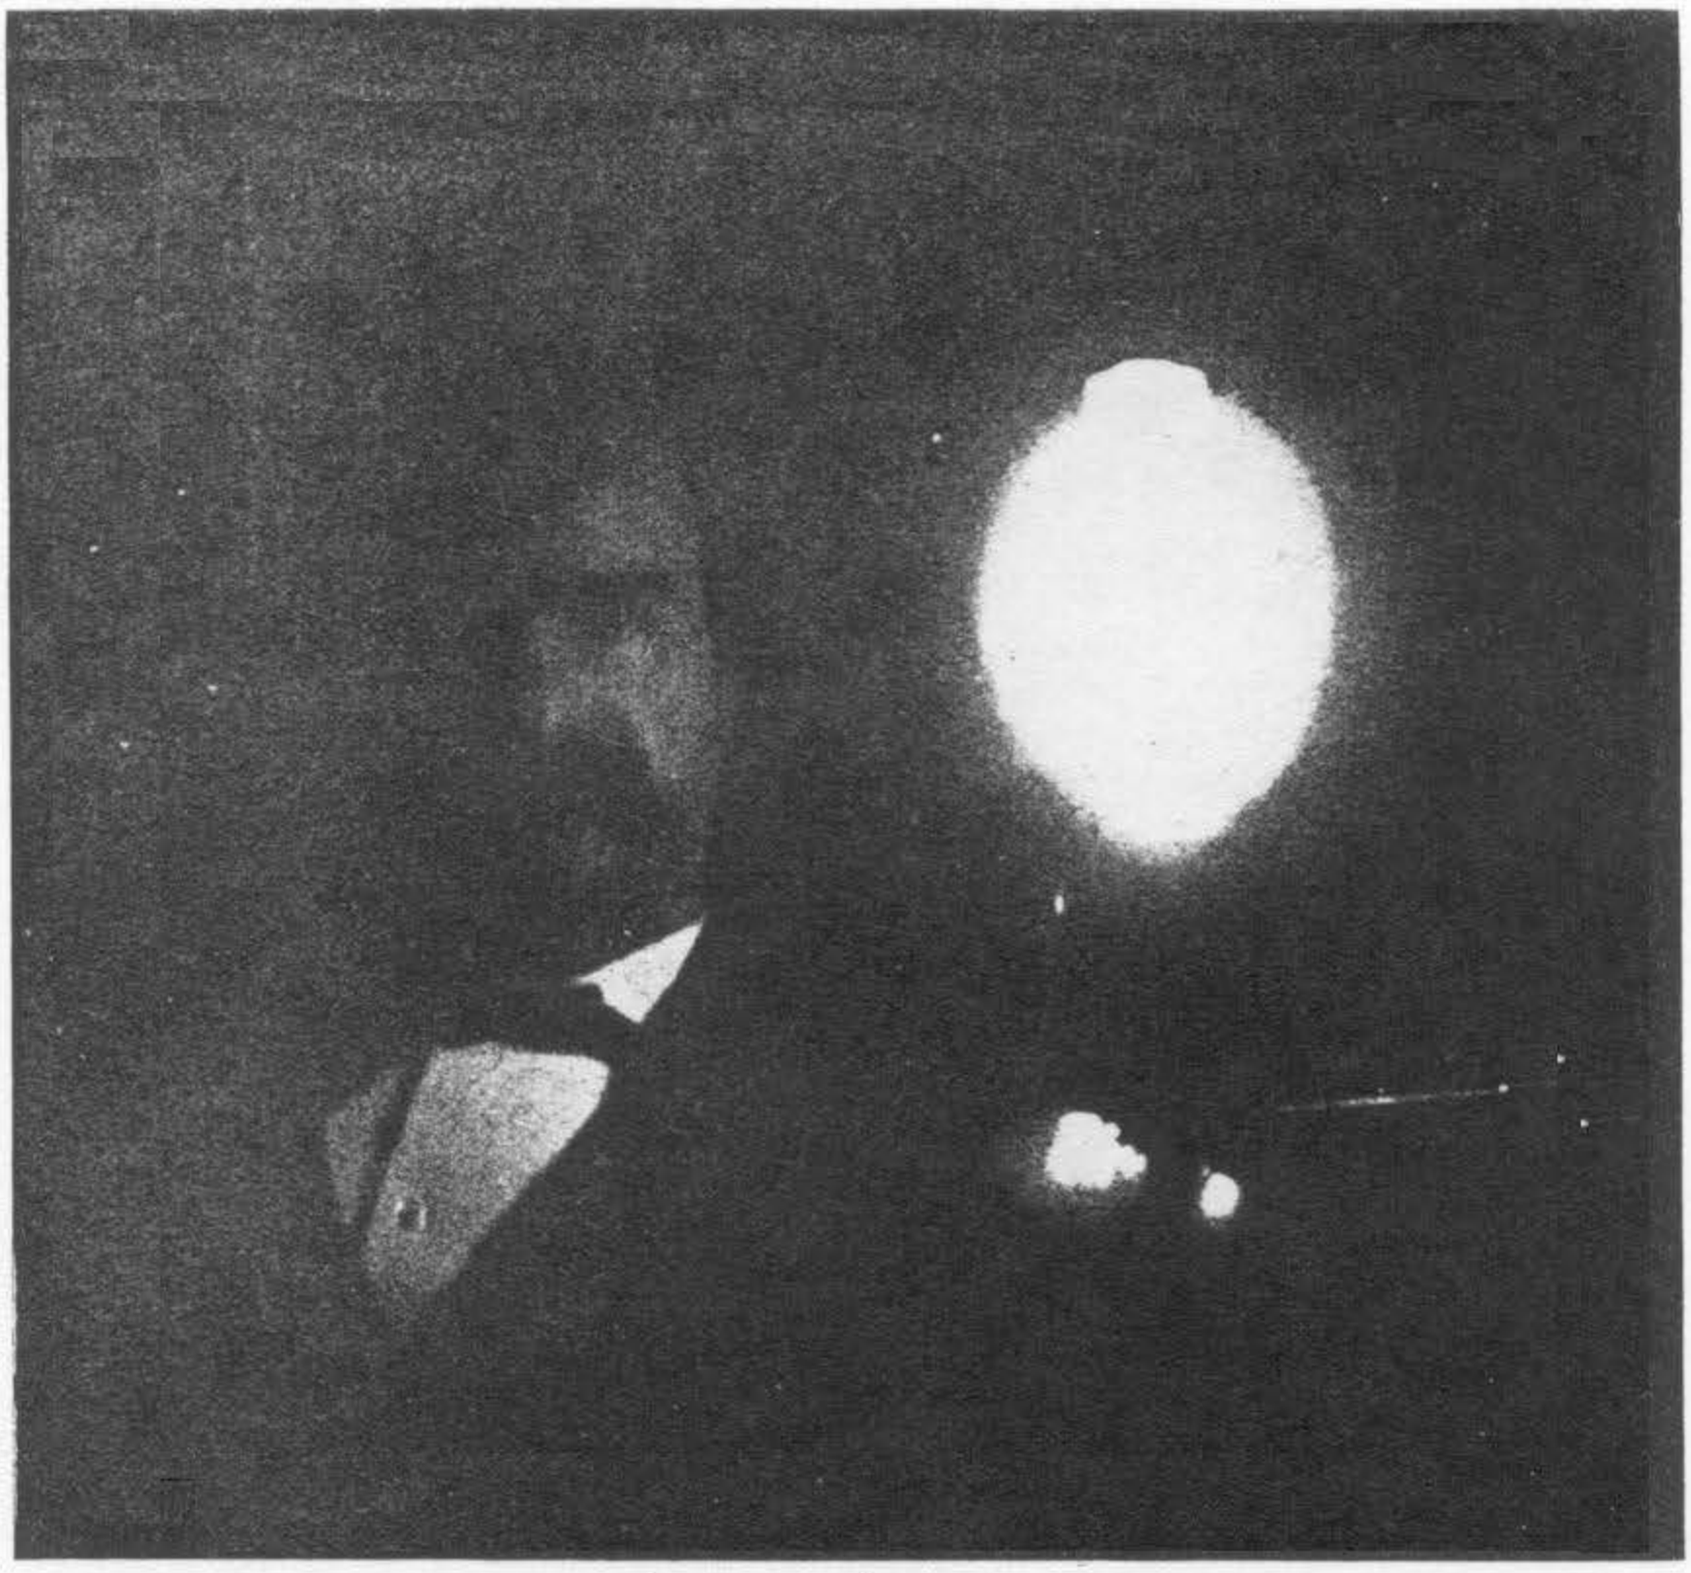

FIG. 4. PHOSPHOGRAPH OF MR. CLEMENS (MARK TWAIN), TAKEN IN THE TESLA LABORATORY JANUARY, 1894. TIME OF EXPOSURE, TEN MINUTES.

note,—"light,"—which we want to strike and to keep on striking; but we fumble at the lower, bass end of the instrument all the time, and never touch that topmost note without wasting the largest part of our energy on the intermediate ones, which we do not at all wish to touch. Light (the high note) without heat (the lower notes) is the desideratum. The inefficiency of the gas flame has been mentioned. In the ordinary incandescent lamp the waste is not so great; but even there the net efficiency of any one hundred units of energy put into it as electric current is at the most five or six of light, the waste occurring in the process of setting the molecules of the filament and the little air left in the bulb into the state of vibration under which they must work before they can throw methods, gets the ether-charged molecules more quickly into the intensely agitated condition necessary to yield light. Using his currents, produced electromagnetically, as we have seen, to load each fugitive molecule with its charge, which it receives and exercises electrostatically, he gets the ether medium into a state of excitement in which it seems to become capable of almost anything. In one of his first lectures, Mr. Tesla said:

> Electrostatic effects are in many ways available for the production of light. For instance, we may place a body of some refractory material in a closed, and preferably in a more or less air-exhausted, globe, connect it to a source of high, rapidly alternating potential, causing the molecules of the gas to strike it many times a second

at enormous speeds, and in this way, with trillions of invisible hammers, pound it until it gets incandescent. Or we may place a body in a very highly exhausted globe, and by employing very high frequencies and potentials maintain it at any degree of incandescence. Or we may disturb the ether carried by the molecules of a gas, or their static charges, causing them to vibrate or emit light.

These anticipatory statements are confirmed to-day by what Mr. Tesla has actually done in one old way revolutionized, and in three new ways: (1) the incandescence of a solid; (2) phosphorescence; (3) incandescence or phosphorescence of a rarefied gas; and (4) luminosity produced in a gas at ordinary pressure.

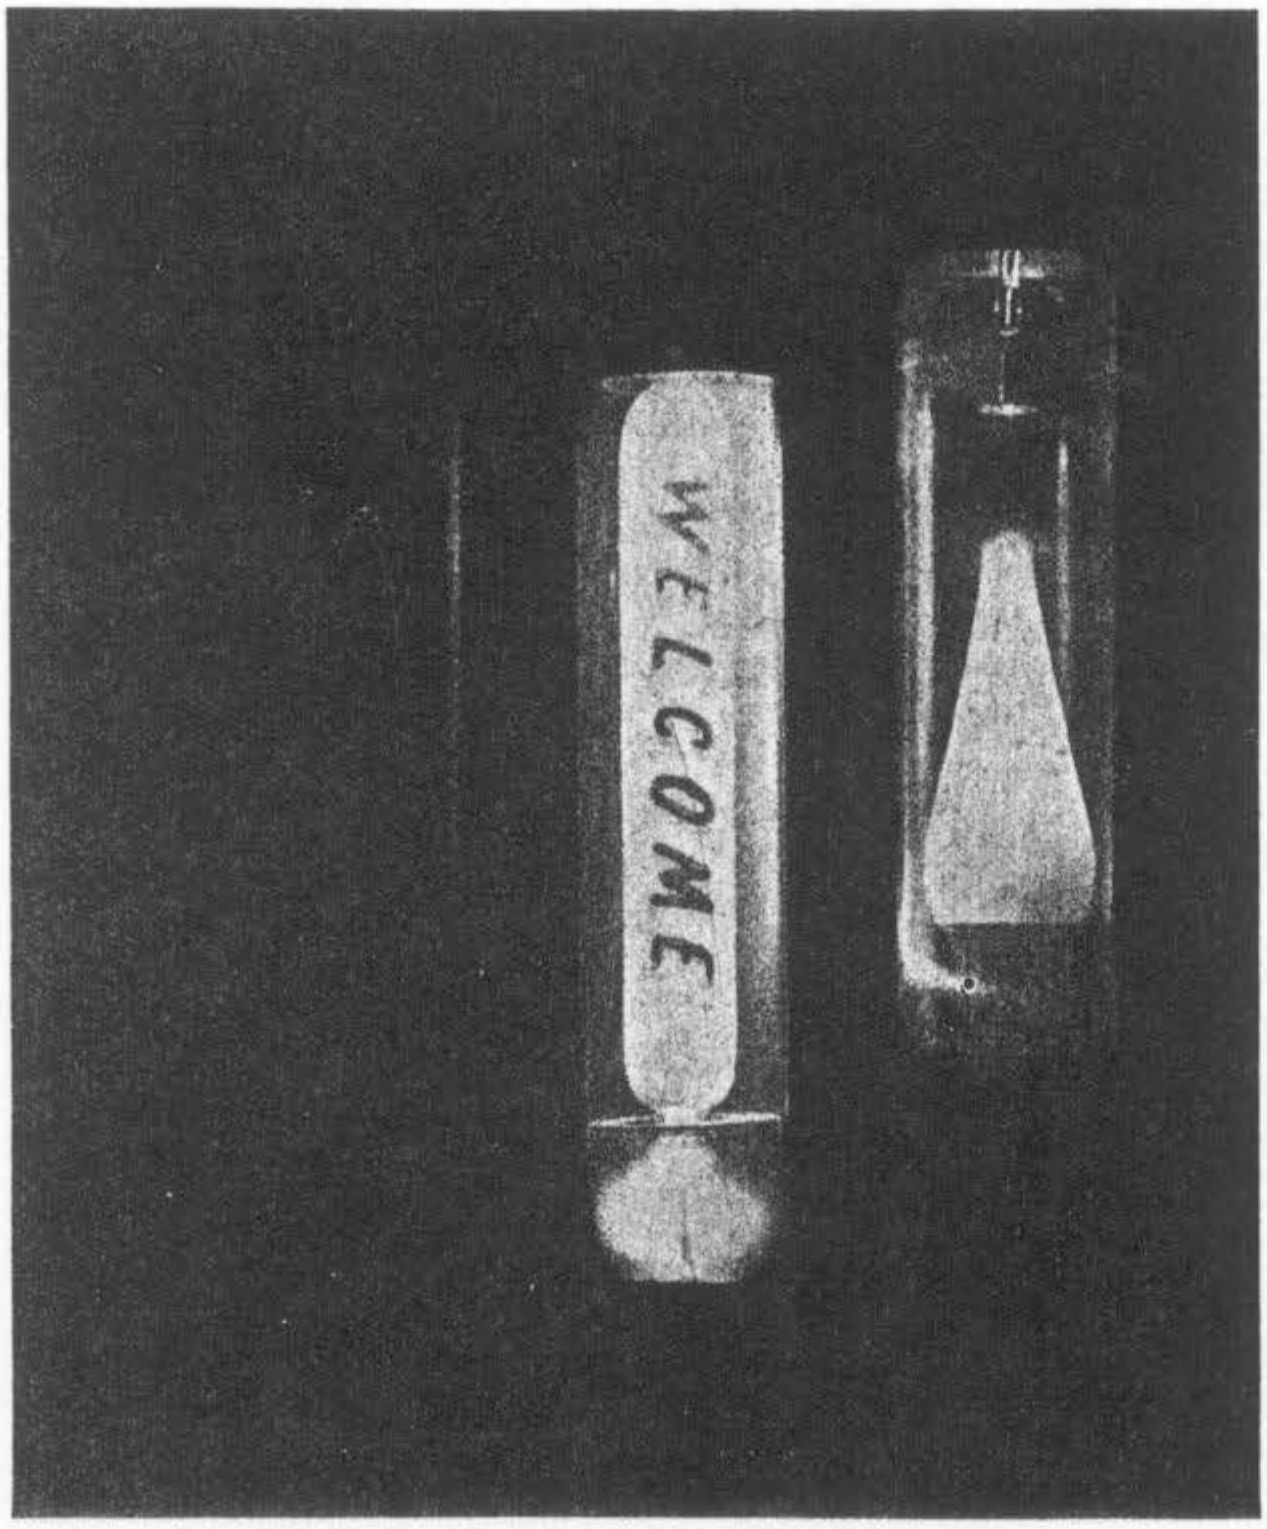

FIG. 5. THREE PHOSPHORESCENT BULBS UNDER TEST FOR ACTINIC VALUE. PHOTOGRAPHED BY THEIR OWN LIGHT.

LAMPS WITH BUTTONS OR BARS IN PLACE OF FILAMENTS.

TAKING lamps in the first category, it may be stated that it had been commonly supposed that the light-giving conductor in the lamp, to be efficient and practical, should be fine; hence the name "filament" given to the carbon loop in such lamps. But with the Teslaic currents the resistance or friction of the filament to the flow of current does not count for anything: the filament may just as well be short and thick, for it will rapidly reach and steadily maintain proper incandescence by the passage of a small current of the right high frequency and potential. An action is set up as the result of which the filament is hit millions of times a second by the bombardment of the molecules around it in a merciless ring of tormentors. The vibrations of the current in similar manner will cause the infinite jostling of the molecules of solid and gas against a small polished carbon or metallic button or bar in a lamp, and brilliant light is also obtainable in this way.

LIGHT AND PHOTOGRAPHS WITH TESLA PHOSPHORESCENT BULBS.

IN the field of lighting by phosphorescence we reach hitherto untrodden ground. Phosphorescent light has been associated with the idea of "cold light," or the property of becoming luminous with the omission of the intermediate step of combustion, as commonly understood. As a physical action, we know it in the light of the firefly, which Professor S. P. Langley rates at an efficiency of 100 per cent., all its radiations lying within the limits of the visible spectrum. By means of the Teslaic currents phosphorescent light strong enough even to photograph by has been obtained; and Fig. 3, representing the inventor himself, is the first portrait or photograph of any kind ever taken by phosphorescent light. A bulb whose light-giving member is coated with sulphide of zinc treated in a special way was rendered phosphorescent by means of current obtained from a high-frequency transformer coil. The current used was alternated or oscillated about 10,000 times per second. The exposure was about eight minutes.

Fig. 4, of Mr. Clemens (Mark Twain), was taken a few weeks later — early in 1894 — with the aid of the same bulb, and with an exposure of about ten minutes. In order to test more closely the actinic value of phosphorescent light, some bulbs subject to high-frequency currents were photographed, or, if we may coin a new word, "phosphographed," with a somewhat longer exposure. They are shown in Fig. 5. The right-hand, bright pair utilize sulphide of zinc in some form for luminosity. The third bulb, seen faintly to the left of them, has a coating of sulphide of calcium. Although, judged by the eye, it glowed with a brightness fully equal to that of the other two, the actinic value was

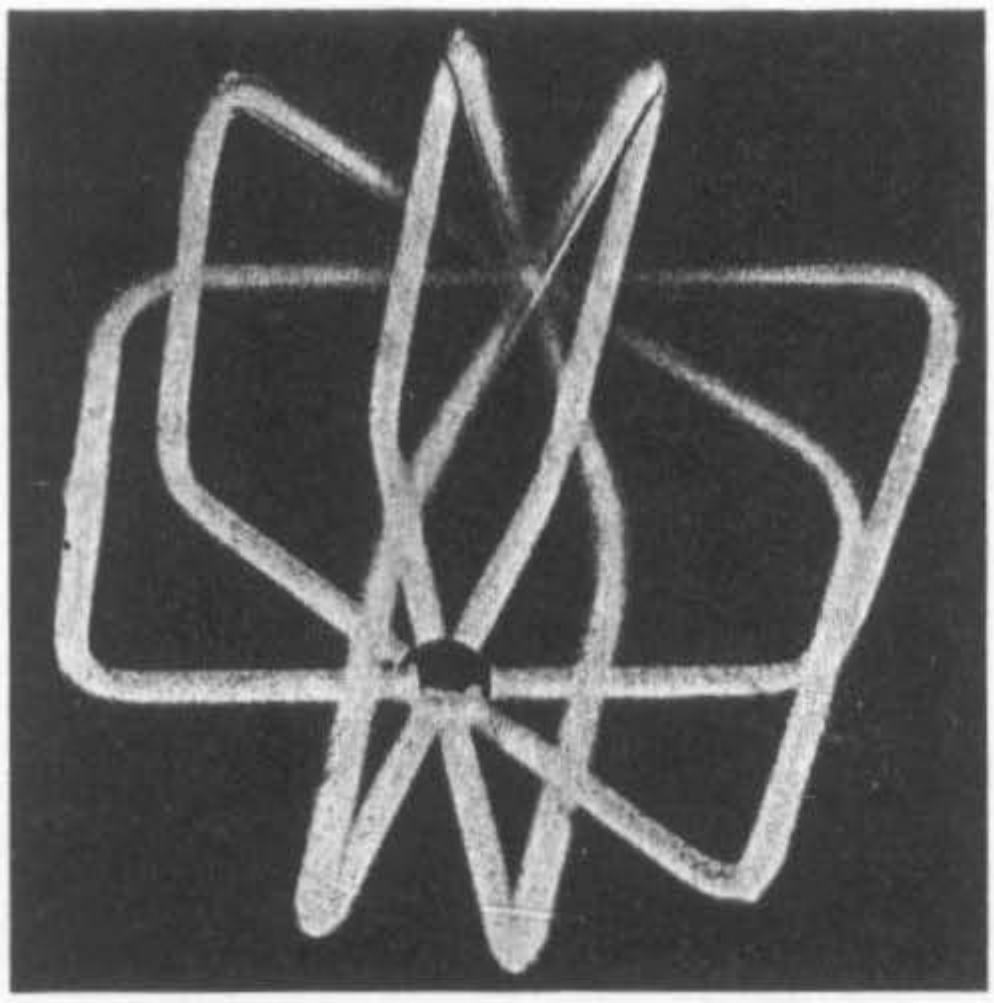

FIG. 6.

FIGS. 6, 7, AND 8 ARE TESLA TUBES OF DIFFERENT FORMS IN WHICH LIGHT IS OBTAINED WITHOUT FILAMENT OR COMBUSTION. (PHOTOGRAPHED BY THEIR OWN LIGHT.)

evidently much less. It is, perhaps, needless to say that these demonstrations invite to an endless variety of experiments, in which investigators will find a host of novel phenomena awaiting them as to phosphorescence and fluorescence produced with electrical currents.

LIGHT FROM EMPTY BULBS IN FREE SPACE.

THE third and fourth classes of lighting enumerated above as obtained by Teslaic currents are those caused by the incandescence or phosphorescence of a rarefied gas and the luminosity of a gas at ordinary pressure. We get pure, beautiful light without any filament or any combustion. In Figs. 6, 7, and 8 we have tubes or bulbs by means of which some of these interesting phenomena are obtained and illustrated. The bulbs shown are more or less exhausted of air. In the case of Figs. 6 and 7 the glass of the tubes is the ordinary German glass. In Fig. 8, uranium glass—green—was employed. This last was held in the hand while a photograph was taken of it by its own light; whence the unsteadiness of the negative. To obtain the beautiful illumination seen in all three, the bulbs were simply approached within a few inches of the terminal of a high-frequency coil or transformer. Just here it may be pointed out that the lamps are spoken of as unattached, in free space. Ordinary incandescent lighting is done, as everybody knows, with the lamps' bases firmly attached to the two current-bearing wires. Even where the lamps have been used on the ordinary alternating circuits in which the transformer is employed to "step down," or reduce, for safe use, the higher-tension current brought to it by the wire from the dynamo, the lamps have to be attached to the "secondary" wires of the coil so as to make a closed circuit for

FIG. 8.

them. But as we rise in the frequency of the current, as we leave behind the electrodynamic conditions for the electrostatic ones, so we free ourselves from the restrictions and limitations of solid wires for the conveyance of the effects sought, until at last we reach a point where all the old ideas of the necessity of a tangible circuit vanish. It is all circuit if we can properly direct the right kind of impulses through it. As Mr. Tesla long ago pointed out, most of the experiments usually performed with a static machine of glass plates can also be performed with an induction-coil of wire if the currents are alternated rapidly enough; and it is in reality here that Mr. Tesla parts company with other distinguished workers who have fixed their attention merely on the results attainable with electrodynamic apparatus. Before passing on, let us quote the inventor himself:

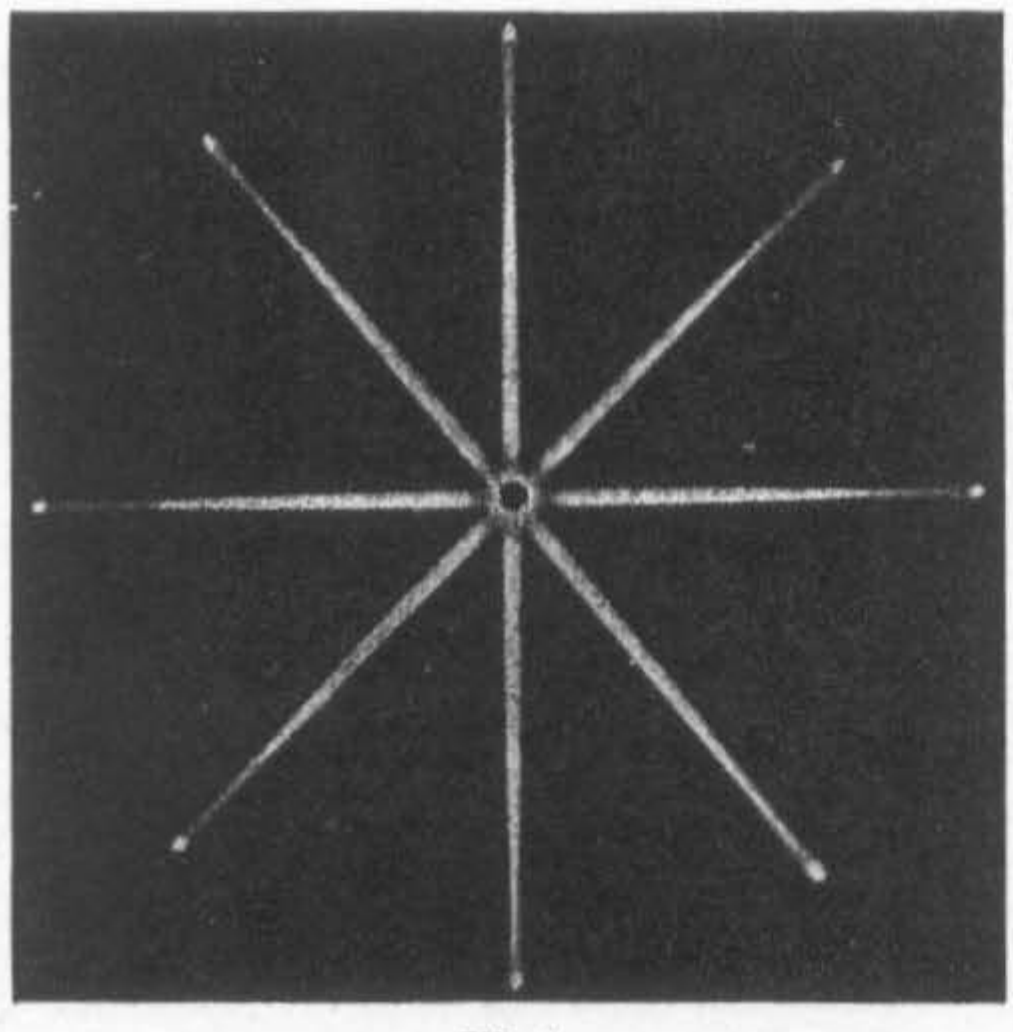

FIG. 7.

Powerful electrostatic effects are a *sine quâ non* of light production on the lines indicated by theory. Electromagnetic effects are primarily unavailable, for the reason that to produce the required effects

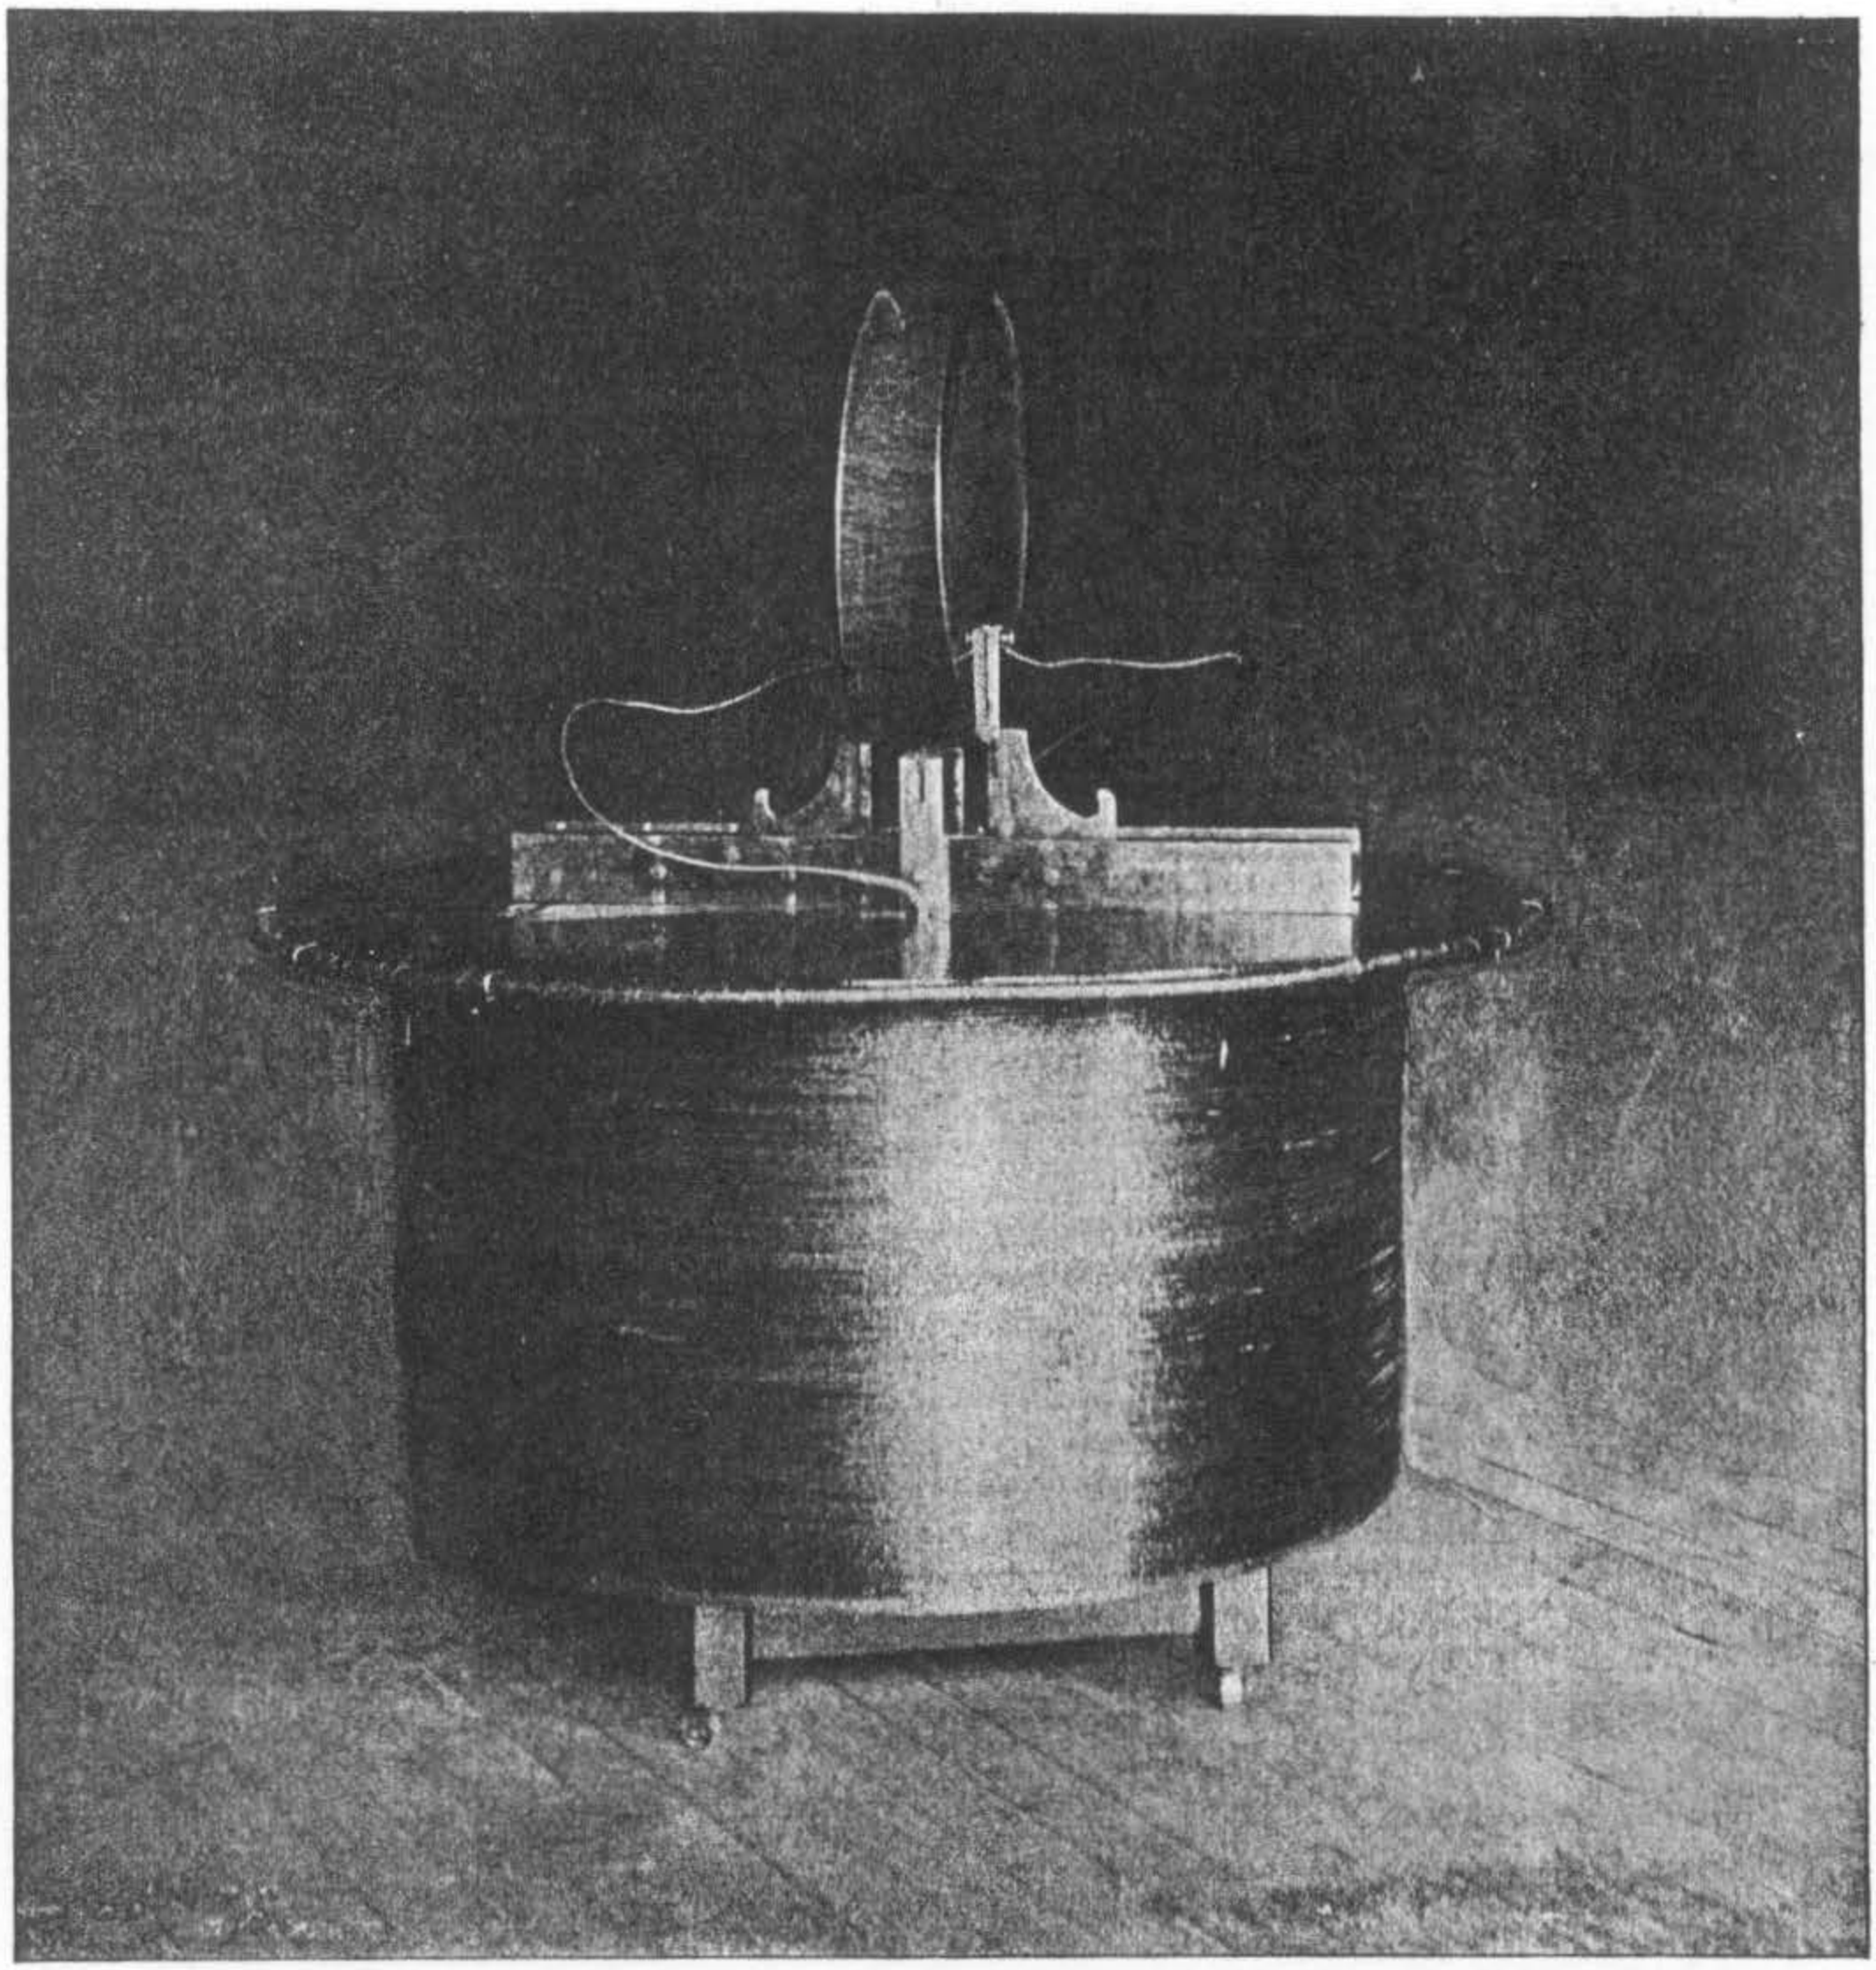

FIG. 9. EXPERIMENT SHOWING PLAY OF ELECTRIC SPARKS BETWEEN CONDENSER PLATES, PRODUCED BY ELECTRIC CHARGE. THE COIL, STANDING IN THE CENTER OF A LARGE ROOM, IS UNCONNECTED WITH THE ENERGIZING CIRCUIT. (FROM FLASH-LIGHT PHOTOGRAPH.)

we would have to pass the current impulses through a conductor which, long before the required frequency of the impulses could be reached, would cease to transmit them. On the other hand, electromagnetic waves many times longer than those of light, and producible by sudden discharge of a condenser, could not be utilized, it would seem, unless we availed ourselves of their effect upon conductors as in the present methods, which are wasteful. We could not affect by means of such waves the static molecular or atomic charges of a gas, and cause them to vibrate and to emit light. Long transverse waves cannot, apparently, produce such effects, since excessively small electromagnetic disturbances may pass readily through miles of air. Such dark waves, unless they are of the length of true light-waves, cannot, it would seem, excite luminous radiation in a Geissler tube, and the luminous effects which are producible by induction in a tube devoid of electrodes, I am inclined to consider as being of an electrostatic nature. To produce such luminous effects straight electrostatic thrusts are required; these, whatever be their frequency, may disturb the molecular charges and produce light.

EFFECTS WITH ATTUNED BUT WIDELY SEPARATED CIRCUITS.

A FEW experiments performed in Mr. Tesla's laboratory workshop afford an idea of the flexibility of the methods by which powerful electrostatic effects are produced across many feet of intervening space. The workshop is a room about forty by eighty feet, and ten or twelve feet

high. A circuit of small cable is carried around it from the terminals of the oscillator. In the center of the clear, open space is placed a coil, wound drum fashion, three or four feet high, and unconnected with the current source save through the medium of the atmosphere. The coil is provided, as shown in the picture, with two condenser plates for adjustment, standing up like cymbals. The plates act after the manner of a spring, and the coil is comparable to an electromagnetic weight. The system of apparatus in the middle of the room has therefore a certain period of vibration, just as though it were a tuning-fork, or a sheet of thin resonant glass. Around the room, over the cable, there are sent from the oscillator electrical current vibrations. By carefully adjusting the condenser plates so that the periodicity or swing of the induced current is brought into step with that of the cable currents, powerful sparks are made to pour across between the plates in the dense streams shown in Fig. 9. In this manner it is easy to reach tensions as high as 200,000 and 300,000 volts.

No one who has witnessed these significant experiments can fail to be impressed with the evidence of the actuality of a medium, call it ether or what you will, which in spite of its wonderful tenuity is as capable of transmitting energy as though it were air or water. Still more impressive to a layman, perhaps, is the confidence and easy precision with which these fine adjustments are brought about.

In Fig. 10 there is a similar coil, in the middle of the same room, which has been so adjusted to the vibrations sent around the shop that an ordinary sixteen-candle-power incandescent lamp is well lighted up.

Fig. 11 pursues this a little further. Above the coil a circle of wire is held by an observer, and an incandescent lamp is attached to the circle. As before, the vibration of the ether in the coil is brought into harmony with the vibrations emitted from the cable. The inductive effect upon the circle held loosely in free space by the observer is so pronounced that the lamp is immediately lighted up, though it may be connected with but one terminal wire, or with two. A 100-volt lamp is used, requiring when employed ordinarily more than one tenth of a horse-power right off the connecting circuit wires direct from the dynamo to bring it up to proper illuminating value. Hence, as will be seen, there is actual proof here of the transmission of at least that amount of energy across a space of some twenty feet and into the bulb by actually no wire at all. This need not surprise us when we remember that on a bright day the ether delivers steadily from the sun a horse-power of energy to every seven square feet of the earth's

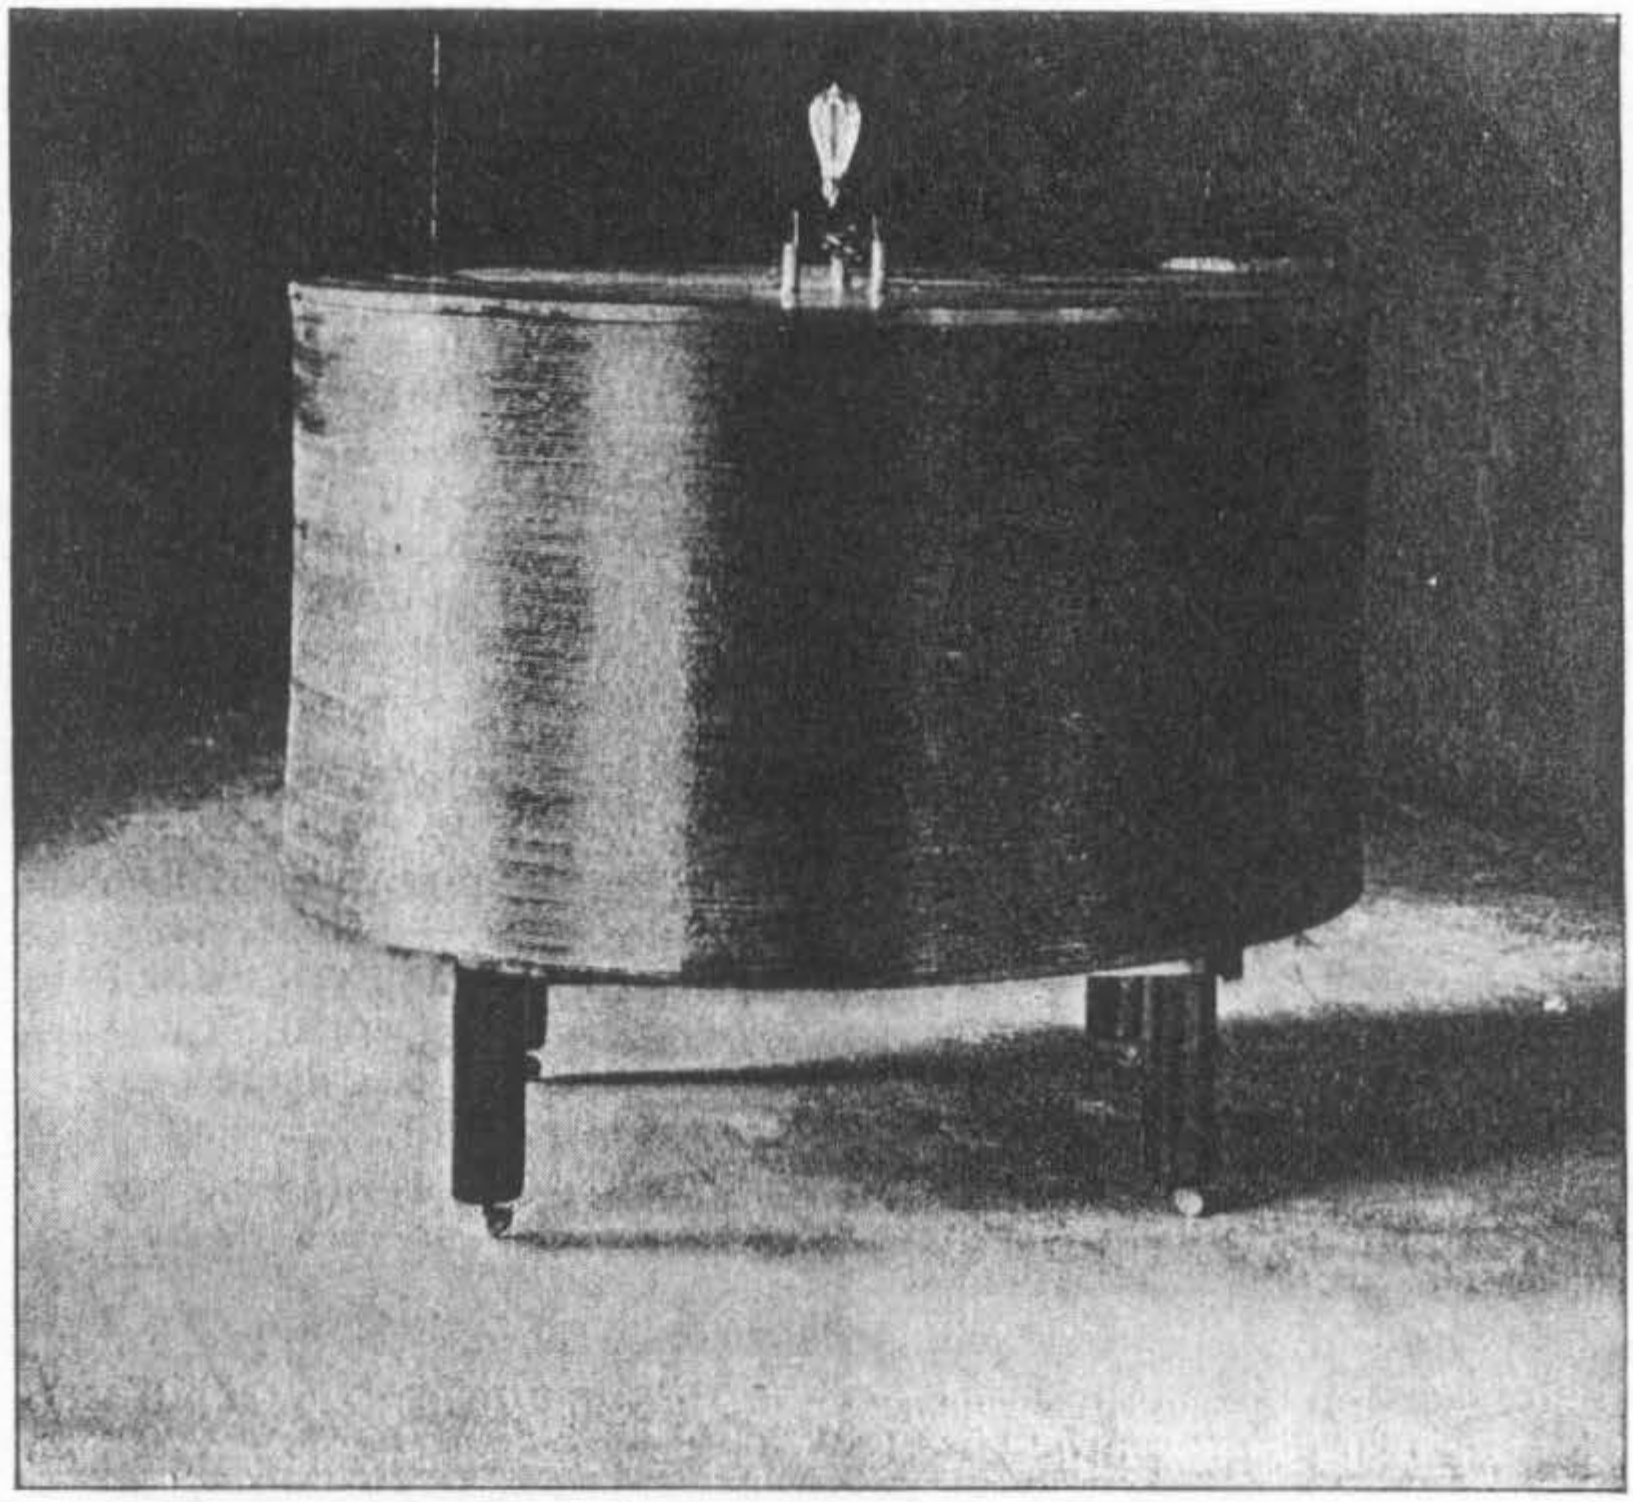

FIG. 10. EXPERIMENT SHOWING THE LIGHTING UP OF AN ORDINARY INCANDESCENT LAMP, AT A DISTANCE, THROUGH THE INFLUENCE OF ELECTRIFIED ETHER-WAVES. (FROM FLASH-LIGHT PHOTOGRAPH.)

surface toward it: so great is its capacity for transmitting energy. Mr. Tesla with his "electrostatic thrusts" has simply learned the knack of loading electrically on the good-natured ether a little of the protean energy of which no amount has yet sufficed to break it down or put it out of temper. We may assume either an enormous speed in what may be called the transmitting wheelwork of the ether, since the weight is inconceivably small; or else that the ether is a mere transmitter of energy by its well-nigh absolute incompressibility.

CURIOUS "IMPEDANCE" PHENOMENON.

IN Fig. 12 we have another remarkable experiment illustrated. Standing over the coil in the center of the room, the observer holds a hoop of stout wire in his hand. One or more lamps are connected with two points on the wire, so that the lamps are "short-circuited" by the short bar of wire. The vibrations are, however, so extremely rapid that in spite of the opposite terminals being united in this way, the current does not flow past them neglectfully, in the apparently easier path, as it should, but brings them to a bright incandescence. We have here an example of what is known as "impedance" phenomena, in which the current is oddly choked back at certain points and not at others. Under the conditions of "impedance," the best electrical conductor loses its property of conducting, and behaves like a highly resisting substance. Elaborating further these experimental results, Mr. Tesla shows that a gas — a perfect non-conductor under ordinary circumstances — may be more conductive than the best copper wire, provided the currents vibrate rapidly enough. The fantastic side of this phenomenon he touched on playfully once by suggesting that perchance in such wise we might some day utilize gas to convey electricity, and the old gas-pipe to insulate it.

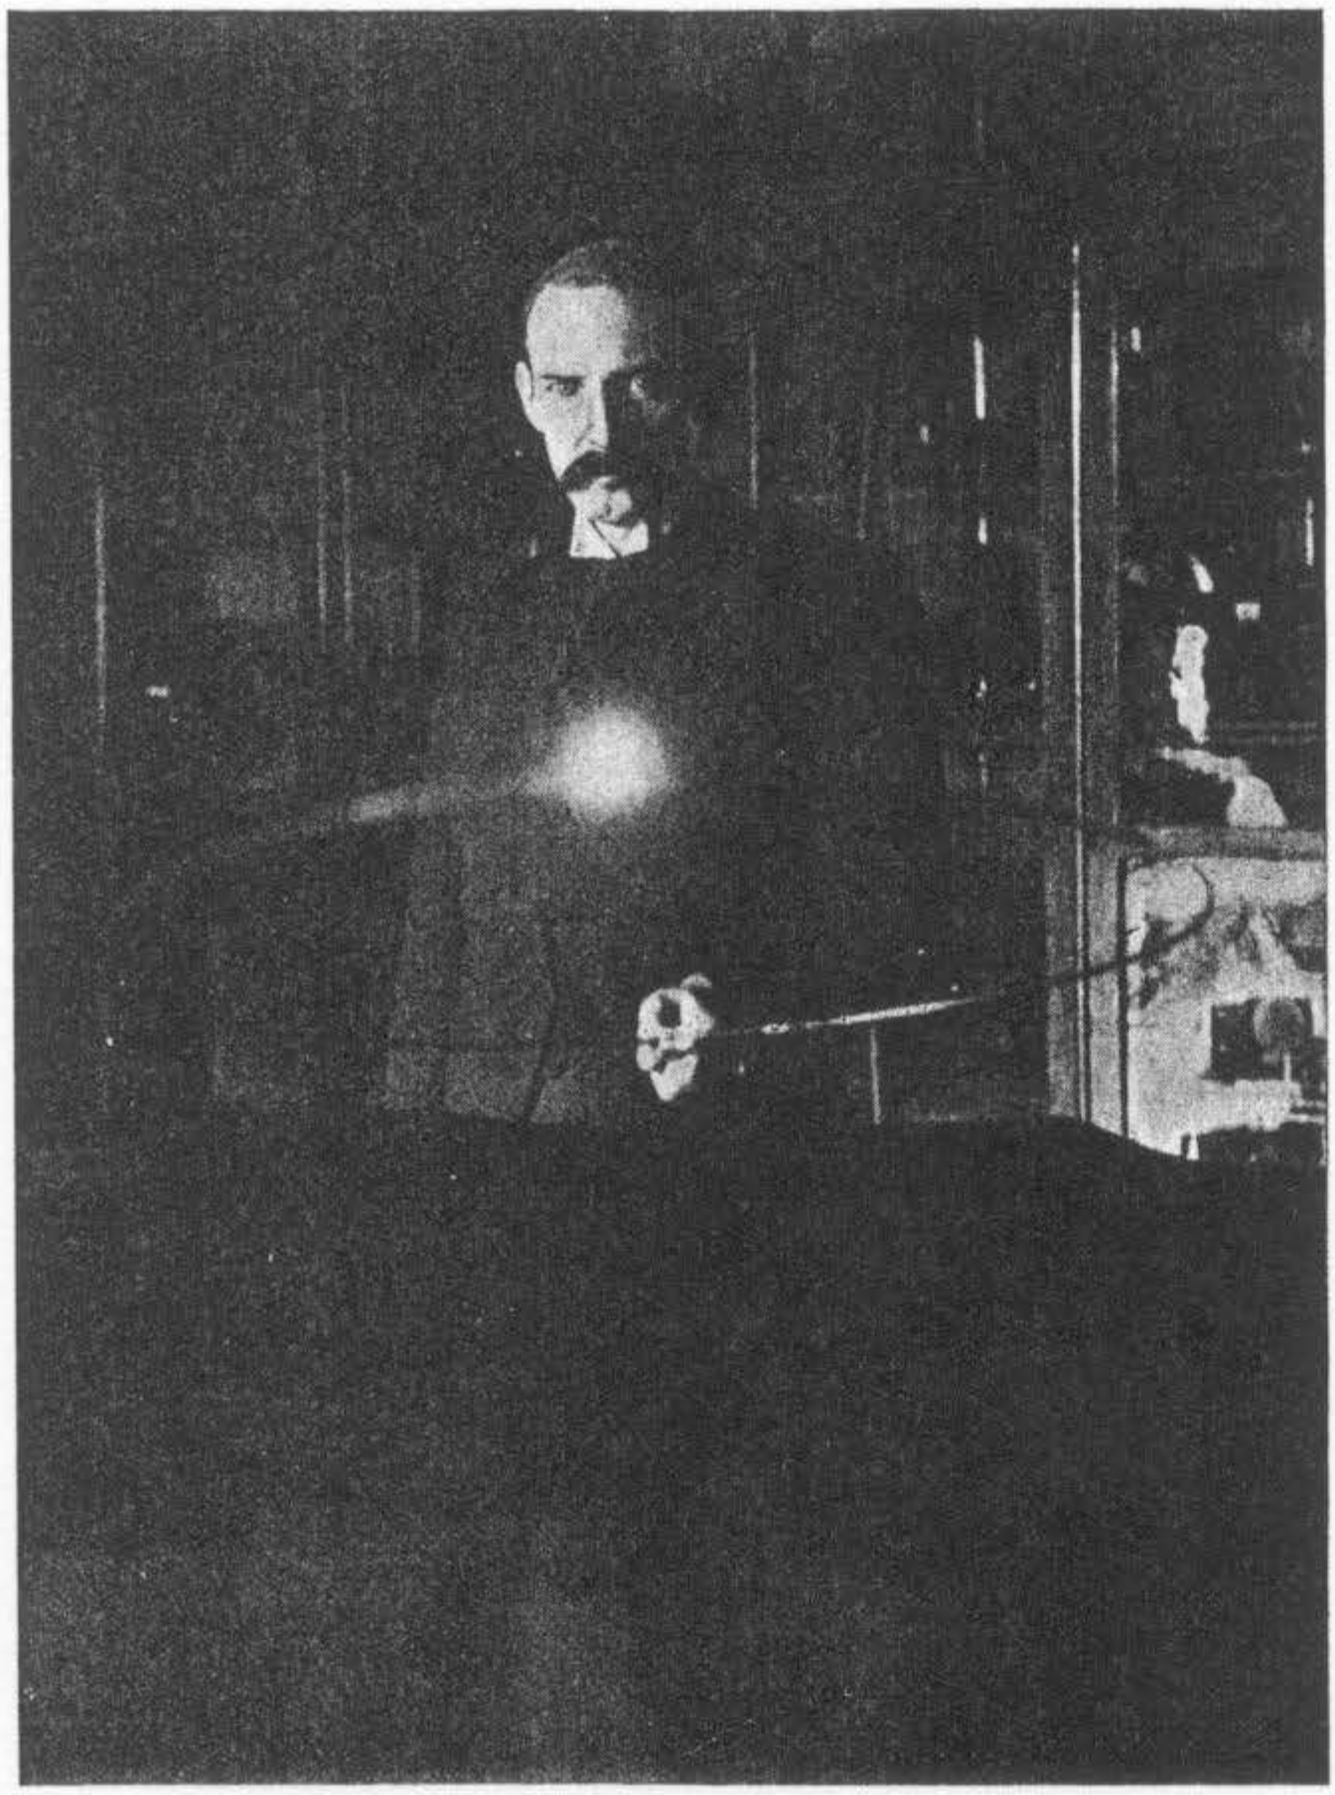

FIG. 11. EXPERIMENT ILLUSTRATING THE LIGHTING OF AN INCANDESCENT LAMP IN FREE SPACE BY INDUCTION FROM COIL BELOW, ENERGIZED BY DISTANT CIRCUIT AROUND THE ROOM. THE LOOP OF WIRE CARRYING THE LAMP IS HELD BY MR. MARION CRAWFORD. (FROM FLASH-LIGHT PHOTOGRAPH.)

LAMPS LIGHTED BY CURRENTS PASSED THROUGH THE HUMAN BODY.

IN Fig. 13 a most curious and weird phenomenon is illustrated. A few years ago electricians would have considered it quite remarkable, if indeed they do not now. The observer holds a loop of bare wire in his hands. The currents induced in the loop by means of the "resonating" coil over which it is held, traverse the body of the observer, and at the same time, as they pass between his bare hands, they bring two or three lamps held there to bright incandescence. Strange as it may seem, these currents, of a voltage one or two hundred times as high as that employed in electrocution, do not inconvenience the experimenter in the slightest. The extremely high tension of the currents which Mr. Clemens is seen receiving prevents them from doing any harm to him.

TRANSMISSION OF INTELLIGENCE BY ATTUNED OR "RESONATING" CURRENTS.

REFERENCE has been made to the "resonating" quality of the circuits and coils. It would be

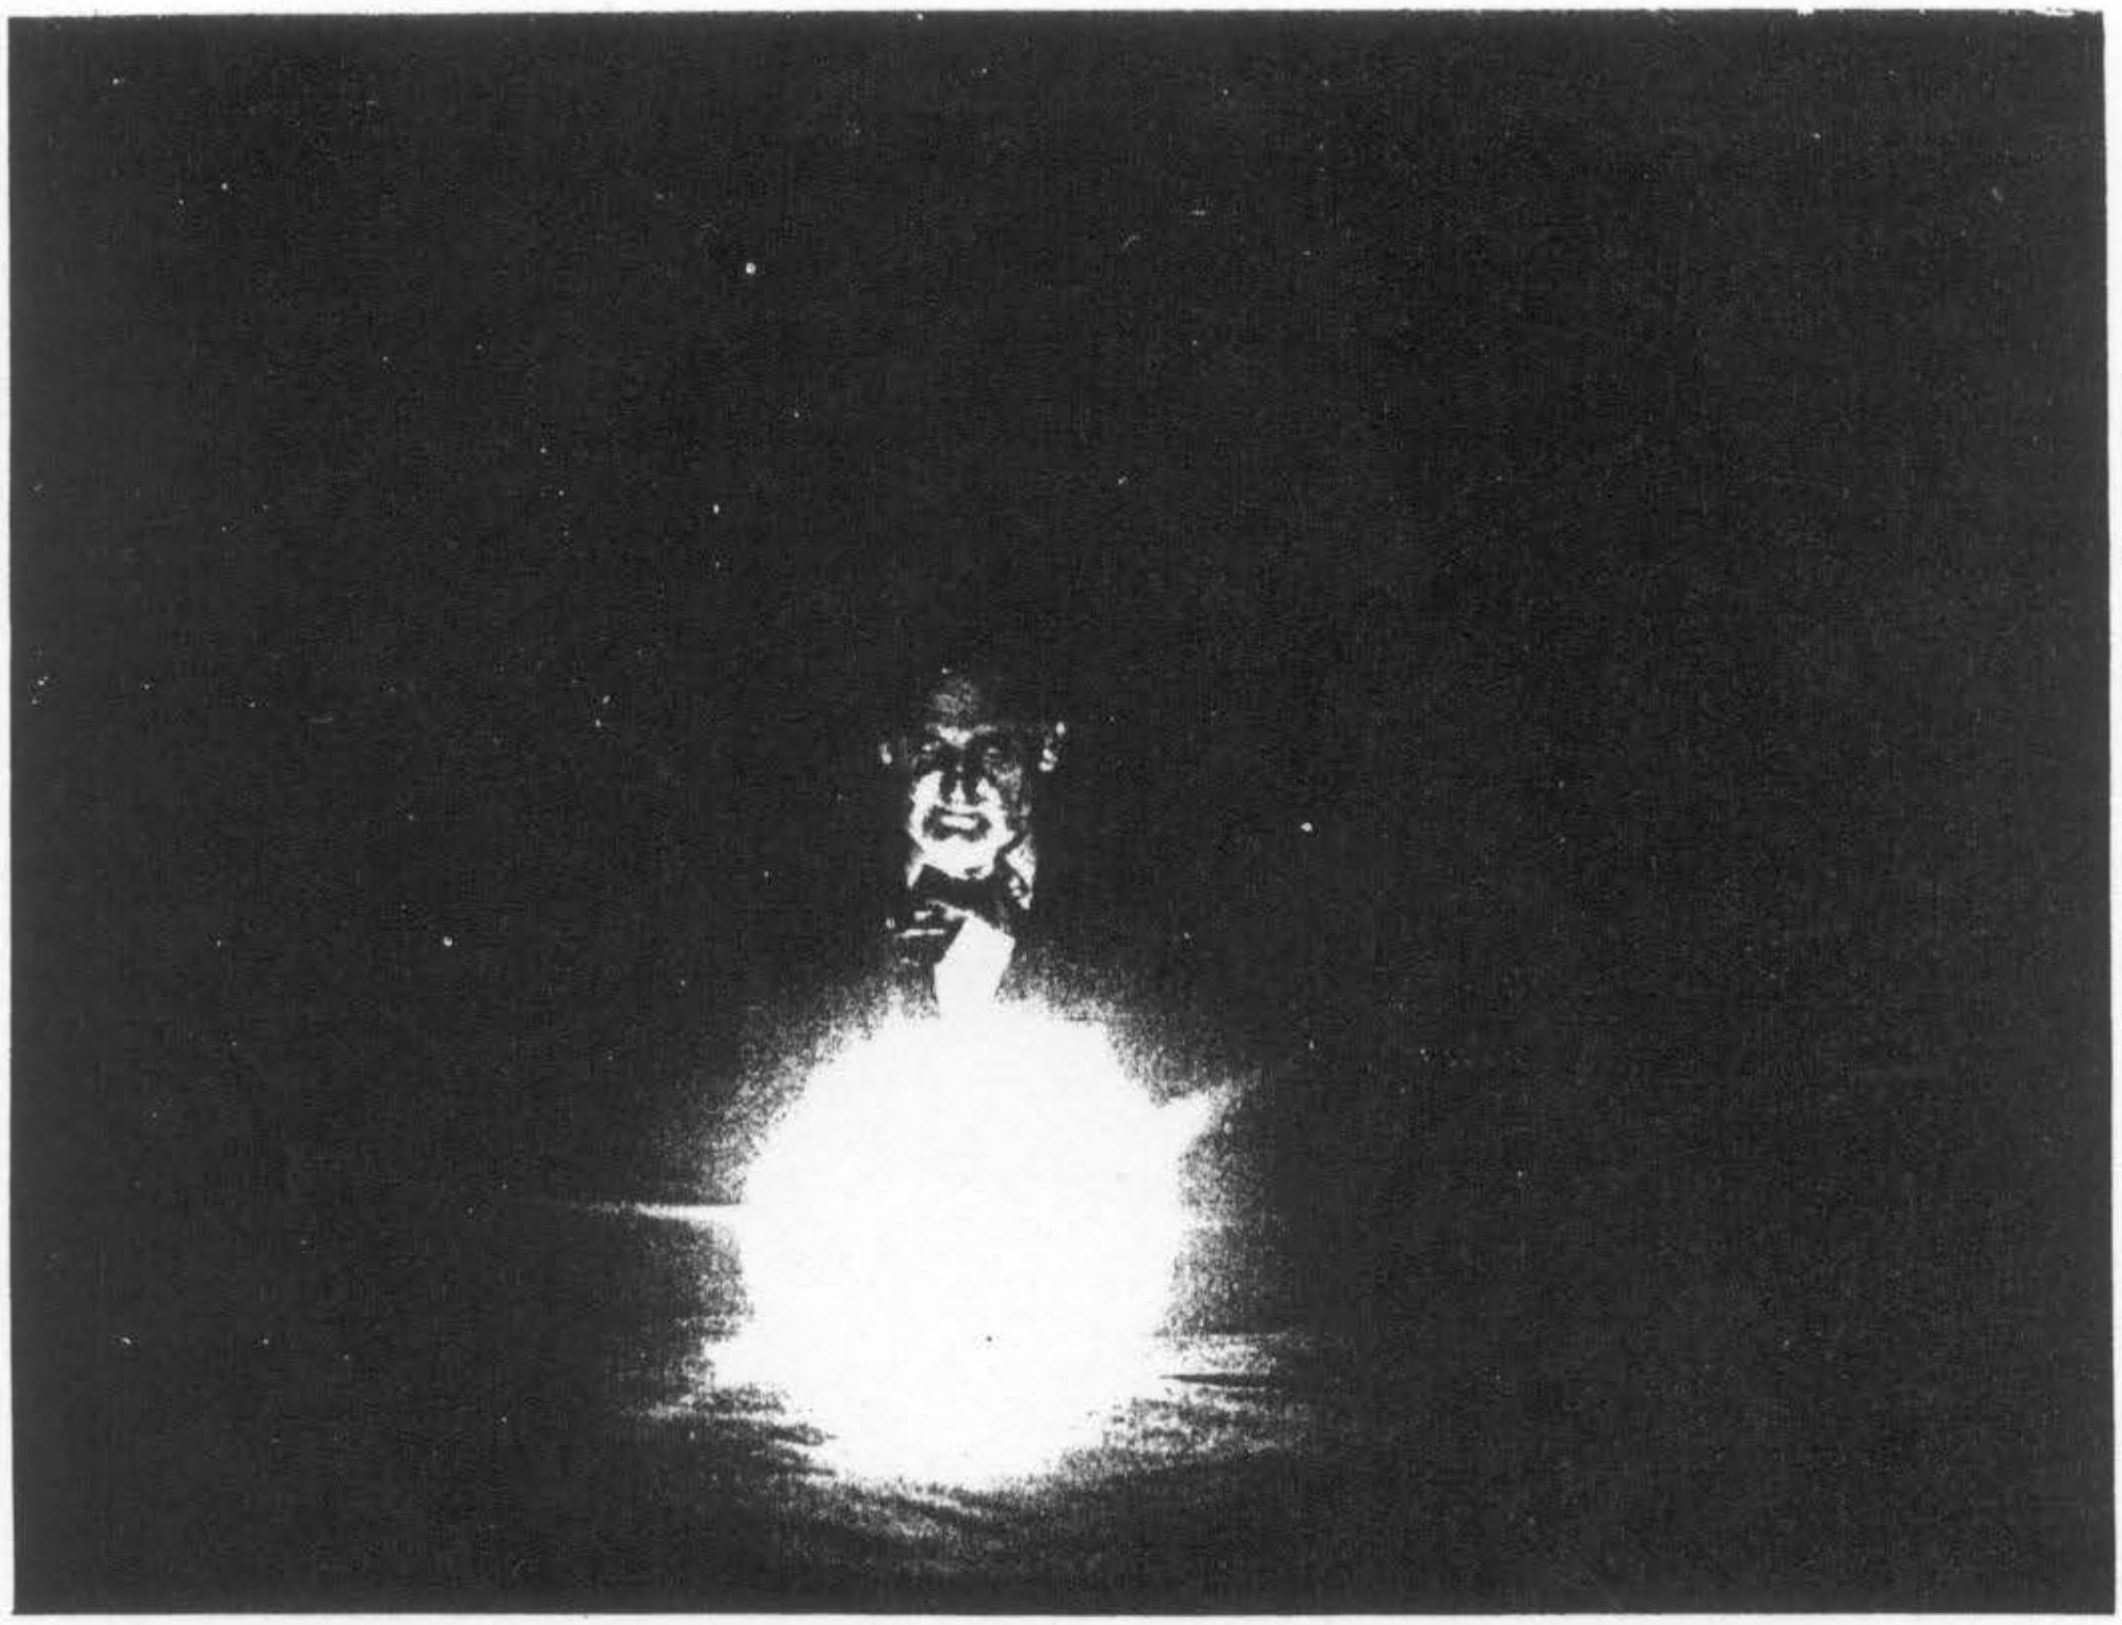

FIG. 12. SIMILAR EXPERIMENT, ILLUSTRATING THE PHENOMENON OF IMPEDANCE. THE LOOP OF WIRE, CARRYING TWO LAMPS, IS HELD BY MR. JOSEPH JEFFERSON. (FROM FLASH-LIGHT PHOTOGRAPH.)

wearisome, and indeed is not necessary, here to dwell on the difficulty often experienced in establishing the relation of "resonance," and the instantaneity with which it can be disturbed. It may be stated, in order to give some idea of the conditions to be observed in these experiments, that when an electric circuit is traversed by a rapidly oscillating current which sets up waves in the ether around the wire, the effect of these waves upon another circuit situated at some distance from the first can be largely varied by proper adjustments. The effect is most pronounced when the second circuit is so adjusted that its period of vibration is the same as that of the first. This harmonizing is deftly accomplished by varying either of the two elements which chiefly govern the rapidity of the vibration, viz., the so-called "capacity" and the "self-induction." Whatever the exact process may be, it is clear that these two quantities in their effect answer almost directly to what are known in mechanics as pliability and as weight or inertia. Attach to a spring a weight, and it will vibrate at a certain rate. By changing the weight, or modifying the pliability of the spring, any period of vibration is obtainable. In very exact adjustments, minute changes will completely upset the balance, and the very last straw of fine wire, for example, in the induction-coil which gives the self-induction will break the spell. As Mr. Tesla has said, it is really a lucky thing that pure resonance is not obtainable; for if it were, all kinds of dangers might lie in store for us by the increasing oscillations of every kind that would be set up. It will, however, have been gathered that if one electrical circuit can be tuned to another effectively, we shall need no return wire, as heretofore, for motors or for lights, the one wire being, if anything, better than two, provided we have vibration of the right value; and if we have that, we might get along without any wires or any "currents." Here again we must quote Mr. Tesla:

In connection with resonance effects and the problem of transmission of energy over a single conductor, I would say a few words on a subject which constantly fills my thoughts, and which concerns the welfare of all. I mean the transmission of intelligible signals, or perhaps even power, to any distance without the use of wires. I am becoming daily more convinced of the practicability of the scheme; and though I know full well that the majority of scientific men will not believe that such results can be practically and immediately realized, yet I think that all consider the develop-

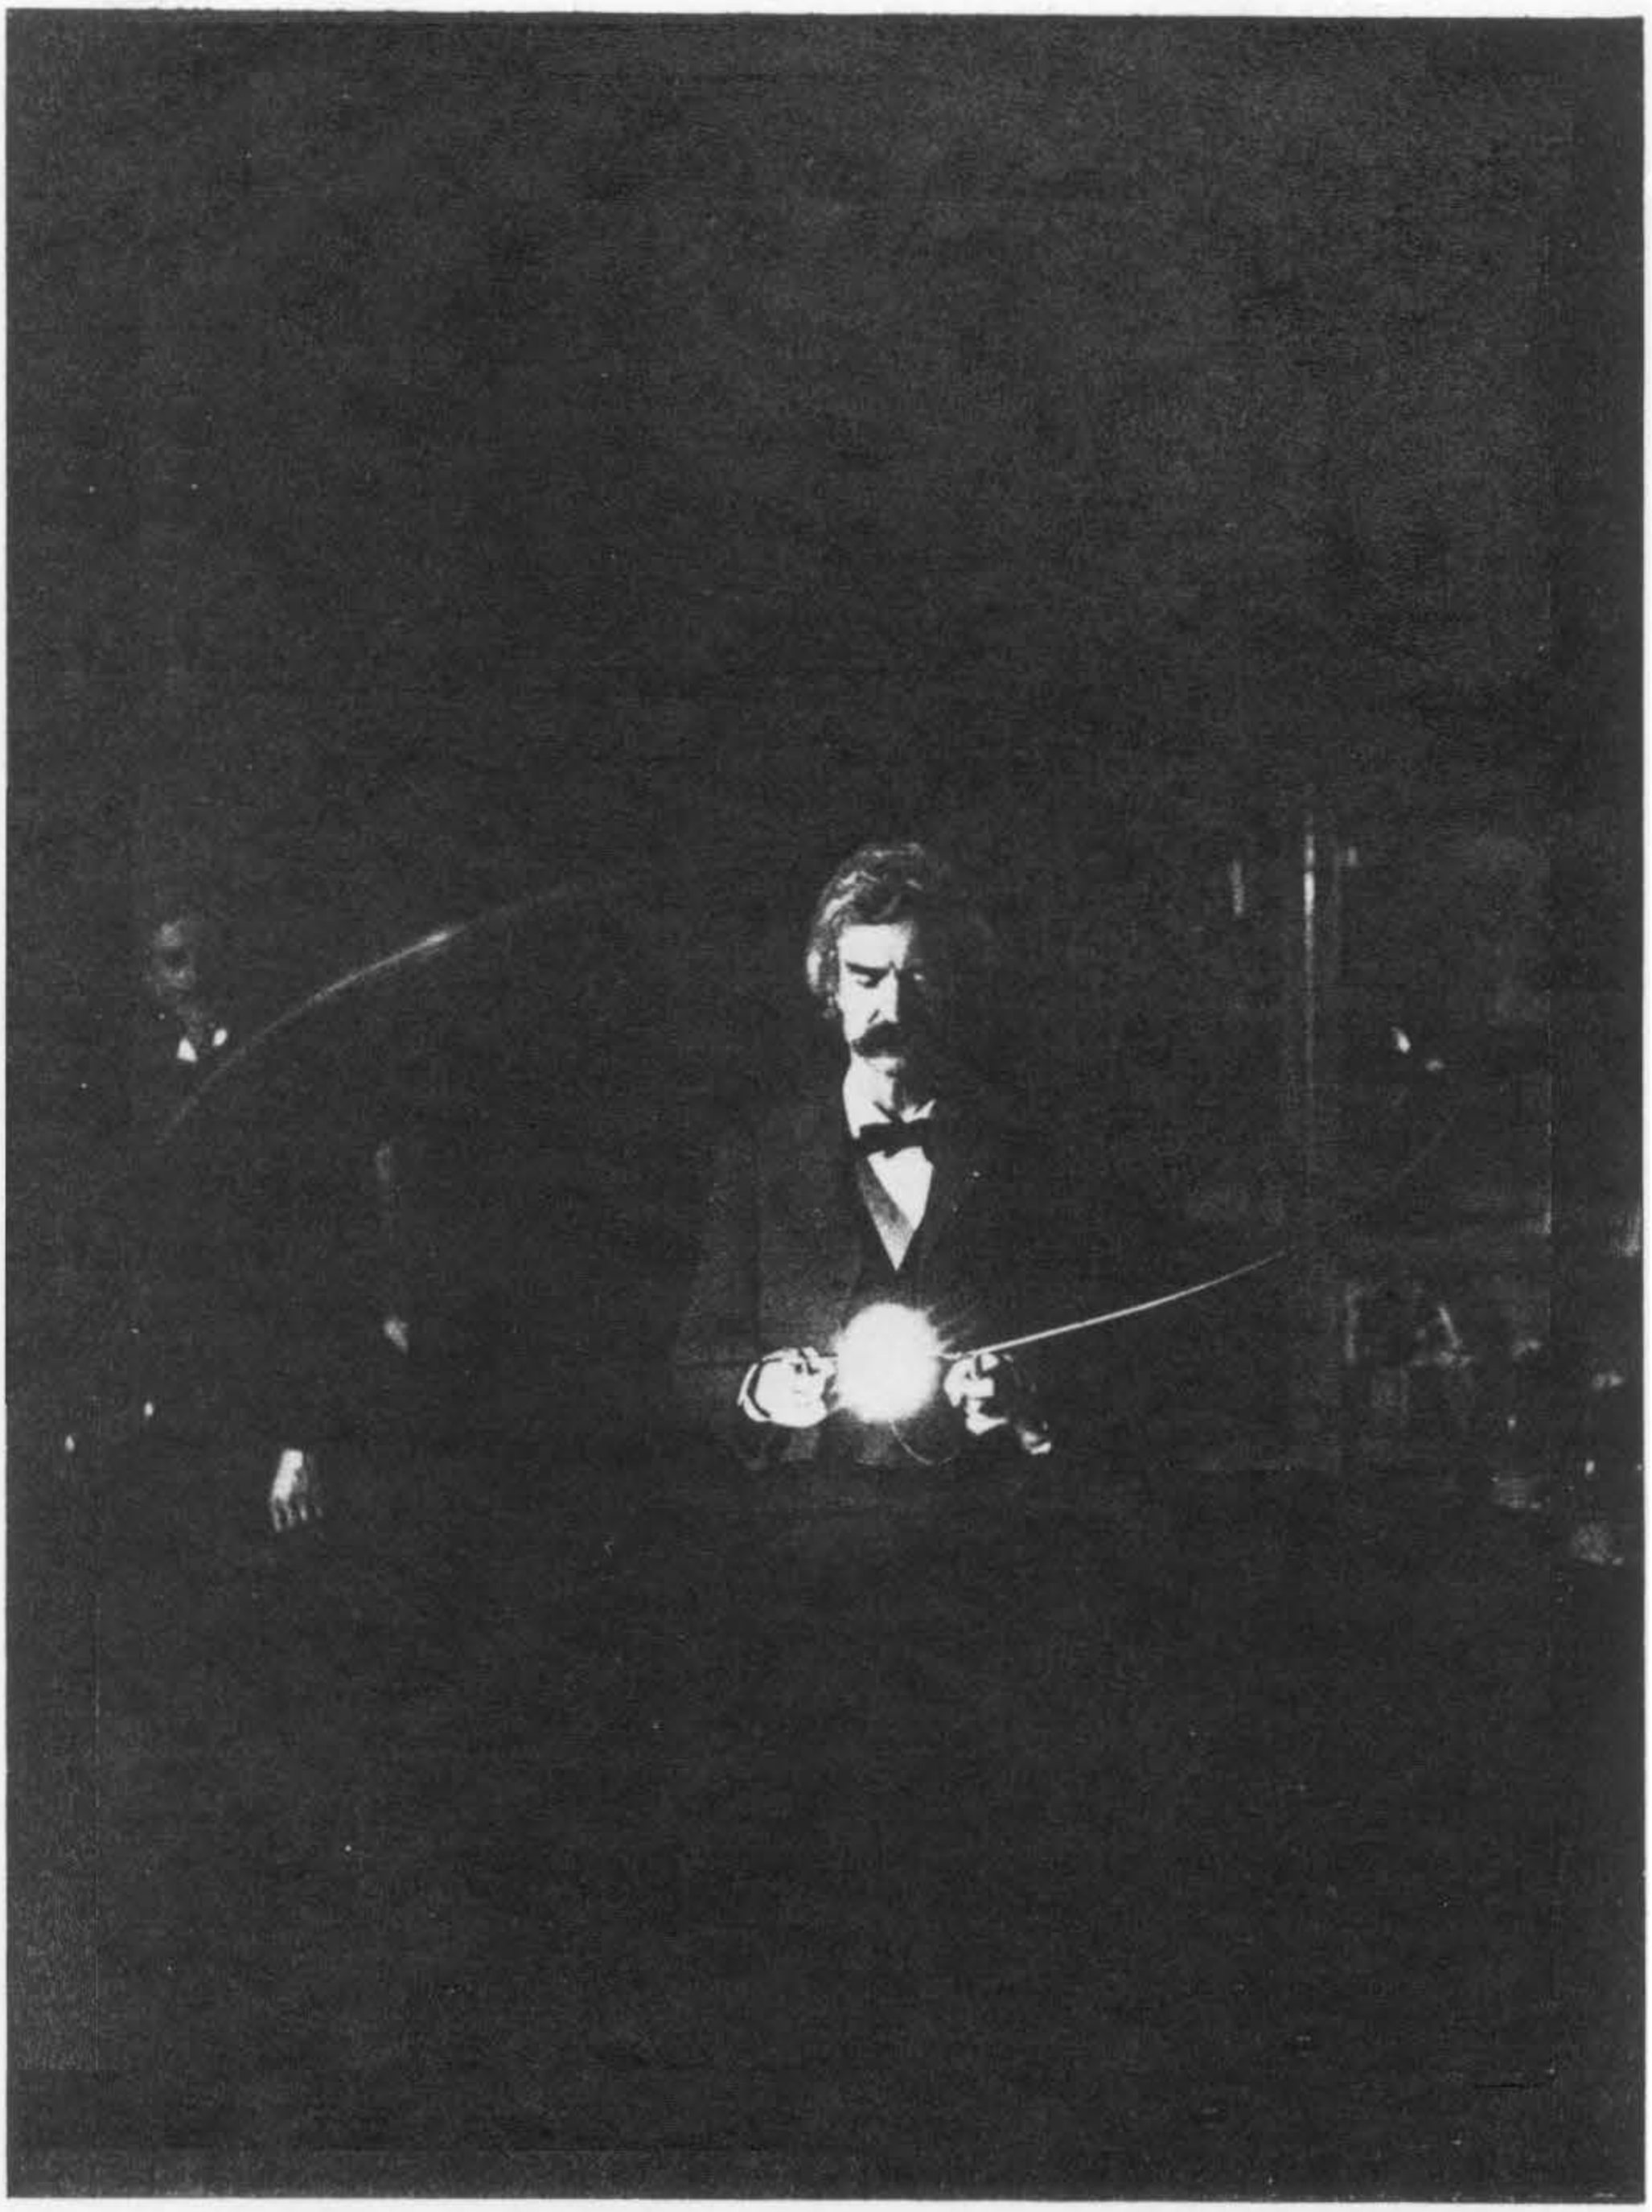

FIG. 13. SIMILAR EXPERIMENT, THE HIGH-TENSION CURRENT BEING PASSED THROUGH THE BODY BEFORE IT BRINGS THE LAMPS TO INCANDESCENCE. THE LOOP IS HELD OVER THE RESONATING COIL BY MR. CLEMENS (MARK TWAIN). (FROM A FLASH-LIGHT PHOTOGRAPH.)

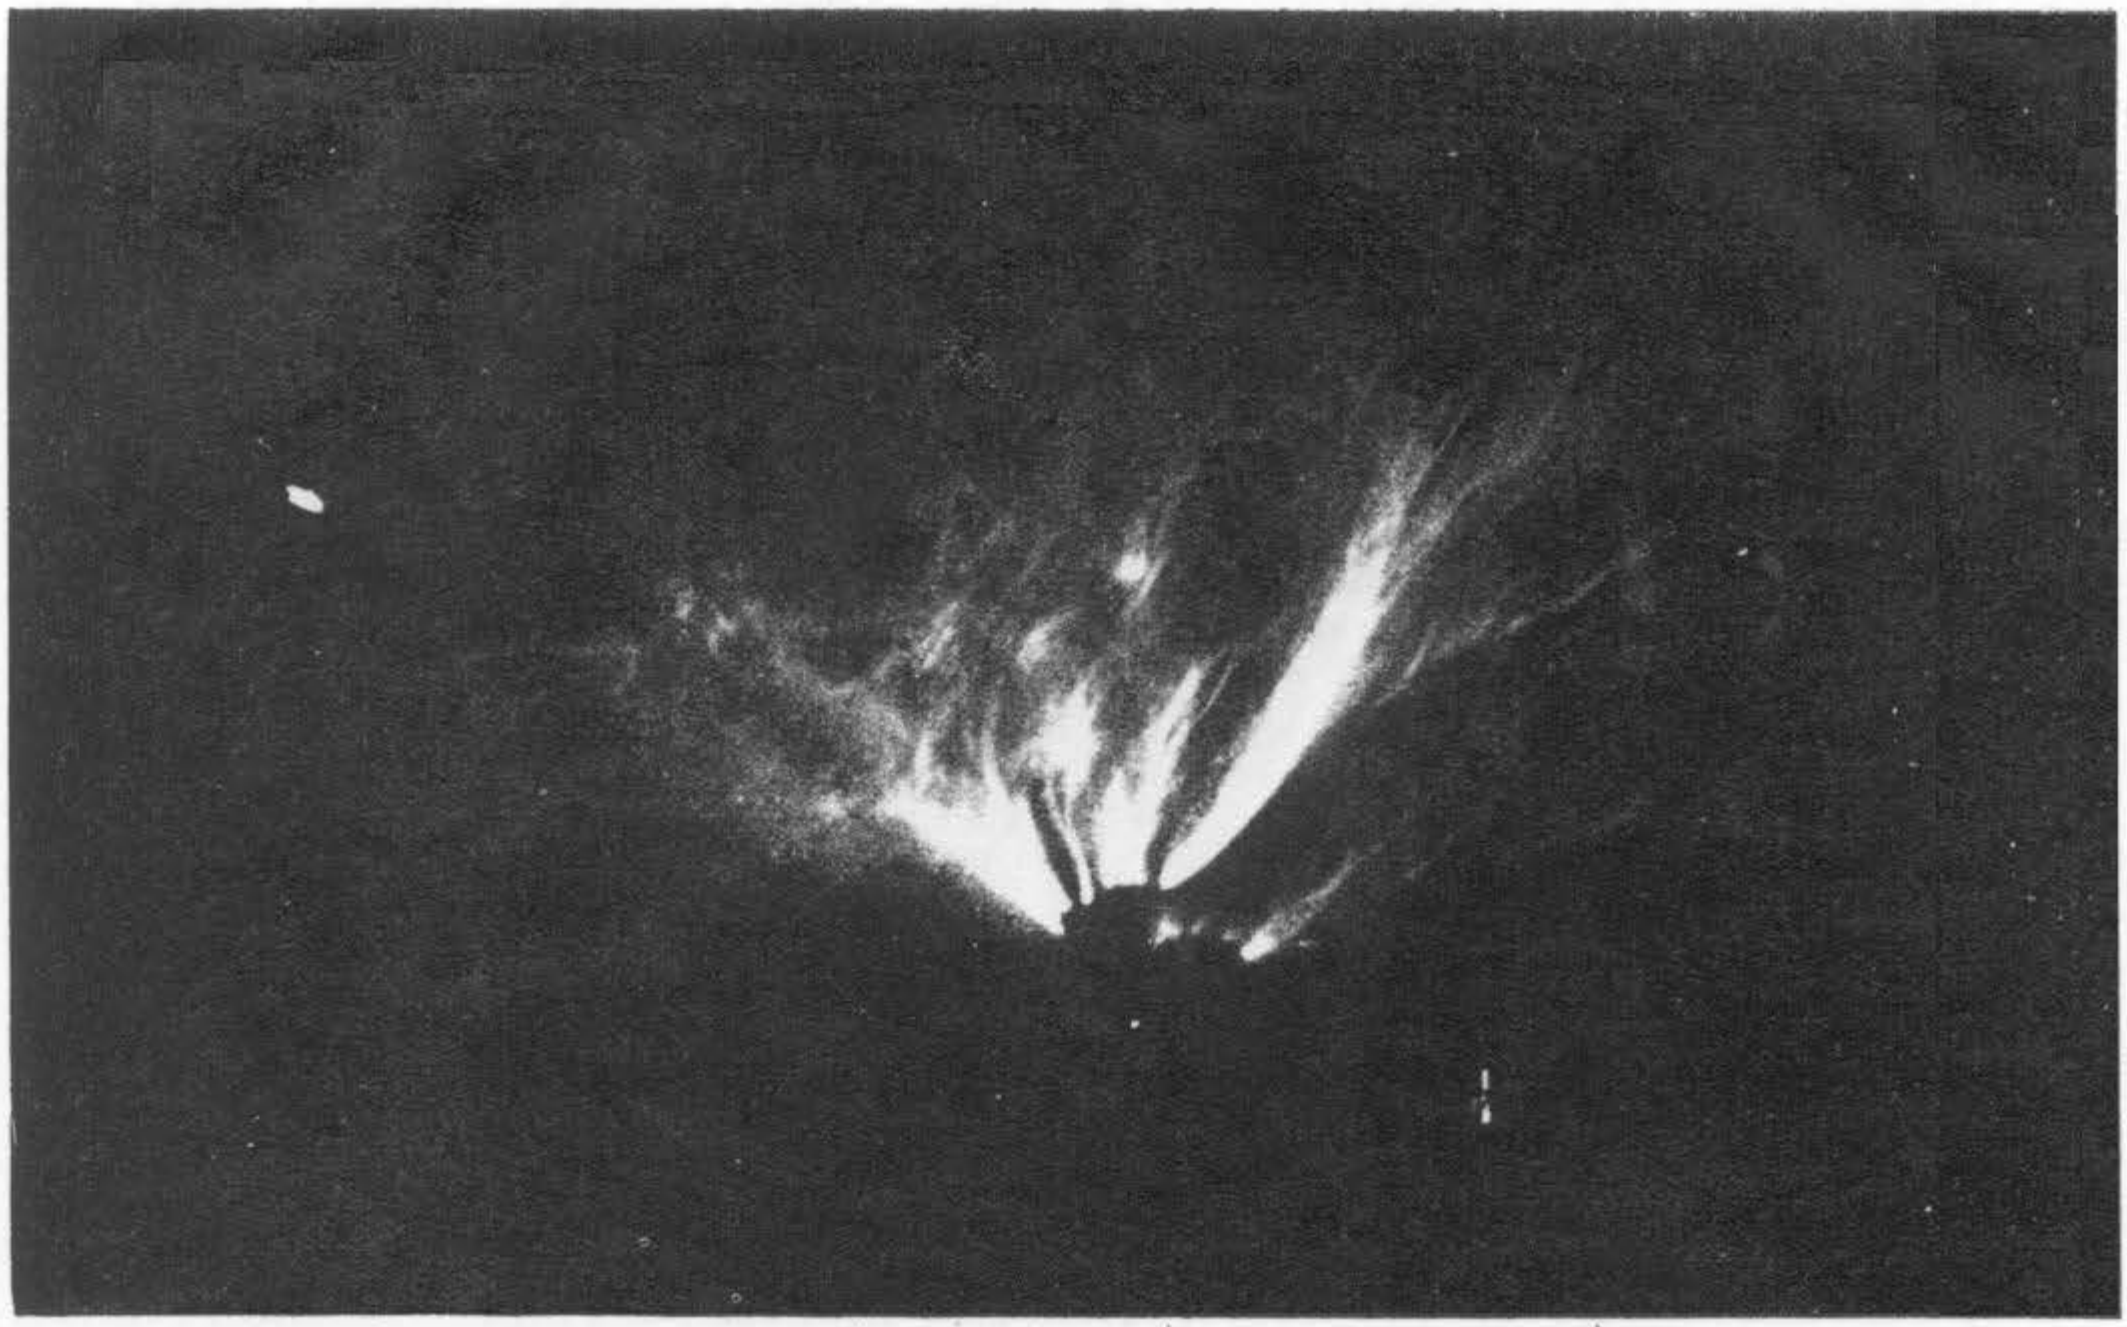

FIG. 14. EFFECT OF ELECTRICAL DISCHARGE FROM THE EARTH BY TESLA COIL. (PHOTOGRAPHED BY ITS OWN LIGHT.)

ments of recent years by a number of workers to have been such as to encourage thought and experiment in this direction. My conviction has grown so strong that I no longer look upon this plan of energy or intelligence transmission as a mere theoretical possibility, but as a serious problem in electrical engineering which must be carried out some day. The idea of transmitting intelligence without wire is the natural outcome of the most recent results of electrical investigations. Some enthusiasts have expressed their belief that telephony to any distance by induction through the air is possible. I cannot stretch my imagination so far; but I do firmly believe that it is practicable to disturb by means of powerful machines the electrostatic condition of the earth, and thus transmit intelligible signals and perhaps power. In fact, what is there against the carrying out of such a scheme? We now know that electric vibration may be transmitted through a single conductor. Why, then, not try to avail ourselves of the earth for this purpose? We need not be frightened by the idea of distance. To the weary wanderer counting the mile-posts the earth may appear very large; but to that happiest of all men, the astronomer, who gazes at the heavens, and by their standard judges the magnitude of our globe, it appears very small. And so I think it must seem to the electrician; for when he considers the speed with which an electric disturbance is propagated through the earth, all his ideas of distance must completely vanish. A point of great importance would be first to know what is the capacity of the earth, and what charge does it contain of electricity.

DISTURBANCE AND DEMONSTRATION OF THE EARTH'S ELECTRICAL CHARGE.

PART of Mr. Tesla's more recent work has been in the direction here indicated; for in his oscillator he has not simply a new practical device, but a new implement of scientific research. With the oscillator, if he has not as yet actually determined the earth's electrical charge or "capacity," he has obtained striking effects which conclusively demonstrate that he has succeeded in disturbing it. He connects to the earth, by one of its ends, a coil (see Fig. 15) in which rapidly vibrating currents are produced, the other end being free in space. With this coil he does actually what one would be doing with a pump forcing air into an elastic football. At each alternate stroke the ball would expand and contract. But it is evident that such a ball, if filled with air, would, when suddenly expanded or contracted, vibrate at its own rate. Now if the strokes of the pump be so timed that they are in harmony with the individual vibrations of the ball, an intense vibration or surging will be obtained. The purple streamers of electricity thus elicited from the earth and pouring out to the ambient air are marvelous. Such a display is seen in Fig. 14, where the crown of the coil, tapering upward in a Peak of Teneriffe, flames with the outburst of a solar photosphere.

The currents which are made to pass in and out of the earth by means of this coil can also be directed upon the human body. An observer mounted on a chair, and touching the coil with a metal rod, can, by careful adjustments, divert enough of it upon himself to cause its manifestation from and around him in splinters of light. This halo effect, obtained by sending the electricity of the earth through a human being,—the highest charge positively ever given in safety,—

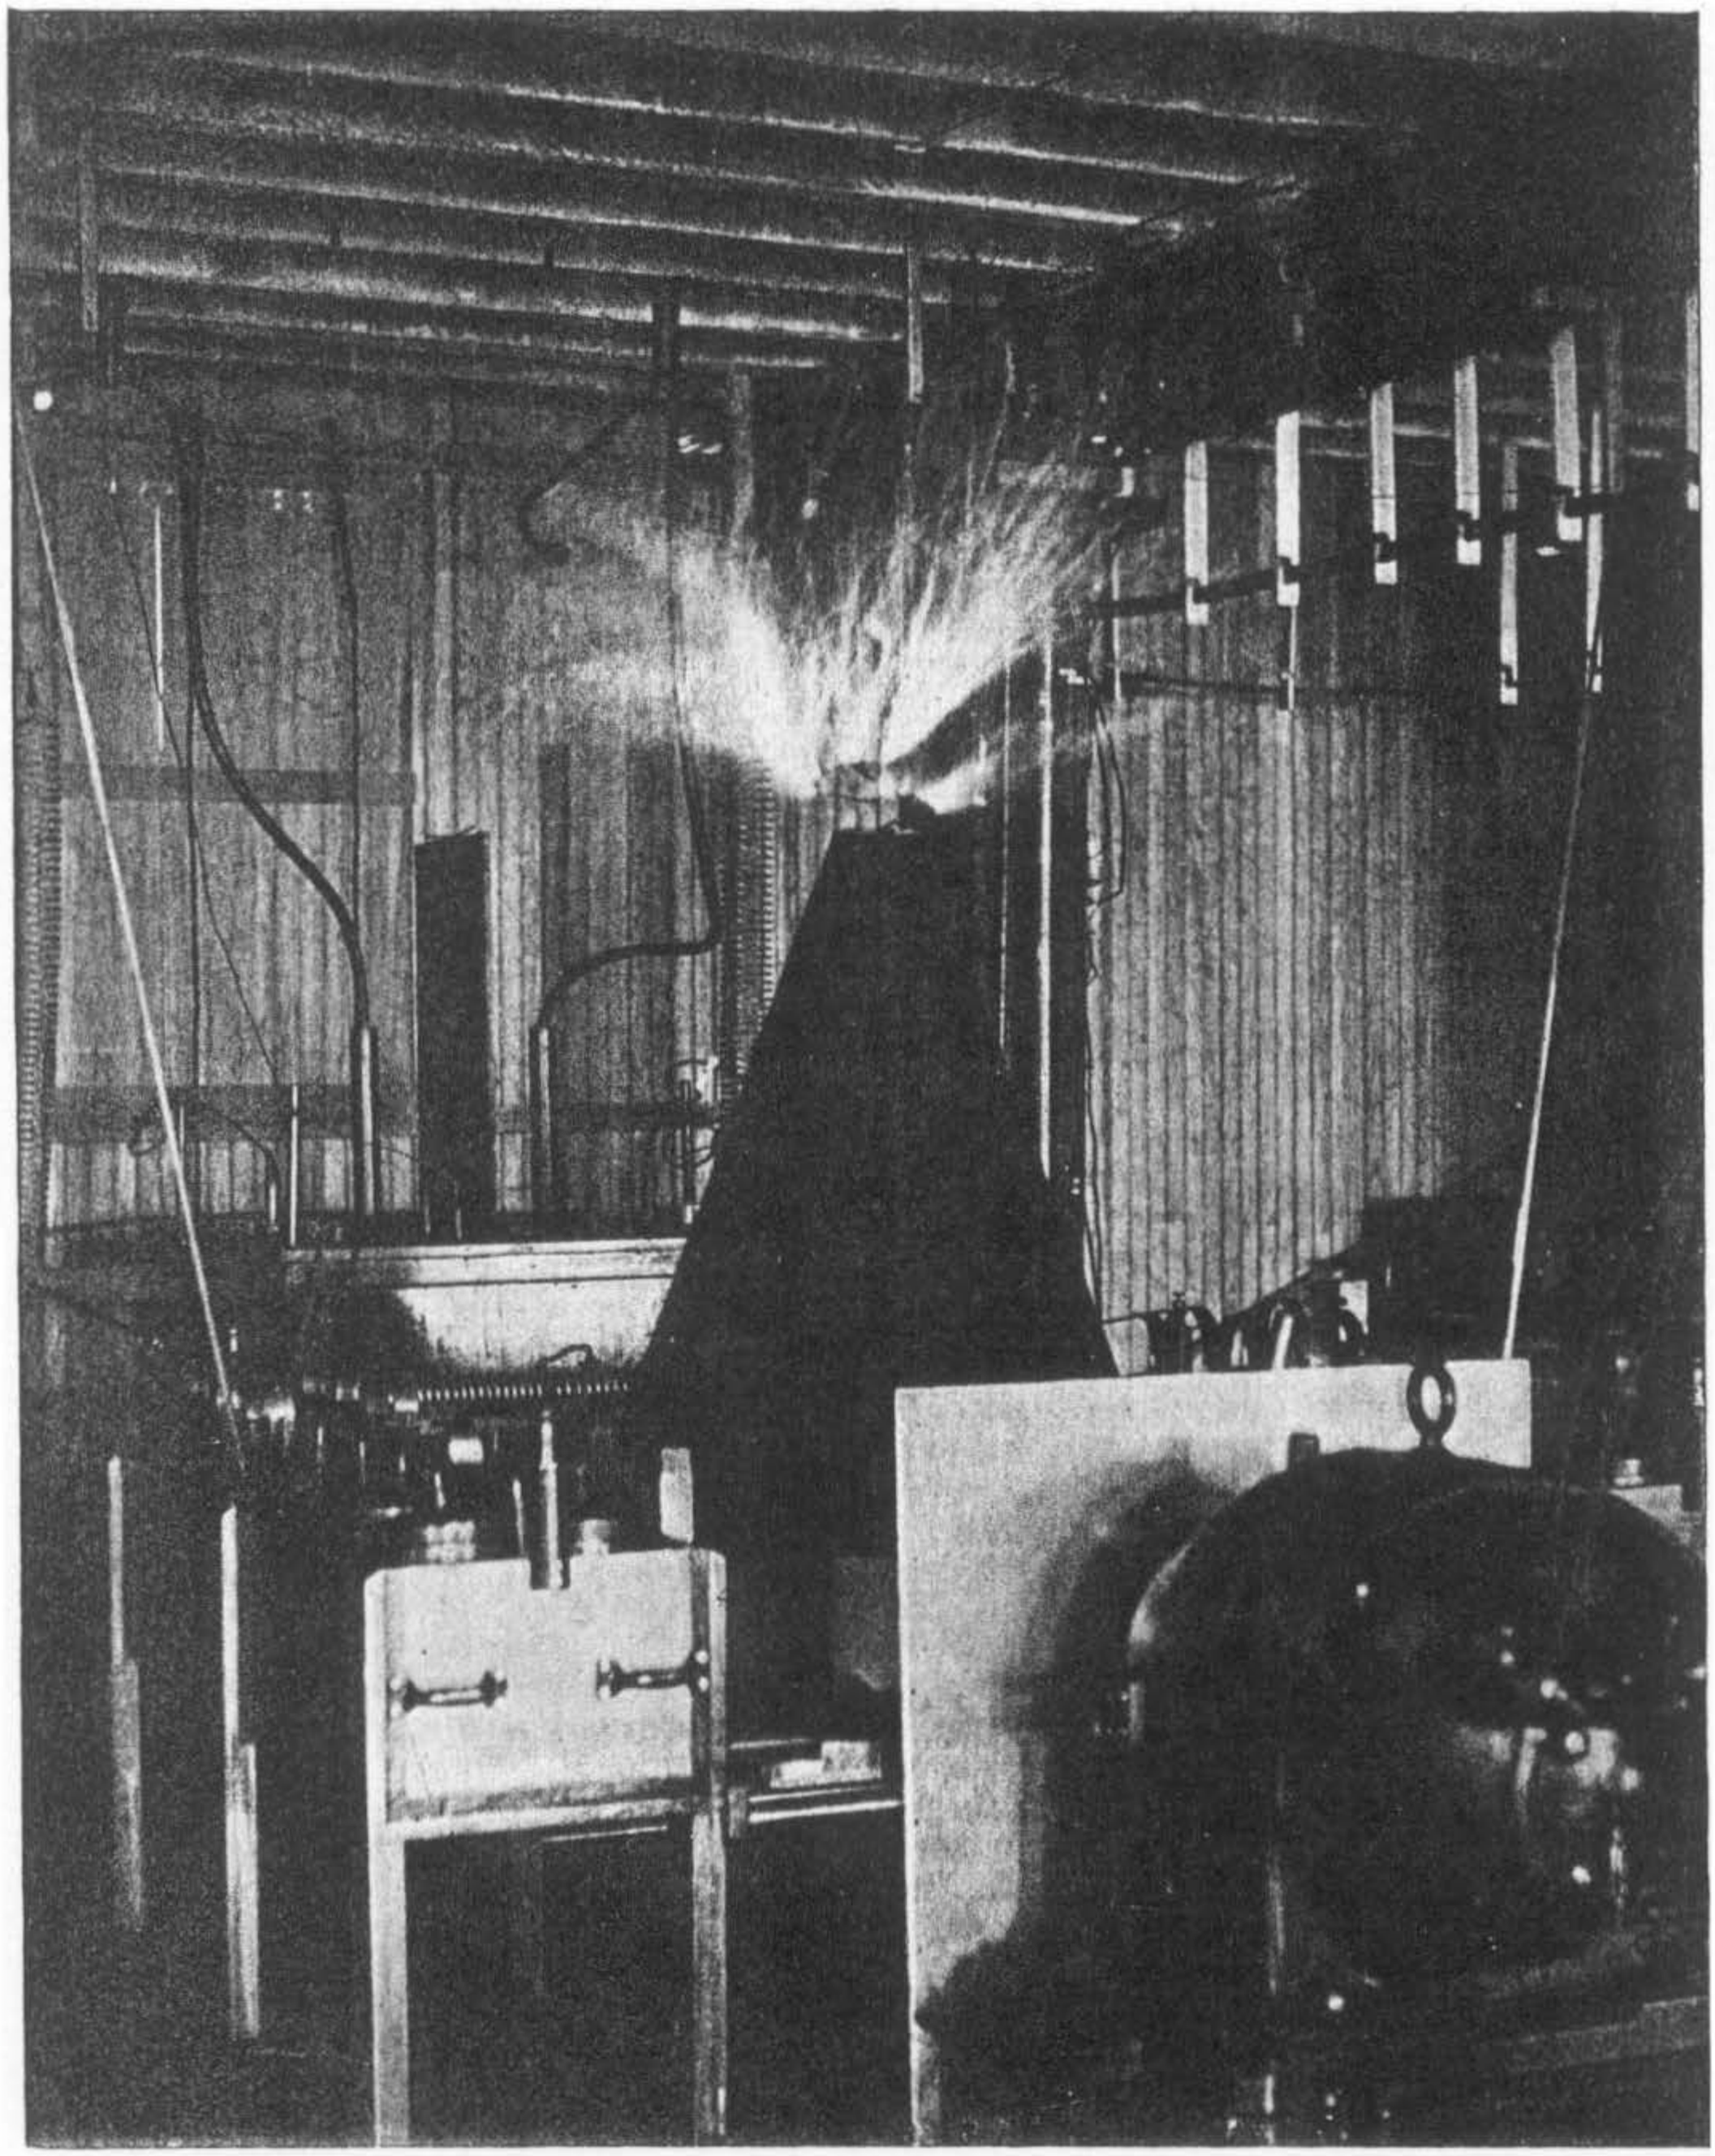

FIG. 15. TESLA COIL FOR ASCERTAINING AND DISCHARGING THE ELECTRICITY OF THE EARTH. THE STREAMERS AT TOP OF COIL ARE OF PURPLE HUE, AND IN FORM RESEMBLE FILAMENTS OF SEAWEED, THE EFFECT OF MASS BEING CAUSED BY PROLONGED EXPOSURE OF FLASH-LIGHT NEGATIVE.

is, to say the least, curious, and deeply suggestive. Mr. Tesla's temerity in trying the effect first upon his own person can be justified only by his close and accurate calculation of what the amount of the discharge from the earth would be.

Considering that in the adjustments necessary here, a small length of wire or a small body of any kind added to the coil or brought into its vicinity may destroy entirely all effect, one can imagine the pleasure which the investigator feels when thus rewarded by unique phenomena. After searching with patient toil for two or three years after a result calculated in advance, he is compensated by being able to wit-

ness a most magnificent display of fiery streams and lightning discharges breaking out from the tip of the wire with the roar of a gas-well. Aside from their deep scientific import and their wondrous fascination as a spectacle, such effects point to many new realizations making for the higher welfare of the human race. The transmission of power and intelligence is but one thing; the modification of climatic conditions may be another. Perchance we shall "call up" Mars in this way some day, the electrical charge of both planets being utilized in signals.

Here are great results, lofty aims, and noble ideas; and yet they are but a beggarly few of all those with which Mr. Tesla, by his simple, modest work, has associated his name during recent years. He is not an impracticable visionary, but a worker who, with solid achievements behind him, seeks larger and better ones that lie before, as well as fuller knowledge. I have ventured to supplement data as to his late inventions by some of his views as to the ether, which throughout this presentation of his work has been treated familiarly as the maid-of-all-work of the universe. All our explanations of things are but half-way houses to the ultimate facts. It may be said, then, in conclusion, that while Mr. Tesla does not hold Professor Oliver Lodge's ingenious but intricate notion of two electricities and two ethers, and of the ether as itself electricity, he does belong to what Lord Kelvin has spoken of as the nineteenth-century school of plenum, accepting one ether for light, heat, electricity, and magnetism, outward manifestations of an inward unity whose secret we shall some day learn.

Thomas Commerford Martin.

IN TESLA'S LABORATORY.

HERE in the dark what ghostly figures press!—
No phantom of the Past, or grim or sad;
No wailing spirit of woe; no specter, clad
In white and wandering cloud, whose dumb distress
Is that its crime it never may confess;
No shape from the strewn sea; nor they that add
The link of Life and Death—the tearless mad,
That live nor die in dreary nothingness:

But blessèd spirits waiting to be born—
Thoughts, to unlock the fettering chains of Things;
The Better Time; the Universal Good.
Their smile is like the joyous break of morn;
How fair, how near, how wistfully they brood!
Listen! that murmur is of angels' wings.

Robert Underwood Johnson.

Tesla's Laboratory Burned.

The laboratory of Nikola Tesla was burned on March 13th with its entire contents. The building in which his laboratory was located was at 33 and 35 South Fifth Ave., New York. The entire building was consumed, and the contents are a total loss. The fire was discovered between two and three o'clock in the morning. The fire gained such headway that it was soon beyond control. The experimental apparatus, models, plans, etc., in the laboratory, whose value can not be estimated in dollars and cents, were destroyed. The loss is felt not only by the wonderful investigator and inventor himself, but by the world at large. The work which was being done by Tesla, received the attention of all scientific and technical persons. A new laboratory is being fitted up and the work taken up again.

Engineering Magazine April 1895

THE BURNING OF TESLA'S LABORATORY.

By Thomas Commerford Martin.

OF Tycho Brahe's famous observatory at Uraniburg remain to-day but a mound of earth and a couple of holes. The same inventory would aptly apply to all that is left of the upper floor where Nikola Tesla has of late years been carrying on his suggestive and beautiful demonstrations in electricity. Two tottering brick walls and the yawning jaws of a sombre cavity aswim with black water and oil were all that could be seen on the morning of March 13 of a laboratory which to all who had visited it was one of the most interesting spots on earth. Beset by the squalor and clamor of plebeian South Fifth Avenue, the building was unpretentious, and its lower stories were given up to the prosaic details of an iron-pipe cutting business. Commonplace also was the origin of the disaster. A flaring gas jet, oil-soaked floors, and a "watchman" have been heard of before as an effective combination for midnight fires.

It has been curiously pathetic to note how universal was the expression of sympathy with Mr. Tesla in his loss. The newspaper dealers in the marvelous had been so relentlessly active in attempting to describe what they imagined to be going on in the laboratory that they experienced no difficulty in arousing regret as to the magnitude of the loss. But even now, if the average citizen were asked to explain definitely what he was grieving about, he would hesitate to answer. Impressions as to the laboratory have been mixed and weird. For example, one vivid young lady of the press, in her anxiety to be instructive, went so far as to depict herself undergoing a brilliant electrical ordeal that is possible only with the body entirely naked. This grotesque kind of misrepresentation has had vastly more terrors for Mr. Tesla than even the grim episode of last month. Nothing is so absurd as to suppose that inventors of his stamp relish the derogatory *persiflage* of the highly-colored articles that purport to reveal them and their work to the lay public. On the contrary, if it were not all so puerile, it would agonize men striving simply after scientific results and appreciative solely of scientific approval thus to be depicted in the *rôle* of charlatans,—that of a

> Katerfelto, with his hair on end,
> At his own wonders wondering for his bread.

Happily, the Tesla laboratory was visited not alone by irresponsible purveyors of popular misinformation, eager for a new topic to be handled with exhaustive inaccuracy. Happily, the selfish lion-hunters

of society have not been the only other class to which Mr. Tesla had an opportunity of presenting, with his unwearied good nature, new theories, new phenomena, and new apparatus. Happily, before the copper, glass, and insulation melted, physicists, electricians, and representative men in art and literature were able to see and judge for themselves what was forward. Indeed the pressure to secure an *entrée* to the laboratory had of recent months been extreme; and, now that the fire has occurred, perhaps it is as well that Mr. Tesla's imperative refusals once and again had their edges turned. The occasions are certainly rare when an inventor draws general notice to himself; and this is natural, for inventions deal chiefly with outward, material things. A poet or an artist can enter by his work into the life-blood of a people, and becomes part of their soul and growth. An ordinary inventor is more often like a man cutting his initials high up in the young bark of a sapling. The stem rises and expands, but the notches harden and stay ever at the same height, and are foreign to the tree's vital processes. At rare intervals the public becomes dimly conscious of new inventions that touch the arteries of social being; and then it is vaguely, but deeply, stirred. These inventions are generically such as affect and change our methods of obtaining light, heat, and power, our modes of travel, and the transmission of intelligence. The public had learned, more by intuition than knowledge, that Mr. Tesla was at work in each of these fields.

The Tesla laboratory was, in a sense, a private museum. The owner kept in it many souvenirs of bygone toil and experiment, and an important part of his records. During the past ten years Mr. Tesla has done an enormous amount of original experimentation, and it was all represented in the contents of the laboratory. His priority and preeminence in the polyphase current domain, which has been created by the development of his principle of the "rotating field," was richly exemplified by models and parts of single, two, three, and multiphase motors of all kinds. Some of the pieces showed how careful of his material the inventor always was. A close observer could discern that he had used it sometimes a dozen ways in a dozen forms. Readers of the ENGINEERING MAGAZINE may remember to have seen these relics in Electricity Building at the World's Fair, as well as the curious ring wound for two-phase circuits over a smooth disc upon which copper balls revolved at wild speed, or near which other bodies could be set spinning rapidly. This illustrated graphically the manner in which Mr. Tesla was able in his motors to dispense with commutators and brushes. Another notable class of apparatus in the laboratory was that employed for researches into the qualities and effects of currents of high potential and high frequency. Mr. Tesla's name is peculiarly associated with this work, and his too infrequent lectures have described a wide range of results obtained in lighting novel electric lamps, or empty bulbs, in free space, without any connection with the distant wires or machinery. In this group may be included his early dynamos for generating high-frequency currents, one of them giving as high as thirty thousand alternations per second; and of equal interest were the disruptive discharge coils designed and built specially to demonstrate a number of recondite and startling discharge phenomena. There were also several unique appliances with which novel conditions could be studied in insulation, induction, impedance, and resonance.

But that which was of largest interest to everybody was the group of oscillators. In the new machine to which he gave quite appropriately the name of "oscillator," Mr. Tesla had blended or merged the dynamo and steam engine, seeking thereby to secure a far higher efficiency than both could give individually at their best. It is curiously typical of the man that he had no sooner placed in the hands of electricians the means for the economical long-distance transmission of water powers—his system being adopted widely, for example, at Niagara—than he threw himself on the problems of getting electrical current more cheaply from steam; and that, while lavishly generous in personal intercourse, he is ever fighting savagely the waste that goes on in our utilization of Nature's resources. It is something to have rendered the waterfalls more useful, but one's sympathies must equally go out to work that is aimed at greater economy of coal. If each 10 hours' work of 1 h. p. from a steam engine requires a total of 6 tons of coal every year, and if that is subject to further tremendous losses when turned into electric current, it is worth the effort to aim at less wasteful processes. This is the goal of Mr. Tesla's oscillator, and he is sanguine enough to believe that he has reached it.

The oscillator is simply a steam chest dissociated from all the orthodox governing mechanism, and joined in a new partnership with sets of electro-magnetic coils, into whose fields of force it thrusts reciprocatively armatures carried by its pistons, the regulation being subtly accomplished by the currents that are thus set up. The reduction in bulk is very striking, but obvious; while the reduction in steam consumption and the higher value of the currents are both elements that Mr. Tesla believes he has insured to a significant degree. He makes few mistakes.

Only one oscillator had ever been shown in public,—that, namely, which Mr. Tesla used in his lecture before the Electrical Congress at Chicago, in August, 1893, employing compressed air as the working fluid, for convenience. That machine and later types were all to be seen at the laboratory. The most advanced form shown to visitors

was a very neat mechanism, entirely practical and successful, by means of which the laboratory had been lighted for months as well as furnished with current for the work done with the high-frequency apparatus alluded to above. It was run at 350 lbs. steam pressure; but, although there was no packing, no leakage of steam could be detected. Two pistons vibrated in opposite phase eighty times per second. The vibrations of these pistons past two sets of electromagnets developed current that was led to a bank of fifty or sixty incandescent lamps, which were lighted up to full candle-power and were steadiness itself in illumination. Current was also furnished by the machine to four arc lamps and to motors, as well as to devices of a fascinating nature, by means of which Mr. Tesla would light up tubes or ordinary incandescent lamps in the centre of the laboratory,—a room perhaps 40 feet by 80. He also used the current to experiment boldly with the electrical charge of the earth itself. One cannot but regret that all these first fruits of penetrative investigation have gone down in the wreck at South Fifth Avenue. They are being swiftly reproduced by incessant labor on the part of the dauntless inventor, but as the first, and, for awhile, the only exemplars of their kind, they are now touched with a sentimental interest unworthy neither of those who feel it or of the objects themselves.

Perhaps the most painful loss of all is the destruction of Mr. Tesla's notes and papers. His memory is all right, and flashes on any experiment of the past with the revealing power of a search-light; but when can leisure now be won to jot things down that, marking achievement on one hand, might also save other experimenters years of toil, and that would show to capital as well the doors open as the paths that are blind. The loss falls least heavily on the loser. Like many another tireless experimenter, he hoped to give the world with due rapidity the report of his failures as well as of his discoveries, but he had not counted on casual destruction of memorabilia by fire as one of the obstacles in his way. Mr. Tesla had taken the papers to his laboratory so that he might work on them in brief leisure spells, and was thus the victim of his own conscientious endeavor to be of use to his fellow-electricians. There seems to be a fate about such things. Galileo's own son, from filial religious motives, destroyed some of his father's dearest manuscripts; and it was no less a friend than John Stuart Mill who burnt up for poor Carlyle the first volume of the unprinted "French Revolution." It took Carlyle four weeks, and heaps of the trashiest novels, to quiet his mind after the miserable accident. Tesla was at work again with clenched determination while the ashes of his hopes lay hot.

THE

Electrical Engineer.

Vol. XIX. APRIL 3, 1895. No. 361.

STAGES AND TYPES OF THE TESLA OSCILLATOR.

Tesla Coil Demonstrating Earth's Electrical Charge (Sketched from April Century). Fig. 9.

THE recent destruction by fire of the building in New York City in which Mr. Tesla's laboratory was situated, and the consequent wreck of all his valuable apparatus, lends special value to the illustrations herewith, never before shown, of a number of Tesla oscillators. It will interest our readers to know that the engravings were made about a year ago, but were laid aside awaiting the completion of other and later work, all of which Mr. Tesla proposed to bring in rounded shape before one or other of the scientific societies, accompanied by actual demonstrations with the machinery. Fate has willed otherwise, and these pictures are practically all that can now be shown, except the engraving secured by the *Century Magazine* of the latest "double oscillator" and printed by that publication in its April issue. In view of the fire, it becomes proper and desirable to bring these machines to general notice, and we have obtained Mr. Tesla's consent to our doing so at this juncture.

In order to render the series of Tesla oscillators in some degree complete and consecutive, we have reproduced here from THE ELECTRICAL ENGINEER of Nov. 8, 1893, the cut of one of the machines shown before the Electrical Congress, at Chicago, using compressed air as the working fluid (Fig. 1.) It will be remembered that the principle involved in the oscillator is that of oscillating a coil or magnet, with great economy of energy, in an intense field, and thus generating current on terms of very high efficiency and regularity, as well as with marked diminution in size and weight of apparatus. The engine resolves itself down to a chest or cylinder for the working fluid and the piston for carrying the armature. The article in the ENGINEER to which we have referred above gives a number of details, with a diagram, and other data will be found in Mr. Martin's work on Mr. Tesla's inventions.

Fig. 2 was one of the oscillators shown at Chicago in August, 1893. It was actuated by compressed air there during the lecture delivered by Mr. Tesla. The machine consists of an engine mounted on an ornamental column, carrying on top a generator similar to that shown in E of Fig. 7.

An analogous form is shown in Fig. 3, without the generator. In the box on top of the column there is a

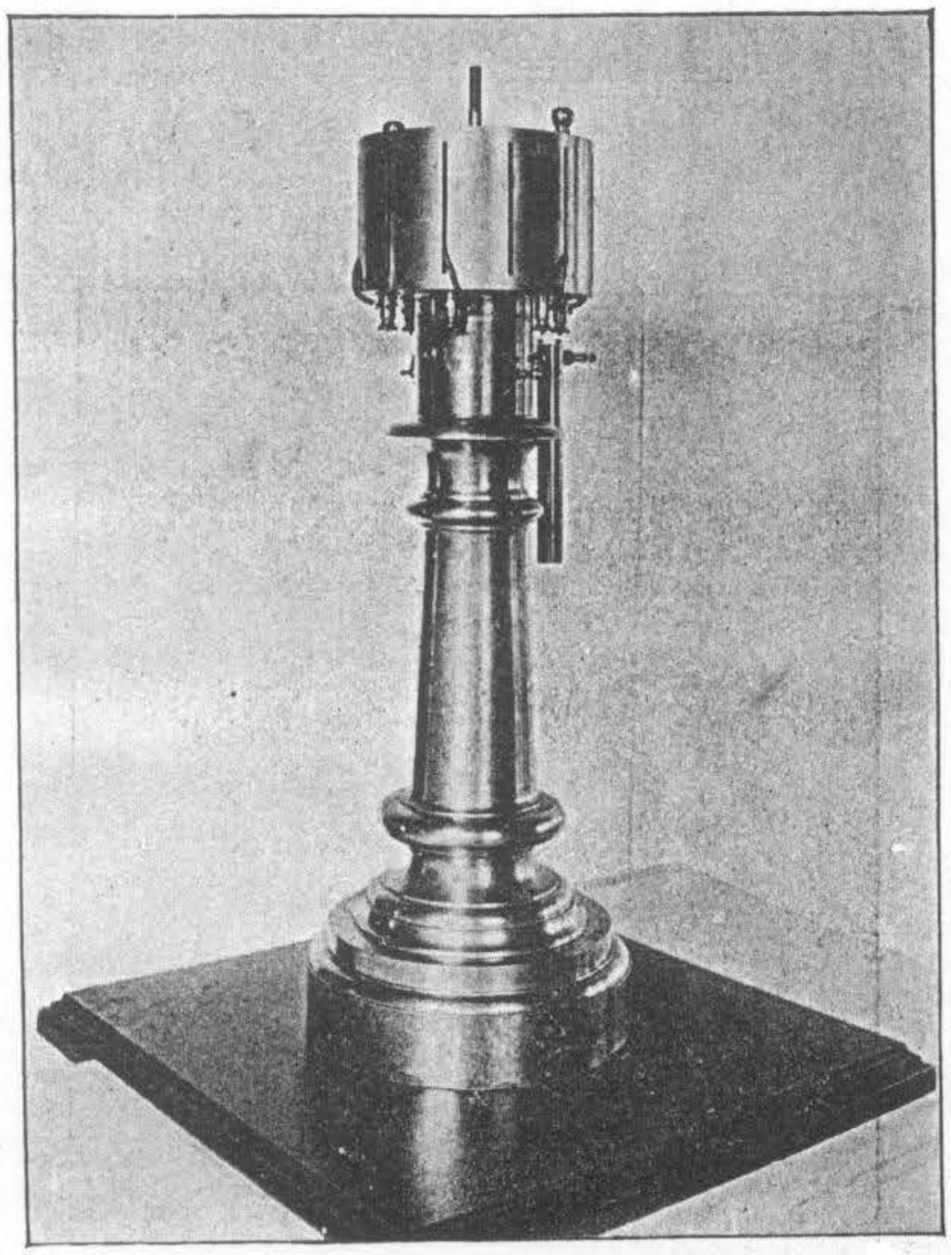

FIG. 2.

TYPES OF TESLA OSCILLATOR.

FIG. 8.—RECENT FORM OF TESLA OSCILLATOR.

very strong air spring. The construction is such that the engine is always in exact synchronism with the vibrations of this spring. The engine can do nothing else but keep the spring vibrating, and eventually will alter the amplitude of the vibration, but the period remains the same, i. e., it is the natural period of vibration of the system. The recoil of the spring is, of course, incomparably greater than the impulse received each time from the engine. There is a chamber around the spring which can be maintained at a constant temperature by any usual means. As the frictional losses are vanishingly small compared with the enormous elastic force, the isochronism is perfect.

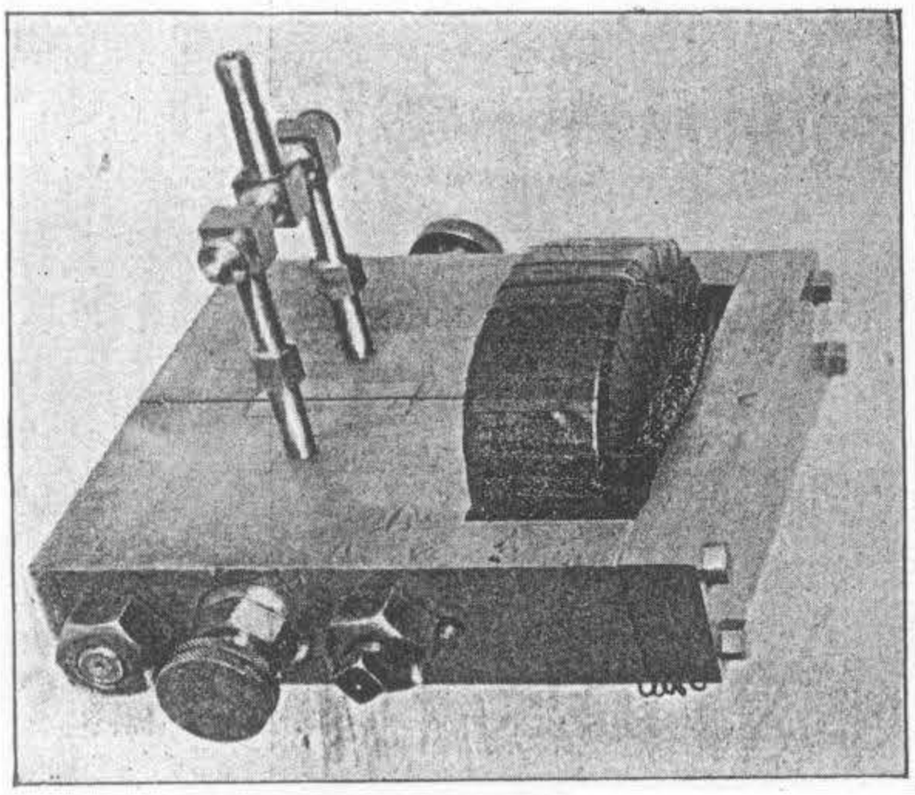
In Fig. 4, another quite distinct type is shown. A small oscillator is mounted on a stand with a dynamo of somewhat unconventional form. This dynamo comprises a circular field magnet in which are arranged to move on each side circular coils. The coils are carried by an arbor which is connected directly to the little engine; and the currents are produced by vibrating the coils within the field of the magnet. In this form, Mr. Tesla says, there is absolutely no useless wire, as all of it is within the field and all equally active.

In Fig. 5, a more advanced form of oscillator is shown, operated by steam and freely used for laboratory purposes. This minute machine had a capacity of 12 lights. It consisted of a small oscillator and a dynamo, the latter comprising a field magnet with its exciting coils and an armature merely of iron. The magnet had on its inside a number of pole projections upon which the induced coils were wound. The armature had projections of lesser number than those of the field. In this way the output of the dynamo was increased, by the number of teeth.

In Fig. 6 we have an interesting experimental apparatus consisting of a field magnet within which there is arranged to vibrate a tongue of steel carrying on its end a coil. This tongue and coil were vibrated in the strong field. There were adjusting screws on each side which allowed the attainment of any periodicity, within wide limits. This apparatus was used for scientific research solely.

Fig. 7 comprises a most interesting group of parts which were shown by Mr. Tesla in his demonstrations. Several of the instruments were used for the exemplification of novel features. The magnets in A, for example, were used to elucidate the principle of the preponderance of one impulse over the other in the current produced by

the oscillator and creating virtually the effect of a direct or continuous current. In B a magnet is shown which was vibrated. When the copper disc D, arranged to rotate freely in bearings, was held between the poles, i. e., in the field of the vibrating ring magnet, it was rotated in one direction, showing that the currents distributed in the



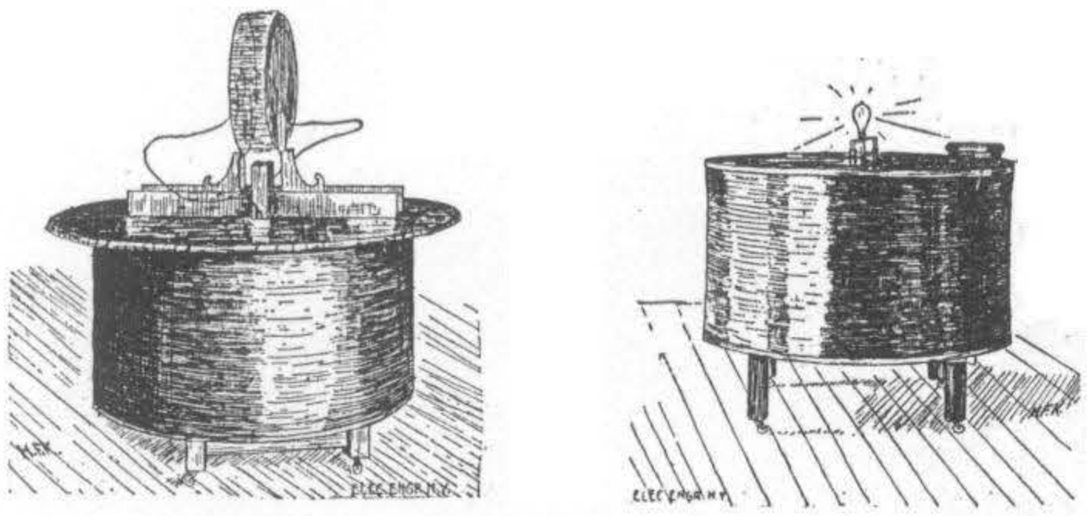


FIG. 6.

disc were asymmetrical. In other words, they were preponderating in one direction.

C, in Fig. 7, is a little motor used to illustrate the constancy or invariability of the speed of the oscillator. G was also a little motor with clockwork, which was used to count the revolutions. Both of these little motors were driven from one circuit, the difference of phase being obtained artificially. E was a little generator comprising three coils, two inducing and one induced; and an iron coil which was vibrated by the oscillator to which it was attached. F, H, I, J, K, are parts of an oscillator for short and long stroke respectively.

In Fig. 8, which we reproduce here by courtesy of the *Century Magazine*, is seen one of the latest types of the Tesla oscillator. It is a steam mechanism, but the "engine" part may be said to have disappeared, so far as that word implies an aggregation of fly wheel, governors, etc. On the one base were mounted two dynamos, or electro-magnetic generating systems and a small steam chest. There were two pistons which were vibrated by the

FIGS. 10 AND 11.—TESLA EXPERIMENTS.
(*Sketched from April Century.*)

steam 80 to 100 times a second. Each of the pistons carried an armature which was plunged reciprocatively into the field of the magnets. Normally the engine was run with the two pistons in opposite phase; but they could be set by an independent device in any phase. Above the chest was mounted an independent little oscillator, which in some experiments controlled the steam admission, and made the vibration of the engine quite independent of the load.

This oscillator was operated with steam at 350 pounds pressure, when it needed no packing, as there was no leakage. It was also used at pressures down to the ordinary 80 or 100 pounds. It was used to light up a bank of 50 or more incandescent lamps, some arc lamps, and to run various motors; while it also furnished current for a variety of most interesting and novel experiments, all of them suggestive of new departures in the electrical arts, including phosphorescent lighting, the transmission of intelligence long distances without wires, the utilization the earth's electrical charge, etc. Some of these branches of work are touched on, in a popular manner, in the April *Century*, from which we have made one or two sketches, in Figs. 9, 10 and 11, illustrative of the devices employed in connection with the oscillator.

Our readers will be glad to know that although, in the fire, Mr. Tesla's apparatus which we have shown above was practically wiped out of existence, the inventor has been most indefatigably at work ever since and will soon have reproduced his oscillator in its latest and most perfect form. There can be no doubt that in this appliance we have a mechanism for the simultaneous utilization of steam and generation of current under conditions that must effect large economies in every direction; while it should also prove a powerful instrument for exhaustive research.

TESLA EXPERIMENTS IN BERLIN.

THE latest addition to the repertoire of the Berlin "Urania," or scientific theatre, is a complete demonstration of the celebrated Tesla experiments with currents of high frequency and high potential. This lecture has been arranged by Prof. Spies and on a recent occasion he was assisted by no less a personage than Prince Henry, brother of the German Emperor. Prince Henry interposed his body between the high tension terminals, and held exhausted tubes glowing under the influence of the Tesla currents.

THE PRACTICAL TESLA OSCILLATOR.

When that notable assemblage of electricians, from whose ranks death has already removed one of its most shining lights, went forth from the lecture delivered by Mr. Tesla at the International Electrical Congress, in Chicago, in 1893, it is not too much to say that many came away with but a vague understanding of what the lecturer had sought to bring to their attention. At that lecture Mr. Tesla was too much engrossed in the description and the operation of his electrical and mechanical oscillator, to bring out clearly and sharply all the possibilities of this type of machine. Even since that time Mr. Tesla has been so absorbed in its development that he has had little time to elaborate on the facts which he brought out on that occasion. The late destruction by fire of practically all of Mr. Tesla's models has, fortunately, not deprived the world of the record of his work.

Thanks to the art of photography, we are enabled to present to our readers the article appearing on another page. The study of the evolution of a concept or machine must always prove instructive, and in the present instance the development of Mr. Tesla's oscillator from its original form constitutes a most valuable record of the origin and growth of an idea, the embodiment of which, in the opinion of its author, will make possible much that has heretofore been relegated to the realm of conjecture. Looking first at the most immediate application of the Tesla oscillator from the point of the steam engineer, a machine which permits of the employment of steam pressures of 300 pounds, or over, per square inch, practically without packing at the joints and without lubrication, at once gives the oscillator an advantage over the present type of steam engine, which a century has failed to secure for any type of the latter. If to this be added the absolute isochronous character of the oscillator over the widest ranges of load, there is gained another advantage which the highest skill of the steam engine builder has yet failed to accomplish fully in the most modern rotary steam engine. It is this absolute regularity of motion which is also destined to play an important part in the utilization of the currents generated through the medium of the oscillator in the attainment of those effects which Mr. Tesla deems essential to the accomplishment of one great problem of modern times, light without heat. While the theories on this point put forward by Mr. Tesla as the result of his experimental work have been called into question in some quarters, he is still as firmly convinced as ever of the correctness of his views. It is not to be denied, of course, that vacuum glow lighting effects can be obtained by other means, but Mr. Tesla is firmly convinced, we believe, that for the economical production of light without heat high potentials and high frequencies are indispensable elements, and that to obtain the highest perfection in this class of apparatus, practically absolute regularity in the production of the primary electrical impulses, which cannot be obtained by the ordinary forms of machinery, is necessary; and this is now made possible. The accomplishment of these immediate results made possible with the oscillator, both as a steam engine and as an electric generator, will, of itself, stamp it as a device of the first order of importance; and we may well leave to the future the working out of the problems which lie beyond and which Mr. Tesla holds forth as tangible possibilities of not distant years.

NIKOLA TESLA'S LOST APPARATUS

ILLUSTRATIONS AND DESCRIPTIONS OF SOME OF THE INVENTOR'S DEVICES DESTROYED BY FIRE—HIS GOOD FORTUNE IN HAVING HAD PHOTOGRAPHS MADE OF THIS APPARATUS MORE THAN A YEAR AGO—THE "OSCILLATOR" AND ITS WONDERFUL EFFICIENCY.

Nikola Tesla some time since established his right to be known as the most promising electrical inventor of to-day. When on March 13 last his laboratory, his workshop and all its contents, and most of his important records were totally destroyed by fire, the loss was felt by every one familiar with recent electrical developments.

Tesla, although an extremely modest man, is very widely known through his achievements in pure electrical science and through the many articles that have been written about him and his work by lay and technical writers. The loss which he recently sustained was a most serious one and called forth expressions of sympathy from every side. It resulted in his receiving one of the highest compliments ever paid to any man. This was from the pen of Charles A. Dana, editor of the New York *Sun*, and a warm admirer of Tesla. Mr. Dana wrote as follows:

> The destruction of Nikola Tesla's workshop, with its wonderful contents, is something more than a private calamity. It is a misfortune to the whole world. It is not in any degree an exaggeration to say that the men living at this time who are more important to the human race than this young gentleman can be counted on the fingers of one hand; perhaps on the thumb of one hand.

Immediately following the fire Mr. Tesla, instead of being prostrated by his misfortune, as reported in several daily newspapers, secured new quarters in which he began all over again the labor of years in the hope of reconstructing what had been totally wiped out. He is now busily engaged at this herculean task.

In view of the fact that Mr. Tesla's most important records were burned, it is extremely fortunate that the persuasions of Mr. Thomas Commerford Martin resulted in securing photographs of a number of pieces of apparatus which Mr. Tesla had developed and constructed more than a year ago. The illustrations which accompany this article were made from the photographs referred to. The half-tone plates were engraved at the time the photographs were taken, another fortunate circumstance, as the original prints were burned with everything else the Tesla laboratory contained.

Naturally, Mr. Tesla does not wish to have complete technical evidence of his work published abroad while he is in his present crippled condition, yet it is by his permission that these particulars are given here.

In the course of lectures, all too few in number, Mr. Tesla has at different times demonstrated before technical societies in this country and abroad a number of experiments wonderful in themselves and yet puny in comparison with the deep work of which they were but a feeble outgrowth. It has come to be pretty generally understood that the principal objects of Mr. Tesla's labors were the more efficient production of light, heat and power by electricity and the transmission of energy over long distances. His name is especially associated with the discovery of new phenomena resulting from his researches into the qualities and effects of high potential and high frequency currents. His first public lecture was based on these discoveries.

Since Tesla's discovery of the "rotating magnetic field" the long-distance transmission of alternating current from Niagara Falls has become possible. The basic idea of this discovery is to produce a circularly shifting magnetism instead of the well-known phenomenon of magnetism in a fixed position.

To the lay mind the most wonderful of all Tesla's experiments was the lighting of electric lamps or empty glass bulbs in free space, without any connection with the wires or generating apparatus. The light from these Tesla tubes is so intense that photographs taken by their illumination have been made with exposures of eight to 10 minutes.

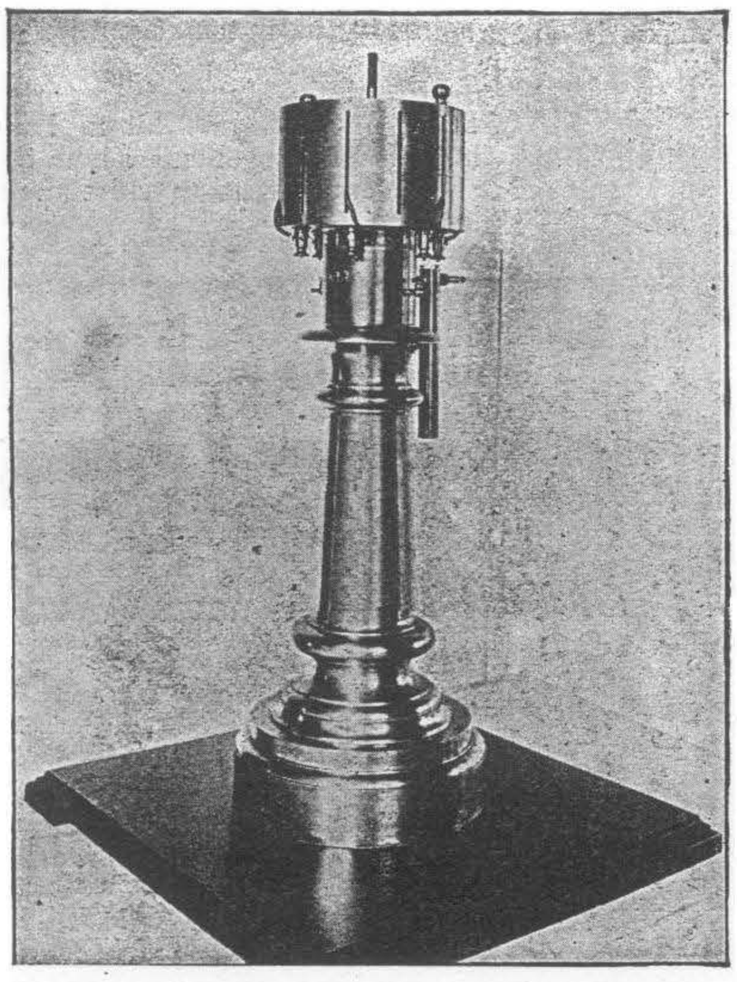

FIG. 1.—THE TESLA OSCILLATOR SHOWN AT CHICAGO IN 1893.

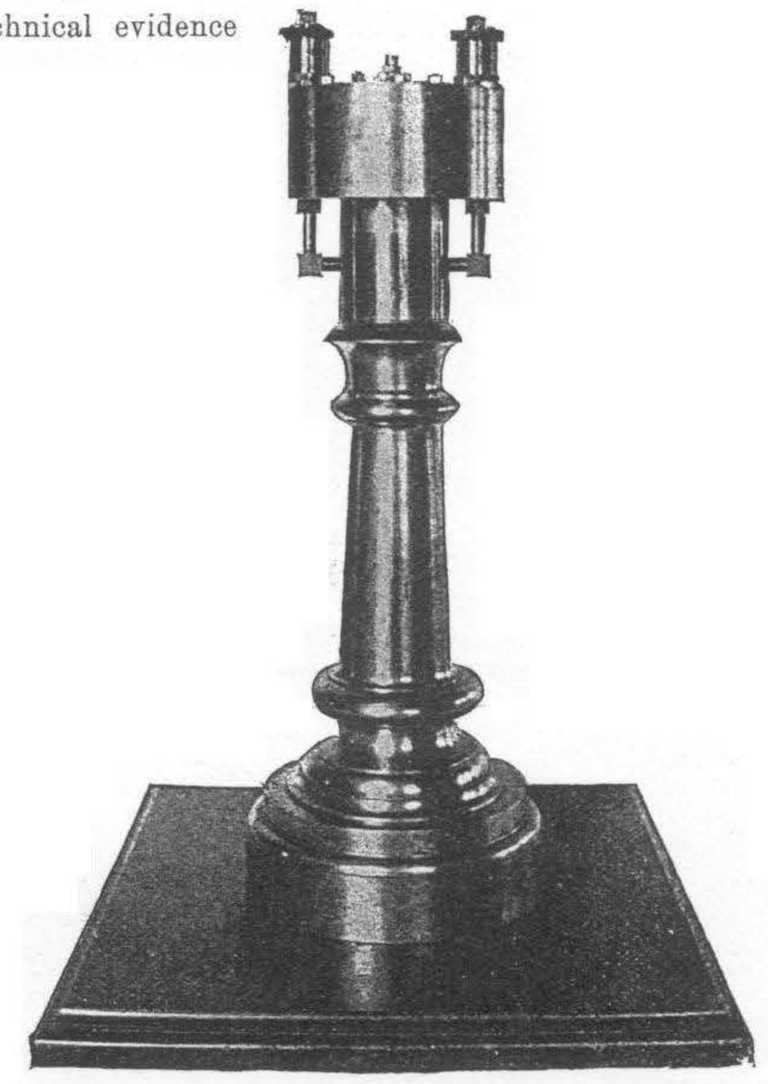

FIG. 2.—A SIMILAR FORM OF OSCILLATOR.

The wide field for improvement open to Mr. Tesla in his efforts to discover more efficient means of generating electrical energy may be better appreciated when it is stated that actual tests have shown that the energy manifesting itself as light in an incandescent lamp is less than five per cent of that received as current. The other 95 per cent is lost between the coal pile and the lamp. An important step in Mr. Tesla's labors to reduce this tremendous loss was the invention of his "oscillator." He reasoned that if large losses occurred in the steam engine and other large losses in the dynamo, it would minimize the combined losses if both machines were blended in one. And in the crudest terms this is what an oscillator is—an engine-dynamo.

In generating current by a revolving armature there is always some part of the wire winding which is doing no work, just as in the steam engine the steam cylinder and its

piston are the only parts doing any work, all the other complex mechanism being used for control or regulation. In brief and popular terms, the Tesla oscillator consists of a bedplate, in the middle of which is located

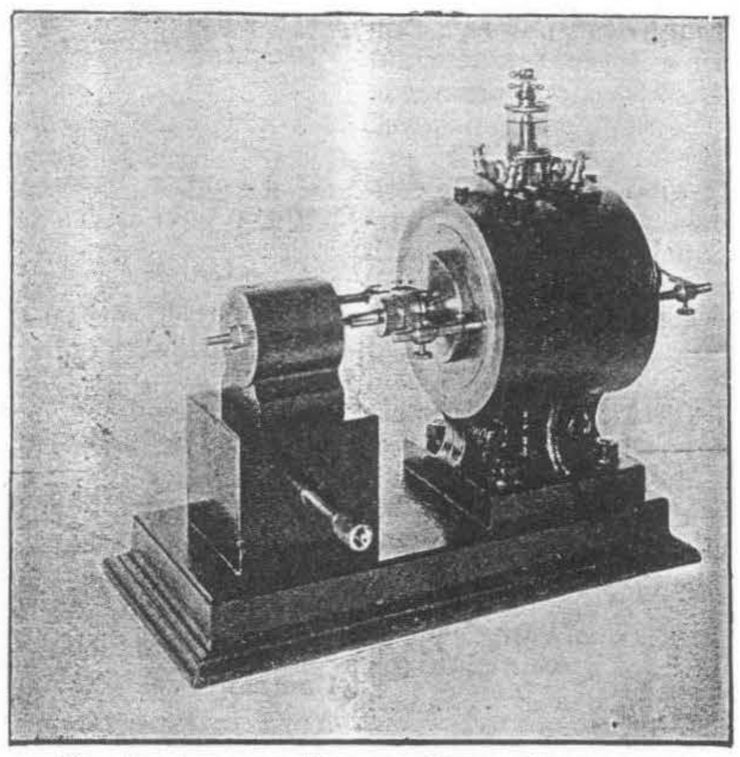

FIG. 3.—ANOTHER TYPE OF TESLA OSCILLATOR.

a steam chest. On each side of the steam chest is an electro-magnetic system consisting of field coils, between which the armatures move.

Two pistons are worked by the steam entering the chest. In one case steam at 350 pounds pressure is used, although as low as 80 pounds is used in other oscillators. At the ends of the pistons are the armature coils, which are thrust in and out of the magnetic fields with a reciprocating motion, thus generating current.

Here, then, is a steam engine stripped of every inefficient complication, and at the same time it is an electrical generator in which every part is doing steady work. The oscillator keeps the high pressure steam under such control that no packing is required to prevent leakage. For the same pressure and the same piston speed the engine part of the oscillator has but one-thirtieth to one-fortieth of the usual weight and consequently occupies a proportionately smaller space. The reduction of bulk and space occupied is also true of the electrical portion of the oscillator. Mr. Tesla believes that in the development of this apparatus he has reached a long way in advance in the reduction of the wasteful processes now present in the generation of electric current from coal.

The most highly developed form of oscillator, and one that was entirely practical and successful, had been used for many months in Tesla's laboratory. It was used to light the rooms with incandescent lamps and also furnished current for four arc lamps, for motors, for experiments with the high frequency apparatus and for other investigations. Many visitors to the laboratory have witnessed this oscillator in successful operation.

The oscillator which Mr. Tesla used in his lecture before the International Electrical Congress, during the World's Fair at Chicago, in August, 1893, is the only one that has ever been exhibited in public. This is shown in the accompanying illustration, Fig. 1. For convenience, compressed air instead of steam was used to operate this oscillator during Mr. Tesla's lecture. The machine consists of an engine mounted on an ornamental column, on top of which is a generator much like that shown at E in Fig. 6. In Fig. 2 is illustrated a similar form without the generator. A very strong air spring is contained in the box on top of the column. The apparatus is so constructed that the vibrations of this spring and the engine are always in perfect synchronism. The only possible function of the engine is to keep the spring vibrating. Eventually the amplitude of the vibration will be altered, but the period will remain the same; that is, it is the natural period of vibration of the system. The recoil of the spring is, of course, very much greater than the impulse received each time from the engine. Around the spring is a chamber which can be maintained at a constant temperature by any usual means. The isochronism is perfect because the frictional losses are infinitesimally small compared with the enormous elastic force.

Another quite distinct type is illustrated in Fig. 3. On a stand with a dynamo of somewhat unusual form is mounted a small oscillator. The dynamo includes a circular field magnet in which circular coils are arranged to move on each side. An arbor directly connected to the small engine carries the coils, and currents are produced by vibrating the coils within the field of the magnet. Mr. Tesla says that in this form there is absolutely no useless wire. All of it is within the field and all is equally active.

An oscillator of more advanced form, operated by steam and freely used for laboratory purposes, is shown in Fig. 4. This extremely small machine had a capacity of 12 incandescent lights. The combination was made up of a small oscillator and a dynamo having a field magnet with exciting coils and an armature simply of iron. The induced coils were wound on a number of pole projections extending from the inside of the magnet. The armature had fewer projections than the field and in this way the output of the dynamo was increased by the number of teeth.

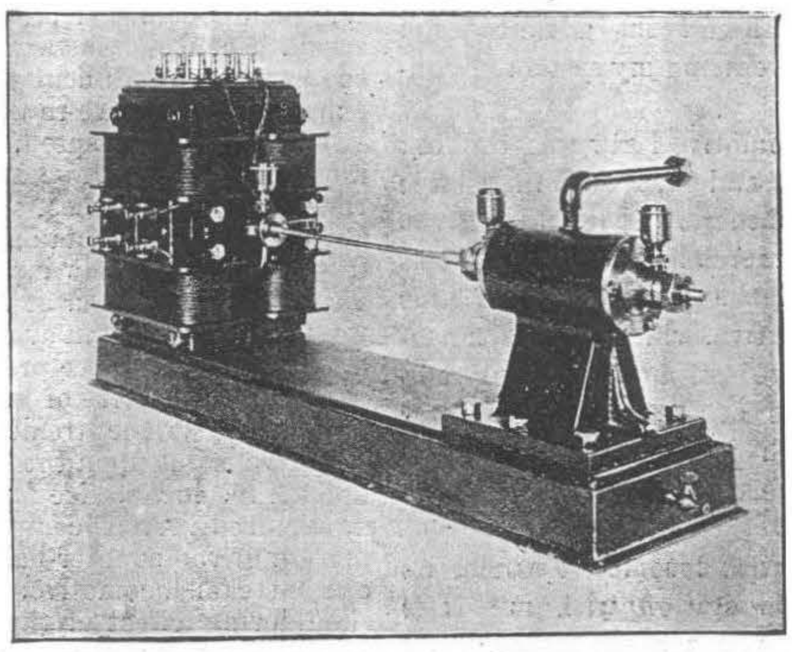

FIG. 4.—OSCILLATOR USED FOR LABORATORY PURPOSES.

An extremely interesting piece of experimental apparatus, used solely for scientific research, is shown in Fig. 5. It consisted of a field magnet within which there was arranged to vibrate a tongue of steel carrying at its end a coil. Both the tongue and coil were vibrated in the strong field, adjusting screws on each side allowed the attainment of any periodicity within a wide range.

A most interesting group of parts used by Mr. Tesla in his demonstrations is illustrated in Fig. 6. Novel features were exemplified by the use of several of the instruments shown. As an example, the magnets in A served to make clear the principle of the preponderance of one impulse over the other in the current produced by the oscillator and creating virtually the effect of a direct or continuous current. A magnet which was vibrated is shown in R. The copper disk D was arranged to rotate freely in bearings. When the disk was held between the poles, that is, in the field of the vibrating ring magnet, it was rotated in one direction. This showed that the currents distributed in the disk were asymmetrical, or in other words, they were preponderating in one direction.

The constancy or invariability of the speed of the oscillator was illustrated by the use of the little motor shown at C in Fig. 6. Another little motor with clockwork attached, shown in G, was used to count the revolutions of the oscillator. Both of these little motors were driven from one circuit, the difference of phase being obtained by artificial means. E was a little generator comprising three coils, two inducing and one induced, and an iron coil which was vibrated by the oscillator to which it was attached. The parts of an oscillator for short and long strokes, respectively, are shown in Fig. 6 at F, H, I, J and K.

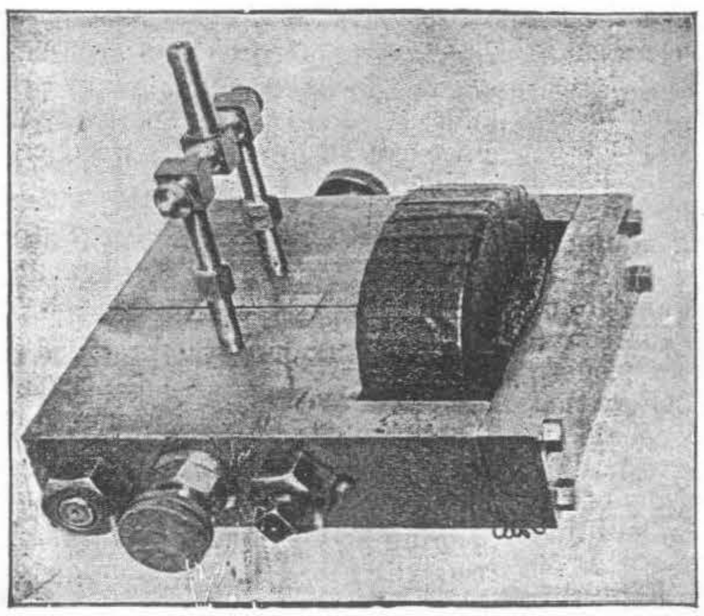

FIG. 5.—TESLA APPARATUS USED FOR SCIENTIFIC RESEARCH.

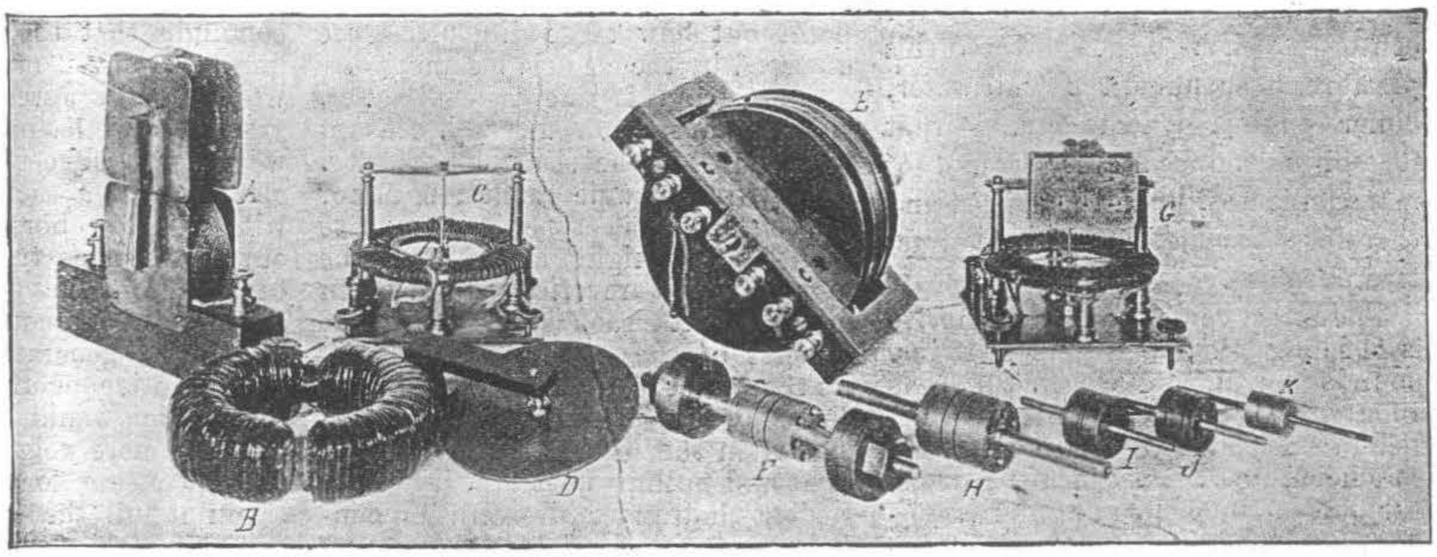

FIG. 6.—A GROUP OF PARTS OF TESLA APPARATUS.

These are only a very few of the Tesla devices which are now blackened ruins; yet they will serve to give a faint idea of the great and interesting achievements which this inventor has been accomplishing. Mr. Tesla is successfully at work reproducing his lost records and apparatus. The sympathy and encouragement he has received since his misfortune occurred will doubtless result in spurring him on to still greater and more brilliant efforts which an appreciative public will not be slow to recognize.

April 3, 1895

ELECTRICAL REVIEW

IN TESLA'S LABORATORY.

BY ROBERT UNDERWOOD JOHNSON.

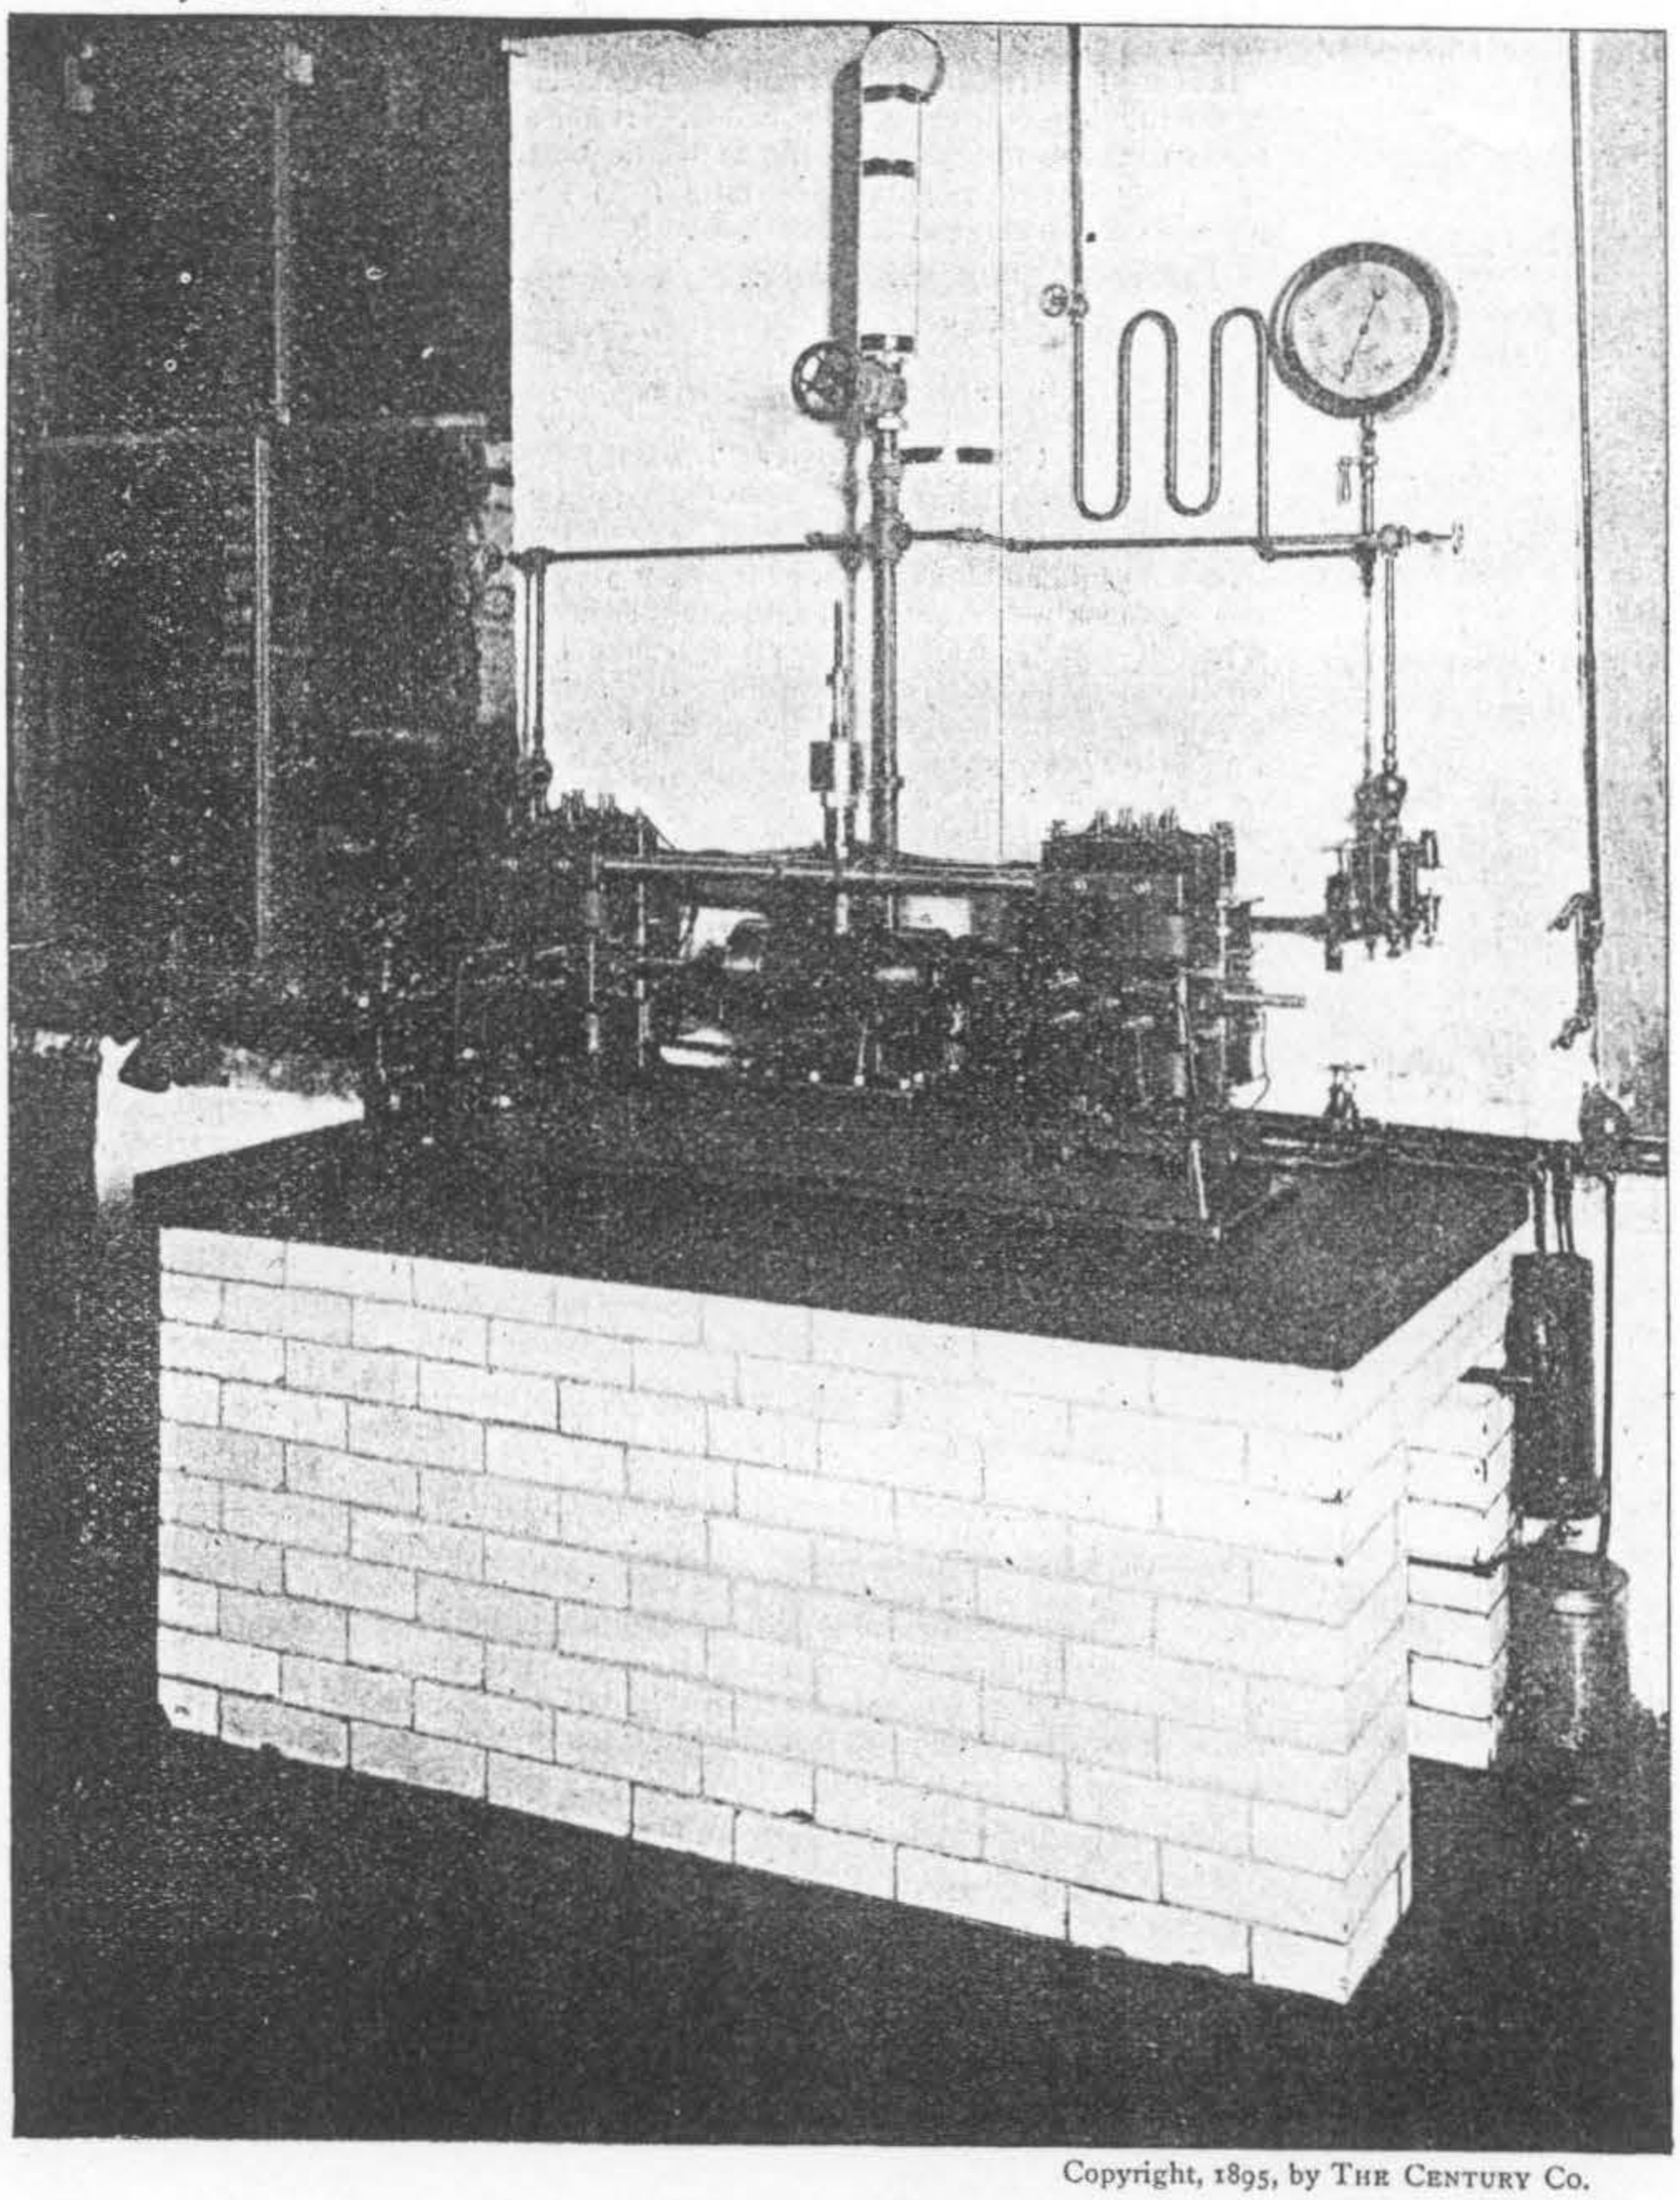
[*From the Century Magazine.*]

Here in the dark what ghostly figures press !—
No phantom of the Past, or grim or sad ;
No wailing spirit of woe ; no specter, clad
In white and wandering cloud, whose dumb distress
Is that its crime it never may confess ;
No shape from the strewn sea ; nor they that add
The link of Life and Death—the tearless mad,
That live nor die in dreary nothingness.

But blessed spirits waiting to be born—
Thoughts, to unlock the fettering chains of Things ;
The Better Time ; the Universal Go d.
Their smile is like the joyous break of morn ;
How fair, how near, how wistfully they brood !
Listen ! that murmur is of angels' wings.

THE TESLA OSCILLATOR.

In view of the recent destruction by fire of Mr. Nikola Tesla's laboratory, with all the apparatus therein contained, some of the mechanism most nearly completed and perfected that has gone has been given an additional interest. There is probably no device of Mr. Tesla's of recent date around which more interest has centered than the electrical oscillator, which he first exhibited before a select audience at the World's Fair during the occasion of the Electrical Congress.



Since those instruments were exhibited the mechanism has undergone a considerable change, not in principle but in detail, which has tended to make it more compact, more efficient and in every way better adapted to the peculiar requirements of experimentation in which Mr. Tesla has been engaged as well as to the everyday requirements of the commercial machine. To such an extent had his work been carried in this line that Mr. Tesla was about ready to put the apparatus on the market, and did in fact for some time previous to the fire have his oscillator in practical service in his laboratory.

Through the courtesy of the *Century Magazine* we are enabled to reproduce here an engraving of the latest type of this machine, made from the last photograph taken of it, which, now that the machine itself has been destroyed, will have additional interest for our readers. This picture was made to accompany an exceedingly well written article by Mr. T. C. Martin which appears in the April number of the *Century*, to which our readers are referred. Mr. Martin, as is well known, is Mr. Tesla's historian, and any statements coming from him in regard to Tesla's work are therefore authoritative.

The Tesla oscillator is a steam mechanism, but the "engine" part may be said to have disappeared, so far as that word implies an aggregation of fly wheel, governors, etc. On the one base were mounted two dynamos, or electro-magnetic generating systems, and a small steam chest. There were two pistons, which were vibrated by the steam 80 to 100 times a second. Each of the pistons carried an armature which was plunged reciprocally into the field of the magnets. Normally the engine was run with the two pistons in opposite phase, but they could be set by an independent device in any phase. Above the chest was mounted an independent little oscillator, which in some experiments controlled the steam admission, and made the vibration of the engine quite independent of the load.

This oscillator was operated with steam at 350 pounds pressure, when it needed no packing, as there was no leakage. It was also used at pressures down to the ordinary 80 or 100 pounds. It was used to light up a bank of 50 or more incandescent lamps, some arc lamps, and to run various motors, while it also furnished current for a variety of most interesting and novel experiments, all of them suggestive of new departures in the electrical arts, including phosphorescent lighting, the transmission of intelligence long distances without wires, the utilization of the earth's electrical charge, etc.

The Tesla Oscillator.

MISCELLANEA.

WE read with regret that on the 13th ult. Mr. Nikola Tesla sustained a severe loss in the total destruction of his laboratory by fire. It is said that several instruments embodying nearly completed inventions were destroyed.

NOTES AND NEWS.

Dr. Nikola Tesla suffered a serious loss in the destruction of his laboratory by fire on March 13th.

The April Magazines

"The Century Magazine"

FIRST IN IMPORTANCE among the contents of this number is the article on "The Latest Electrical Inventions and Discoveries of Nikola Tesla," by T. C. Martin, editor of *The Electrical Engineer*. It is a survey of all the electrical advances of the last fifty years, and a forecast of the work of the next fifty. Text and illustrations deal with lighting, power transmission, telegraphy without wires, means for obtaining illumination by phosphorescence, the feasibility of using lamps without life-giving members and in free space, the disturbance and manipulation of the earth's electrical charge, and a variety of unclassified phenomena. Of great importance among these discoveries is the "oscillator," which is "not simply a new practical device, but a new implement of scientific research." With it Mr. Tesla, "if he has not as yet actually determined the earth's electrical charge or 'capacity,' has obtained striking effects, which conclusively demonstrate that he has succeeded in disturbing it." The great inventor has aimed at manipulating this electrical charge of the earth itself, and, says Mr. Martin, "aside from their deep scientific import and their wondrous fascination as a spectacle, such effects point to many new realizations making for the higher welfare of the human race. The transmission of power and intelligence is but one thing; the modification of climatic conditions may be another. Perchance we shall 'call up' Mars in this way some day, the electrical charge of both planets being utilized in signals." Among the illustrations accompanying the article are several photographs, of Tesla himself, Mark Twain, Marion Crawford and Joseph Jefferson, taken by phosphorescent light. As is well known, Mr. Tesla's laboratory was destroyed in March, and this article is the only record of some of his most important discoveries. Mr. Tesla has gone to work undismayed to reconstruct his lost appliances and machinery.——Besides Prof. Sloane's "Life of Napoleon," there is another historical paper, on "Lincoln's Reëlection," by Noah Brooks, whose recent work in this field, we think, is now so widely and well known that it requires no further praise or recommendation.——A third deals with Paul Jones, and is from the pen of Molly Elliot Seawell, who has taken our naval heroes under her special charge, and is making old and young America—especially the latter—better acquainted with the details of their lives.——Dr. Lyman Abbott in his essay on "Religious Teaching in the Public Schools" reviews again the mooted question, indicating, as many have done before him, what education in a democracy should be, and expressing his conviction that some day the ideal will be attained.——In the meanwhile, S. W. Powell discusses another important educational question, "Should Higher Education be Provided for the Negro?" This higher education of a few gifted Negroes seems to Mr. Powell of more immediate importance than the common education of the masses of the race; or, rather, he thinks that the latter will be accelerated and made more effective by the former. His reasons are sound and clearly stated, but—funds are low.——Our readers remember, of course, that only a short while ago Paul Griggs the novelist visited New York and was intimate with the Lauderdale clan, and especially with Katharine Ralston. He now makes his appearance in Italy, in Mr. Crawford's "Casa Braccio," which interesting tale glides here into a period of calmness.——Among the rest of the contents we can only mention, *en passant*, an excellent full-page portrait of Mme. Réjane, with a short appreciation by Justin Huntly McCarthy, short stories by Mrs. Roger A. Pryor, George I. Putnam and Alice Turner, a biographical sketch of Bernhard Stavenhagen, by Henry T. Finck, and several poems, among them an unsigned sonnet on "Robert Louis Stevenson," and another, "Resurrection," by Maurice Francis Egan.

Tesla's Laboratory.—In a short article in the "Eng. Mag." for April Mr. Martin discusses the nature and significance of the event of the burning of Tesla's laboratory; he mentions briefly that the most advanced form of the oscillator had been used to light the laboratory for months.

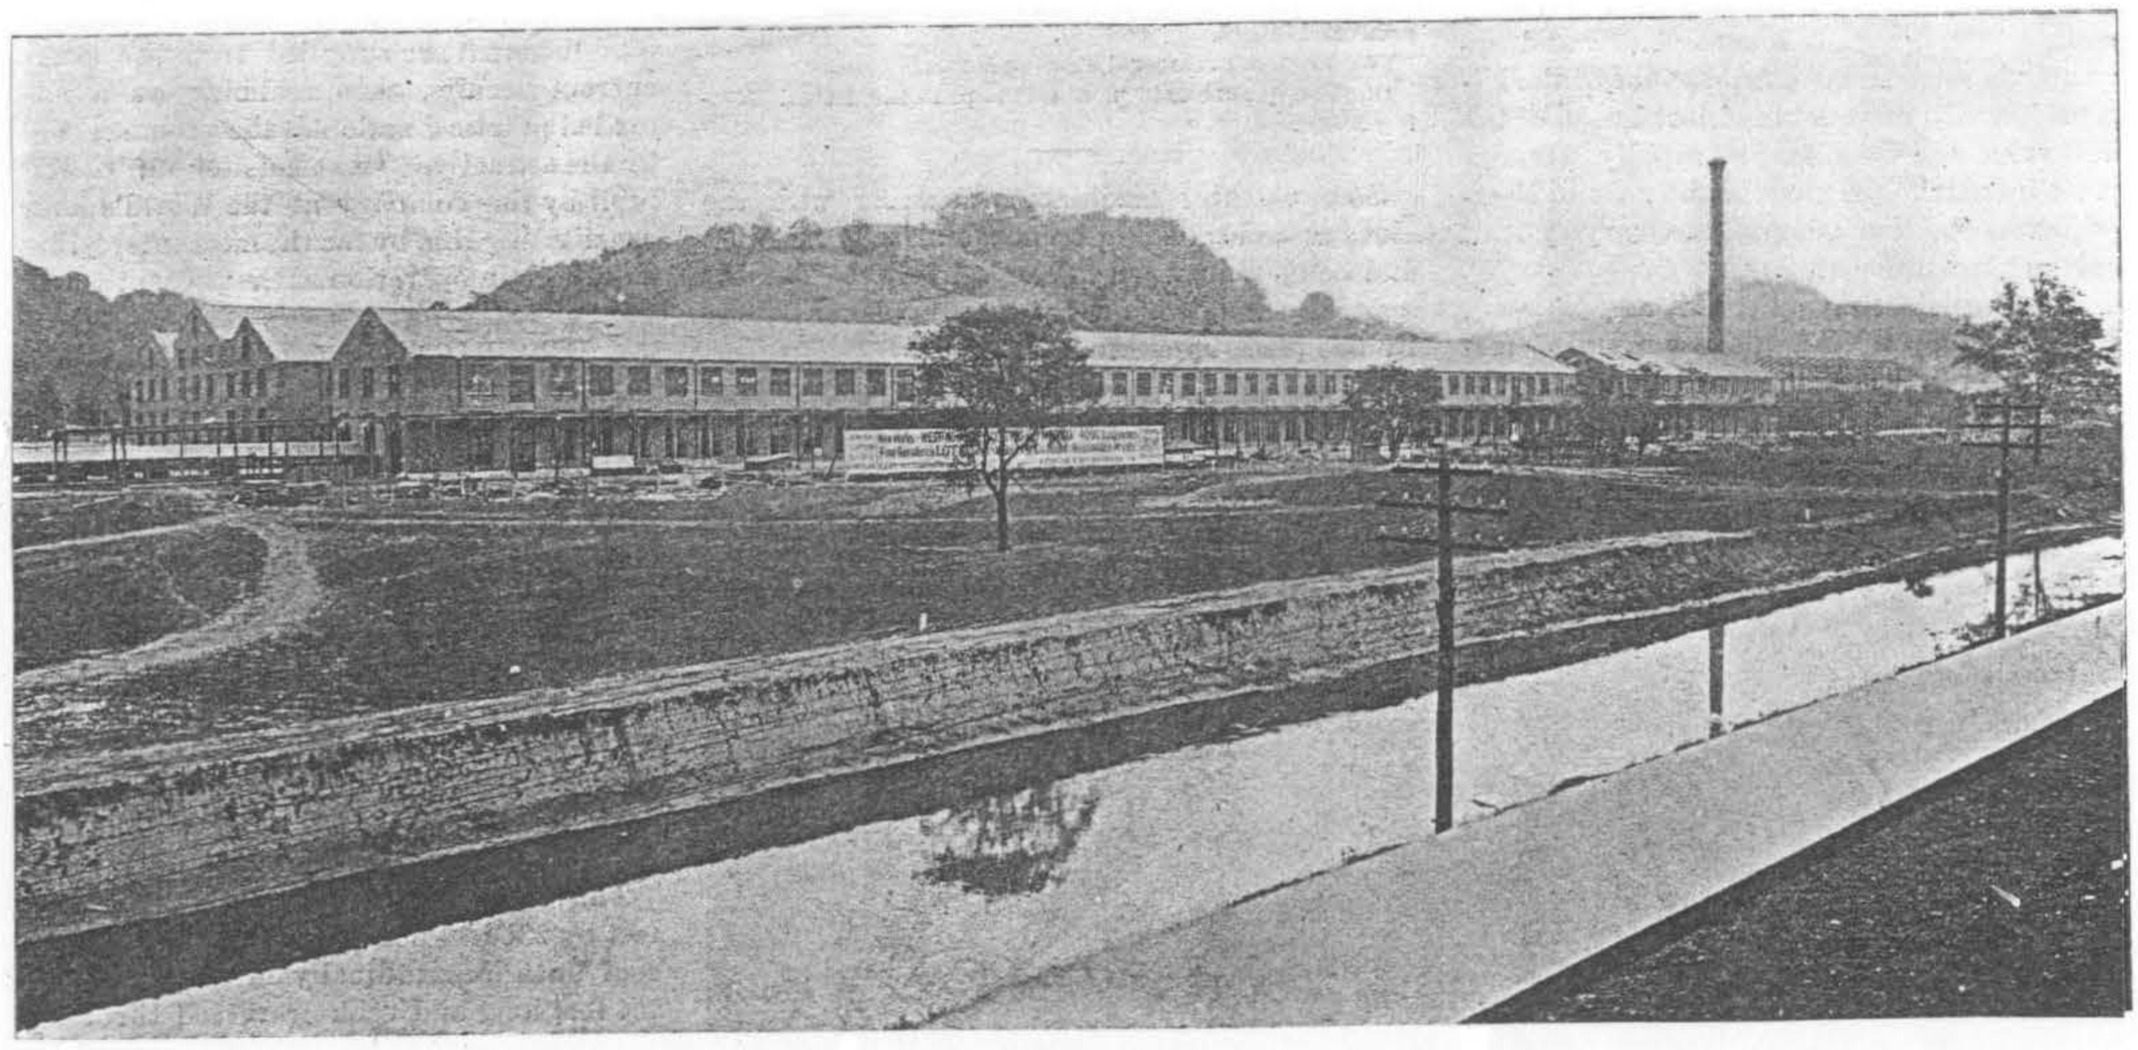

FIG. 1.—WESTINGHOUSE ELECTRIC AND MANUFACTURING COMPANY'S PLANT, BRINTON, PA.

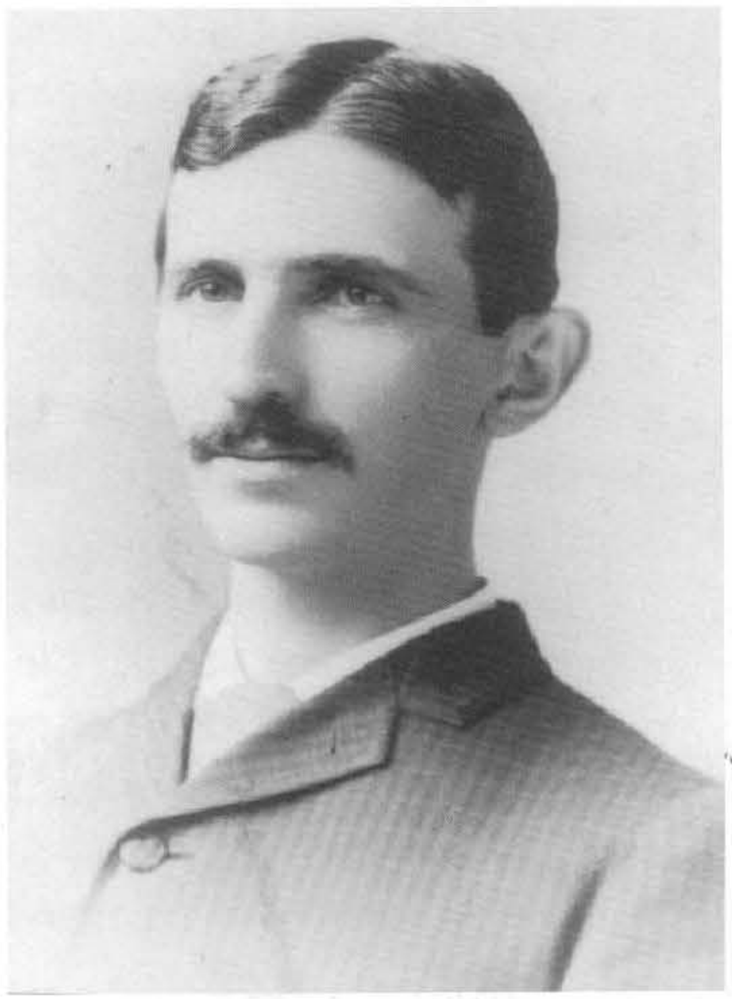
The Tesla Two-Phase System.

Extensive Use at the Westinghouse Works, Brinton.

The New Plant Fully Equipped with Alternating-Current Apparatus—The Most Important Installation Thus Far Attempted.

BY NELSON W. PERRY, E. M.

For many years it was a matter of reproach to the electrical industry that the manufacturers of electrical apparatus who zealously urged its adoption in all other industries failed to use it in their own. While recommending their wares to others they used them not themselves, except in a few isolated cases where small electrical apparatus was erected in the works to show to prospective purchasers that it would run under favorable circumstances. On the conservative business man the claims of superior economy, efficiency and convenience made for electrical methods produced rather the opposite effect to that intended when he saw in these great establishments the same methods in vogue which their proprietors were urging him to discard in his own.



Gradually, however, things changed, and the electrical manufacturer began himself to follow the advice which he had so long been giving to others.

Direct current methods are the oldest, commercially speaking at least, and first reached a perfection leaving little to be desired; and for some years past several of our largest electrical companies have been distributing power throughout their works by electrical means instead of by long belts and shafting, and have driven almost all of their tools either directly from direct current motors or from short lines of shafting driven locally in the same way.

Next in point of time came the simple alternating current which seemed to present possibilities for the future which would relegate direct current practice to the rear. For incandescent lighting purposes and long distance transmission *per se* it seemed all-sufficient almost from the invention of Gaulard and Gibbs, but for motor service it proved inadequate to the demands. Early in the history of the art alternating current motors of good efficiency had been constructed, which, when once brought up to speed, would do good work, but from that day to this, notwithstanding the persistent efforts of the best talent, a simple alternating current motor that could be started and stopped and reversed while under load, and thus fulfil all the requirements of commercial practice, has not been built.

From time to time claims have been made that this has been accomplished, but the test has never verified the promise. Not until the invention of the polyphase motor by Nikola Tesla, in which two or more simple alternating currents differing in phase were employed, was the alternating current adapted to the demands of commercial power practice.

Although Tesla's seven earliest patents were issued on May 1, 1888, followed by four others during the same year, the value of the polyphase system was not generally realized until 1891, when the Frankfort-Lauffen experiment attracted world-wide attention to its merits. Both before and since that date, however, many modifications of Tesla's method had sprung into existence

NIKOLA TESLA.

whose claims for utility were strongly urged by their respective promoters, and the history of the direct current method from the manufacturer's standpoint was repeated. Although extraordinary claims were advanced for these systems, and latterly numerous successful installations had been made, the manufacturer himself neglected them in the equipment of his own shop. With one or two exceptions, while the manufacturer of alternating current apparatus equipped his factory with electrical power apparatus, it was of the direct current type, which his own wares were professedly intended to supplant by reason of their superiority.

There were often more or less valid reasons for this seeming inconsistency, but the public knew them not, and from this circumstance, perhaps, more than any other has looked upon polyphase systems with lack of confidence, if not suspicion.

The greatest difficulty that the manufacturer has had to contend with in replacing an established system by a new one, has been to adapt the speeds of the new motors to the old pulley relations—either this had to be done or the pulley relations had to be adapted to the new motor speeds, either of which would involve an expense scarcely warranted by the results.

But when the Westinghouse Electric and Manufacturing Company began equipping their magnificent new works at East Pittsburg they were hampered by neither of these considerations, and were left entirely free to choose that system which they thought promised the best results. This company being the owners of all the Tesla polyphase patents, had for years been recommending the system to their patrons as universally applicable for general power distribution; and they have given evidence of their faith in the system by equipping their new works throughout with it.

This plant, which is now described for the first time, though not yet complete, forms the most interesting installation of polyphase apparatus thus far made, for several reasons. In the first place, the same type of apparatus, the same method of distribution and the same frequency of alternation of current (3,000 per minute) are employed as are to be used at Niagara. Its sufficiency for all the multifarious demands of these large works is therefore a demonstration of its sufficiency for all the demands that can be made upon it at Niagara. Furthermore, it is the first practical demonstration of this on a sufficiently extended scale to settle the matter beyond question. In the second place it is the first demonstration

on a practical scale of the system to machinery and work of the greatest heterogeneity and severity of exactions and as a forerunner of the Niagara project will serve as an object lesson of the greatest value and do more to rapidly advance the great industrial progress in and around Niagara, which has to depend upon this very system, than almost any other agency.

Although anticipating a little, it may be well, in order to convey an idea of the variety of service that this system is supplying in the Westinghouse works, to catalogue the apparatus it is now driving.

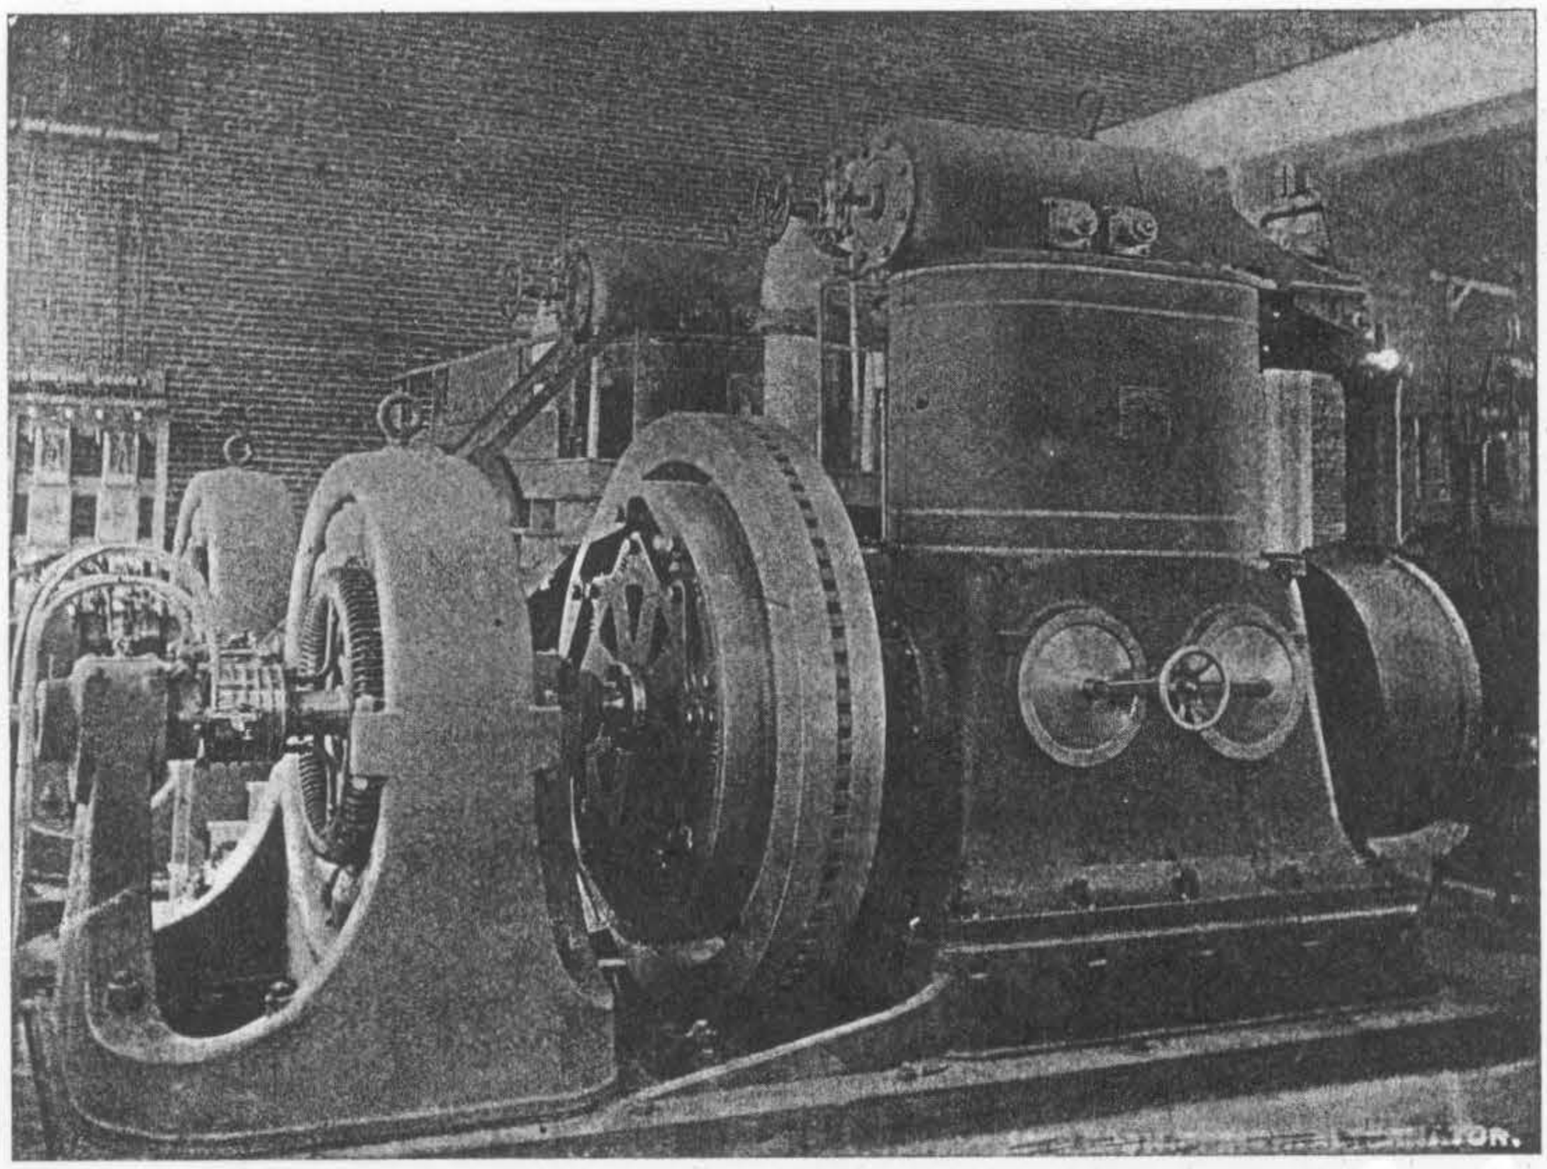


FIG. 2.—TWO-PHASE GENERATORS FURNISHING POWER AND LIGHT TO THE WESTINGHOUSE SHOPS. 500 H. P. UNITS.

PRESENT INSTALLATION.

Main Machinery Building, 754 feet long by 235 feet wide.

SMALL GENERATOR DEPARTMENT—MACHINES BELOW 100 H. P.

Ground Floor—

Two 40 h. p. motors each, driving planers, drill presses, lathes, etc., to the number of about 100 machines.

Galleries—

One 30 h. p., driving about 40 screw machines of various sizes.

Two 20 h. p. each driving 40 tools of various kinds in Too Department.

One 40 h. p. driving about 40 tools of various sizes in Commutator Department.

One 20 h. p. driving about 25 or 30 tools in Brush-holder Department.

One 30 h. p. driving about 60 tools in Controller Department.

One 20 h. p. driving about 15 tools in Converter Department.

One 20 h. p. driving 15 punches and various tools in Mica Department.

Four 20 h. p. driving 200 winding lathes.

Six 40 h. p. driving fans for heating.

Making 20 motors of an aggregate of 620 h. p. already installed in this building.

There still remain to be installed in this building the following motors:

One 30 h. p. to drive 3 Ingersoll milling machines.

Two 30 h. p. in Railway Motor Armature Department, each of which will drive some 40 tools, lathes, etc.

One 15 h. p. in Motor Armature Winding Department.

Two 30 h. p. in Motor Machinery Department, each driving some 30 heavy tools, boring mills, lathes, drills, etc.

One 30 h. p. to drive 3 boring mills, one 122 inch by 35 inch lathe, two 72 inch radial drills, two large planers.

One 30 h. p. to operate planers, boring mills and drill presses.

Three 20 h. p. to drive large planers, boring mills, drill press and lathes.

Two 500 h. p. in General Testing Room.

One 75 h. p., one 60 h. p., one 40 h. p. in the Detail Testing Room.

Some of this machinery, together with the elevator and traveling cranes, is already installed and being temporarily driven by direct current apparatus, but it is intended to supplant all these by two-phase apparatus.

WAREHOUSE, 76 FEET X 754 FEET.

Motors already installed—

Four 20 h. p., each driving some 40 tools.

Two 30 h. p., each driving some 45 tools.

Two 40 h. p., each driving fans for heating purposes.

Making 8 motors of 220 h. p.

CARPENTER AND CABINET SHOP, 102 FEET X 60 FEET.

100 h. p. in small units, all direct current at present, but to be replaced with two-phase motors.

BLACKSMITH SHOP, 242 FEET X 82.6 FEET.

Two 20 h. p., on exhaust fans.

Two 10 h. p., on pressure fans.

One 20 h. p., driving two large shears and punches and 5 smaller tools.

Total—5 motors of 80 h. p.

POWER HOUSE, 206 FEET X 76 FEET.

At present this contains—

Two 500 h. p. direct connected alternating current (two-phase) and two 500 h. p. direct connected direct current machines.

The full complement will be 3 units of 500 h. p. each of each kind.

PUNCH SHOP, 258 FEET X 76 FEET.

Two 80 h. p., each driving 40 odd punching machines.

Recapitulating, we find that there are at present installed and in operation 37 alternating current motors of an aggregate capacity of 980 h. p. There are yet to be installed 16 more of a capacity of 1,390 h. p., besides several hundred horsepower direct current motors now installed to be replaced by two-phase alternate current motors.

It will be seen from this catalogue that the new plant constitutes by far the largest installation of polyphase motors that has heretofore ever been attempted and that these motors are doing almost every conceivable class of service except electrolytic work. In addition to this, all of the lights, both arc and incandescent, for the whole establishment are supplied from the alternating current circuits, thus realizing on a most extended practical scale all the promises held out by the attractive "transmission of power" exhibit by this company at the World's Fair, and constituting this by far the most interesting plant anywhere in operation at the present time.

DESCRIPTION OF THE PLANT.

The site of the Westinghouse Electric & Manufacturing Company's new shops, which has been christened East Pittsburg, is 12 miles from Pittsburg, on the Pennsylvania Railroad. The buildings at present erected and occupied are seven in number, and in the order of size are the main machine shop, warehouse, punch shop, blacksmith shop, power house, carpenter shop, and temporary brass foundry. All of these are substantial brick buildings except the carpenter shop and the brass foundry, which are of corrugated iron.

THE MAIN MACHINE SHOP.

This, by far the largest, covers an area of 754 feet by 231 feet 6 inches, and is divided by the roof lines longitudinally into three aisles, each 754 feet long and each traversed throughout its whole length by railroad tracks connecting with the main line of the Pennsylvania Railroad. The main aisle is unbroken from floor to roof and traversed throughout its length by a 30-ton electric crane. Here all the heavy machine work and large generator erecting is carried on. The side aisles are both divided midway of their height by floors, under which in each case is a 10-ton electric crane with a 754-foot runway.

On the ground floor of the north aisle are located the motor armature winding, fitting, and assembling departments and storerooms, and in the south aisle are found the small generator department, small generator armature winding and assembling departments and more storerooms, and the entire eastern quarter of the three aisles as general testing rooms for the classes of work done in their respective western portions.

On the second floor of the north wing, beginning at the west and going east, are the screw department, tool and storeroom, brush-holder department and railway equipment rooms, and similarly situated in the south wing are the wire storeroom, winding and insulation department, mica department, detail testing room and converter department.

Each of these longitudinal sections of the building is traversed by line shafting divided

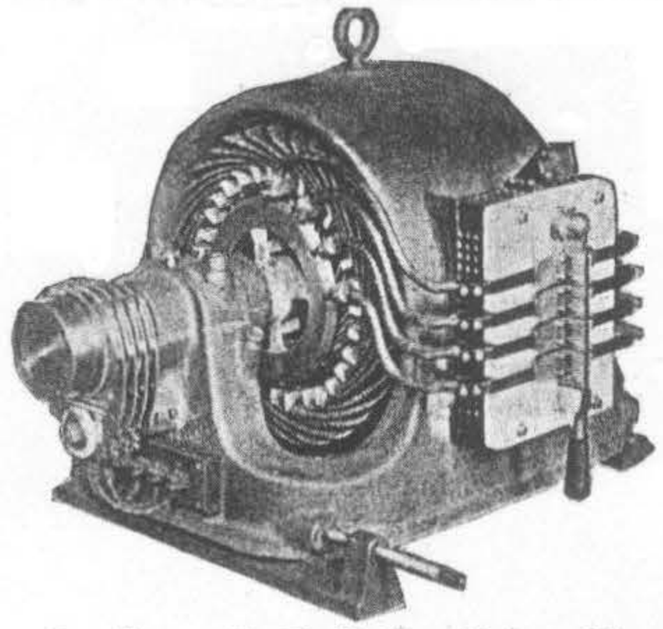

FIG. 3.—TESLA 50 H. P. TWO-PHASE MOTOR. OLD STYLE SWITCH. NEW STYLE COLLECTOR BRUSHES.

into numerous sections, each of which is belted to an individual two-phase motor situated on the floor, and from which are belted the various tools and machines already enumerated. This plan of transmission from motor to tool is observed throughout the various buildings and need not be again referred to. It may also be stated here that with the exception of three small steam

hammers for copper forging, in the blacksmith shop, every piece of machinery in the establishment is electrically driven.

THE WAREHOUSE.

Directly south of the machine shop is a building of equal length, but only 76 feet 2 inches broad, whose entire first floor is occupied as a warehouse, in which all finished and returned material is stored for further disposal. For the

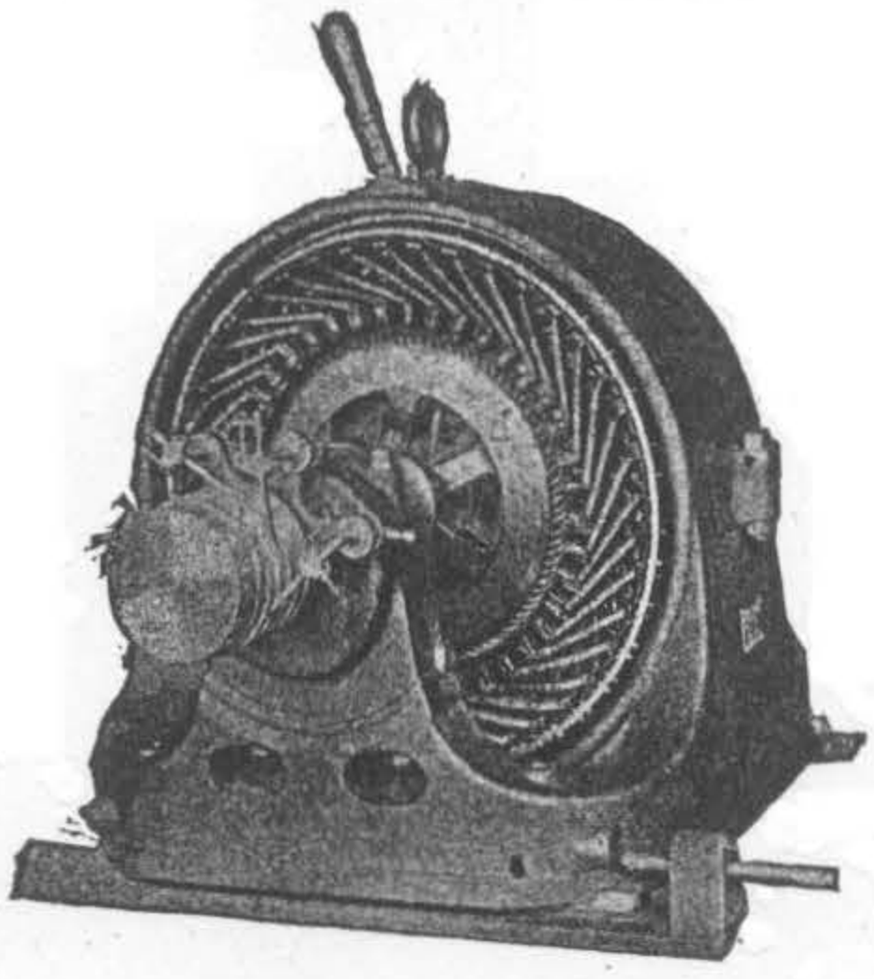

FIG. 4.—TESLA 50 H. P. TWO-PHASE MOTOR. NEW STYLE SWITCH RING. OLD STYLE COLLECTOR BRUSHES.

handling of this material there are two 10 ton electric cranes with runways extending the entire length of the building.

The second floor is connected by five bridges with the second floor of the south wing of the machine shop thus practically making the two one. The west end of this floor is devoted to the general offices of the administrative, engineering and draughting departments and the eastern end to the instrument department, including meter, arc lamp and switchboard equipments.

THE POWER HOUSE.

East of the warehouse, and separated from it by a passageway 52 feet wide, is the power house. This is 206 feet long by 76 feet 2 inches wide, and devoted in its western part to the engines and dynamos and two hand-operated overhead cranes and in its eastern part to the boilers. The latter are Pierpoint boilers of 2,500 h. p., and there is room for an equal number more. These boilers are equipped with the Roney mechanical stoker. The fuel is delivered from cars on an elevated track direct into large iron hoppers from which it descends as needed to the grates without manual handling of any sort. The present engine and dynamo equipment consists of two 500 h. p. Westinghouse compound engines directly connected by means of two standard Westinghouse flexible couplings to two 500 h. p. two-phase Tesla generators, and two similar engines connected in the same way to two 500 volt

FIG. 5.—TESLA 10 H. P. MOTOR. ROTATING PRIMARY.

multipolar direct current generators. The foundations are all ready for one more 500 h. p. unit of each kind.

PUNCH SHOP.

Fifty feet to the east of the power house and on the same lines is the punch shop, 258 feet long by 76 feet 2 inches wide. Upon the ground floor are the shearing and heavy punching machines, and storage for sheet iron. In the extreme east end are the annealing ovens. The second story is devoted exclusively to the machines for punching armature disks, converter and other shapes for laminated structures.

Running along the north fronts of the warehouse, power house and punch shop is a surface railroad track connecting with the Pennsylvania Railroad's main line, and along the south walls an elevated track by which shipments to and from the second stories of the buildings are made.

TEMPORARY BRASS FOUNDRY.

Just north of the punch shop is a one-story corrugated iron building, 40 feet by 242 feet, used as a brass foundry, and north of this is the

BLACKSMITH SHOP.

This is a substantial brick building covering an area of 242 feet by 82 feet 6 inches. These last three buildings complete the extreme eastern tier of buildings, as do the machine shop and warehouse the western.

Through the center of the building runs a track for local transportation purposes. There are already erected and in operation within this building twenty-five forge fires, and there are fifteen more to be installed. The blast for these forges is supplied by two 10 h. p. two-phase motors. Over each fire is suspended a large sheet-iron hood to collect the smoke and other products of combustion, and these are connected with a system of flues in which a strong draft is created by exhaust fans operated by two 20 h. p. Tesla motors. There are also two large Allstatter combined shears and punches and some smaller tools operated by one 20 h. p. motor. Besides these there are three small steam hammers for forging copper bars of the largest size used in dynamo construction.

CARPENTER SHOP.

The carpenter shop, 60 by 192 feet, lying east of the machine shop, is a one-story corrugated iron building, fully equipped for the purpose. In

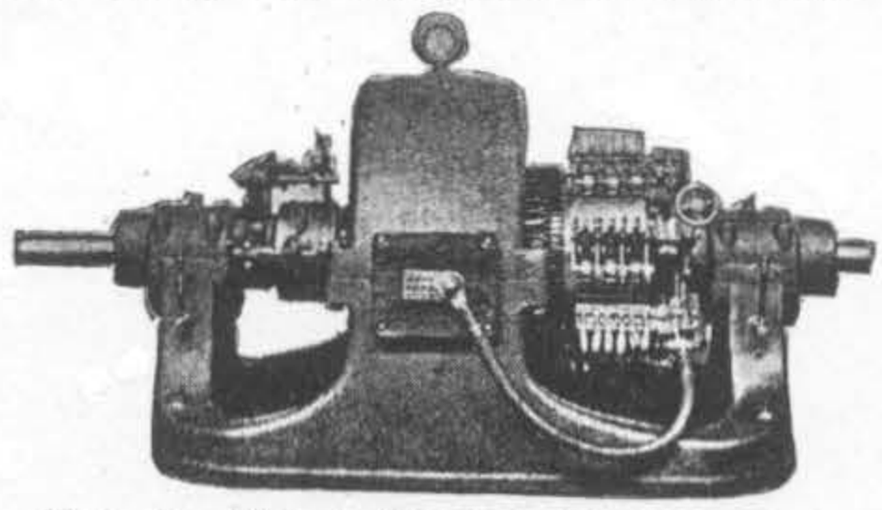

FIG. 6.—TESLA ROTARY TRANSFORMER.

the 65 feet space separating the machine shop from the warehouse is located the

COIL-BAKING AND OIL STORAGE HOUSE,

which is a small brick building, 182 feet 10 inches long by 27 feet 4 inches wide, devoted to the purposes indicated in its name. On the roof of this has been constructed a light, airy room in which the thousands of blue prints used by this great establishment are prepared.

(To be continued.)

The Tesla Two-Phase System.

II.

EXTENSIVE USE AT THE WESTINGHOUSE WORKS, BRINTON.

The New Plant Fully Equipped with Alternating-Current Apparatus—The Most Important Installation Thus Far Attempted.

BY NELSON W. PERRY, E. M.

Returning to the power-house we find, as already stated, two 500 H. P. direct connected direct current units furnishing current at 500 volts. These are used for testing the direct current apparatus manufactured by the company and are at present operating the five electric traveling cranes, the elevators and several large direct current motors, all of which it is intended to replace as soon as possible with alternating two-phase motors. As these generators are of the standard street railway type with which all are familiar, they need not take more of our attention at this time.

Turning now to the alternating current machines on the other side of the building, we find them very different from the two-phase apparatus employed for lighting purposes at the World's Fair. In those machines, it will be remembered, there were practically two armatures revolving in a common field. The windings of these two armatures were in such relation to each other that the phases of the two currents were in quadrature with each other. In fact the World's Fair generators were really two separate machines operated on the same shaft and in a common field. The frequency of the currents was 7,200 and their voltage approximately 2,000. The present machines, which are admirably illustrated in Fig. 2 (page 170 of last issue), in many respects resemble multipolar direct current machines, except that four collecting rings replace the familiar commutator. The field magnet yoke is of massive cast-iron with inwardly projecting laminated pole-pieces, fourteen in number. The armature is single instead of double and resembles very closely in outward appearance a Gramme ring. The winding is continuous and connections are brought out at four points, 90° from each other, to collecting rings, as represented in diagram, Fig. 7, the two terminals of each diameter forming the terminals of a different circuit the phases of which differ also by 90°.

In the diagram A and B represent the collector rings of one circuit and their connections, and C and D those for the other circuit.

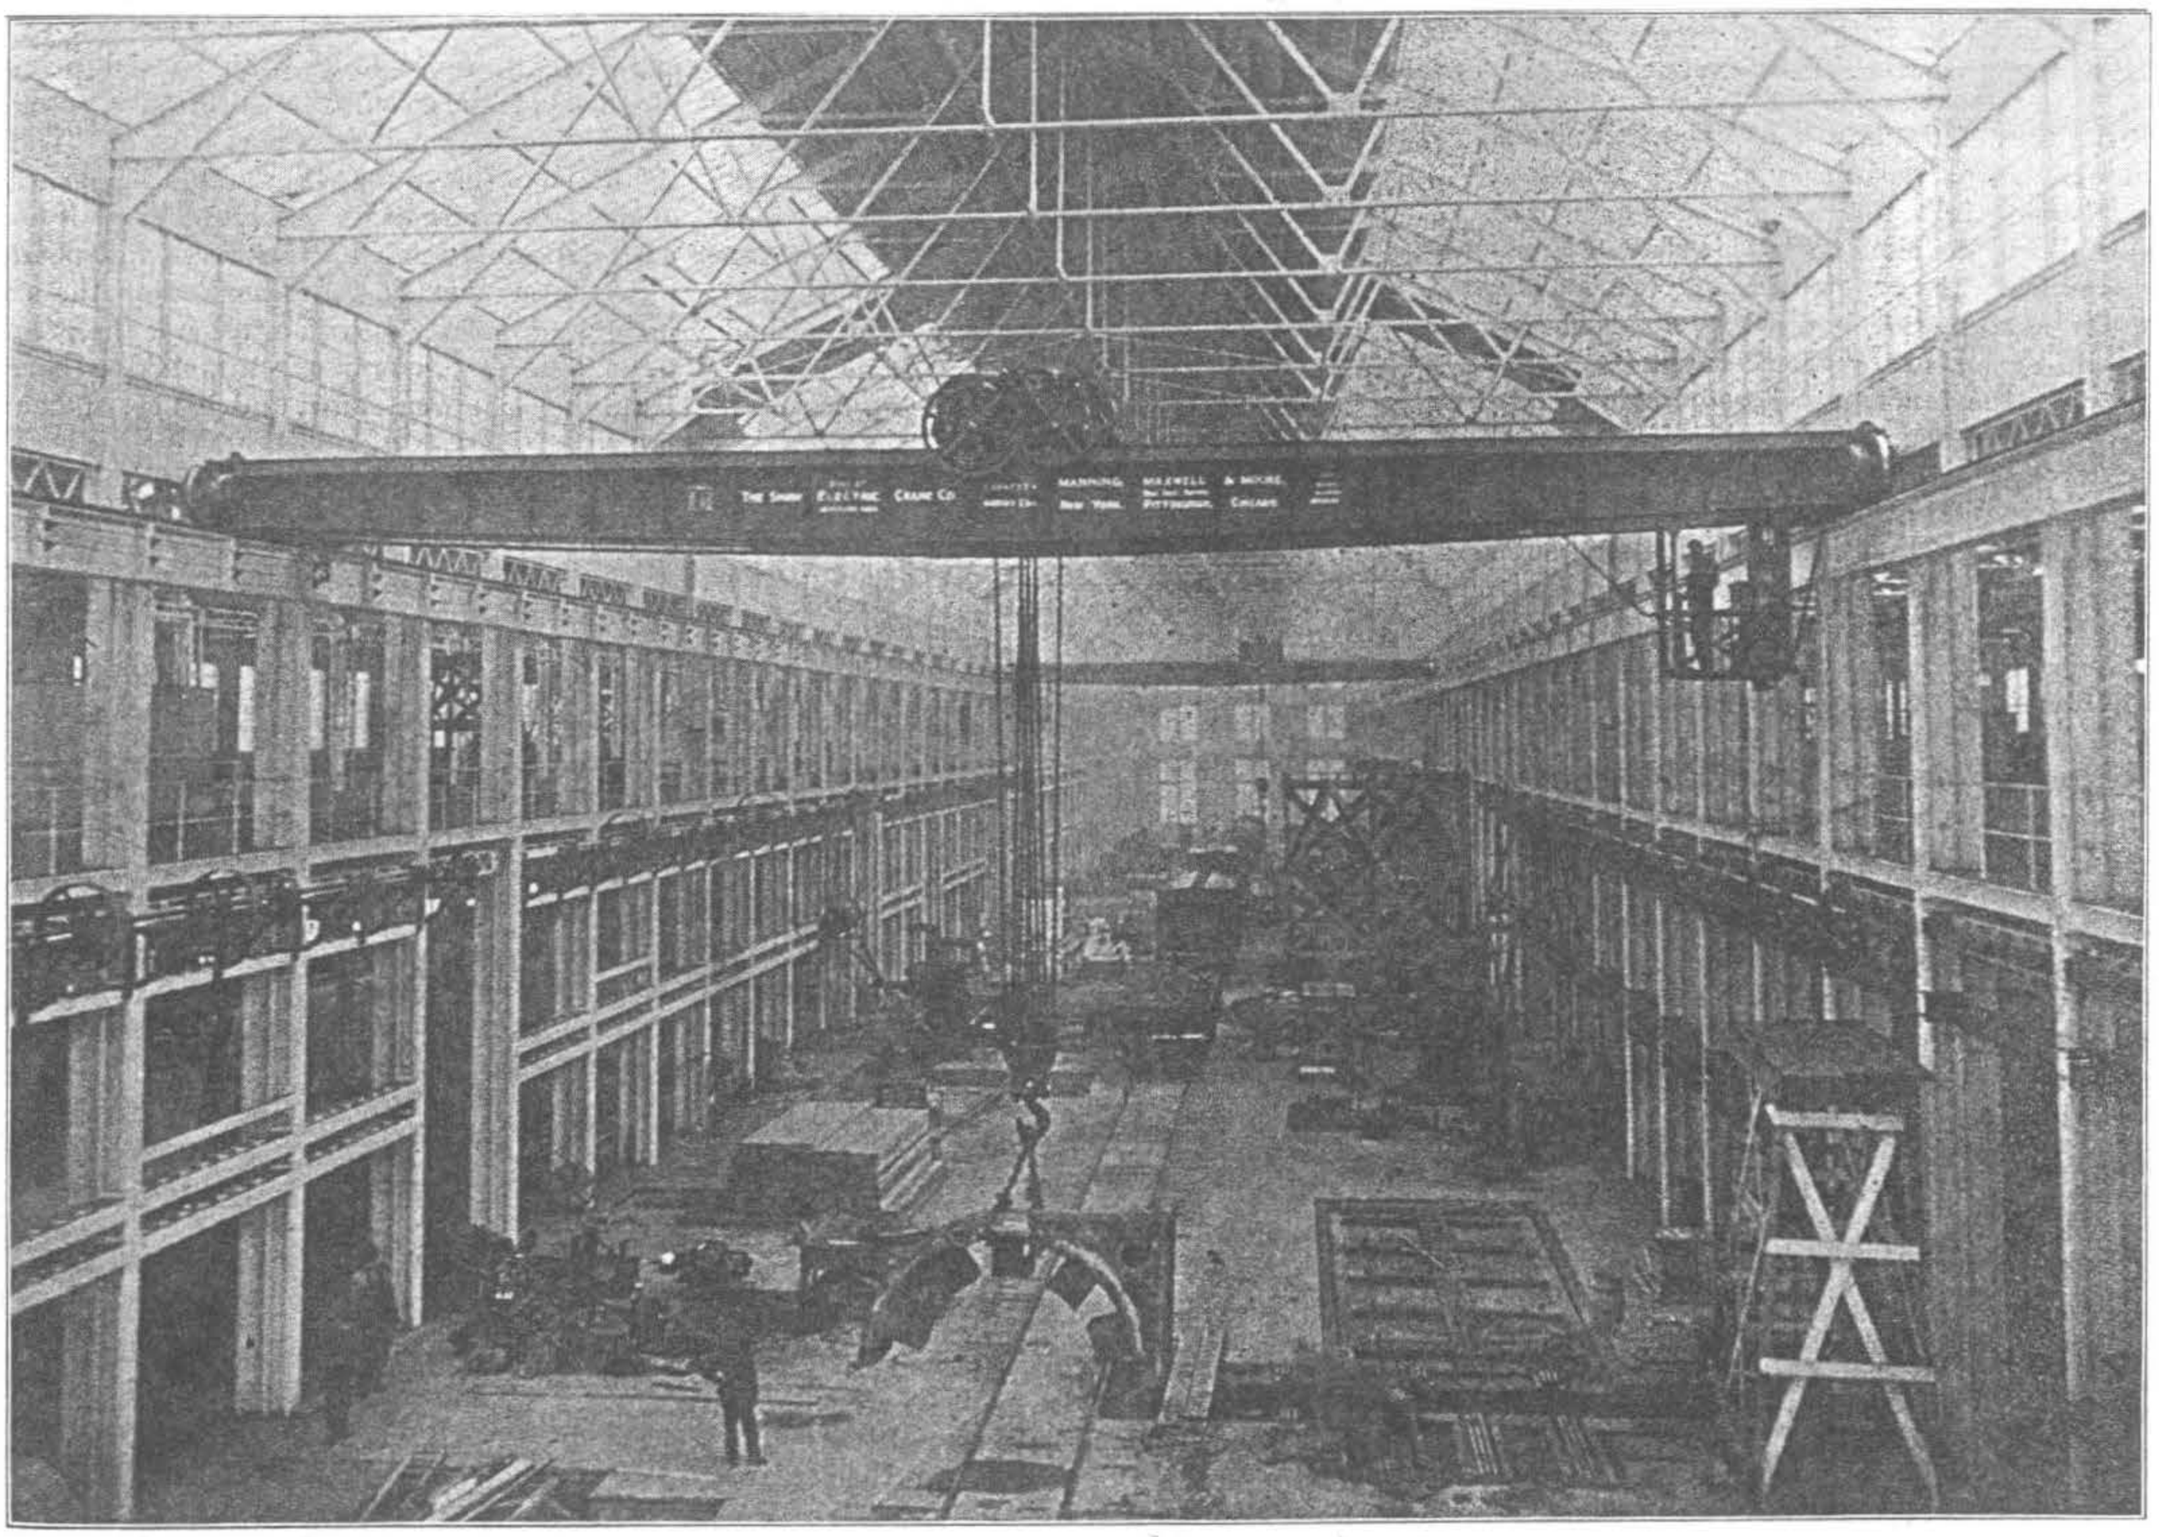
In three of these wires are placed automatic circuit breakers, so that in case of a short circuit between any two of the wires the circuits involved will be opened.

The windings of the armature are carried in slots in its cylindrical surface and held against centrifugal force by vulcanized fiber rods slipped into grooves in the slots just over the conductors. No binding wire is therefore employed on the cylindrical surface of the armature as is necessary when the conductors lie upon the surface.

The pole-pieces are fourteen in number and consist of laminated iron inserted into the yoke at time of casting. This insures the most perfect continuity between the two and obviates the reluctance factors due to mechanical joints. The magnetic circuit of the yoke is of high conductivity by reason of its massiveness, and the high permeability required of the pole pieces is obtained by the soft iron, and the prevention of foucault currents where they are most likely to occur is obtained by its lamination.

In the machines under discussion the fields are separately excited from a Tesla rotary transformer, illustrated in Fig. 6 (page 171).

This receives the alternating currents at the collector ring end, running as an alternating current motor and transforming them to direct currents which are taken off the commutator end for field excitation.



The two generators run at 220 revolutions, giving currents of 3,000 alternations—the same frequency as is to be employed at Niagara. Since in this installation the greatest distance of transmission is but about 1,100 feet, high potentials were not necessary nor desirable. The voltage employed is therefore only 230 at the generator terminals or about 220 at the motors.

Much has been written about the practicability of coupling alternators in multiple, and while it has been successfully done in a number of cases it has also failed in a sufficient number to give rise in the popular mind to a question as to its practicability. It is of the utmost importance to the central station man that he have the ability to throw units in and out of action, in multiple, as his load changes, for without this ability he must drop out in the race for supremacy. One of the points which the Westinghouse Company wished to emphasize, therefore, was that their two-phase generators could be operated in multiple, and upon their ability to operate in this way they staked the entire success of the new plant. It had not been a question with them, for it had already been demonstrated to their entire satisfaction, but the public required assurance on this point, and the object lesson which these works was intended to afford would have been incomplete had the two generators been employed on separate sets of circuits. They are therefore coupled up in multiple, and during the days when the writer saw them operating were giving a combined output of more than 400 amperes on each of the two circuits. The variation between the two machines was practically negligible, and they seemed to work in parallel in every respect as well as two direct current machines similarly connected are accustomed to do.

Where longer distances are concerned, machines giving higher potentials would be employed and step-down transformers used at the point of distribution to bring the voltage down to that suitable for motor work or lighting; or if very long distances were involved, requiring higher potentials than it would be desirable to generate directly in the armature, these same machines generating 230 volts could be used, step-up transformers employed at the power station to raise the voltage to that required for economical transmission, and step-down transformers at the point of distribution employed as before to reduce the pressure to the requirements of service.

The simplicity and efficiency of the closed magnetic circuit transformer are too well known to require remark here further than to say that they are the most efficient transformers of energy known to man. So high has this efficiency been for several years past that little improvement seemed possible or even desirable in this direction. There has been room for improvement, however, in methods of insulation against the increasingly high potentials now being used and in the dissipation of the heat energy which constitutes inevitable losses in the transformer. Theoretically a transformer working with a hot core and a cool coil would be the most efficient, but these two conditions are incompatible. They have been partially realized, however, in the Westinghouse transformer, which is illustrated in Fig. 8. This photograph shows very clearly the method of building up the laminated core around the coils adopted by this company, but the main feature to which it is desired to call attention at this time is the spreading of the ends of the coils after they come out of the iron, which affords a much better opportunity for the dissipation of the heat energy developed in the coils than any other method thus far suggested which does not at the same time dissipate the heat from the iron as well.

Still another essential to a good transformer or converter, as the Westinghouse people call it, is that it shall be proof against the breaking down of the dielectric. Where comparatively low potentials are concerned, it is not difficult to insulate against them, but when extreme pressures such as long-distance transmissions require are used, the insulation against these pressures becomes a question of the utmost importance. Tesla has shown that the air itself is a most fruitful cause of discharge across either from static or dynamic charges, and that if this be removed many of the difficulties of transformer insulation are also removed. The Westinghouse Company, therefore, exclude the air from the transformer chamber by utilizing a fluid dielectric, which has the further quality, not possessed by solid dielectrics, of repairing itself in case it does at any instant break down. The transformer shown is the latest type of the oil transformer now manufactured and used on high-potential circuits. As will be observed, no attempt is made at high insulation in the winding of the coils, they being simply wrapped in untreated cotton tape. The transformer, however, when ready for use is simply immersed in an oil

VIEW CENTRAL AISLE OF MACHINE SHOP. 30 TON ELECTRIC CRANE.

bath, the air driven out as far as possible and then connected up for service.

The Westinghouse Company was the first to appreciate the possibilities of the alternating current in long-distance transmission, and when

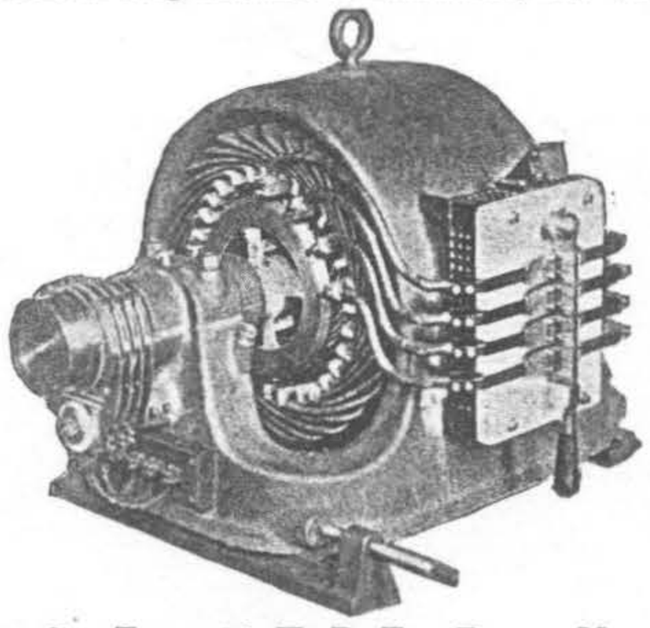


FIG. 3.—TESLA 50 H. P. TWO-PHASE MOTOR. OLD STYLE SWITCH. NEW STYLE COLLECTOR BRUSHES.

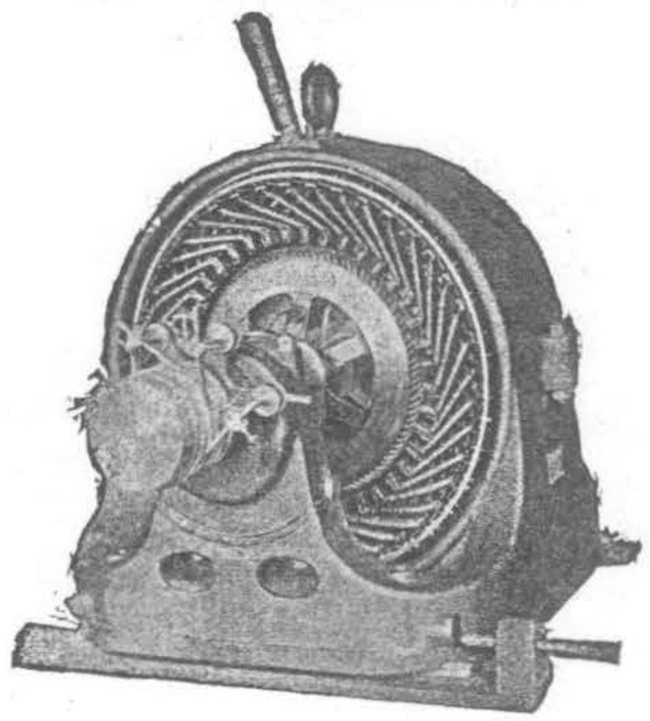
the inventions of Gaulard and Gibbs had placed it on a commercial basis, they at once procured the exclusive right to their use. They have therefore been the pioneers in this class of apparatus, and while the system of to-day bears little resemblance to that elaborated by Gaulard and Gibbs, the system of transformation is based primarily upon the fundamental patents issued to those two gentlemen. Many other fundamental patents bearing upon this important field were also early acquired, among the most important of which are the Tesla polyphase patents, which it is claimed completely cover the whole field of polyphase transmission and distribution and which will find their highest and most extensive application in the great Niagara scheme.

The Tesla polyphase patents upon which the Westinghouse Company base their claims of ownership in this field are the following:

May 1, 1888, Nos. 381,968—381,969—381,970—382,279—382,280—382,281, 382,282.
October 2, 1888, Nos. 390,413—390,414.
October 9, 1888, Nos. 390,721—390,820.
April 16, 1889, No. 401,520.
June 25, 1889, No. 405,858—405,859.
December 3, 1889, Nos. 416,191--416,192—416,-193—416,194—416,195.
December 31, 1889, No. 418,248.
March 25, 1890, No. 424,036.
August 5, 1890, Nos. 433,700—433,701—433,702—433,703.
January 27, 1891, No. 445,207.
June 30, 1891, No. 445,067.
September 22, 1891, No. 459,772.
December 8, 1891, No. 464,666.

Making twenty-nine patents all told, which



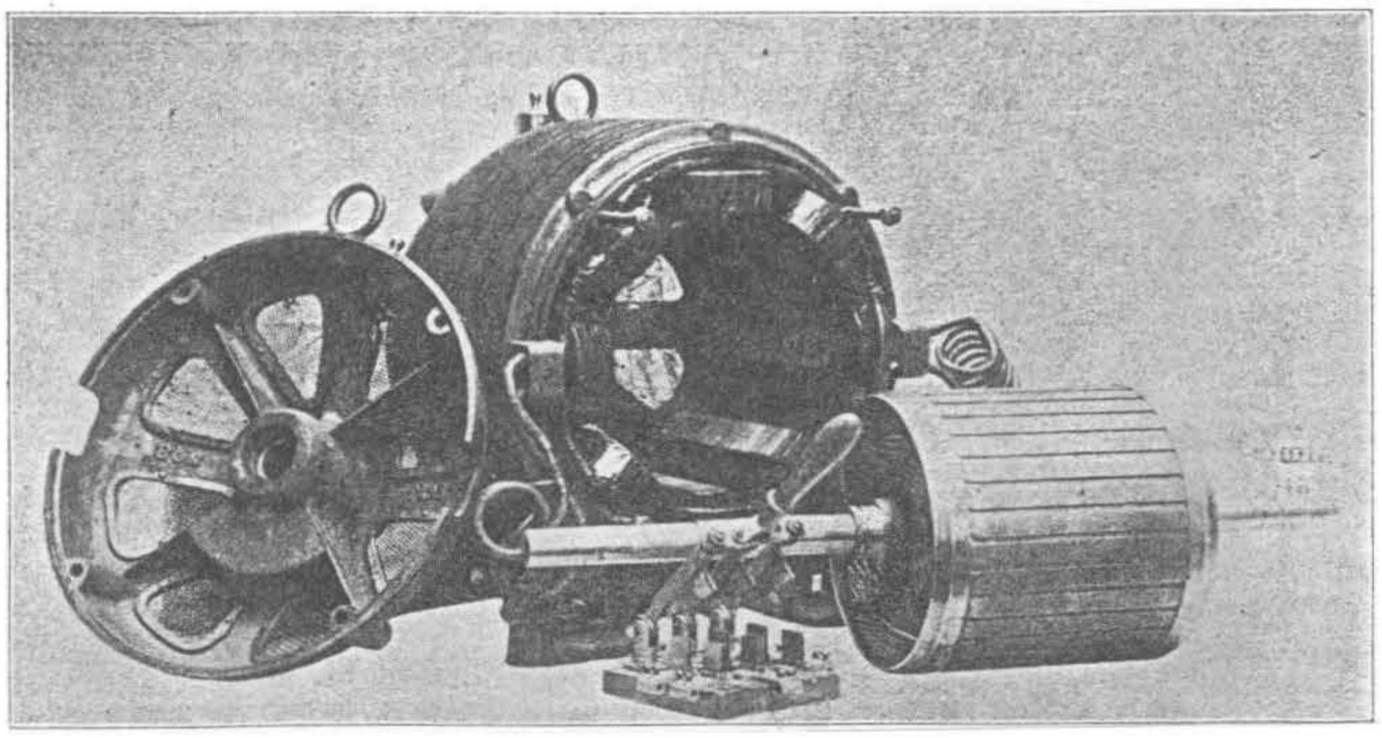


FIG. 4.—TESLA 50 H. P. TWO-PHASE MOTOR. NEW STYLE SWITCH RING. OLD STYLE COLLECTOR BRUSHES.

the company believe completely cover the polyphase field so far at least as it has been developed.

It is not to be supposed, however, that any one mind has contributed all that goes to make up the completed commercial system of to-day. Many minds indeed have contributed to the perfected system as exemplified in the plant under discussion, and while, if we were to confine ourselves strictly to this particular plant, we would necessarily pass lightly over some of these features, or not mention them at all, the description of the system as a whole would be incomplete. At the risk, therefore, of seeming a little prolix some of the more important accessories will be referred to.

Where lights are to be supplied as well as power, it is of the utmost importance to have means at hand by which the potential on the various circuits may be regulated so as to compensate for the change of losses due to variations in load. The voltmeter as usually employed in the generating station indicates only the pressure at the generator terminals and not that at the point of consumption where the variable effects of drop are encountered. In ordinary practice it has been customary to bring back small *pressure* wires from the points of distribution, by which means the pressures at those points were indicated and the proper regulation indicated to the station manager. A method of equalizing the pressures among a number of distribution points, often resorted to, has been

TESLA 5 H. P. MOTOR, OLD TYPE.

that of connecting them all together with equalizing wires. Both of these methods are cumbersome and expensive, and have been discarded by the Westinghouse Company. In their places have been substituted the following arrangements:

The voltmeter is supplied by the secondary of a small converter, usually reducing in the ratio of 30 to 1 where the initial voltage is 3,300, or in a greater ratio if higher. In the voltmeter circuit there is placed a compensator. This is shown in Fig. 9, and consists of a small transformer with its primary in series with the main circuit and its secondary in series with the voltmeter circuit, and connected in such a way that the compensator pressure to the main current opposes the voltmeter pressure to an extent proportional to the loss in the conductors. The voltmeter by this arrangement, therefore, indicates the potential--not at the station, but at the point of distribution.

Now as this pressure varies it becomes necessary to have some means of correspondingly varying the station pressure. If there were but one circuit extending from each generator, this would easily be accomplished either by varying the field excitation or the speed of the armature, but in practice there are usually a number of circuits extending from each machine in each of which a different compensation is required, and the methods referred to would not be applicable. To meet such cases resort is had to the Stillwell Regulator, represented in diagram in Fig. 10.

THE STILLWELL REGULATOR.

The great value and importance of this instrument as a part of the modern complete central station equipment has been demonstrated beyond question. The principle of the instrument—as beautiful as it is simple—is that of induction. For this reason no similar device can by operated from a direct current system. It consists primarily of a converter, suitably designed, with secondary coil adjustable in length, i. e., with connections brought out from different parts of the secondary coil to a multipoint switch. By means of this switch the whole or any part of the secondary coil may be thrown in series with the main circuit, thus adding to the initial primary potential of the circuit the additional potential of the secondary coil, or a part thereof. Within the limits of the voltage thus added the potential of the supply circuit is, therefore, subject to the most delicately shaded adjustment, independent of whatever may be the potential at the alternator terminals. Consequently, it is the practice to have several supply circuits taking current from the same generator, and hence, of course, they are at absolutely the same potential. Although each circuit may be operated at a different percentage of loss, by the use of the Stillwell Regulator all lamps will be maintained at a uniform voltage and brilliancy. The attachment of a double-throw switch makes it practicable to reverse the action of the regulator and decrease instead of increase the initial potential. This may

FIG. 6.—ARMATURE ROTARY TRANSFORMER.

be frequently done to meet local conditions, and is an additional convenience.

It will be noted that this instrument simply increases the electromotive force in the circuit by a few volts. To do this it is necessary to transform but a small portion of the electrical energy passing through the regulator. The

efficiency of conversion of this fraction of energy is easily 95 per cent., and it is therefore evident that the loss of energy in the regulator will be but an extremely small percentage of the total energy of the circuit. For example, at full load a 100 ampere regulator, designed to raise the initial potential 10 per cent., would receive at the

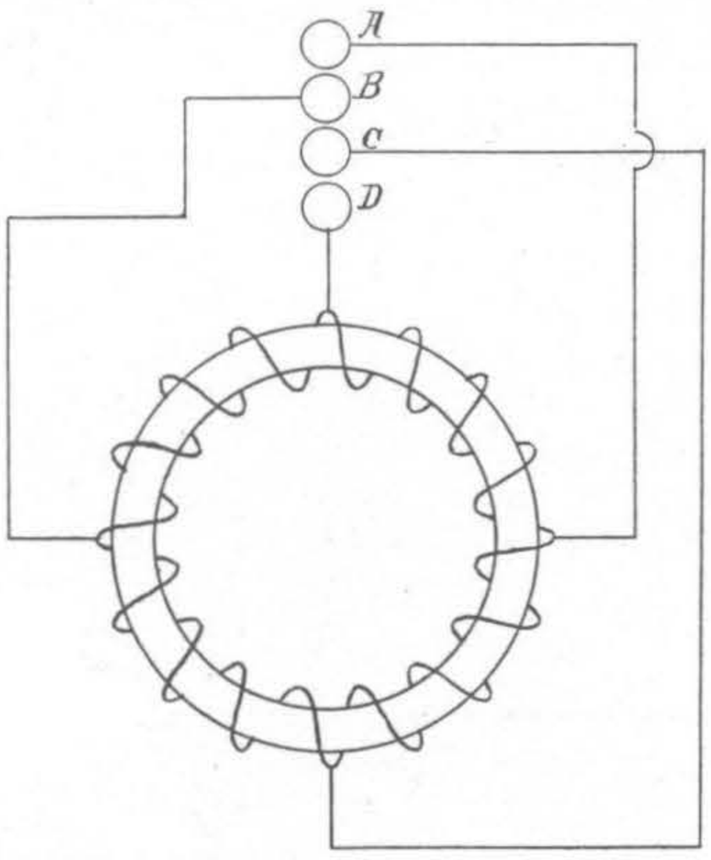

FIG. 7.—DIAGRAM OF GENERATOR ARMATURE CONNECTIONS.

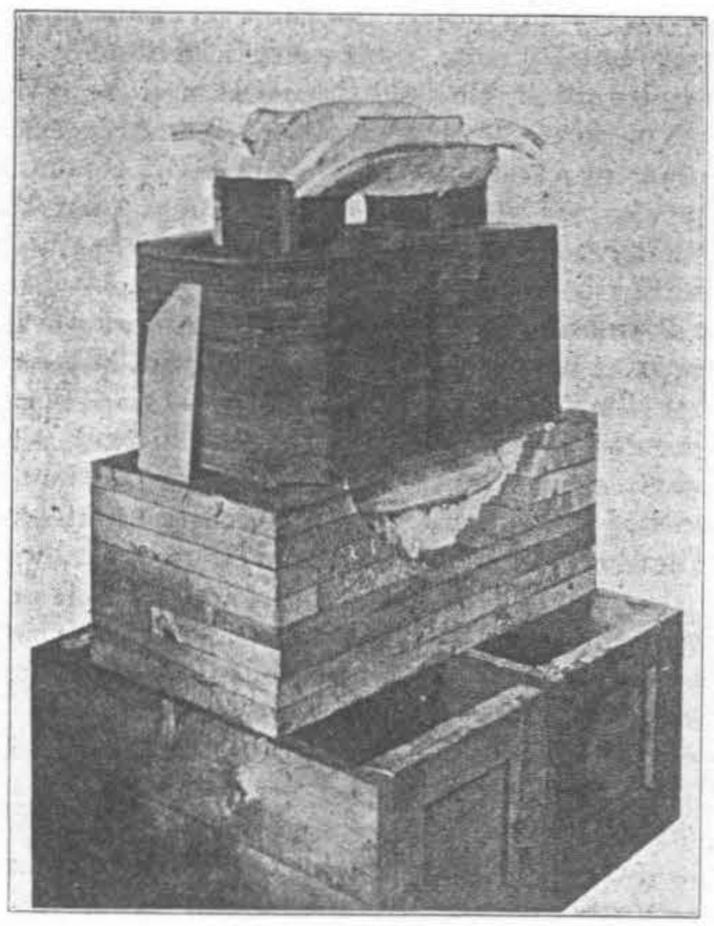
terminals of its primary coil 10 amperes at 1,000 volts, and at the terminals of its secondary coil would deliver 100 amperes at 100 volts, less any losses suffered in conversion. These losses, being the same as those of a standard converter of equal capacity, aggregate not to exceed 5 per cent., i. e., 500 watts. The total energy supplied to the circuit by the generator being 110 amperes at 1,000 volts, i. e., 110,000 watts, the percentage of loss is therefore .00455, or less than $\frac{1}{2}$ per cent.

The extreme flexibility supplied by the use of the regulator is illustrated by an example which occurs almost daily in practice. Let us assume a small station operating under ordinary conditions with, say, a loss of $2\frac{1}{2}$ per cent. in its feeders and 1 per cent in its mains, the territory supplied being within a radius of one mile from the station. Let us further assume that there is



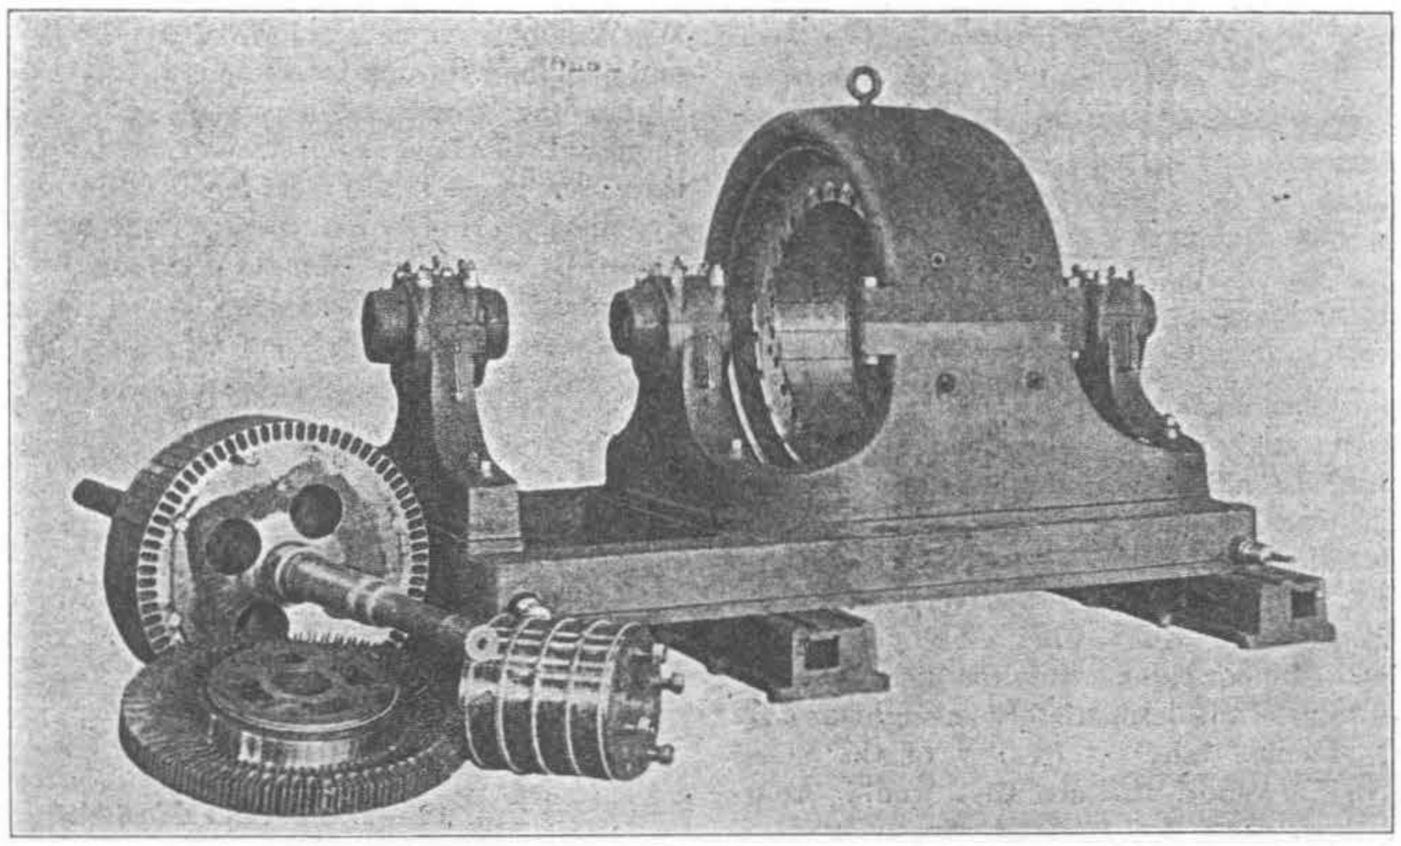


FIG. 8.—OIL TRANSFORMER PARTLY BUILT UP.

a point two and one-half miles distant where an additional 500 lights can be secured. It would evidently not pay to erect a special alternator to supply this number of lights, and yet to supply them from the same alternator sufficient additional copper must be put into the new circuits to reduce the losses over the greater distance to those already incurred in the shorter circuits. This also would prove uneconomical and the station manager would find himself confined to a choice of three undesirable methods: 1st, to install a new alternator for the 500 lights; 2d, put in a sufficiently heavy wire to maintain the same loss at the greater distance, and 3d, abandon the idea entirely of supplying the new customers. I do not know whether dilemmas usually have three horns, but this one seems to have and they all promise to be equally uncomfortable to sit upon. The regulator, however, comes to the station manager's assistance in this way: Assuming an average of $\frac{1}{20}$ ampere in the primary line for every 16 C. P. lamp on the secondary circuits and a 10 per cent. Stillwell Regulator to be attached to the new circuit, it is immediataly possible to raise the initial electromotive force 10 per cent. above the electromotive force of the other circuits supplied from the same dynamo, and to therefore allow an additional loss of the same amount on the line. The line cost for supplying these lights by this means (including the cost of the regulator) would be only about one-third what it would were the extra copper otherwise required employed. It also effects economies in operation and renders possible much better service by placing in the hands of the station manager a most perfect means of independent regulation of the various circuits extending from the same dynamo.

In the regulators as now put on the market, the secondary is divided into small sections, each of which has an electromotive force equal to 1 per cent. of the primary. Any number of these sections may be placed in series with the supply circuit, and thus with standard apparatus the variations in pressure at the point of distribution may be compensated for through all variations in load within less than 1 per cent.

All long lines of overhead wire, and particularly such as traverse mountainous sections, are subject to violent atmospheric conditions which if not provided against in some efficient manner are liable to result in the destruction of the machinery at both ends of the line. The popular belief is that these destructive effects are due to lightning, but while they are apt to occur most frequently in sections of country where severe thunder-storms prevail it is doubtful if the lightning itself ever, or at least frequently, actually strikes the wires. The so-called lightning strokes on circuits are now known to be chiefly inductive effects, due to sudden changes of potential of the earth or clouds due to lightning flashes occurring not necessarily in the immediate proximity of the circuits, but which by inductive effects set up electrical surgings in the wires. These surgings if they reach the transformer or dynamos are liable to cause disruptive discharges across the insulation which may lead to its destruction. It is not the disruptive discharge, however, that does so much damage, as it is the dynamo current which, having had this path opened to it by the disruptive discharge, follows it. An effective lightning arrester, therefore, has two distinct offices to fill: 1st, to offer an easier path for the surgings than that through the coils of the machinery whereby it may be drawn off the line, and second, to prevent the passage of the dynamo current over the same path that the disruptive discharge has opened for it. The old idea was that the first of these functions was fulfilled

TESLA 300 K. W. MOTOR, WORLD'S FAIR TYPE.

when a grounded conductor was separated by a short air-gap from the circuits to be protected, and the second by providing some mechanism, either mechanical or magnetic, by which the arc which followed might be broken instantaneously and the normal air gap re-established for subsequent protection. Experience has taught, however, that these electrical surgings do not seek to

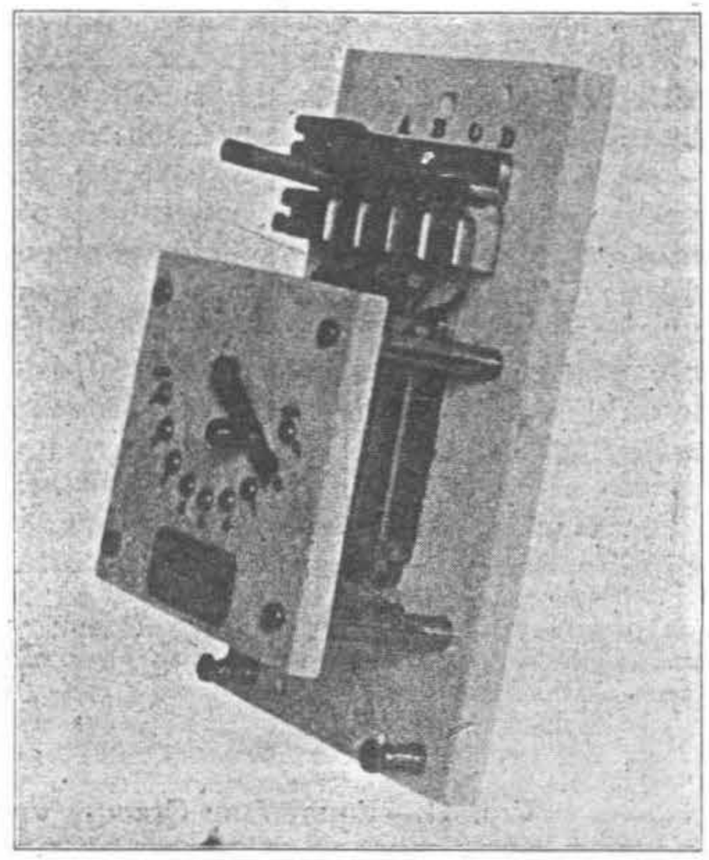

FIG. 9.—COMPENSATOR.

leave the wires with equal force at all points and that they will frequently pass by a number of short air gaps and then find the ground through a much longer and apparently more difficult path. The reason for this is now well understood and is implied by the name by which I have

described them, viz., surgings. If an air gap be provided where the crest of the wave happens to be, a discharge will take place, whereas similar air-gaps, or even shorter ones, would be passed by by the same surging if they happened to be situated at any other point than where the crest happened to be found.

Mr. Alexander Jay Wurtz of the Westinghouse

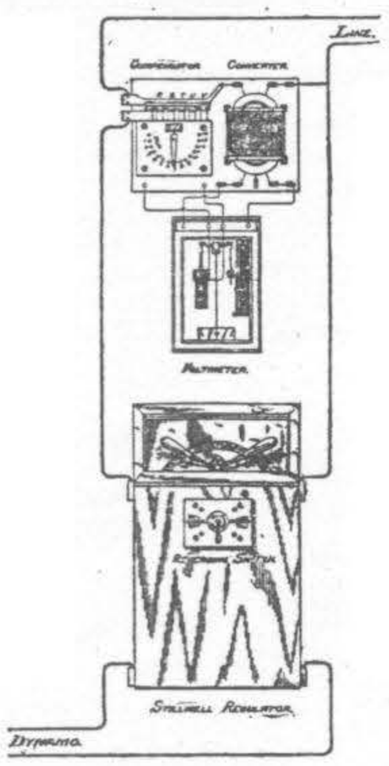

FIG. 10.—STILLWELL REGULATOR.

Company has made, under their auspices, a very exhaustive study of the phenomena of so-called lightning discharges on overhead circuits, and has discovered a method by which the lines are afforded almost absolute protection from these dangers. The basis of this discovery is that of a non-arcing metal which, when employed as the terminals of an air gap, permits the disruptive discharge to pass but immediately extinguishes, by virtue of some inherent quality of the metal itself or its vapor, the arc that would otherwise follow. In his completed arrester he employs seven cylinders of the metal—each one inch in diameter, and three inches long. These are mounted side by side, separated from one another by $\frac{1}{64}$ of an inch. The central one is connected to the ground while the two outside ones are connected to the two sides of the circuit. With these metals and this arrangement it has been found impossible to start and maintain an arc when they are separated by an air gap of this size, but strange to say, where the gap is longer—say half an inch—the arcing is said to be very vicious. In recognition of the value of this discovery of non-arcing metals and their application to the protection of circuits, the Franklin Institute of Philadelphia awarded to Mr. Wurtz the John Scott Legacy premium and medal. These lightning arresters are placed at such frequent intervals along the line that some one or more of them is sure to be in the proper position to draw off the charge at the crest of the wave. The arresters are also placed in the stations at both ends of the line. As showing the frequency of these discharges in some localities, an instance is cited in the experience of a line at Telluride, Colorado, when forty-two discharges of the lightning arresters were observed in as many minutes, any one of which might, if not thus provided for, have damaged or destroyed the machinery at one or the other end of the line.

The above digression has been indulged in to call attention to some of the accessories to a transmission plant installed on the Westinghouse system. This is scarcely pertinent to the subject in hand, but we may consider that the Westinghouse shops are located at the further end of a long line of transmission, and that the high voltage transmission currents of 5, 10 or 20 thousand volts have been transformed down in the power house to 230 volts for distribution, the dynamos previously described being simply replaced by step-down transformers, and we have the conditions exactly as they would be if the shops were actually hitched on to Niagara or

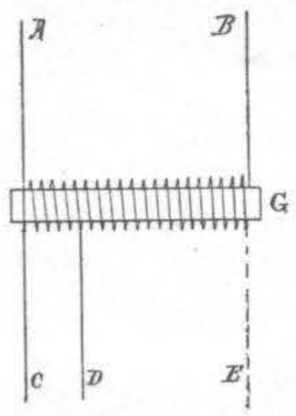

FIG. 12.—BALANCING COIL.

any other distant source of power. The switchboard would remain as it is, and from it would run, as they do now, the four circuits—two for each of the two-phase currents.

At Pittsburg these wires are carried overhead on insulators to the various buildings where power and light are required.

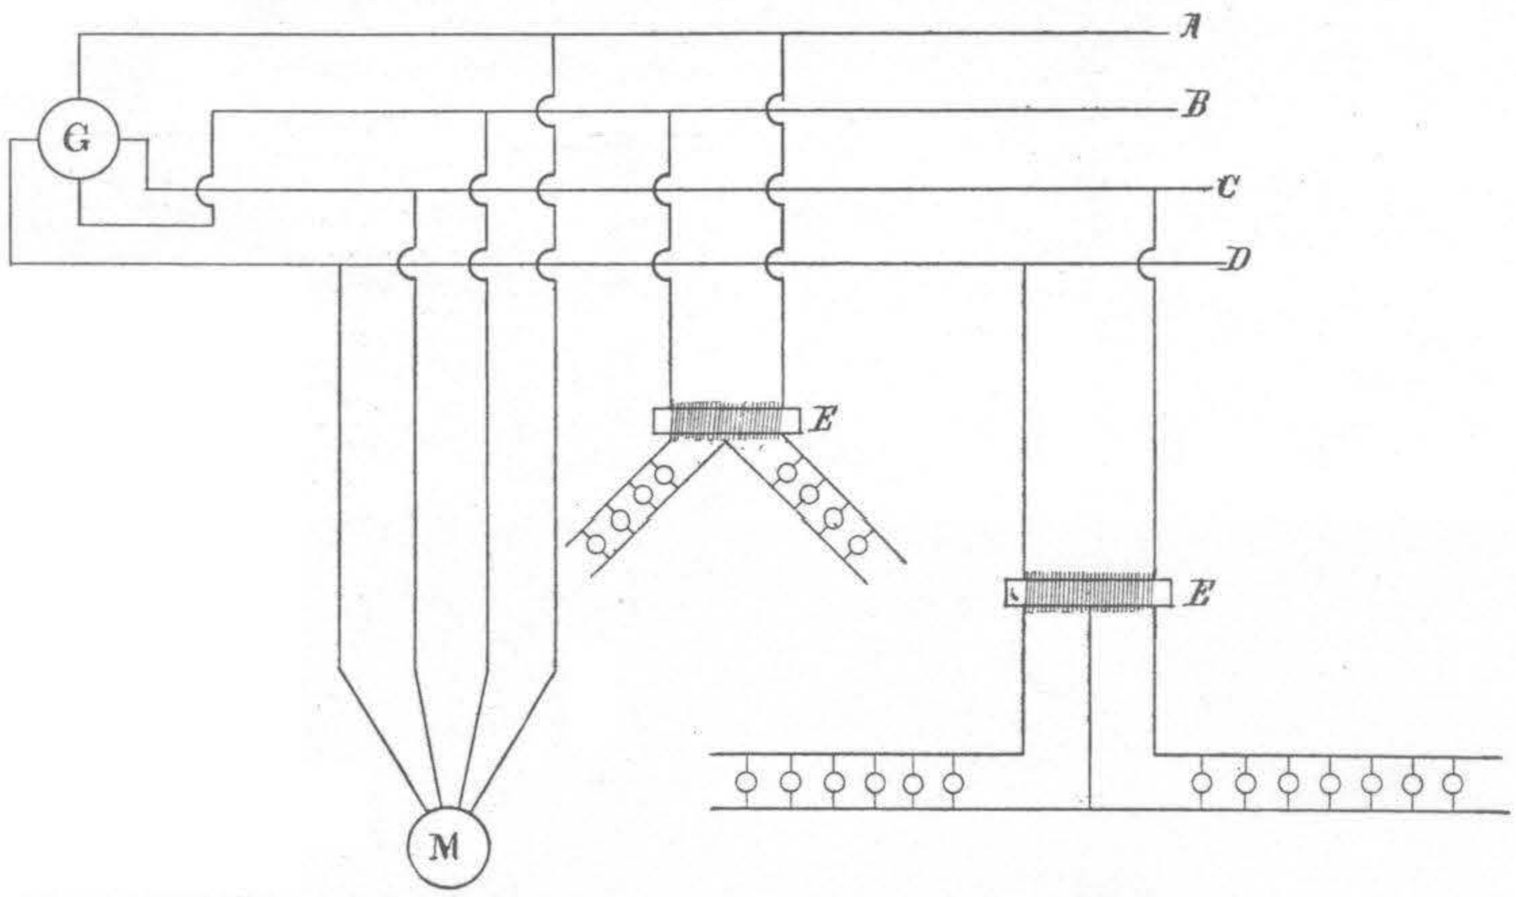

FIG. 11.—FOUR-WIRE CIRCUIT WITH MOTOR AND LIGHT CONNECTIONS.

Fig. 11 shows the methods of distribution and the manner of taking current off from the circuits both for motors and light. It will be observed that the lights are taken off of both circuits indiscriminately. Usually, it would be better to divide the lights about equally between the two circuits, for the reason that where all the motors used are two-phased motors, as in this establishment, the only chance for unbalancing the circuits is by overloading one circuit with lights at the expense of the other. Some writers have held that this unbalancing of the circuit would

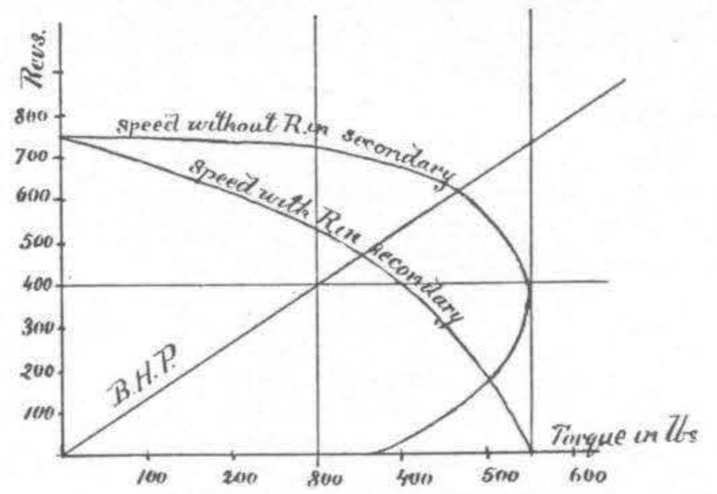

FIG. 13.—CURVE OF TORQUE.

introduce undesirable complications in the operation of the apparatus. There seems to have been no foundation for these fears, for the irregularities do not develop in practice. The Westinghouse Company have put the system to the severest test of fully loading one side with lamps and

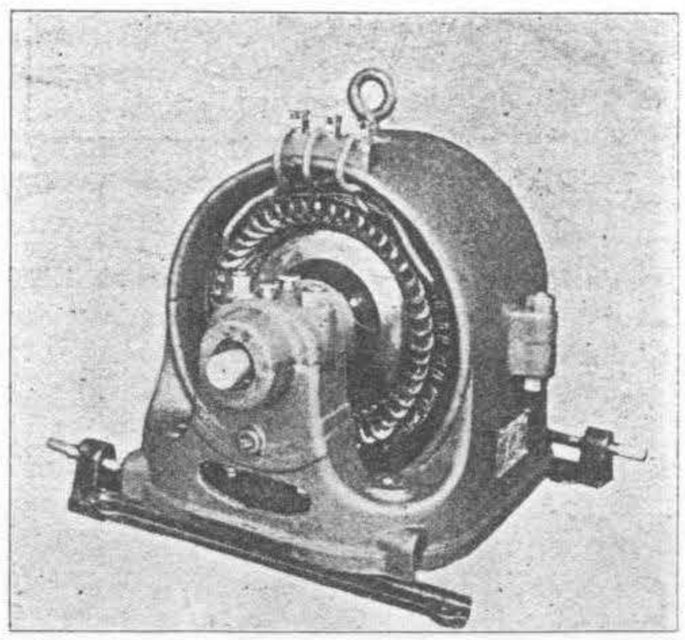

FIG. 14.—TESLA THREE-PHASE MOTOR.

operating them with no load on the other side. The difference observed under these conditions between the two sides was only 4 per cent.

THE BALANCING COILS.

It will be observed in the diagram (Fig. 11), that the lights are taken off of either circuit, between which there is a difference of potential at this point of about 220 volts. The lamps require but 110 volts. The usual method would require either that the lamps should be wired two in series or that the potential be reduced by means of a transformer. Instead of the usual transformer with separate primary and secondary windings, the balancing coil is here used. While the functions of this coil are doubtless well understood by many of the readers of this paper, it may be well for the benefit of others to describe it in detail. In Fig. 11 this coil is represented by E, and in Fig. 12 on a larger scale by G. In the latter figure, A and B are the two sides of the 220 volt circuit connected to the terminals of a coil with iron core G. If there were no secondary coil, or if the secondary coil were open, this coil would act by self-induction as a choking coil, and no current could pass from A to B. For the purposes of illustration I have represented this coil as having twenty complete turns. If to one end the wire C were attached, and another one D were attached to the fifth turn, then the twenty turns would act as a primary and the five as a secondary—the currents in the two being in opposite phase, and the reduction of potential between these two wires would be from 220 volts to 55. If now a third wire E were attached to the other end of the coil, the whole coil would again act as a primary to that portion of the coil between D and E as

a secondary—in this case fifteen turns—and the potential between these two wires would be $\frac{15}{20}$ of the primary voltage, or 165 volts. By this means it is possible with a single coil to divide up the voltage into two or more parts by including between the secondary wires the proper proportions of the coils to effect the desired reduction. It is in fact a transformer, but one of exceedingly simple and economical construction, and for distributing a 220 volt current to 110 volt lamps is made use of by connecting a neutral wire into the center of the coil, and from this elementary three-wire circuit taking off the two-wire circuits at convenient points. Since the coil is equally divided between the two circuits, the electromotive force of the primary is also equally divided between the two branches, and there is obtained 110 volts in each branch. If it were desired to take off four circuits of 55 volts each, for arc lamps or other purposes, the coil would be divided into four equal portions, or any other portion of the primary voltage could be obtained in the secondary by simply including between the two wires of the secondary the proper proportion of the primary coils.

The advantage of this arrangement over the two-coil transformer for this purpose is its simplicity and the economy both of copper and of attendant copper losses.

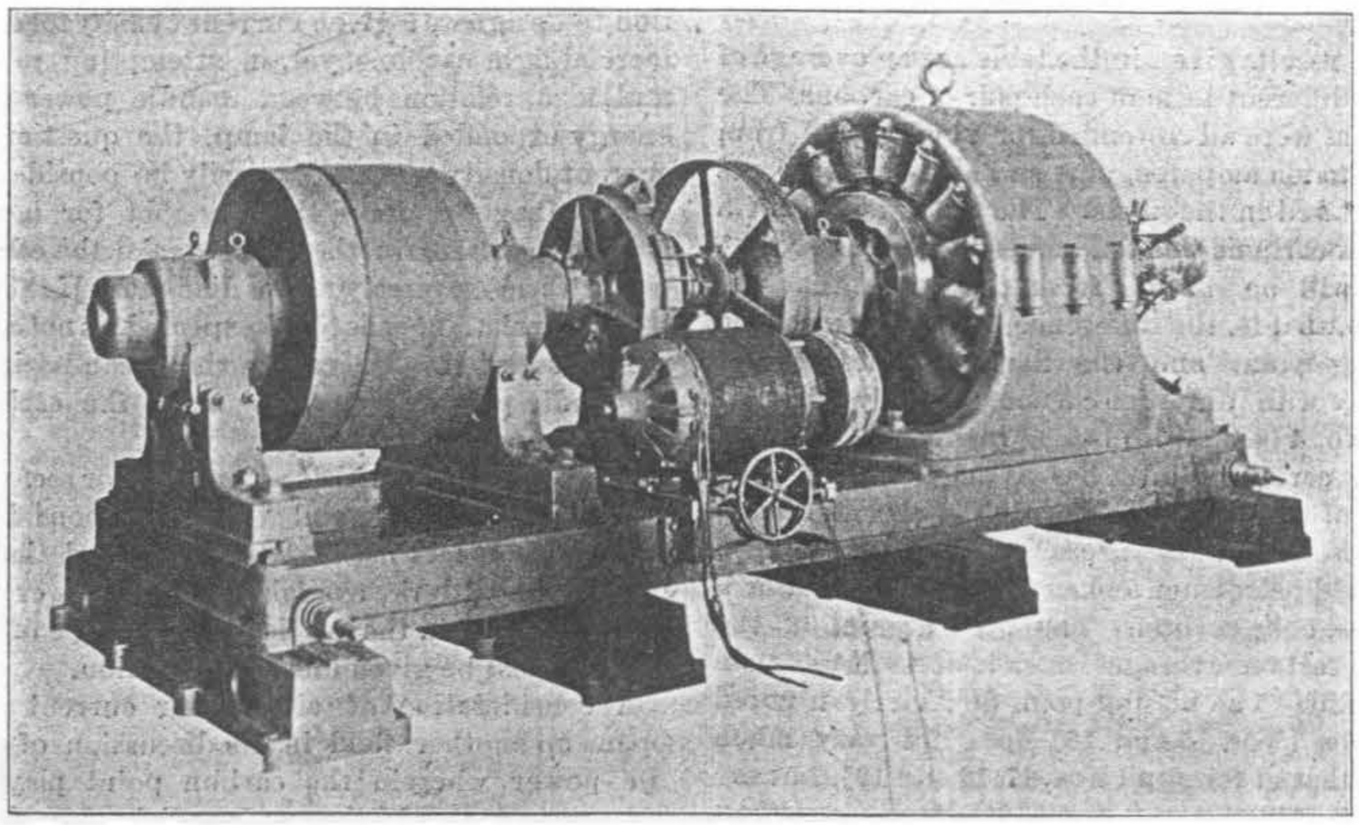

FIG. 15.—250 H. P. SYNCHRONOUS AND STARTING MOTOR.

TWO-PHASED MOTORS.

The motors' currents are taken off the two circuits as shown in Fig. 11, the connections being made as shown at M. The alternating current motor is in reality a transformer so constructed as to permit of relative motion between the primary and secondary coils. If either one of these be fixed in position, the other becomes the rotating part, and from one point of view it is entirely immaterial which is made the stationary and which the rotating part. Carelessness in the use of language has accustomed us to refer to the rotating member of a motor as the armature, but strict scientific accuracy forbids such indiscriminate use of the term. The Westinghouse Company are therefore to be commended for introducing a more accurate nomenclature, which is bound to find general acceptance as soon as it is better known. At the Westinghouse Works the word "armature" is no longer used when speaking of the two-phased motor, but it is described as the "rotating primary" or rotating secondary" as the impressed E. M. F.'s are led into the rotating or the stationary part. There is nothing in direct current practice to indicate the advisability of introducing resistances into the armature circuit, and they are avoided as far as possible except for starting purposes, when their function is simply prevent too great a rush of current. These resistances are not only wasteful, but actually cut down the starting torque of the motor by the exact amount by which they cut down the current. The starting resistance in a direct current motor is therefore the lesser of two evils, because nothing could be worse for the motor than to have its armature burn out, as it most surely would do if started under heavy load without the resistance. It has been found, however, that in the polyphase motor the starting resistance has performed a valuable service, viz., it *increases* the starting torque of the motor.

For the purpose of illustration the diagram, Fig. 13, is given. These curves are not intended to be correct, but merely to illustrate the point which it is desired to emphasize. If a polyphase motor were started without a resistance in its secondary, the curve determined by torque and speed would be something like the upper one. The torque would be comparatively low at start, but reach a maximum in this case when the speed had reached 400 revolutions per minute.

Now the torque of that particular motor can never exceed this maximum, but the position of the maximum may be made to come anywhere on the vertical line passing through this point desired and will descend as the resistance in the secondary increases. If this resistance be just right, the point will be brought down to the intersection of this vertical line with the line of no speed, or in other words, the motor will have its maximum torque at starting. Under these conditions the curve will take the form shown in the lower of the two curves, which is an actual curve taken from a 40 H. P. 220 volt two-phase motor with old style switch.

The resistance which performed this valuable function of giving the motor its maximum torque at starting in addition to preventing a too great rush of current at that time, will, after speed has been attained, be a detriment, so that means are provided by which it can be then cut out. To facilitate the cutting in and out of the starting resistances the larger sized motors which are likely to be called upon to exert a heavy starting torque are usually made with a stationary secondary—the current from the line being led to the revolving part by means of brushes bearing upon four rings on the shaft. Fig. 3 represents a motor of this kind. In this the brushes are of an improved type, but the switch is one that, although still used, is being superseded by another to be described later. In the old style, Fig. 3, all of the windings of the secondary are in series with each other, and when the switch is open are also in series with the starting resistances. When speed is attained these resistances are simply short-circuited by closing the switch, as shown in the engraving. The new style switch shown in Fig. 4, is considered a great improvement on this and is arranged as follows: At starting each conductor of the secondary is in series with a small resistance and with every other conductor. By means of a closed copper ring and sliding contacts connected with it, by a movement of the controlling switch, not only are the starting resistances thrown out of circuit but all of the conductors of the secondary are thrown from a series arrangement into a parallel one, being short-circuited on this ring. This not only greatly reduces the internal resistance of the secondary windings over that which is possible by the previously described arrangement, where at best they are in series, but leaves each of the short conductors free to act independently irrespective of the disturbing influences which the others might have upon it were they all in series. In Fig. 4 the brushes are of the old style. No photograph has yet been taken of the improved type motor, and it cannot therefore be shown here, but if the brushes shown in Fig. 3 were substituted for those shown in Fig. 4 the latter would then accurately represent the latest development of the Tesla two-phase motor with revolving primary.

For the smaller sizes, where a starting torque is not so essential, the primary coil is made the stationary part and the secondary coil the revolving part. The primary is a continuous winding of the drum type with connections brought out to binding posts from the points 90° apart. The secondary consists of a laminated iron cylinder into whose surface are sunk copper bars of large section, forming elements of the cylindrical surface. These copper bars, which form the windings of the secondary, are simply short-circuited at both ends on heavy copper rings, as is the case in Fig. 4 when the latter has reached speed. There are no collecting rings, brushes or other means of connection between the rotating part and the outside circuit on motors of this type, and although they do not attain a maximum torque until considerable speed is reached, they still have an initial torque sufficient to start under a very considerable load.

While the two-phase motor is the only kind at present in use in these shops, the company also makes several other types, one of which, the three-phase motor, similar to those employed in the Lauffen-Frankfort experiment, is shown in Fig. 14. Another type is the single-phase synchronous motor, such as has been in successful use for about four years in the long mining transmission plant at Telluride, Col. This latter type will not start under load, but when brought up to a speed synchronous with the generator it will then take the load and maintain it without further attention. In this motor the fields are excited by a direct current derived from a second winding parallel with the main coils around the teeth of the armature. This is commutated and led to the field coils.

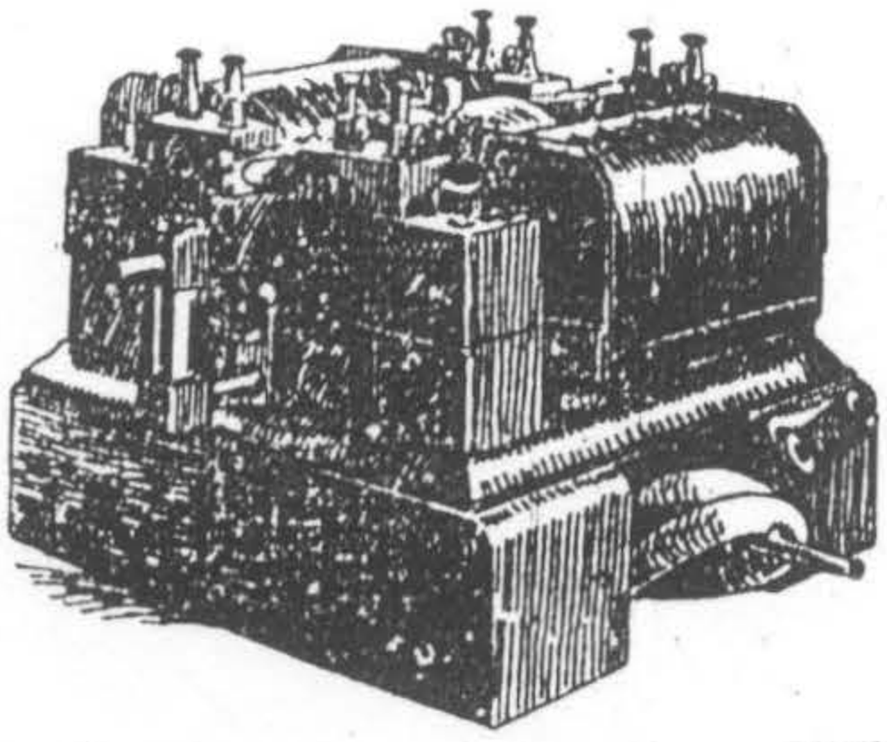
A motor of the synchronous type requires an auxiliary device for starting, however, which is usually a small motor—a special modification of the Tesla type. Fig. 15 is a photograph of a 250 H. P. synchronous motor, with the Tesla starting motor and friction clutch, installed at Telluride some years ago and still in successful operation.

With this somewhat hasty and necessarily incomplete description of the New Westinghouse Works this paper must be brought to a close. Much that would be of interest has been passed over lightly or omitted entirely, but enough has been said probably to verify the opinion expressed in the beginning, that this is the most interesting, and from many points of view the most important, electrical installation thus far attempted.

Tesla's Inventions.—The "Century Mag." for April contains a long well illustrated article on "Tesla's Oscillator and Other Inventions" by Mr. Martin; it is written in a popular style describing the oscillator and a number of light effects, which latter are well illustrated, some of them by means of photographs made by their own light; among the light effects are those of the incandescence of a solid, phosphorescence, incandescence or phosphorescence of a rarefied gas and luminosity produced in a gas at ordinary pressure. He describes also effects with widely separated resonating circuits in one of which it is claimed that at least one-tenth of a horse power was transmitted across a space of some 20 feet into the bulb of a lamp without using any wires at all; other experiments show how lamps were lighted by currents passed through the human body; an experiment is described showing the disturbance of the earth's electrical charge.

Some other illustrations of the oscillators are reproduced with a brief description in the "Elec. Eng." and "Elec. Rev.," April 3, and one of them in "El'ty," April 3. In the former it is stated that the principle involved in the oscillator is that of "oscillating a coil or magnet with great economy of energy in an intense field and thus generating current on terms of very high efficiency and regularity as well as with marked diminution in size and weight of apparatus. The engine resolves itself down to a chest or cylinder for the working fluid and the piston for carrying the armature." There is a strong air spring in the top of the apparatus and the construction is such "that the engine is always in exact synchronism with the vibrations of this spring;" the engine varies the amplitude of the vibration but the period remains always the same; "the recoil of the spring is of course incomparably greater than the impulse received by it from the engine." Several distinct types are shown and briefly described, that of the more advanced form being as follows: "this minute machine had a capacity of 12 lights. It consisted of a small oscillator and a dynamo, the latter comprising a field magnet with its exciting coils and an armature merely of iron. The magnet had on its inside a number of pole projections upon which the induced coils were wound. The armature had projections of lesser number than those of the field. In this way the output of the dynamo was increased, by the number of teeth." It is stated that there is a preponderance of one impulse over the other creating virtually the effect of a direct or continuous current, but this is not described. With the latest form of oscillator which is illustrated, the frequency is 80 to 100 and the steam pressure 350 pounds, the steam admission being controlled by a small independent oscillator. In conclusion it is stated that "there can be no doubt that in this appliance we have a mechanism for the simultaneous utilization of steam and generation of current under conditions that must effect large economies in every direction; while it should also prove a powerful instrument for exhaustive research."

SCIENCE AND MECHANICS.



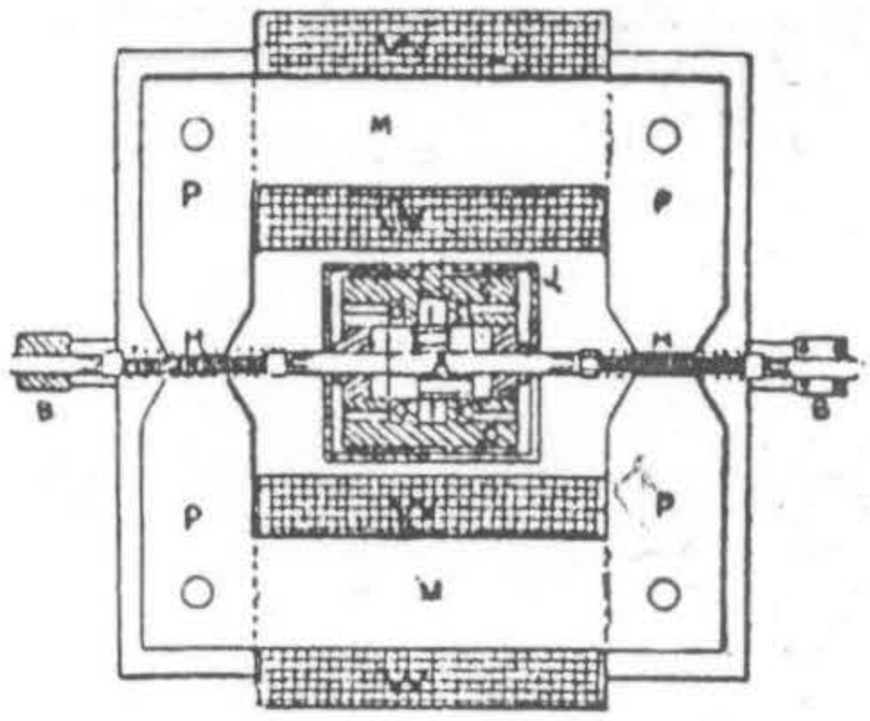
(From The Weekly Tribune).

MR. TESLA'S OSCILLATOR.

A GREAT AND RECENT INVENTION.

GENERATING ELECTRICITY WITH MUCH MORE SIMPLE AND ECONOMICAL APPARATUS THAN THAT NOW IN USE.

Countless are the directions in which Nikola Tesla, the greatest living genius now at work in the electrical field, has experimented, but there are four things with which, in the minds of people familiar with his labors, he is particularly identified. He has introduced an entirely new system into the operation of dynamos and motors, by causing what is called the "magnetic field" to revolve and drag the armature along with it. This is an improvement of immense practical importance in the transmission and use of alternating currents for power purposes, and is alone sufficient to render him famous for generations. He has shown that alternating currents of tremendously high potentials may be handled with practical impunity under certain circumstances—an exceedingly brilliant achievement, although of less practical value than some others. Then he has very nearly, if not quite, solved the problem of producing electric light without heat—an object which numerous scientists have eagerly sought with little result so far, but which is highly desirable in the interests of economy, to say nothing of safety and beauty. Finally, he has invented a combination of steam engine and dynamo, called an "oscillator," which is designed greatly to simplify the mechanism necessary in



generating electricity, and hence to revolutionize that art. Several specimens of this device, differing among themselves in form but not in principle, were publicly exhibited and explained by Mr. Tesla nearly two years ago. He has since improved it in detail, with a view to still greater simplicity and efficiency, and it is said that just before the fire which destroyed his laboratory a few weeks ago this invention had reached such a degree of perfection that it was ready for the commercial stage of its career. Although some of its less important features are still kept private, and while it is impossible yet to measure with accuracy the possibilities of its usefulness, the oscillator is just now attracting renewed attention and provoking much enthusiasm among electrical engineers.

The fundamental idea of this machine is that the coils of wire in which a current is excited are moved to and fro horizontally, instead of being whirled around by a rotating shaft. What electricians call the "field" is the area in front of the poles or pole pieces of a magnet. Out into that space there extend invisible "lines of force." If a piece of soft iron be moved transversely past these poles, and near them, cutting the lines of force, it is momentarily magnetized by induction; and in any coil of insulated copper wire surrounding it there is induced, for the same brief instant, an electric impulse. In the ordinary dynamo a ring of soft iron is used instead of a bar, a number of connected coils are wound on it, and the whole "armature" is revolved between and in very close proximity to the field magnets; but Mr. Tesla winds his coils on a straight bar, and oscillates the latter between his magnets. By this change of method, he is able to accomplish several things not secured by the ordinary dynamo. He reduces the size of the apparatus greatly. The steam engine is said to weigh from one-thirtieth to one-fortieth as much as any standard type of stationary engine having the same steam pressure and piston speed; he gets rid of governor, fly-wheel, eccentrics, cutoffs, packing and other "jig-a-ma-rees"; and with the same amount of steam he generates about twice the current obtained from the old, cumbrous, complicated and more costly machinery.

The outward appearance of one of the early oscillators is shown in the first illustration, and the general arrangement of parts in the second. The cores of the big field magnets are indicated at MM, and the insulated copper wires wound around them at W W W W. The pole pieces, P P P P, attached to the ends of the cores, extend the magnetic fields to the narrow gaps, H H. At these points are placed small armature coils wound upon the shaft A, which latter slides in the bearings B B, under the influence of a piston screwed on to it. The walls of the cylinder C C, the jacket J and the inlets I I tell their own story; and the further details need not be explained. In the model here represented, compressed air was used instead of steam; but the latter is to be employed in the perfected oscillator. The motive fluid, whatever it be, smites the two sides of the piston alternately. A very short stroke results. In some of Mr. Tesla's models this ranged from one-sixty-fourth to three-eighths of an inch. But this movement is enough to excite a brief electric impulse in the coils at H H, whence, the alternating current is led off to its work, without the intervention of a commutator. This last improvement is in itself a great gain, to say nothing of the other merits already mentioned. Besides, Mr. Tesla claims that in his machine there is no idle wire, as in the rotating system.

One of the most exquisitely beautiful, as well as essential, features of the oscillator is yet to be mentioned. It is desirable that the frequency of the alternations in a current—its "period," as the experts call it—shall remain constant in the face of all

variations of "load," or work demanded of it. This can be regulated with a spring of the proper stiffness attached to the oscillating rod. An "air-spring," consisting of a piston inside an air-tight cylinder, may be made to perform this office, and the supplementary cylinder may be situated either close to the working cylinder or at some distance away, both pistons, however, being secured to the same rod. Again, proper air chambers at the end of the working cylinder may be made to serve as springs. By proportioning the size of the chamber of the air spring to the weight of the moving parts, the desired period is produced. Greater or less pressure of steam and any fluctuation in load may affect the length of the stroke, but not the frequency. There is still another mode of regulating the vibrations. It has been shown that electrical currents exhibit certain phenomena resembling those of sound. A circuit of a given "capacity" and "potential" is more favorable to vibrations of one frequency than any other. An instrument known as the "condenser" can be introduced into an electrical circuit to "tune" the latter to the desired frequency of oscillation—thirty, fifty, eighty or any other number per second. Mr. Tesla has applied this principle of "resonance" to some of his experimental oscillators, and thus imparted to his apparatus a selective affinity for whatever rate of vibration he wants. This is an automatic governor, which corrects any tendency to fall below or exceed the required speed. With such precision will this period be maintained that a clock may be driven with an oscillator and keep good time.

The illustrations are modified reproductions of two given in "The Electrical Engineer."

SCIENTIFIC

The Work of Nikola Tesla

THOMAS C. MARTIN, in the *Century* Magazine for April. Condensed for PUBLIC OPINION

Perhaps nine-tenths of all the hundreds of thousands of dynamos in the world to-day are operated by means of the ordinary steam engine, the remainder being driven by water-wheels, gas engines, and compressed air. Now, each step from consuming the coal under the boilers that deliver steam to the engines, up to the glow of the filament in an incandescent lamp, is attended with loss. In his oscillator Mr. Tesla, to begin with, has stripped the engine of all governing mechanism. By giving also to the coils in which the current is created as they cut the "lines of force" of the magnets, a to-and-fro or reciprocating motion, so that the influence on them is equal in every direction, he has overcome the loss of the idle part of the wire experienced in rotating armatures; and, moreover, greatest achievement of all, he has made the currents regulate the mechanical motions. In one of his latest forms of oscillator the steam-chest is situated on the bed-plate between the two electromagnetic systems, each of which consists of field coils between which is to move the armature or coil of wire. There are two pistons to receive the impetus of the incoming steam in the chest, and in the present instance steam is supplied at a pressure of 350 pounds, although as low as 80 is also used in like oscillators, where steam of the higher pressure is not obtainable. We note immediately the absence of all the governing appliances of the ordinary engine. They are non-existent. The steam-chest *is* the engine, bared to the skin like a prize-fighter, with every ounce counting.

Mr. Tesla has boldly assailed the problem of the production of light in a manner nearer, perhaps, to that which gives us sunshine than was ever attempted before. He takes his currents of high frequency and high potential, subjects the incandescent lamp to them, and, skipping some of those intermediate wasteful heat stages of lower wave vibration experienced in the old methods, gets the ether-charged molecules more quickly into the intensely agitated condition necessary to yield light. Ordinary incandescent lighting is done, as everybody knows, with the lamps' bases firmly attached to the two current-bearing wires. But as we rise in the frequency of the current, as we leave behind the electrodynamic conditions for the electrostatic ones, so we free ourselves from the restrictions and limitations of solid wires for the conveyance of the effects sought, until at last we reach a point where all the old ideas of the necessity of a tangible circuit vanish. It is all circuit if we can properly direct the right kind of impulses through it. As Mr. Tesla long ago pointed out, most of the experiments usually performed with a static machine of glass plates can also be performed with an induction coil of wire if the currents are alternated rapidly enough; and it is in reality here that Mr. Tesla parts company with other distinguished workers who have fixed their attention merely on the results attainable with electrodynamic apparatus.

A few experiments performed in Mr. Tesla's laboratory workshop afford an idea of the flexibility of the methods by which powerful electrostatic effects are produced across many feet of intervening space. The workshop is a room about 40 by 80 ft., and 10 or 12 ft. high. A circuit of small cable is carried around it from the terminals of the oscillator. In the center of the clear, open space is placed a coil, wound drum fashion, three or four feet high, and unconnected with the current source save through the medium of the atmosphere. The coil is provided with two condenser plates for adjustment, standing up like cymbals. The system of apparatus in the middle of the room has a certain period of vibration, just as though it were a tuning-fork, or a sheet of thin resonant glass. Around the room, over the cable, there are sent from the oscillator electrical current vibrations. By carefully adjusting the condenser plates so that the periodicity or

swing of the induced current is brought into step with that of the cable currents, powerful sparks are made to pour across between the plates in dense streams. In this manner it is easy to reach tensions as high as 200,000 and 300,000 volts. There is a similar coil in the middle of the same room which has been so adjusted to the vibrations sent around the shop that an ordinary sixteen-candle-power incandescent lamp is well lighted up.

In another experiment a most curious and weird phenomenon is illustrated. The observer holds a loop of bare wire in his hands. The currents induced in the loop by means of the "resonating" coil over which it is held, traverse the body of the observer, and at the same time, as they pass between his bare hands, they bring two or three lamps held there to bright incandescence. Strange as it may seem, these currents, of a voltage one or two hundred times as high as that employed in electrocution, do not inconvenience the experimenter in the slightest.

Mr. Tesla belongs to what Lord Kelvin has spoken of as the nineteenth century school of plenum, accepting one ether for light, heat, electricity, and magnetism, outward manifestations of an inward unity whose secret we shall some day learn.

Electrical Progress.

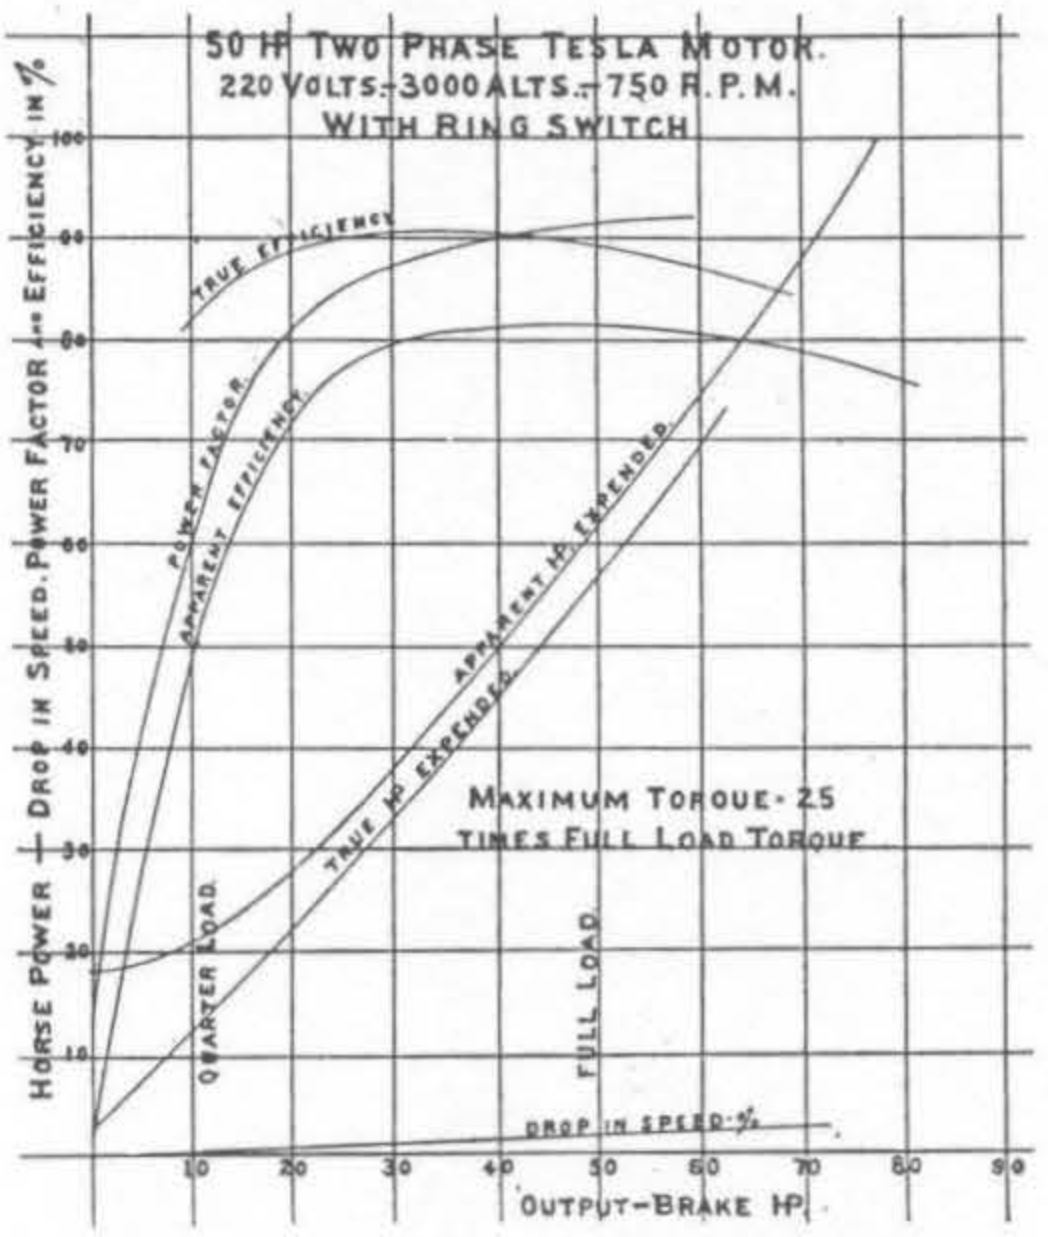
Tesla's Oscillator.

Countless are the directions in which Nikola Tesla has experimented, but there are four things with which, in the minds of people familiar with his labors, he is particularly identified. He has introduced an entirely new system into the operation of dynamos and motors by causing what is called the "magnetic field" to revolve and drag the armature along with it. This is an improvement of immense practical importance in the transmission and use of alternating currents for power purposes, and is alone sufficient to render him famous for generations. He has shown that alternating currents of tremendously high potentials may be handled with practical impunity under certain circumstances—an exceedingly brilliant achievement, although of less practical value than some others. Then he has very nearly, if not quite, solved the problem of producing electric light without heat—an object which numerous scientists have eagerly sought with little result so far, but which is highly desirable in the interests of economy, to say nothing of safety and beauty. Finally, he has invented a combination of steam engine and dynamo, called an "oscillator," which is designed greatly to simplify the mechanism necessary in generating electricity, and hence to revolutionize that art. Several specimens of this device, differing among themselves in form but not in principle, were publicly exhibited and explained by Mr. Tesla nearly two years ago. He has since improved it in detail, with a view to still greater simplicity and efficiency, and it is said that just before the fire which destroyed his laboratory, a few weeks ago, this invention had reached such a degree of perfection that it was ready for the commercial stage of its career. Although some of its less important features are still kept private, and while it is impossible yet to measure with accuracy the possibilities of its usefulness, the oscillator is just now attracting renewed attention and provoking much enthusiasm among electrical engineers.

The fundamental idea of this machine is that the coils of wire in which a current is excited are moved to and fro horizontally, instead of being whirled around by a rotating shaft. What electricians call the "field" is the area in front of the poles or pole pieces of a magnet. Out into that space there extend invisible "lines of force." If a piece of soft iron be moved transversely past these poles, and near them, cutting the lines of force, it is momentarily magnetized by induction; and in any coil of insulated copper wire surrounding it, there is induced, for the same brief instant, an electric impulse. In the ordinary dynamo a ring of soft iron is used instead of a bar, a number of connected coils are wound on it, and the whole "armature" is revolved between and in very close proximity to the field magnets; but Mr. Tesla winds his coils on a straight bar, and oscillates the latter between his magnets. By this change of method, he is able to accomplish several things not secured by the ordinary dynamo.

One of the most exquisitely beautiful, as well as essential, features of the oscillator is yet to be mentioned. It is desirable that the frequency of the alternations in a current—its "period," as the experts call it—shall remain constant in the face of all variations of "load," or work demanded of it. This can be regulated with a spring of the proper stiffness attached to the oscillating rod. An "air spring," consisting of a piston inside an air-tight cylinder, may be made to perform this office, and the supplementary cylinder may be situated either close to the working cylinder or at some distance away, both pistons, however, being secured to the same rod. Again, proper air chambers at the end of the working cylinder may be made to serve as springs. By proportioning the size of the chamber of the air spring to the weight of the moving parts, the desired period is produced. Greater or less pressure of steam and any fluctuation in load may affect the length of the stroke, but not the frequency. There is still another mode of regulating the vibrations. It has been shown that electrical currents exhibit certain phenomena resembling those of sound. A circuit of a given "capacity" and "potential" is more favorable to vibrations of one frequency than any other. An instrument known as the "condenser" can be introduced into an electrical circuit to "tune" the latter to the desired frequency of oscillation—thirty, fifty, eighty or any other number per second. Mr. Tesla has applied this principle of "resonance" to some of his experimental oscillators, and thus imparted to his apparatus a selective affinity for whatever rate of vibration he wants. This is an automatic governor which corrects any tendency to fall below or exceed the required speed. With such precision will this period be maintained that a clock may be driven with an oscillator and keep good time.

TESLA CURRENT TUBES.



The *Buffalo Express* of April 21, favors the public with the following, which, to say the least, is interesting, if rather mixed and confused:—"It was stated here to-night that Nikola Tesla had lately made further improvements in his method of transmitting electricity by fluid and had declared that he was more certain than ever that the current could be sent from Niagara Falls to New Orleans and Chicago and delivered there at less than it would cost to generate power on the spot by steam. The fluid he uses in the tubes costs scarcely more than water, and loses so little electricity in transit that the cost of transmission is little more than the cost of putting up the poles and tubes. It is asserted that the Niagara Falls Power Company, having at last obtained all the consents for the right of way from the Falls to Buffalo along the shore (the Grand Island route having been given up) will prepare at once to supply power for the trolley line between the two cities, and every one else along the route who will pay the price. What the price will be cannot be determined until the line for transmission has been actually completed and the loss of power in transit has been determined. If Mr. Tesla's predictions about his tubes are fulfilled, it is believed that the company will agree to the maximum price insisted upon in Buffalo." The tube method is also described as "a solution of some metallic salt contained in a metal tube surrounded by rubber."

THE PERFORMANCE OF THE TESLA MOTOR.

Supplementary to Mr. Perry's article on the new Westinghouse Electrical Works at East Pittsburg, which appeared in our issues for April 10th and 17th, we give the following curves of performance made especially for this purpose but completed too late for insertion with the rest of the matter. The motor under test was one of those referred to in the article rated at 50 H. P. It is running on the regular shop two-phase currents, 220 volts—3,000 alternations, 750 revolutions per minute. The switch for throwing in and out the starting resistances was of the ring or most recent type, and was illustrated in Fig. 4 on page 176.

The curves will sufficiently explain themselves, but it seems worth while to draw particular attention to several points in the performance of the motor.

The maximum starting torque of which the motor is capable is a little over 2½ times the full load running torque, but as in ordinary practice such a starting torque is not required, the starting resistance in the secondary of the motor is given such value that the torque at starting is about 1½ times the full load running torque. This is done to avoid the excessive current which is necessarily required by any motor, whether for direct or alternating currents, for the development of an

abnormal torque. With such a resistance the current taken by the motor at the instant of starting is about 50 per cent. in excess of that taken at full load. When the motor has nearly attained full speed the starting resistance is short-circuited.

The motor when running unloaded takes only 18 apparent H. P., or 36 per cent. of the full load output.

The falling off of speed from no load to full load is less than 2 per cent.

The apparent and true efficiencies rise very rapidly as the load increases. At one quarter load the apparent efficiency is 57 per cent. and true efficiency 84 per cent. At full load the apparent efficiency is 81.5 per cent. and the true 89.5 per cent. The full load efficiency is better than is ordinarily attained by direct current machines of the same output, and the light load efficiencies are much better. Such a motor as this will have, therefore, a much higher all-day efficiency than a direct current motor of the same output in places where the power required is variable. It is claimed for this type of motor that, in addition to its electrical superiority, the simplicity and durability of construction and the consequent freedom from breakdowns, its ability to carry severe overloads without any harm resulting, and the ease with which it can be controlled both as to speed and as to direction of rotation, make such a machine as this much superior to any direct current motor for all ordinary purposes for which an electric motor can be used.

The Burning of Tesla's Laboratory.—Now that a little time has elapsed since the disaster which overwhelmed Nikola Tesla's laboratory, it is possible to sum up the significance of the event. Our sympathies have been with this unfortunate physicist from the first, and for good reasons. But the average newspaper man, who, by the way, was mostly extravagant with his commiseration, would probably hesitate to venture upon an answer were he asked to explain definitely what he was grieving about. The thing was terribly overdone at the time it happened, and, in illustration of this, we believe it to be a fact that one vivid young lady of the trans-Atlantic press, in her anxiety to be instructive as well as "alive" in her descriptions, went so far as to depict herself undergoing a brilliant electrical ordeal, that is possible only with the body *in puris naturalibus!* For Tesla's future we have no fear. He is young and indomitable. It took Thomas Carlyle four weeks to quiet his mind after that miserable accident in which John Stuart Mill was concerned, which entailed the destruction of the first volume of the unprinted "French Revolution." But, in spite of sensational reports, we know it to be a fact that Tesla was at work again with clenched determination while the ashes of his hopes were still hot. No! The loss falls least heavily upon the loser. Like many another tireless experimenter, he hoped to give the scientific world the report of his failures as well as of his discoveries: he had not counted upon the casual destruction of his memorabilia and apparatus by fire. The loss falls most heavily upon those scientists who are at work upon the phenomena of high-frequency currents, of insulation, induction, impedance, and resonance, and the problems of obtaining cheap electricity by means of oscillators. In time, Tesla will doubtless reproduce all that was of value in those unfortunate notes and papers. In his own immediate work their loss will scarcely be felt, for his memory is all right, and flashes upon any experience of the past with the revealing power of a search light. But the years of toil which his work might have saved experimenters by indicating the paths which are open as well as those which are blind, are gone for ever.

Performance of the Tesla Motor.—"El'ty," May 15, publishes a number of curves of the performance of a 50-hp motor which is running at the Westinghouse works, on the regular two-phase circuits at 220 volts, 3,000 alternations and 750 revolutions. The maximum starting torque of which the motor is capable, is a little over 2.5 times the full load running torque but this starting torque is not required in ordinary practice, as a resistance in the secondary of the motor has such a value that the starting torque is about 1.5 times the full load running torque; with this resistance the current taken by the motor at starting is about 50 per cent. more than that at full load; when running unloaded the motor takes 18 apparent horse-power; the speed falls less than 2 per cent. from no load to full load; the apparent and true efficiencies rise very rapidly as the load increases; at one quarter load the former is 57 per cent. and the latter 84 and at full load they are 81.5 and 89.5, respectively; the latter is said to be better than that ordinarily attained by direct current machines of the same output, and the light load efficiency is much better; the all-day efficiency will therefore be higher than that of a direct current motor if the power required is variable; the ease with which it can be controlled both "as to speed" and as to direction of rotation make it superior to the ordinary motor.

LITERATURE.

Nikola Tesla's Untersuchungen ueber Mehrphasenströme und ueber Wechselströme hoher Spannung und Frequenz. By Thomas Commerford Martin. Authorized German edition, Translated by H. Maser. Halle, a. S.: 1895. Wilhelm Knapp. 508 pages, 6½ x 9½ inches. Paper.

MR. MARTIN'S book is too well known to English readers to require any review at our hands, but it is interesting to note that the demand for information relating to Mr. Tesla's work has so soon called for a German edition. The translator, Herr Maser, has done the work in an admirable manner, so that German readers are now placed on the same footing as English in the facilities at their command for following the researches of Mr. Tesla. The book is admirably printed in good type on good paper, and the cuts are the same as in the American editions.

The Burning of Tesla's Laboratory.

Now that a little time has elapsed since the disaster which overwhelmed Nikola Tesla's laboratory, it is possible to sum up the significance of the event. Our sympathies have been with this unfortunate physicist from the first, and for good reasons. But the average newspaper man, who, by the way, was mostly extravagant with his commisseration, would probably hesitate to venture upon an answer were he asked to explain definitely what he was grieving about. The thing was terribly overdone at the time it happened, and, in illustration of this, we believe it to be a fact that one vivid young lady of the transatlantic press, in her anxiety to be instructive as well as "alive" in her descriptions, went so far as to depict herself undergoing a brilliant electrical ordeal, that is possible only with the body *in puris naturalibus!* For Tesla's future we have no fear. He is young and indomitable. It took Thomas Carlyle four weeks to quiet his mind after that miserable accident in which John Stuart Mill was concerned, which entailed the destruction of the first volume of the unprinted "French Revolution." But, in spite of sensational reports, we know it to be a fact that Tesla was at work again with clenched determination while the ashes of his hopes are still hot. No! The loss falls least heavily upon the loser. Like many another tireless experimenter, he hoped to give the scientific world the report of his failures as well as of his discoveries; he had not counted upon the casual distruction of his memorabilia and apparatus by fire. The loss falls most heavily upon those scientists who are at work upon the phenomena of high-frequency currents, of insulation, induction, impedance, and resonance, and the problems of obtaining cheap electricity by means of oscillators. In time, Tesla will doubtless reproduce all that was of value in those unfortunate notes and papers. In his own immediate work their loss will scarcely be felt, for his memory is all right, and flashes upon any experience of the past with the revealing power of a search-light. But the years of toil which his work might have saved experimenters by indicating the paths which are open as well as those which are blind, are gone forever.--*London Electrical Review.*

NO DELAY IN THE TESLA PATENT SUITS.

In the suit of the Westinghouse Co., against the General Electric Co., for infringement of the Tesla multiphase patents, Judge Townsend of the U. S. Circuit Court at Hartford, Conn., has handed down an order requiring the General Electric Co., to complete its proofs by October 7 next.

The Electrician.

(The Oldest Electrical Journal, 1861—1878.)

Published every Friday, Price Sixpence; Post Free, Sixpence Halfpenny
Editorial, Publishing and Printing Offices,

1, 2 & 3, SALISBURY COURT, FLEET ST., LONDON.

Telephone No. 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER LONDON."

SPECIAL NOTICE.

Owing to the growth of the electrical and allied industries the demands for space in "THE ELECTRICIAN" are, for the greater part of the year, so pressing that a permanent increase in the size of the journal has become necessary. To meet the increased cost involved by this step, and by other improvements, such as heavier paper and more numerous illustrations, the price of "THE ELECTRICIAN" has from May 3rd been advanced to 6d.

The Subscription to "THE ELECTRICIAN," commencing with Vol. XXXV. (May 3, 1895), is as follows:—

	YEAR.	HALF-YEAR.	QUARTER.
United Kingdom.....	26s. 0d.	13s. 6d.	7s. 0d.
Postal Union	30s. 0d.	16s. 0d.	8s. 0d.

(Post free, payable in advance.)

NOW READY.—Vol. XXXIV. of "THE ELECTRICIAN," bound in strong cloth. Price 12s. 6d., post free 13s. 6d. Also ready, Cases for binding. Price 2s., by post 2s. 3d.

POLYPHASE PATENT LITIGATION.

It has often been asked, Why has the transmission of power by polyphase currents made so little progress in this country, in comparison with its use on the Continent and in America? This difference cannot be wholly attributed to ignorance on the part of British manufacturing firms, nor even to a natural conservatism tinged with the feeling that the advantages of polyphase motors have been somewhat overstated. The cause of the delay in this country has, we think, to a large extent been due to the uncertainty that exists as to what claims would be made by the owners of certain patents, and as to the ground that they considered covered by those patents. British firms have hardly yet sufficiently recovered from the costs and expenses incurred in litigation over compound winding, over incandescent lamps, and over telephones, to wish again to embark without due consideration on the troubled waters of the law. Nor is that feeling unjustified in view of the position which affairs have now assumed in America. The Westinghouse Electric Company, which controls the patents and inventions of NIKOLA TESLA, have instituted suits against the General Electric Company of America, and against the Stanley Manufacturing Company, for alleged infringements of TESLA's patents, claiming, as their advertisements state, that these patents cover broadly any system of polyphase alternate current distribution of power. It is interesting to note, as showing how broad is the ground

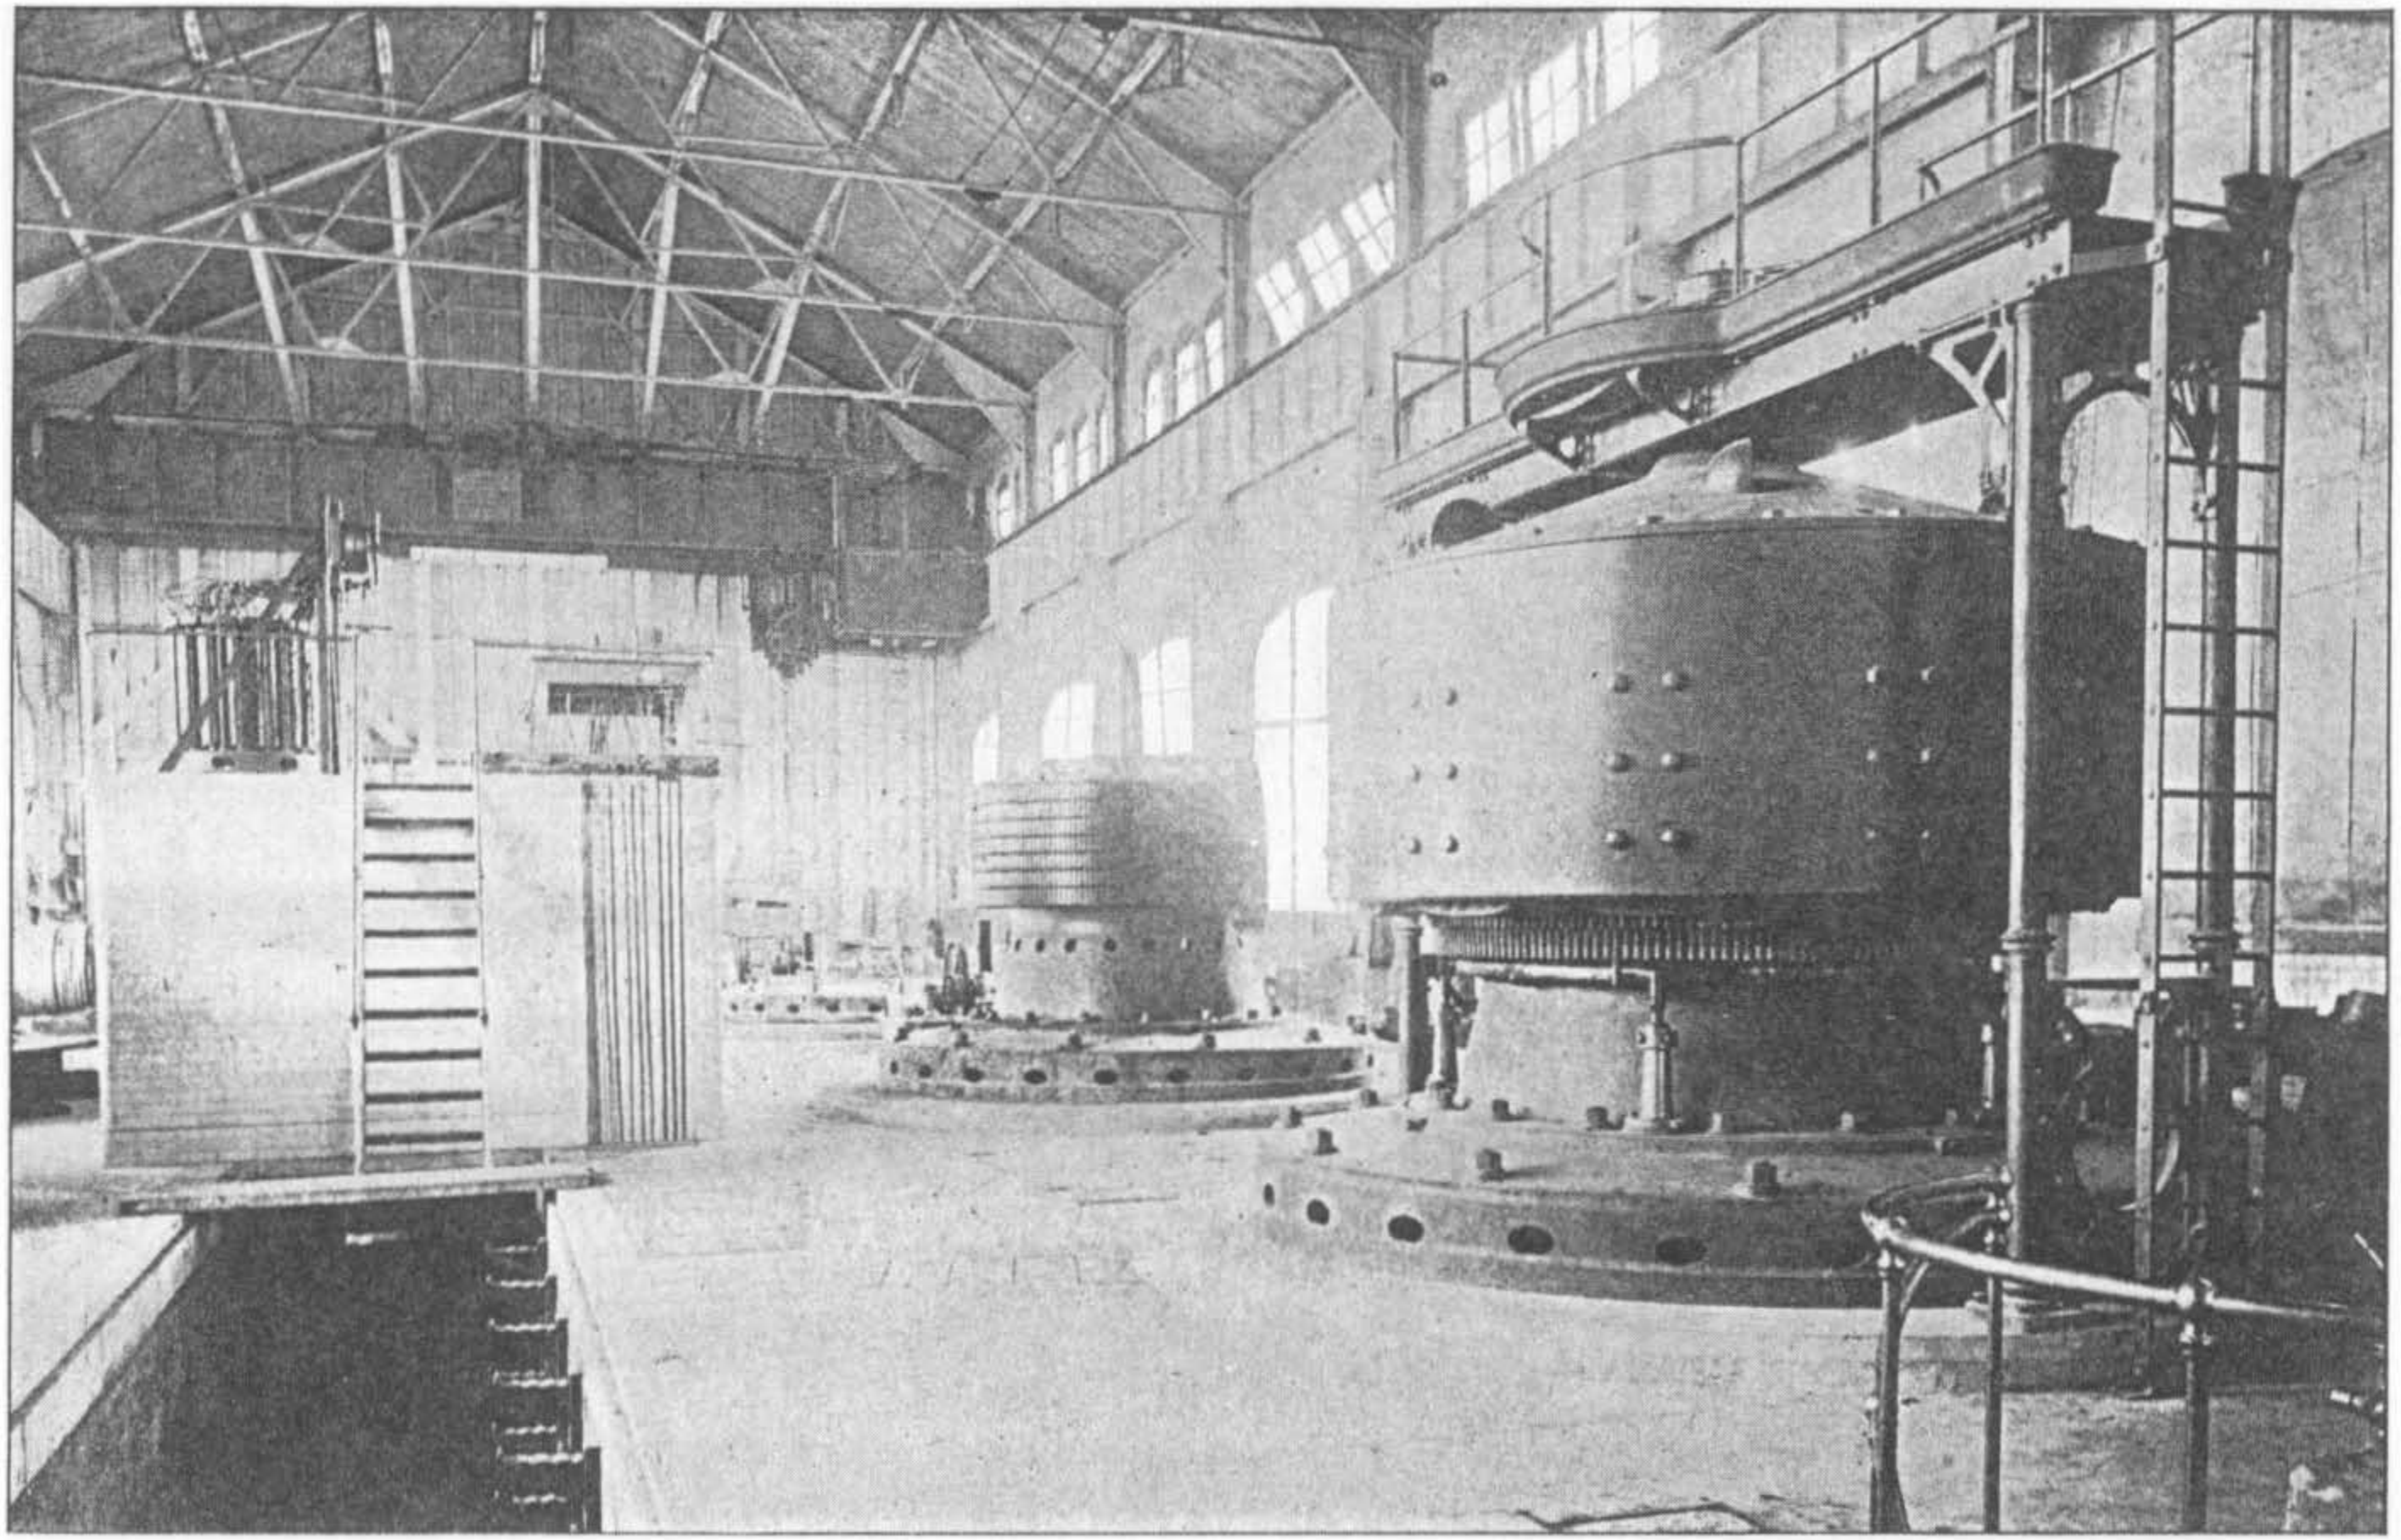
claimed, that neither in the "monocyclic" system of the General Electric Company, nor in the two-phase system of the Stanley Manufacturing Company, are the motors simple rotary field motors, but modifications which have the appearance of being expressly designed to avoid any claim on behalf of the owners of TESLA's patents. The results of these actions will be regarded with interest in Europe, as it is only to be supposed that if successful in America a similar line is likely to be taken in this country and elsewhere where TESLA's patents are in force. That this question is not lightly regarded by the owners of the TESLA patents is evident from the fact, that the valuation of the TESLA patents is said to have been the point at which the recently negotiated "combine," as to patents, between the General Electric Company and the Westinghouse Company, came to a deadlock.

The ground on which the priority of TESLA's patents is likely to be contested, is probably the, till recently, forgotten rotary field motor of BAILY (1879), and the motors of FERRARIS; but these do not appear to entirely touch the issue. In the first of these the rotary field was produced by commutating a continuous current; in the second, by splitting a single-phase alternating current into two phases by proper arrangements of self-induction or condensers. This is a different thing from the reproduction in a motor of a rotating magnetic field, the image or reflection if the term may be used, of an existing rotating magnetic field, produced in a dynamo with multiple coils, connected to similar coils in the motor. This is the kernel of TESLA's inventions, and it remains to be seen whether his patents of 1888 will withstand the fire to which they will now be exposed. The Westinghouse Company, in any case, can claim little credit for the practical introduction of polyphase motors, for whilst the patents date back to 1888, for some years after this no definite information as to the results that had been obtained by their use was forthcoming, whilst even as late as 1894, the current lists of the Westinghouse Company, only described and showed their use, like FERRARIS' motors, on single-phase transmission plants for starting up synchronous motors. The credit of showing what it is possible to effect with polyphase transmission will always be connected with the names of C. E. L. BROWN and DOLIVO-DOBROWOLSKI. It is to be hoped, in the interests of all parties, that this question will be settled shortly and decisively, as until its conclusion a cloud will necessarily hang over a system which, in many cases, may prove of considerable value.

Meanwhile it is interesting to note what is the real position now to be assigned to polyphase power transmission and distribution, in what respects it is superior to continuous current systems, in what respects it is inferior. The answer in general terms is this, where the transmission or distribution is satisfied by motors running at a constant speed, and not requiring a turning moment greater than, say, 50 per cent. above the full load running moment, no system can beat the polyphase, either in economy in first outlay, simplicity of working or efficiency. But where variations of speed are required, or a largely increased turning moment is necessary, either at starting or when running, polyphase plant is not applicable. Great loss of efficiency always occurs when a polyphase motor revolves at a speed differing considerably from the speed of the revolving field, and the turning moment appears at any speed to have a maximum beyond which a reduction of speed decreases instead of increasing it, thus producing instability. These generalisations omit the consideration of the possibility of using higher pressures owing to the power of transforming alternating currents with simple apparatus. It may, therefore, be taken that with polyphase motors as at present made, they will be used for transmission of power in manufacturing, but for mining, for traction, for lifts, and analogous purposes, continuous current machinery may be expected to hold its own.

ELECTRIC POWER GENERATION AT NIAGARA.

By Lewis Buckley Stillwell, Electrical Engineer.



ELECTRICITY as an agent for transmitting and distributing power has received its most weighty endorsement in its adoption by the Cataract Construction Company, of New York, for their great project at Niagara. No enterprise of modern times, involving special and extraordinary engineering problems, has been more carefully, more patiently, more systematically or more intelligently studied than has the utilization of this, the greatest water power in the world. The officers and directors of the company, controlling financial means ample for their purpose, have, for five years, energetically and persistently endeavored to avail themselves of the best resources of modern engineering science. Confronting a problem without precedent in its magnitude, and almost without parallel in its significance, they have attacked it with energy and ability of the highest order, studied it with keen insight and sound judgment and, in solving it with success, have contributed a chapter of rare interest and meaning to the history of industrial progress.

The utilization of Niagara for industrial purposes imposes upon those undertaking it a responsibility far beyond that which is measured by the capital invested. Science is cosmopolitan; she recognizes no boundary of race or nation; and engineering science of the twentieth century, in passing judgment upon the methods and apparatus employed, while not failing to take into consideration the difficulties and limitations imposed by the boundaries of our present knowledge, will allow no excuse for failure to find out and use the best means known to our age.

It is, therefore, a source of profound gratification that, from the outstart, the policy of the company has been characterized by a breadth of view commensurate with the far-reaching importance of the enterprise. The directors have allowed no local or even national prejudice to bias their judgment. They early threw the lists wide open and in the original competition which they inaugurated, the international commission passed upon no less than twenty-two plans covering practically the whole known range of electric, hydraulic and pneumatic distribution of power, and originating from places as far East as the city of Buda-Pesth, and as far West as San Francisco.

It must be gratifying to Americans that under these conditions a system developed by an American company has been adopted, but for the recent rapid advancement in engineering science which has made this work possible, America is in no position to claim exclusive credit, if she would. In the plans for the hydraulic plant, Switzerland, the land of water powers, shows the way, while in the design of the great electric generators, the most powerful as yet produced, Great Britain is represented directly in the excellent general form of construction adopted, which was proposed by Prof. Geo. Forbes, and indirectly in the work of Hopkinson, Kapp, Thompson, Mordey, and others, whose careful study of the principles underlying the construction of electrical machinery has done much to make it possible to design a machine so far beyond the range of actual experience, in full confidence that the results predicted from theory would

THE INTERIOR OF THE POWER HOUSE, SHOWING ONE GENERATOR COMPLETED.

be realized in practice. Perhaps no country is more largely or more creditably represented in the great Niagara installation than Smiljan Lika, —that sturdy little province on the Adriatic, which has honoured itself by producing Mr. Nicola Telsa, and were it possible to trace to its true source each one of the great number of ideas embodied in the complete installation, it is probable that we should find nearly every civilized nation represented—England, America, Switzerland, France, Germany, Italy, some in greater degree, some in less, but all co-operating to achieve what is, beyond question, one of the most significant triumphs of nineteenth century engineering skill.

The problem in electrical engineering presented by the Cataract Construction Company, as defined by the organization of the hydraulic plant in the power house and the requirements of the proposed market for the power developed, may be stated as follows:

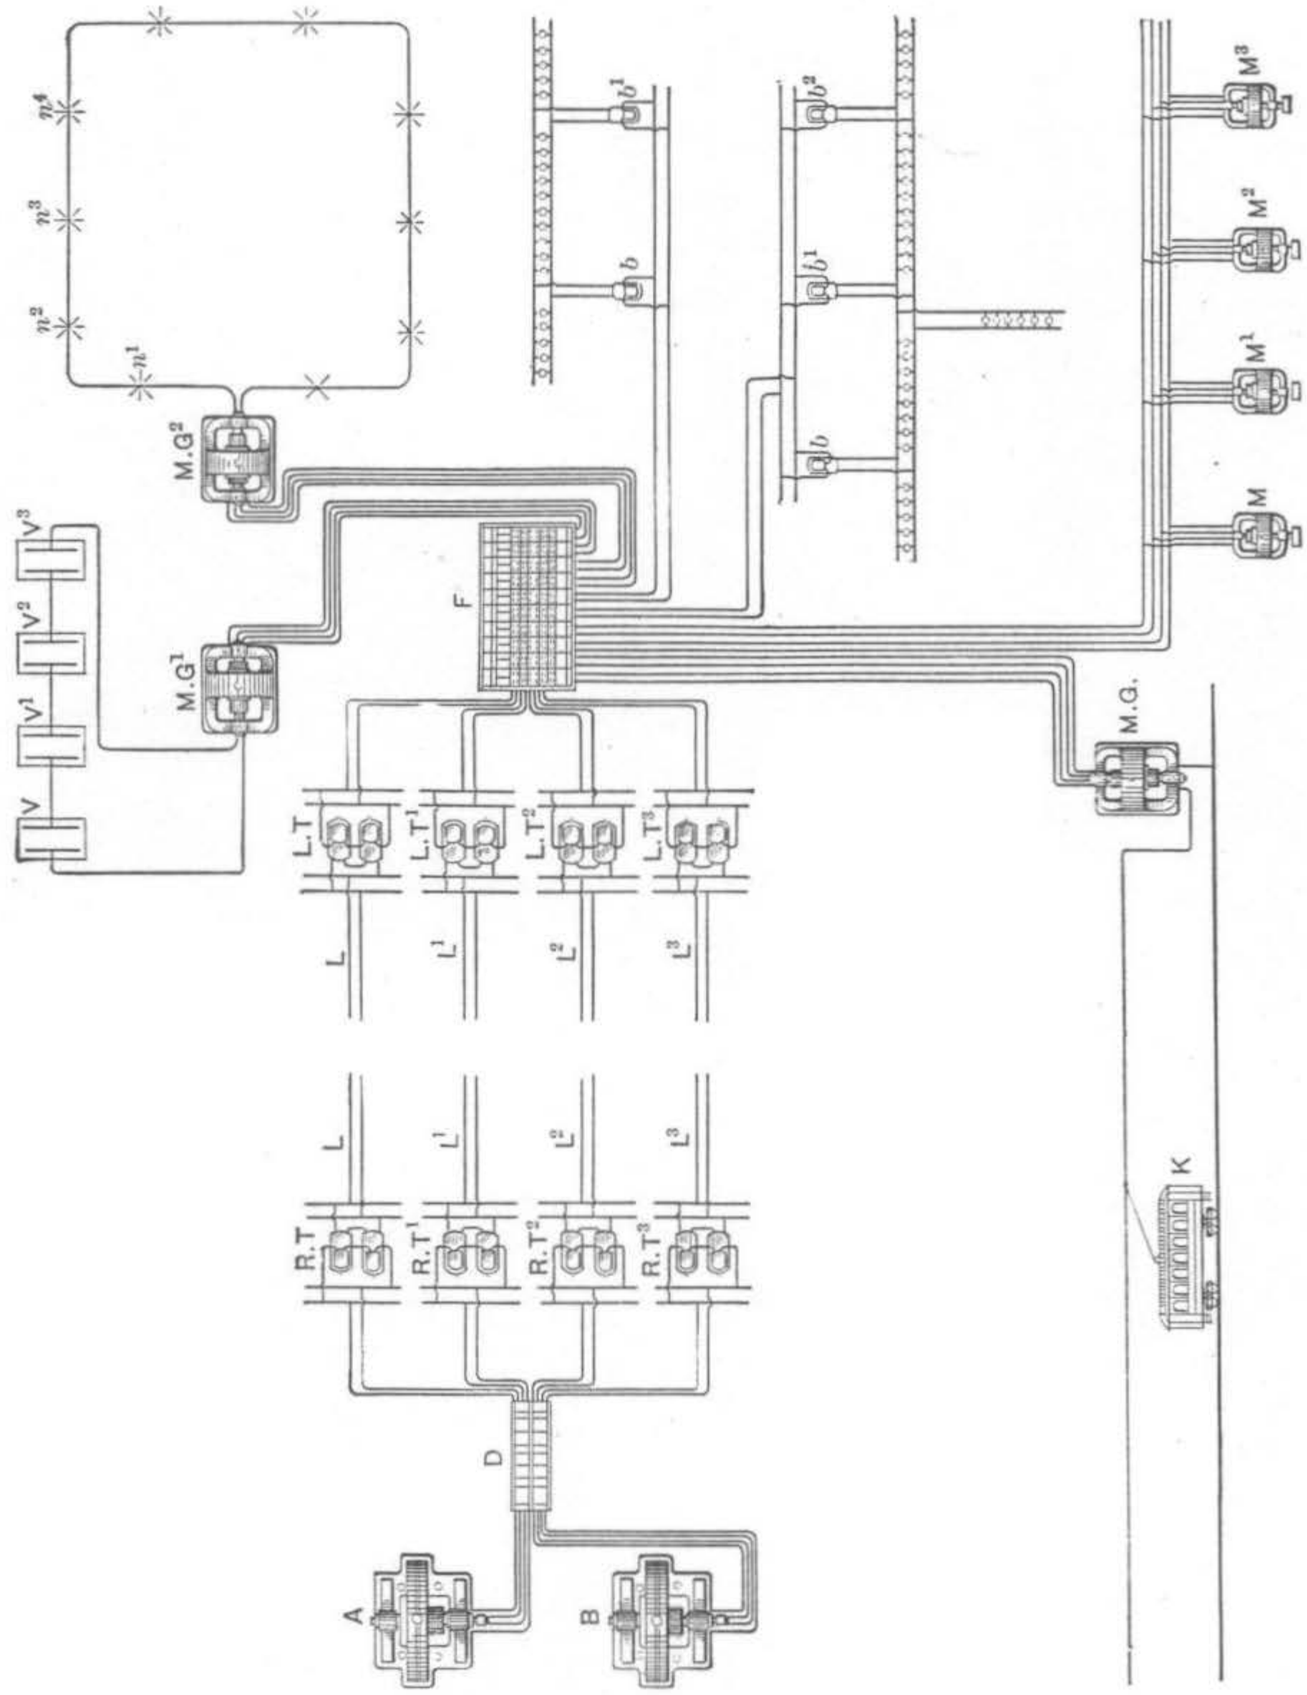
Given, 1st:—Four vertical shafts, direct-driven by turbines making 250 revolutions per minute and capable of delivering at the top of each shaft from 5000 to 5500 mechanical horse-power. Additional turbines and shafts to be installed as the demand for power increases. 2d:—A market for power, beginning just outside the walls of the power house and extending at least twenty miles (and as much further as possible), said power to be used for, (A) general industrial purposes, such as the operation of machinery in mills and factories; (B) the operation of street railways; (C) lighting by arc and incandescent lights; (D) electrolytic purposes; (E) heating.

Required:—The most reliable and efficient method and machinery for utilizing the power for the purposes named.

The system or organization of electric apparatus which was adopted is known as the Tesla Polyphase Alternating-Current System. Each generator delivers alternating current to each of two circuits, the currents in these circuits differing from each other in their time relation, or phase, by 90 degrees; that is to say, the current delivered to each circuit attains its maximum value at the instant when the current delivered to the other circuit is zero. The frequency is 25 cycles per second,—in other words, the direction of the current is reversed 3000 times per minute. By means of rheostats, controlling the field circuits of the generators, the potential of the current delivered is adjustable up to the limit of 2400 effective volts. In ordinary service, and until transmission over great distances is undertaken, the normal potential will approximate 2100 volts, but, to compensate for the losses incident to long distance transmission, the generators may be operated at any potential not exceeding 2400 volts.

The currents delivered by the generators are conveyed through heavily insulated cables to the switchboard. There, by means of suitable switching devices, the engineer in charge of the station may, at will, connect any one of the generators, or any combination of the generators, to the external circuits which convey the currents from the power house to the consumers. These external circuits, known as feeder or supply circuits, passing from the switchboard, are supported upon iron brackets in a brick-lined subway within the power house, as shown in the illustration on page 286. Insulated, lead-covered cables are used, and these, leaving the subway, are continued through the bridge connecting the power house with the transformer house on the east bank of the power canal. The cables conveying current, intended for the use of tenants of the company and other consumers of power within a radius of 2 or 3 miles of the power house, pass directly through the transformer house and enter a conduit leading to the works of those tenants who are, at present, the principal users of the power.

Current intended for transmission to considerable distances, as, for example, to Buffalo, will pass from the switchboard through similar lead-covered cables in the power house subway and the bridge to the transformer house. There it will enter the "step-up" transformers, and from these current at high potential (E. G. 20,000 volts) will



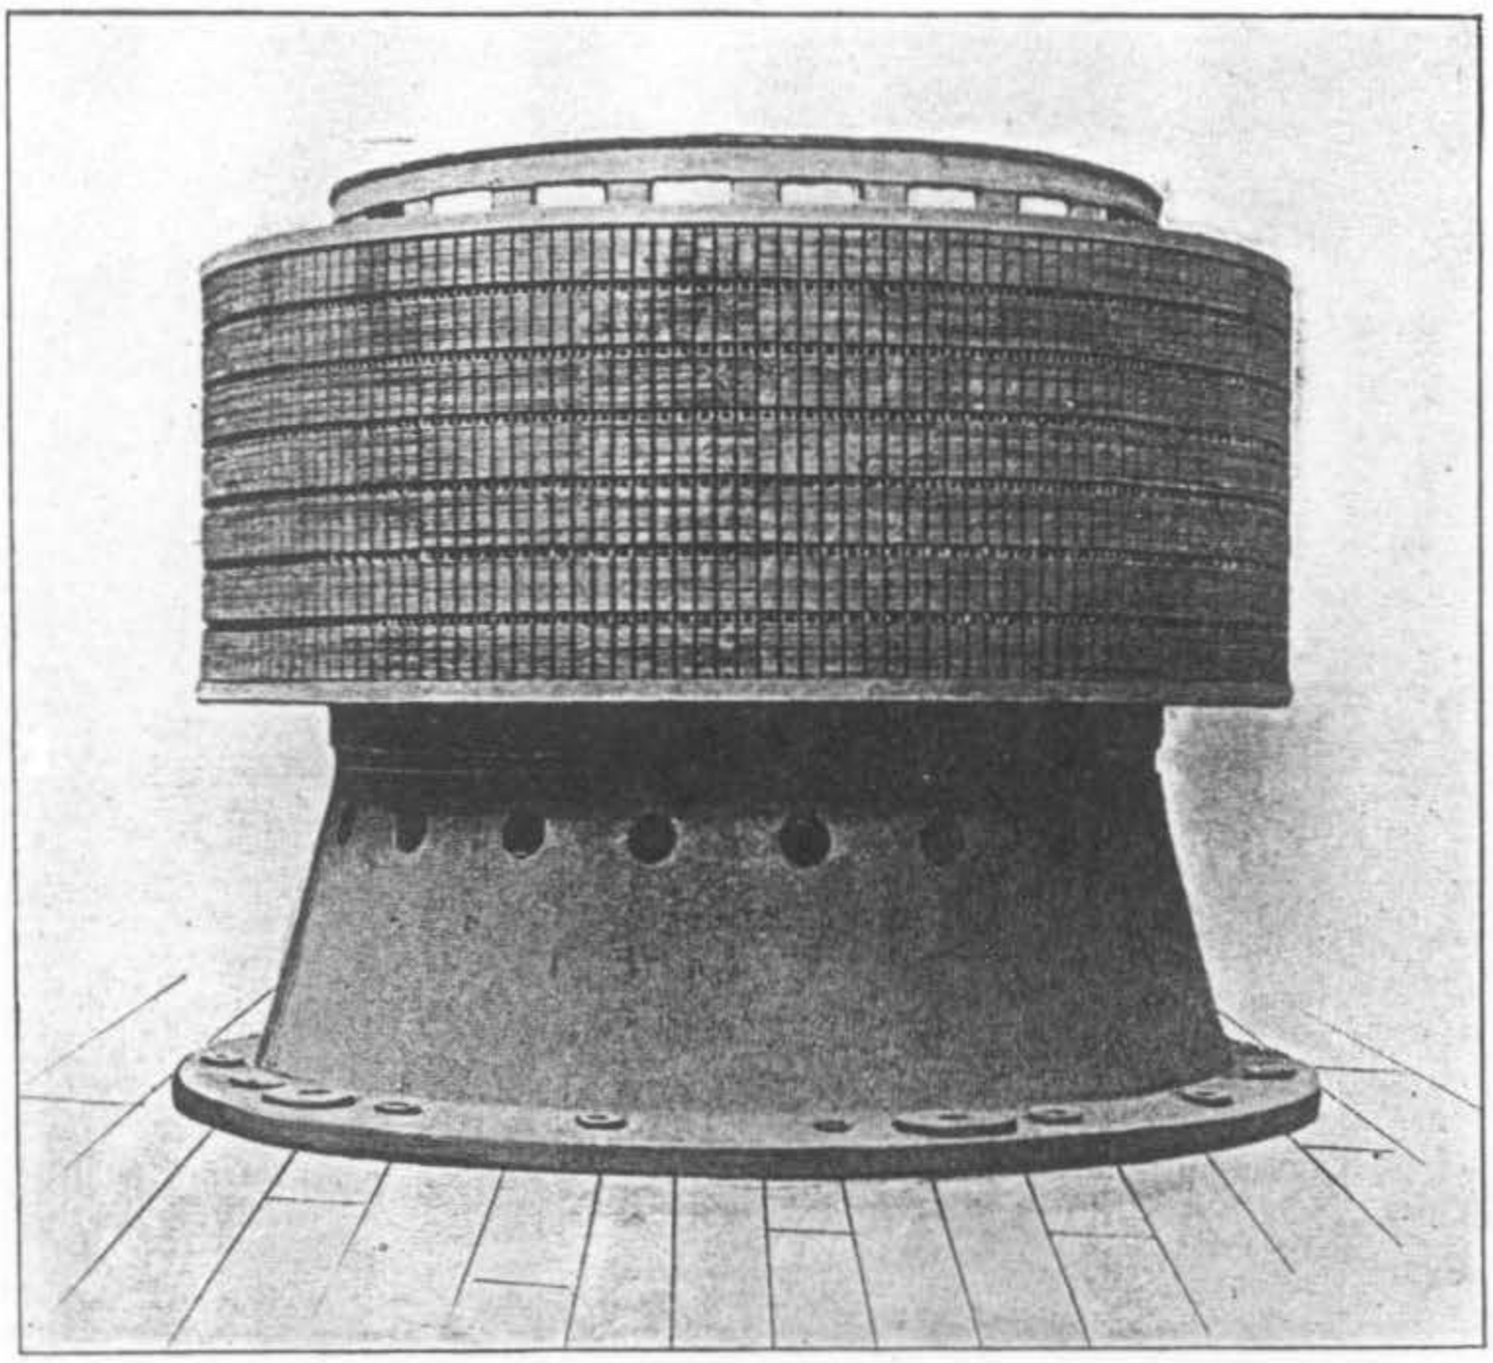


DIAGRAM OF A MULTI-PHASE SYSTEM OF ELECTRIC TRANSMISSION AND DISTRIBUTION.

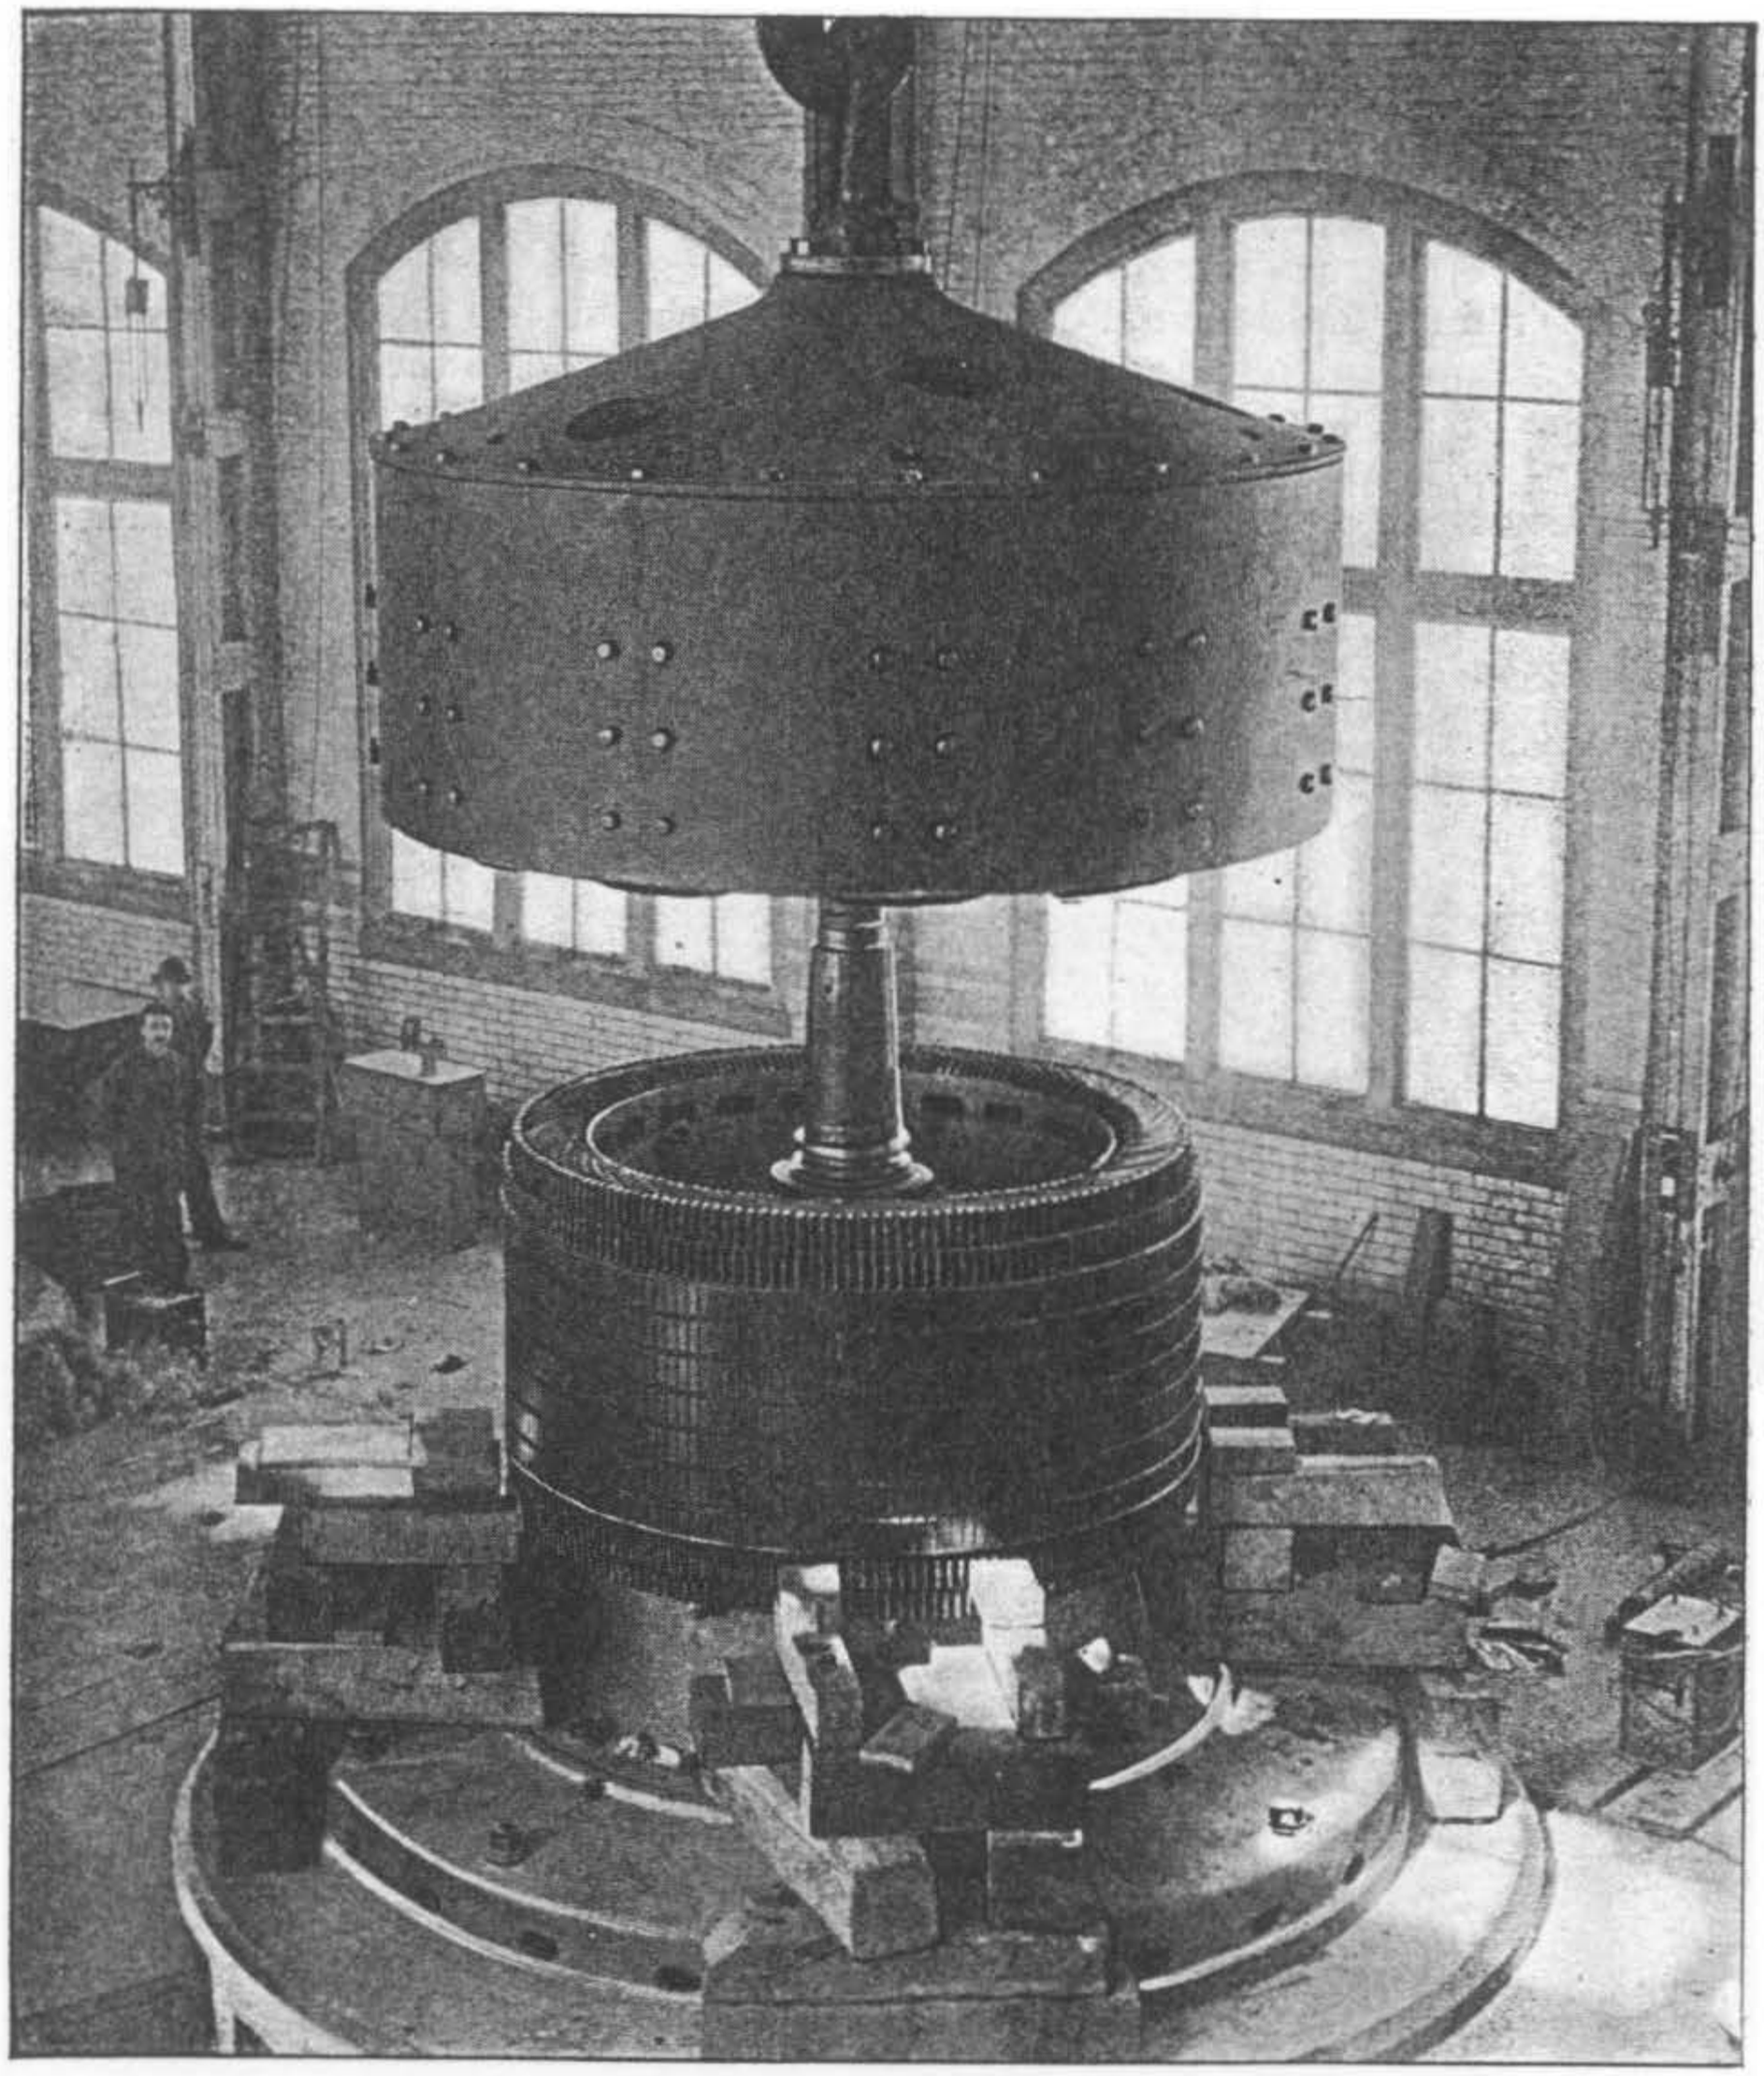
be delivered to the long-distance transmitting circuits. It has not yet been determined whether these long-distance circuits shall be overhead or underground. At the distant end of the circuits "step-down" transformers will be employed to reduce the potential of the currents to an amount suitable for local distribution.



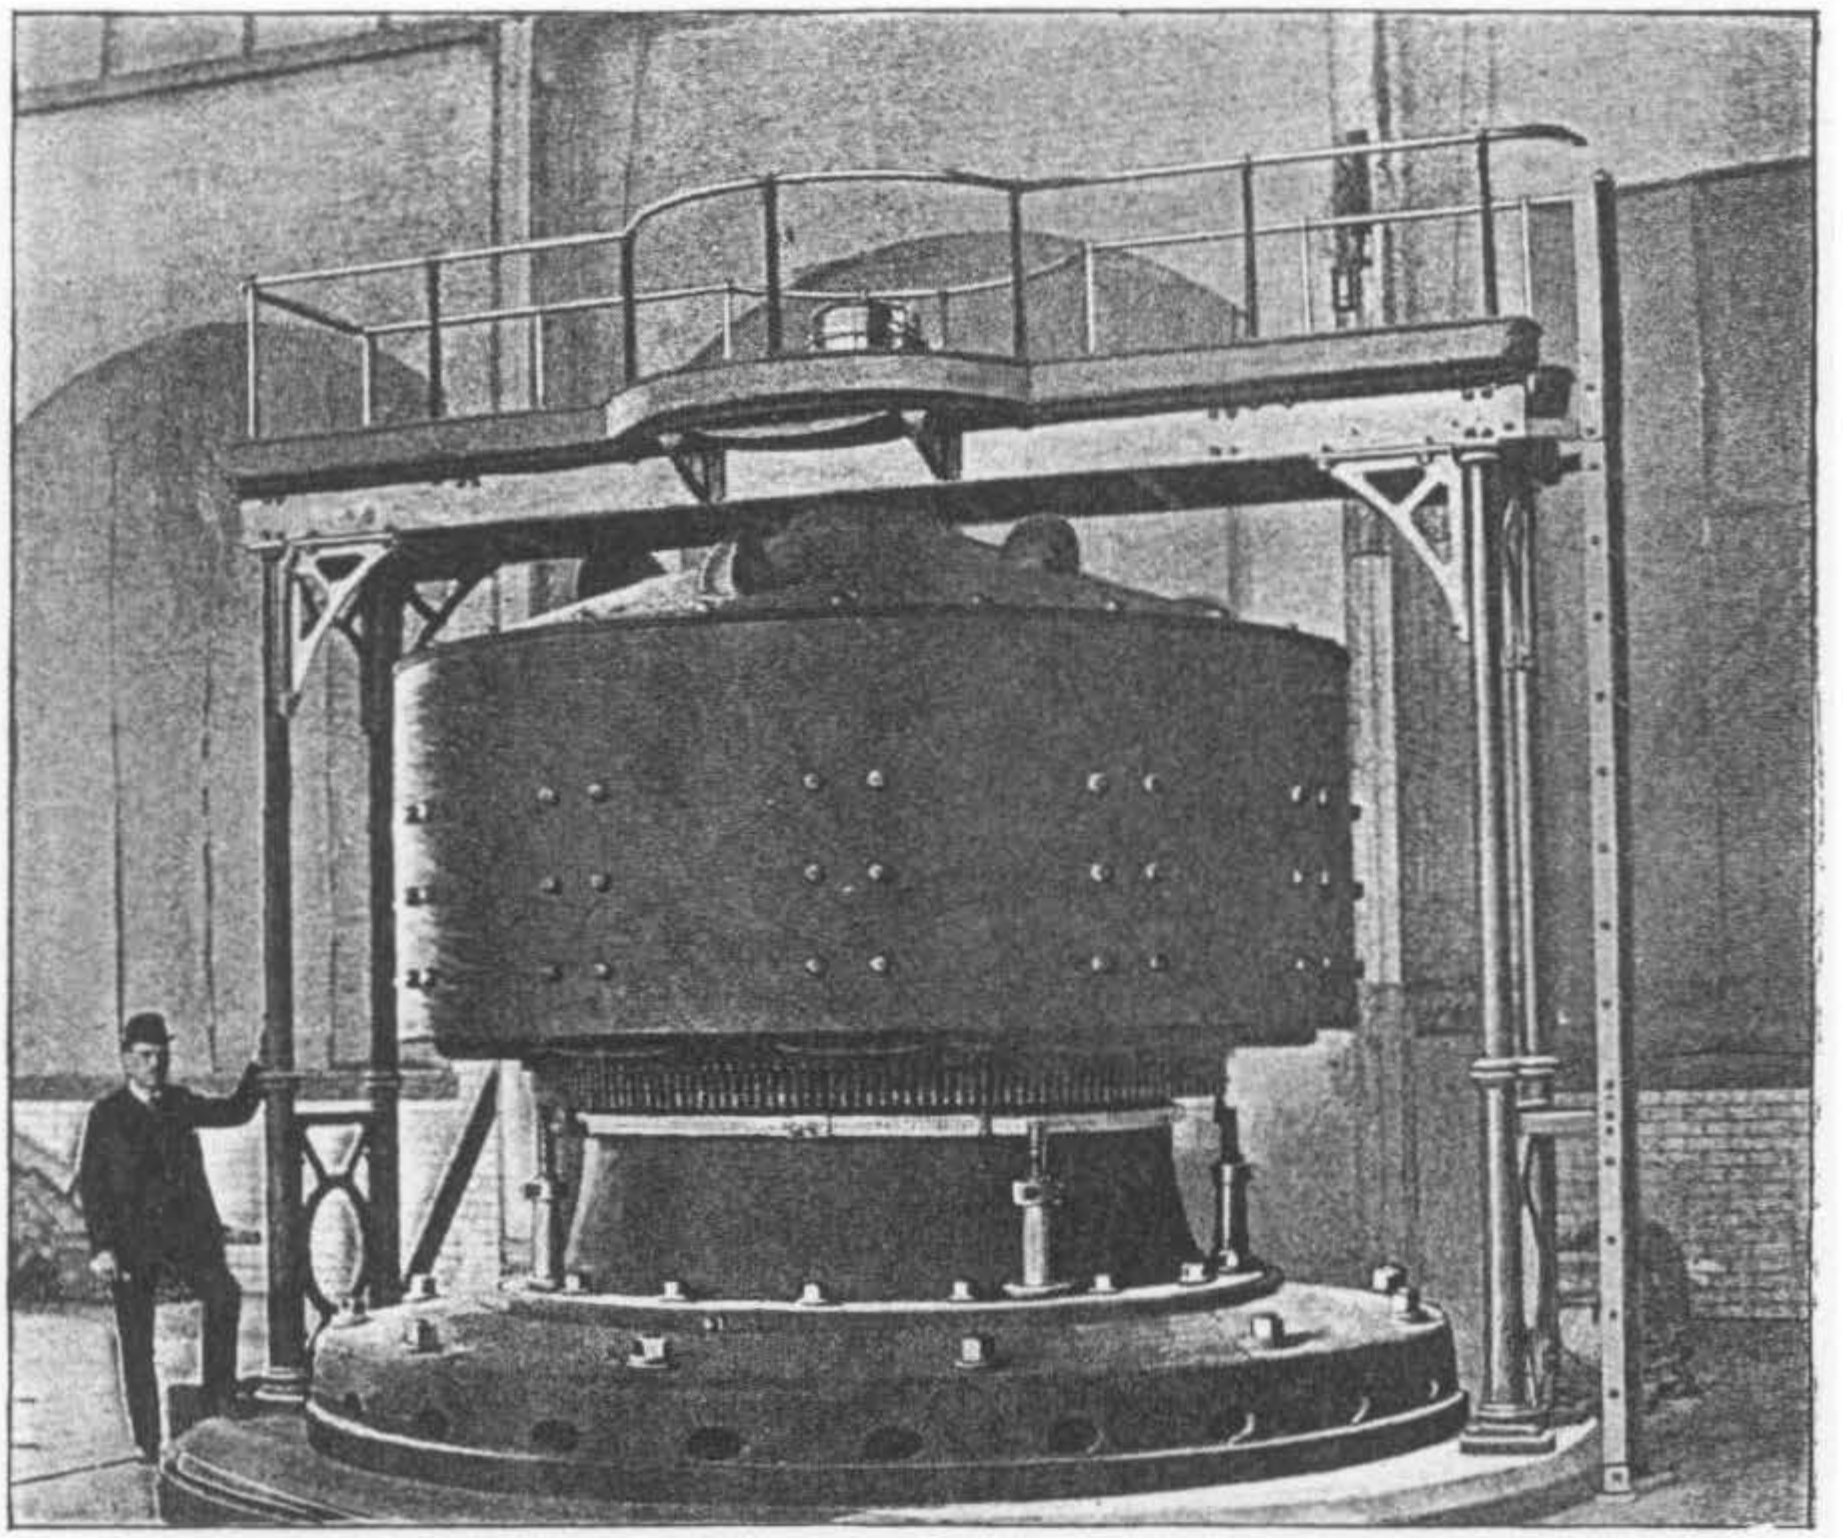
The kind and amount of apparatus which it will be necessary to install upon the premises of the users of power depends upon the kind of service required. In the case of large motors, the current delivered by the local distributing circuits at Niagara may be supplied to the machines without reduction of potential by transformers. In the case of smaller motors, and in the case of commutating machines used to supply direct current, step-down transformers will ordinarily be employed. The general organization of the system and character of the apparatus required for each of the principal types of service are illustrated in the diagram on the opposite page.

ONE OF THE 5000 HORSE-POWER ARMATURES.

Referring to this diagram, each of the generators A and B delivers two separate and distinct alternating currents to the step-up or raising transformers RT, RT^1, RT^2, and RT^3, through the switchboard D. The current, delivered by the generators at 2000 volts, is transformed by the raising transformers to a high potential suitable to long-distance transmission, say 20,000 volts, and is delivered by them to the transmission circuits L, L^1, L^2, and L^3. At a point conveniently located with reference to the district where lights and motors are to be supplied a sub-station is erected. The transmission circuits enter the station and deliver their currents to the step-down or lowering transformers LT, LT^1, LT^2, and LT^3, which, in turn, deliver currents at moderate potentials, suitable for local distribution.

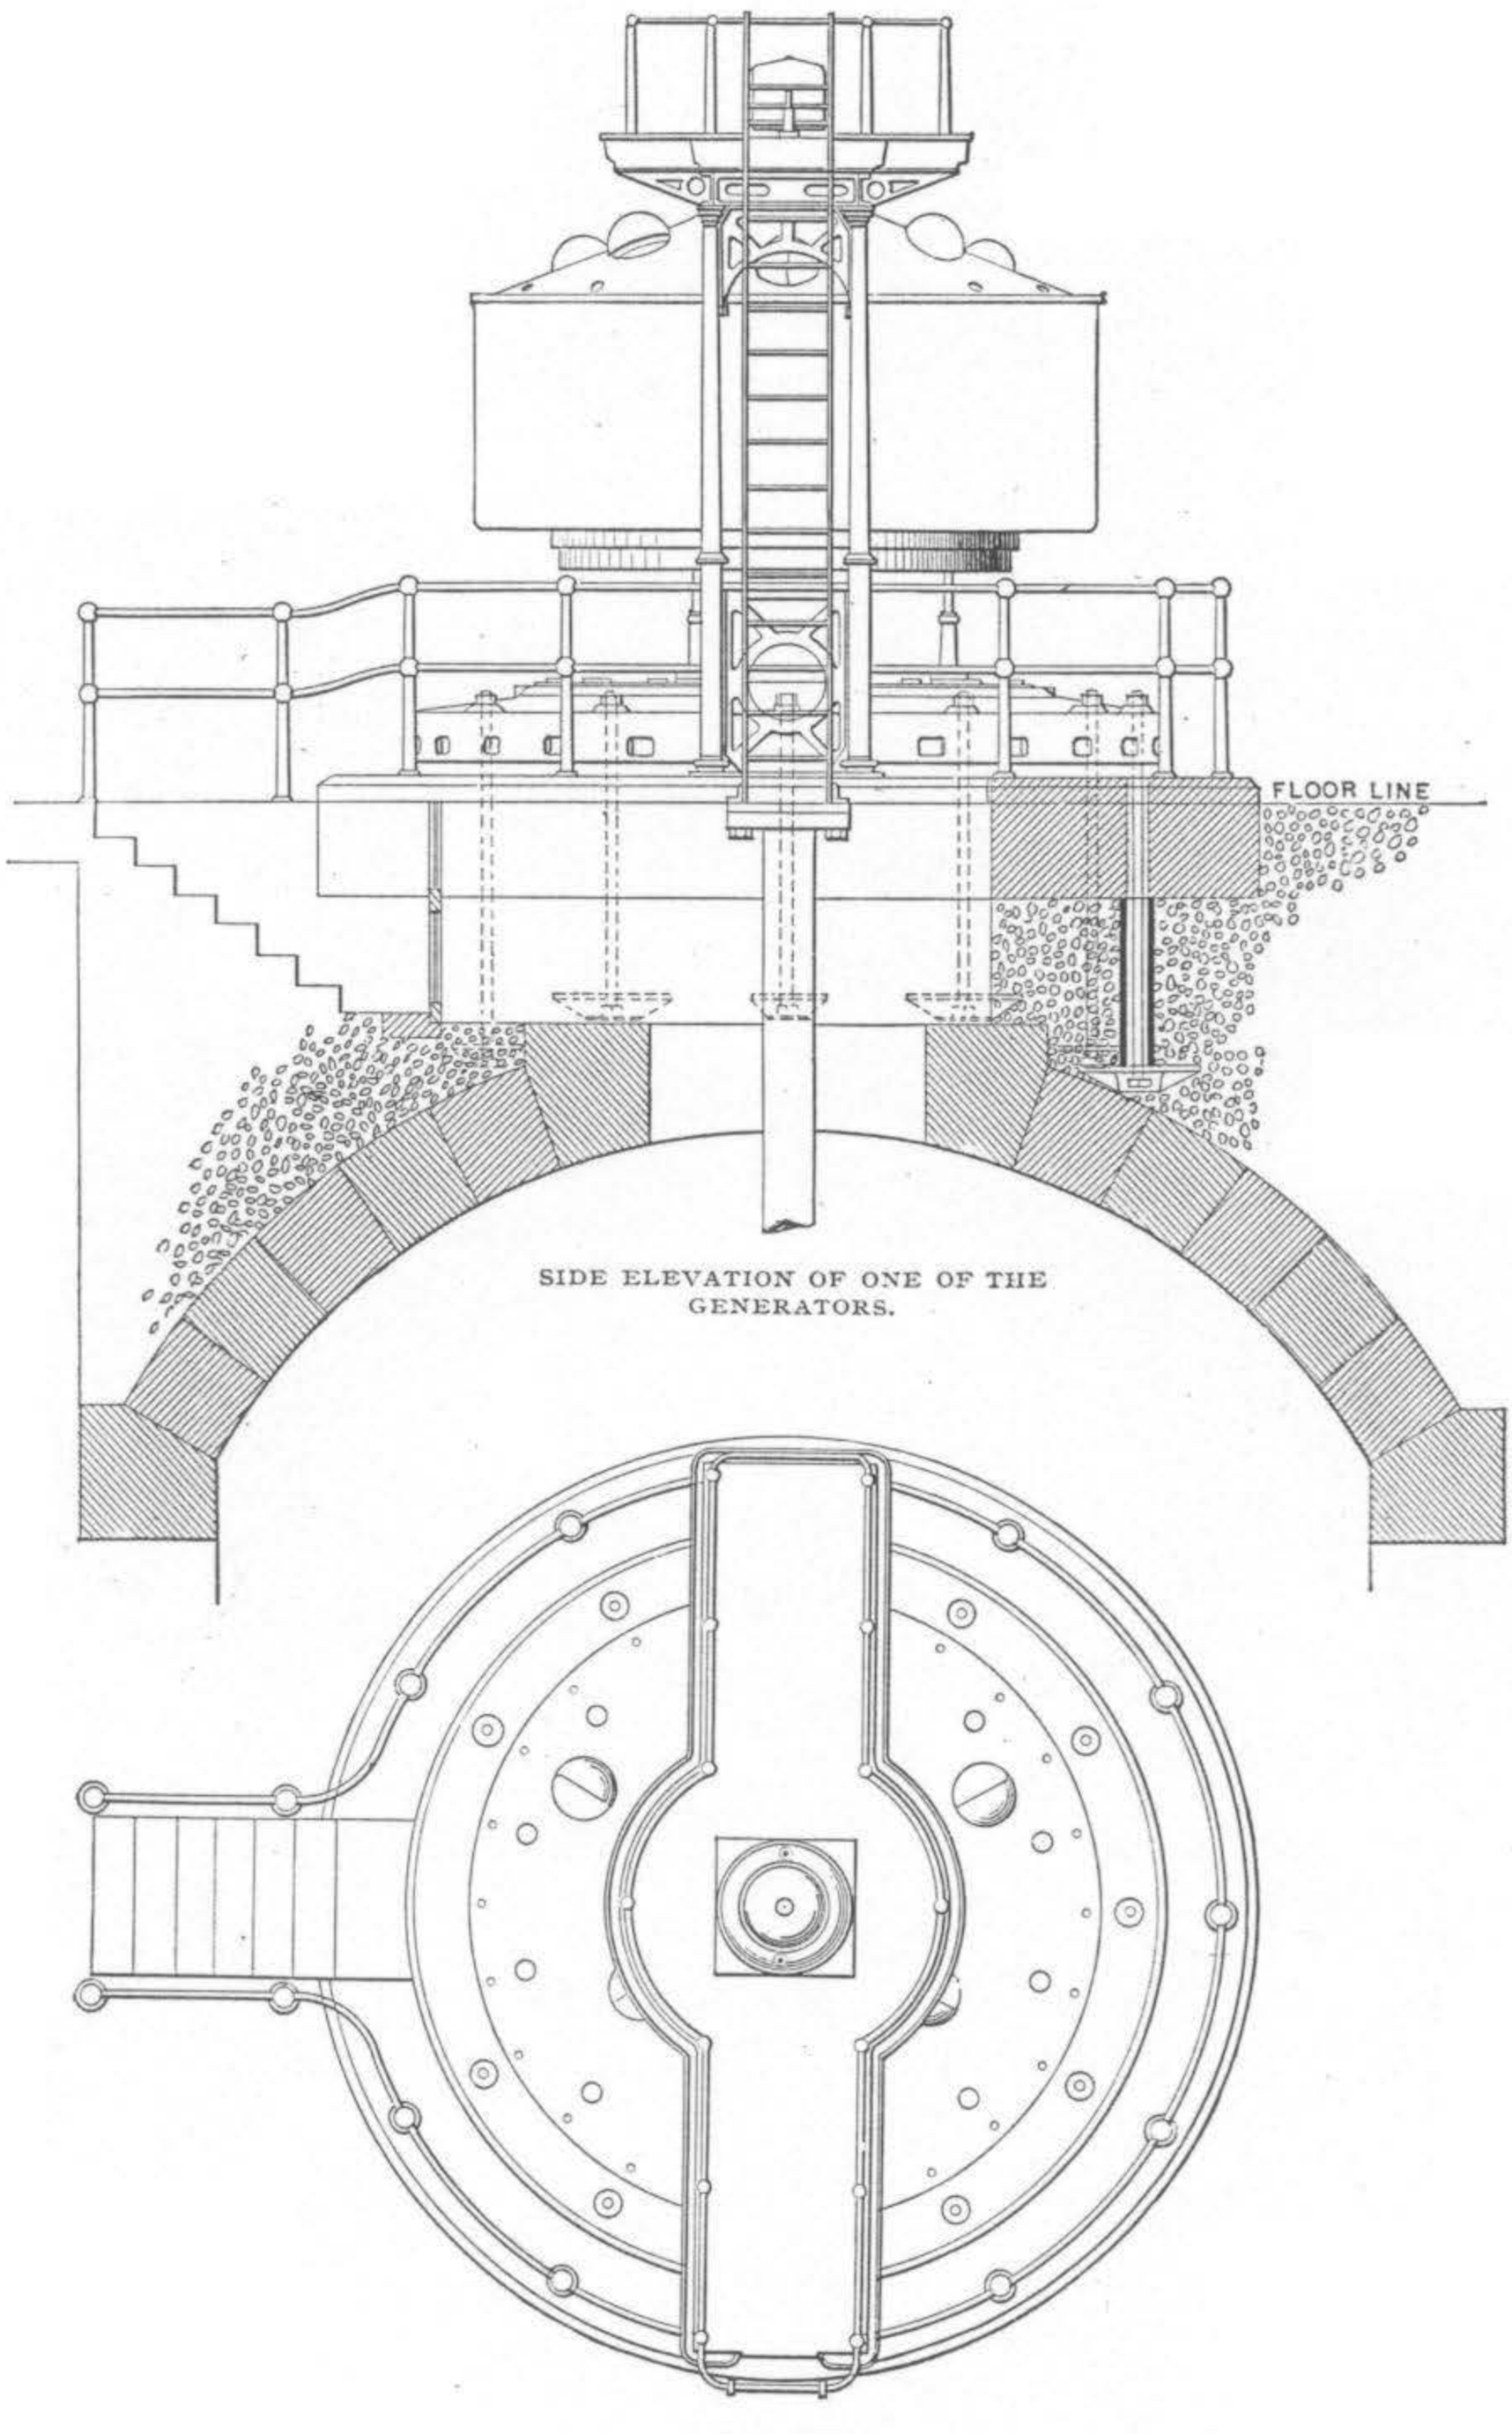
The switchboard F affords means whereby the circuits coming from the various groups of lowering transformers may be readily transferred and inter-

A FIELD RING READY TO BE LOWERED ON A GENERATOR SHAFT.



changed, so that any of the transmission circuits may be used to supply any of the local distributing circuits, as may be advantageous or convenient, or all of the local circuits may be supplied with current from bus bars to which the transmission circuits of like phase are connected in parallel.

In the diagram, beginning at the left of the switchboard, the first four-wire circuit is used to supply alternating current to the motor-generator or rotary transformer MG, which, in turn, delivers direct current at 500 volts to a trolley line, from which the street car K is supplied. The second circuit supplies the motors M, M^1, M^2, and M^3 of the two-phase, synchronous type, or of the induction type, which are adapted to general power purposes in mills, fac-

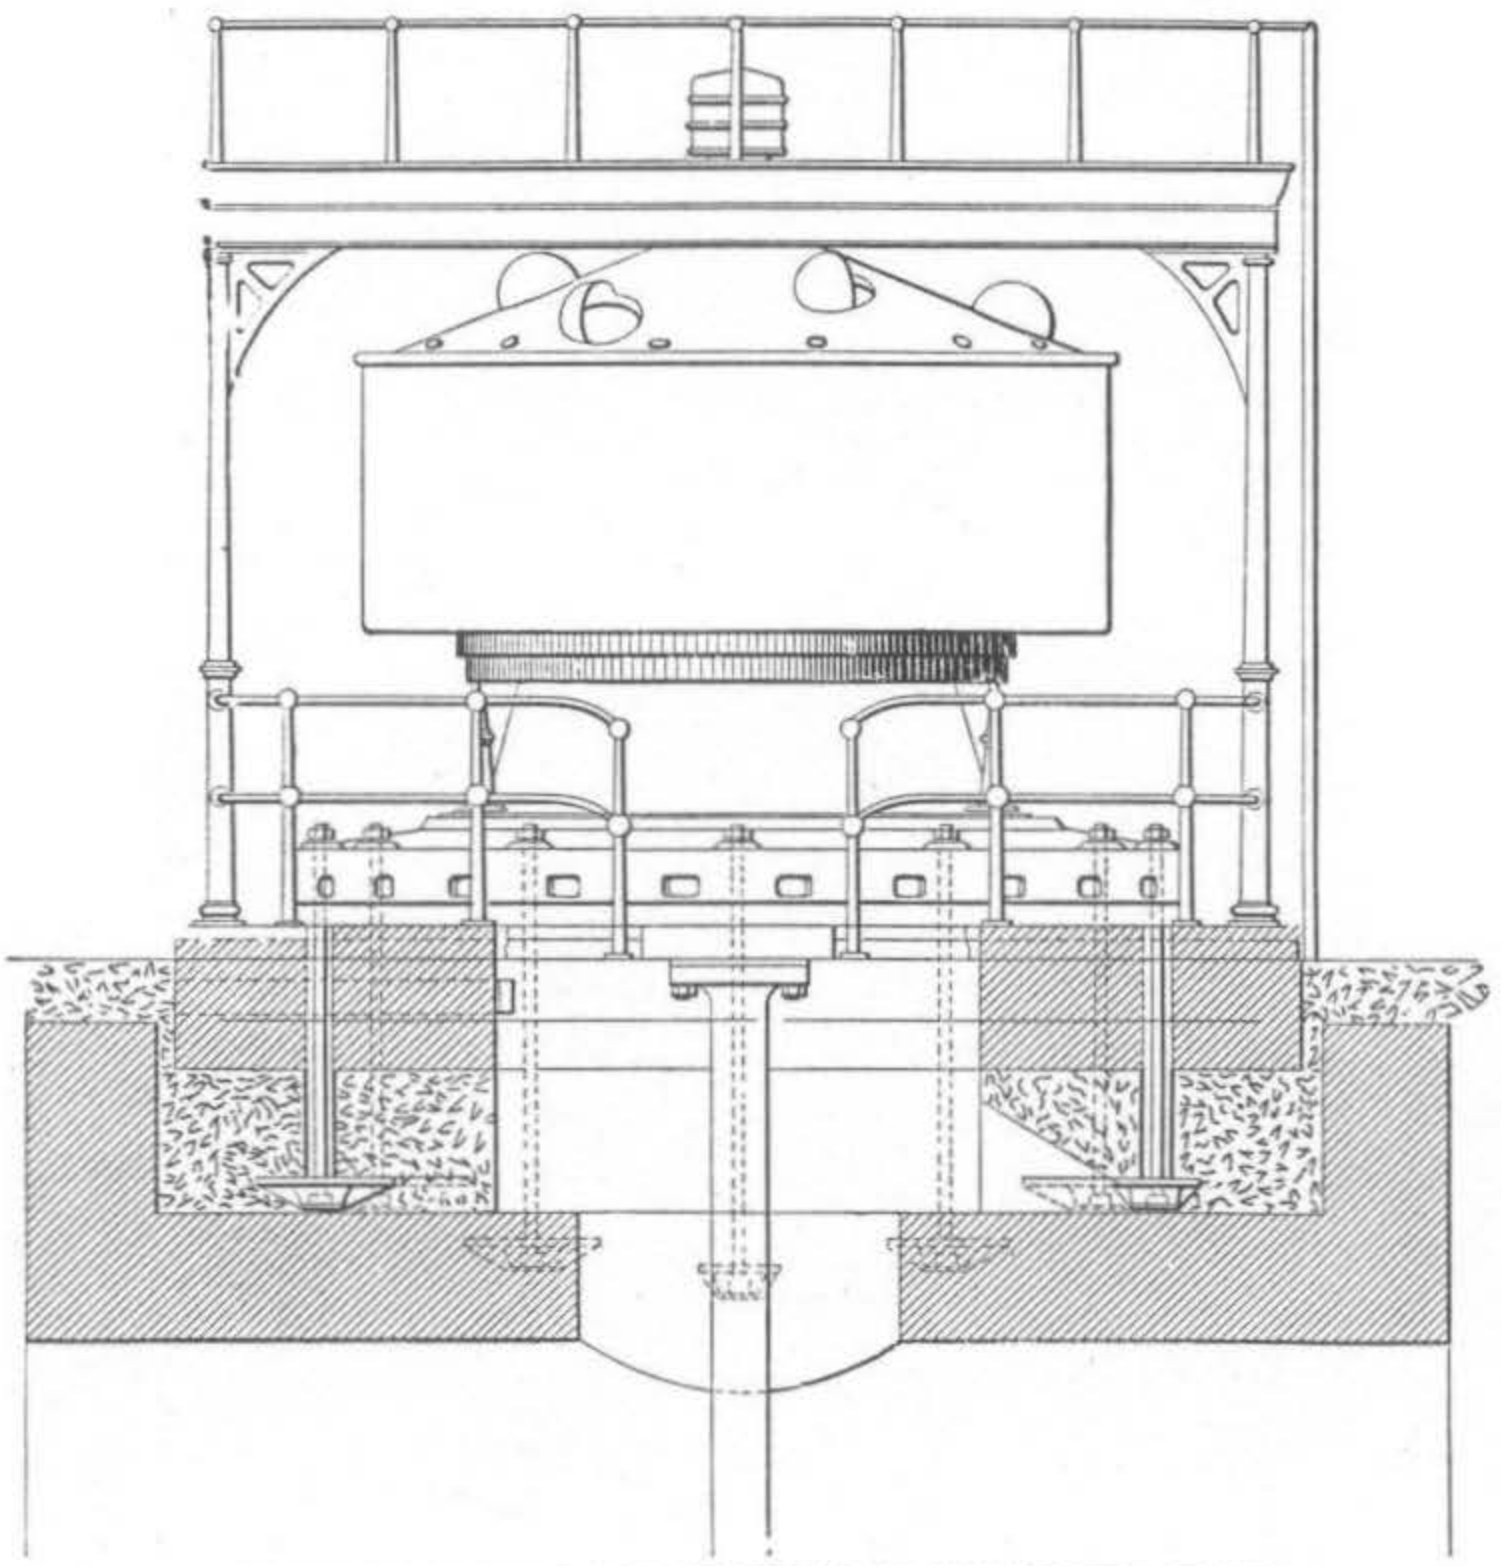


tories, etc. The next four-wire circuit is divided into two two-wire circuits, and is used to supply incandescent lamps through the transformers b, b^1, and b^2. The next circuit supplies alternating current to the motor-generator MG^2, which delivers direct current for arc lighting purposes. The last circuit shown supplies the motor-generator MG^1, which, in turn, delivers direct current at a low potential for electrolytic purposes, as indicated in the vats V, V^1, V^2, and V^3.

It is not intended to attempt the supply of incandescent lights in general in the manner indicated in the diagram, as the frequency is rather low for that purpose. At 25 cycles per second a slight wavering or variation in the intensity of the light is perceptible under certain conditions in the case of lamps having especially thin filaments, such as a 10 candle-power lamp for a 100-volt circuit. In 100-volt lamps of greater candle-power, and in 50-volt lamps, the light is entirely satisfactory. Arc lighting can, of course, be accomplished not only in the way shown in the diagram, but also by the indirect method of employing polyphase motors to drive arc light machines of the types generally in use.

The frequency selected is in every respect admirable for power purposes, and was chosen in preference to a higher frequency because the amount of energy required for lighting from Niagara will, for many years, and perhaps for all time, constitute but a comparatively small part of the energy distributed. At present the only practicable way to utilize Niagara power for lighting purposes is by substituting motors for the engines now used in arc and incandescent lighting plants in Niagara, Tonawanda, Buffalo and other cities and towns to which the circuits may be extended. When the demand for

THE FIRST GENERATOR IN POSITION IN THE POWER HOUSE AT NIAGARA.

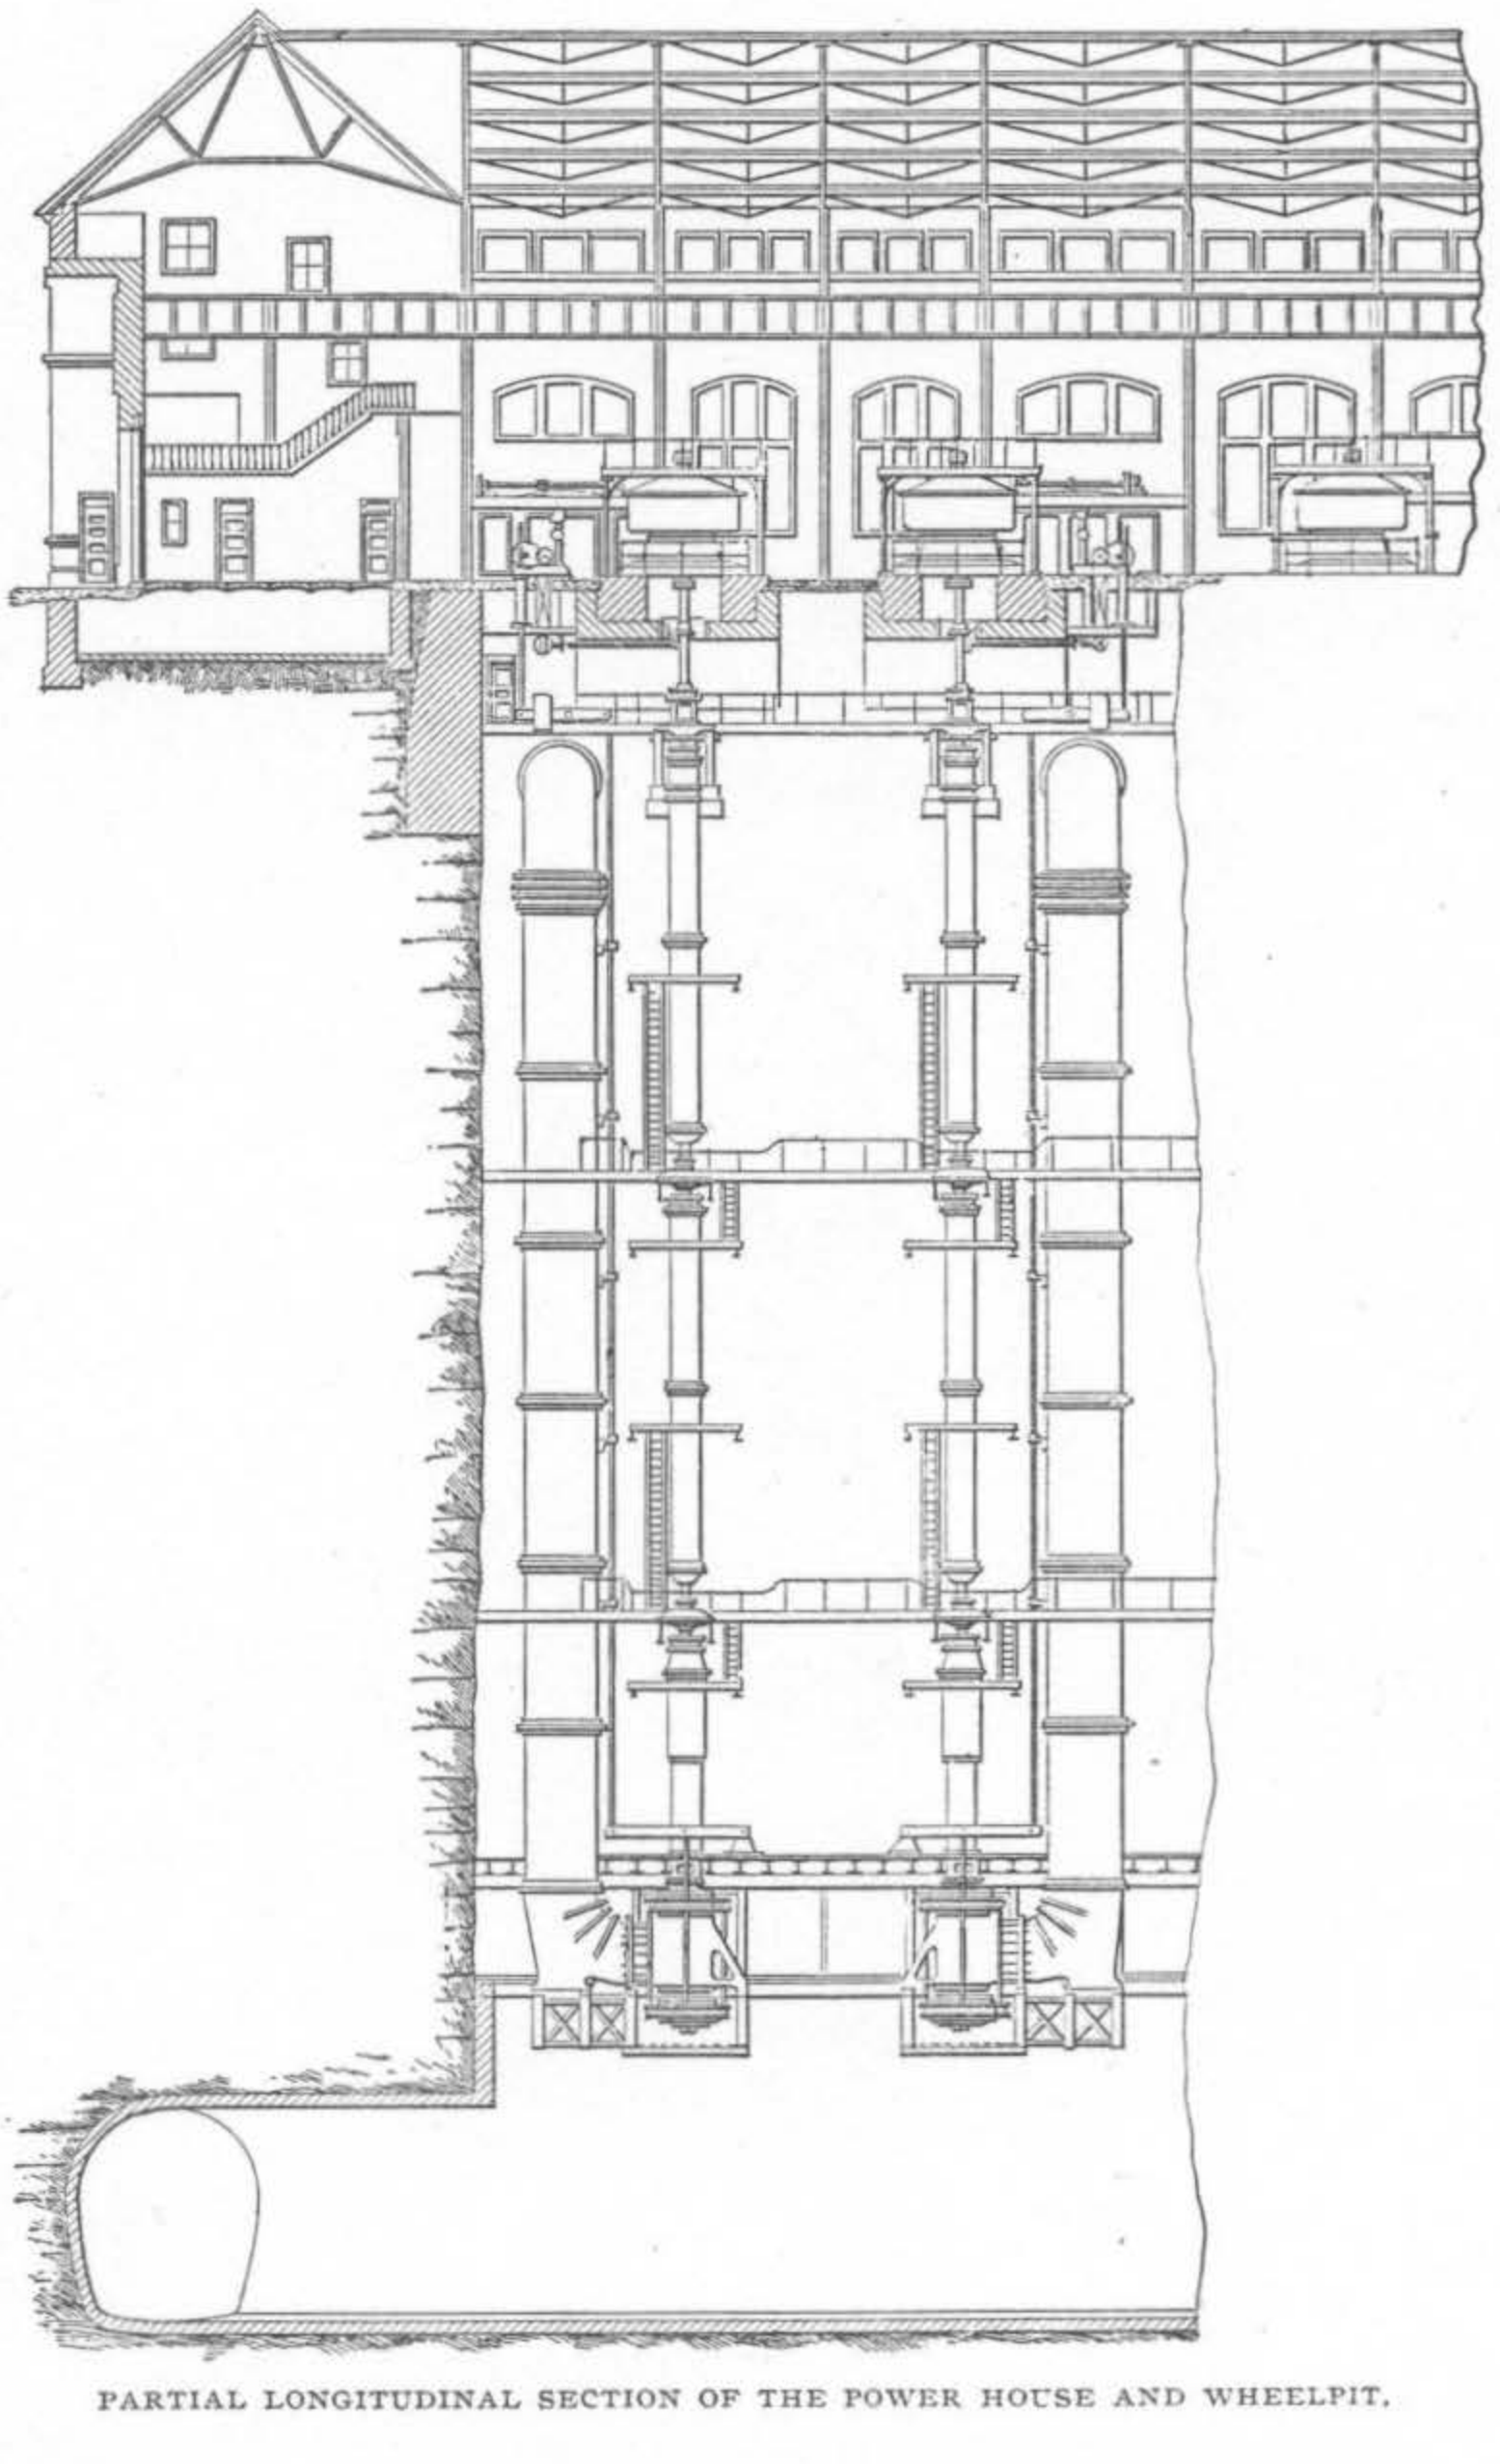


SIDE ELEVATION OF ONE OF THE GENERATORS.

A TOP VIEW.

current to be used for lighting purposes becomes sufficiently important to justify a change in the apparatus, and, perhaps, in the methods now employed for lighting the cities and towns to which the circuits may be extended, a certain number of generators of higher frequency may be installed.

The drawings reproduced on this and the opposite pages are front and side elevations and a plan, showing the relation of the generator, the bed



FRONT ELEVATION AND SECTION THROUGH FOUNDATION.

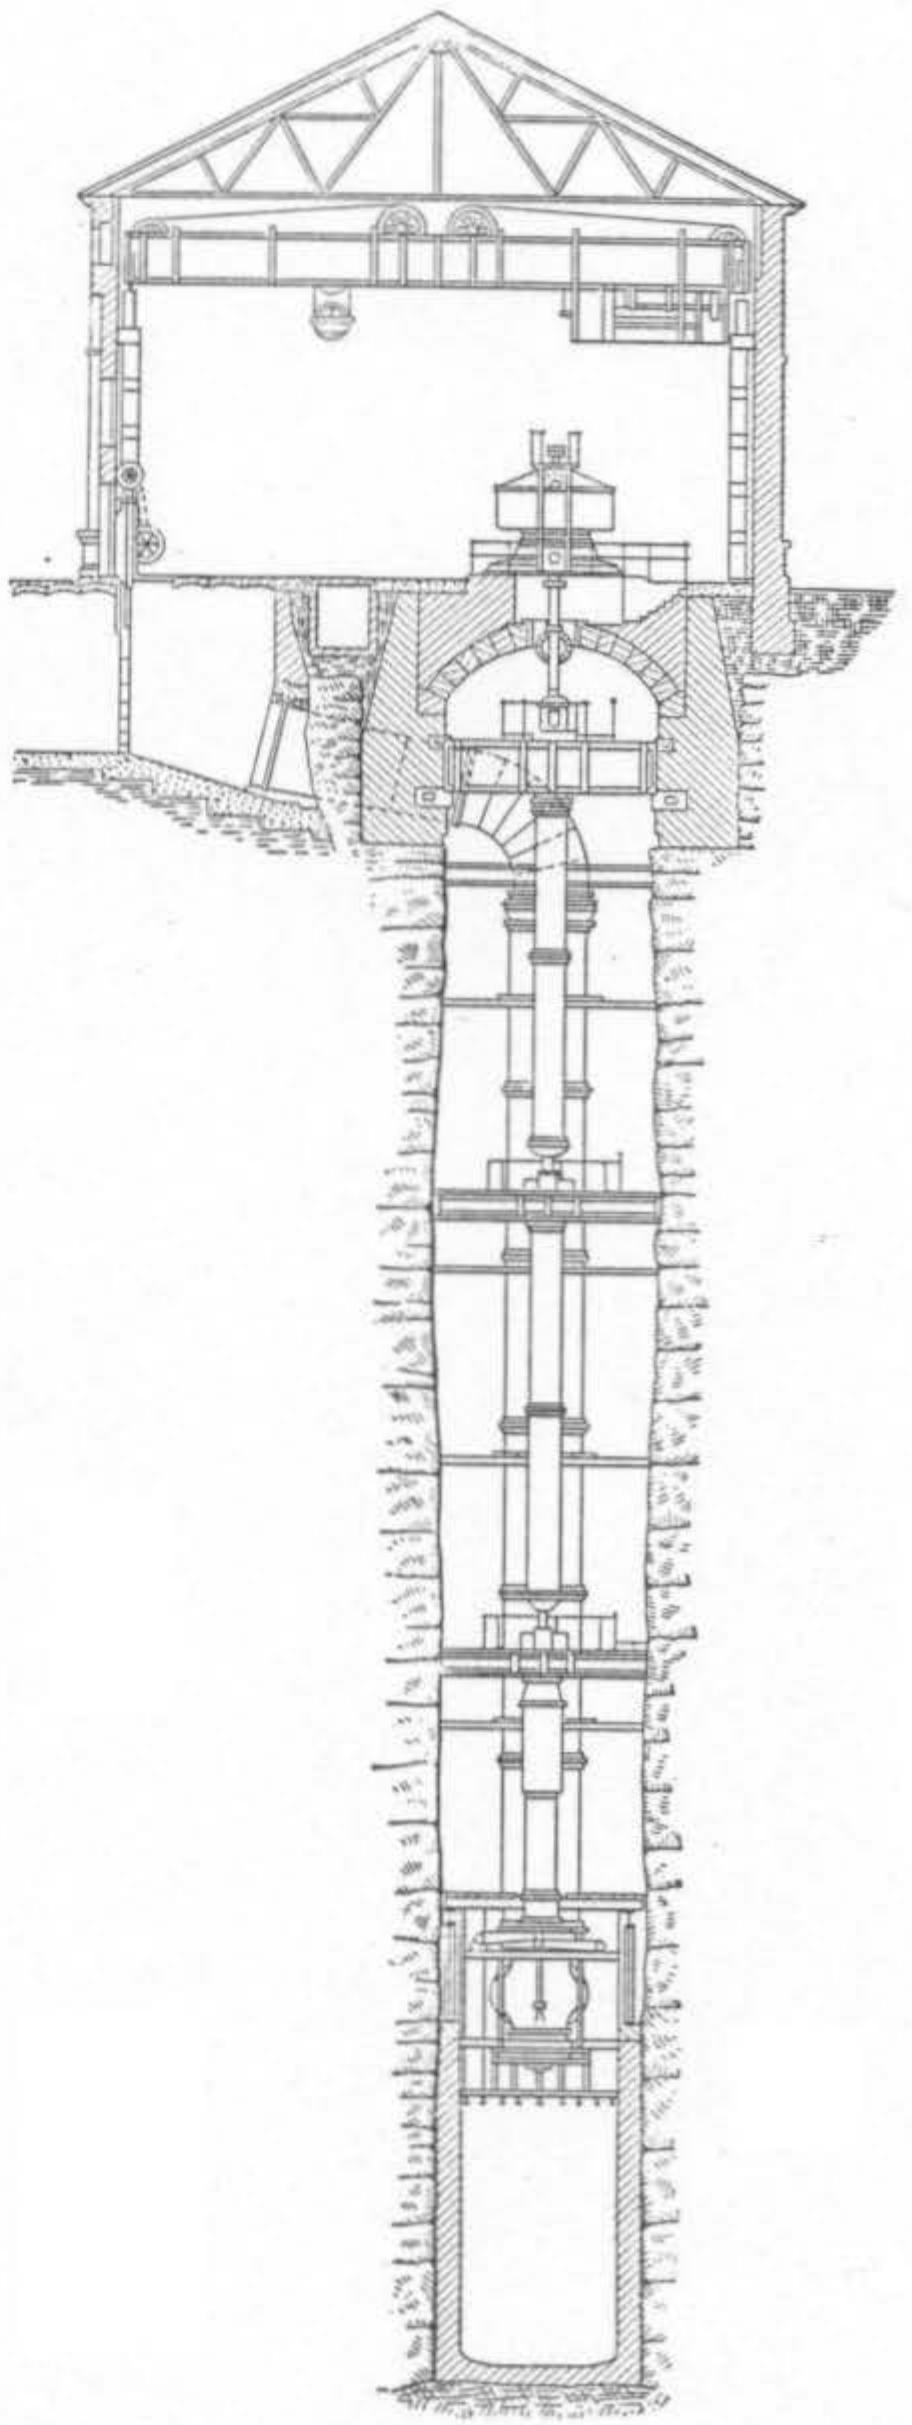
of concrete supporting the massive capstone and the excellently constructed arch which spans the wheel pit. On pages 262 and 263 sections through the power house and wheel pit, reproduced from the general drawings, show the generators in relation to the power house, the wheel pit and the hydraulic plant. The large scale upon which the work has been planned and carried out is graphically evident upon comparison of these sections, illustrating the relatively small space occupied by the generators, with the actual size of the machine as shown on page 258.

The height of each generator from the bottom of the bedplate to the top of the floor of the bridge is 11 ft. 6 in. The diameter of the bedplate is 14 ft., and the outside diameter of the revolving field ring is 11 ft. 7⅛ in. Each generator delivers 5000 electrical horsepower, and requires about 5150 horsepower delivered through the turbine shaft to drive it under full load. Exclusive of the bridge, which is simply used to give access to the brushes bearing upon the collecting rings at the top of the shaft, the entire machine could be placed in a room 15 ft. square and 15 ft. high.

The weight of each generator is 170,000 lbs., of which about 79,000 lbs. are in the revolving element, which is made up of the shaft, the driver to which the field ring is attached, the

PARTIAL LONGITUDINAL SECTION OF THE POWER HOUSE AND WHEELPIT.

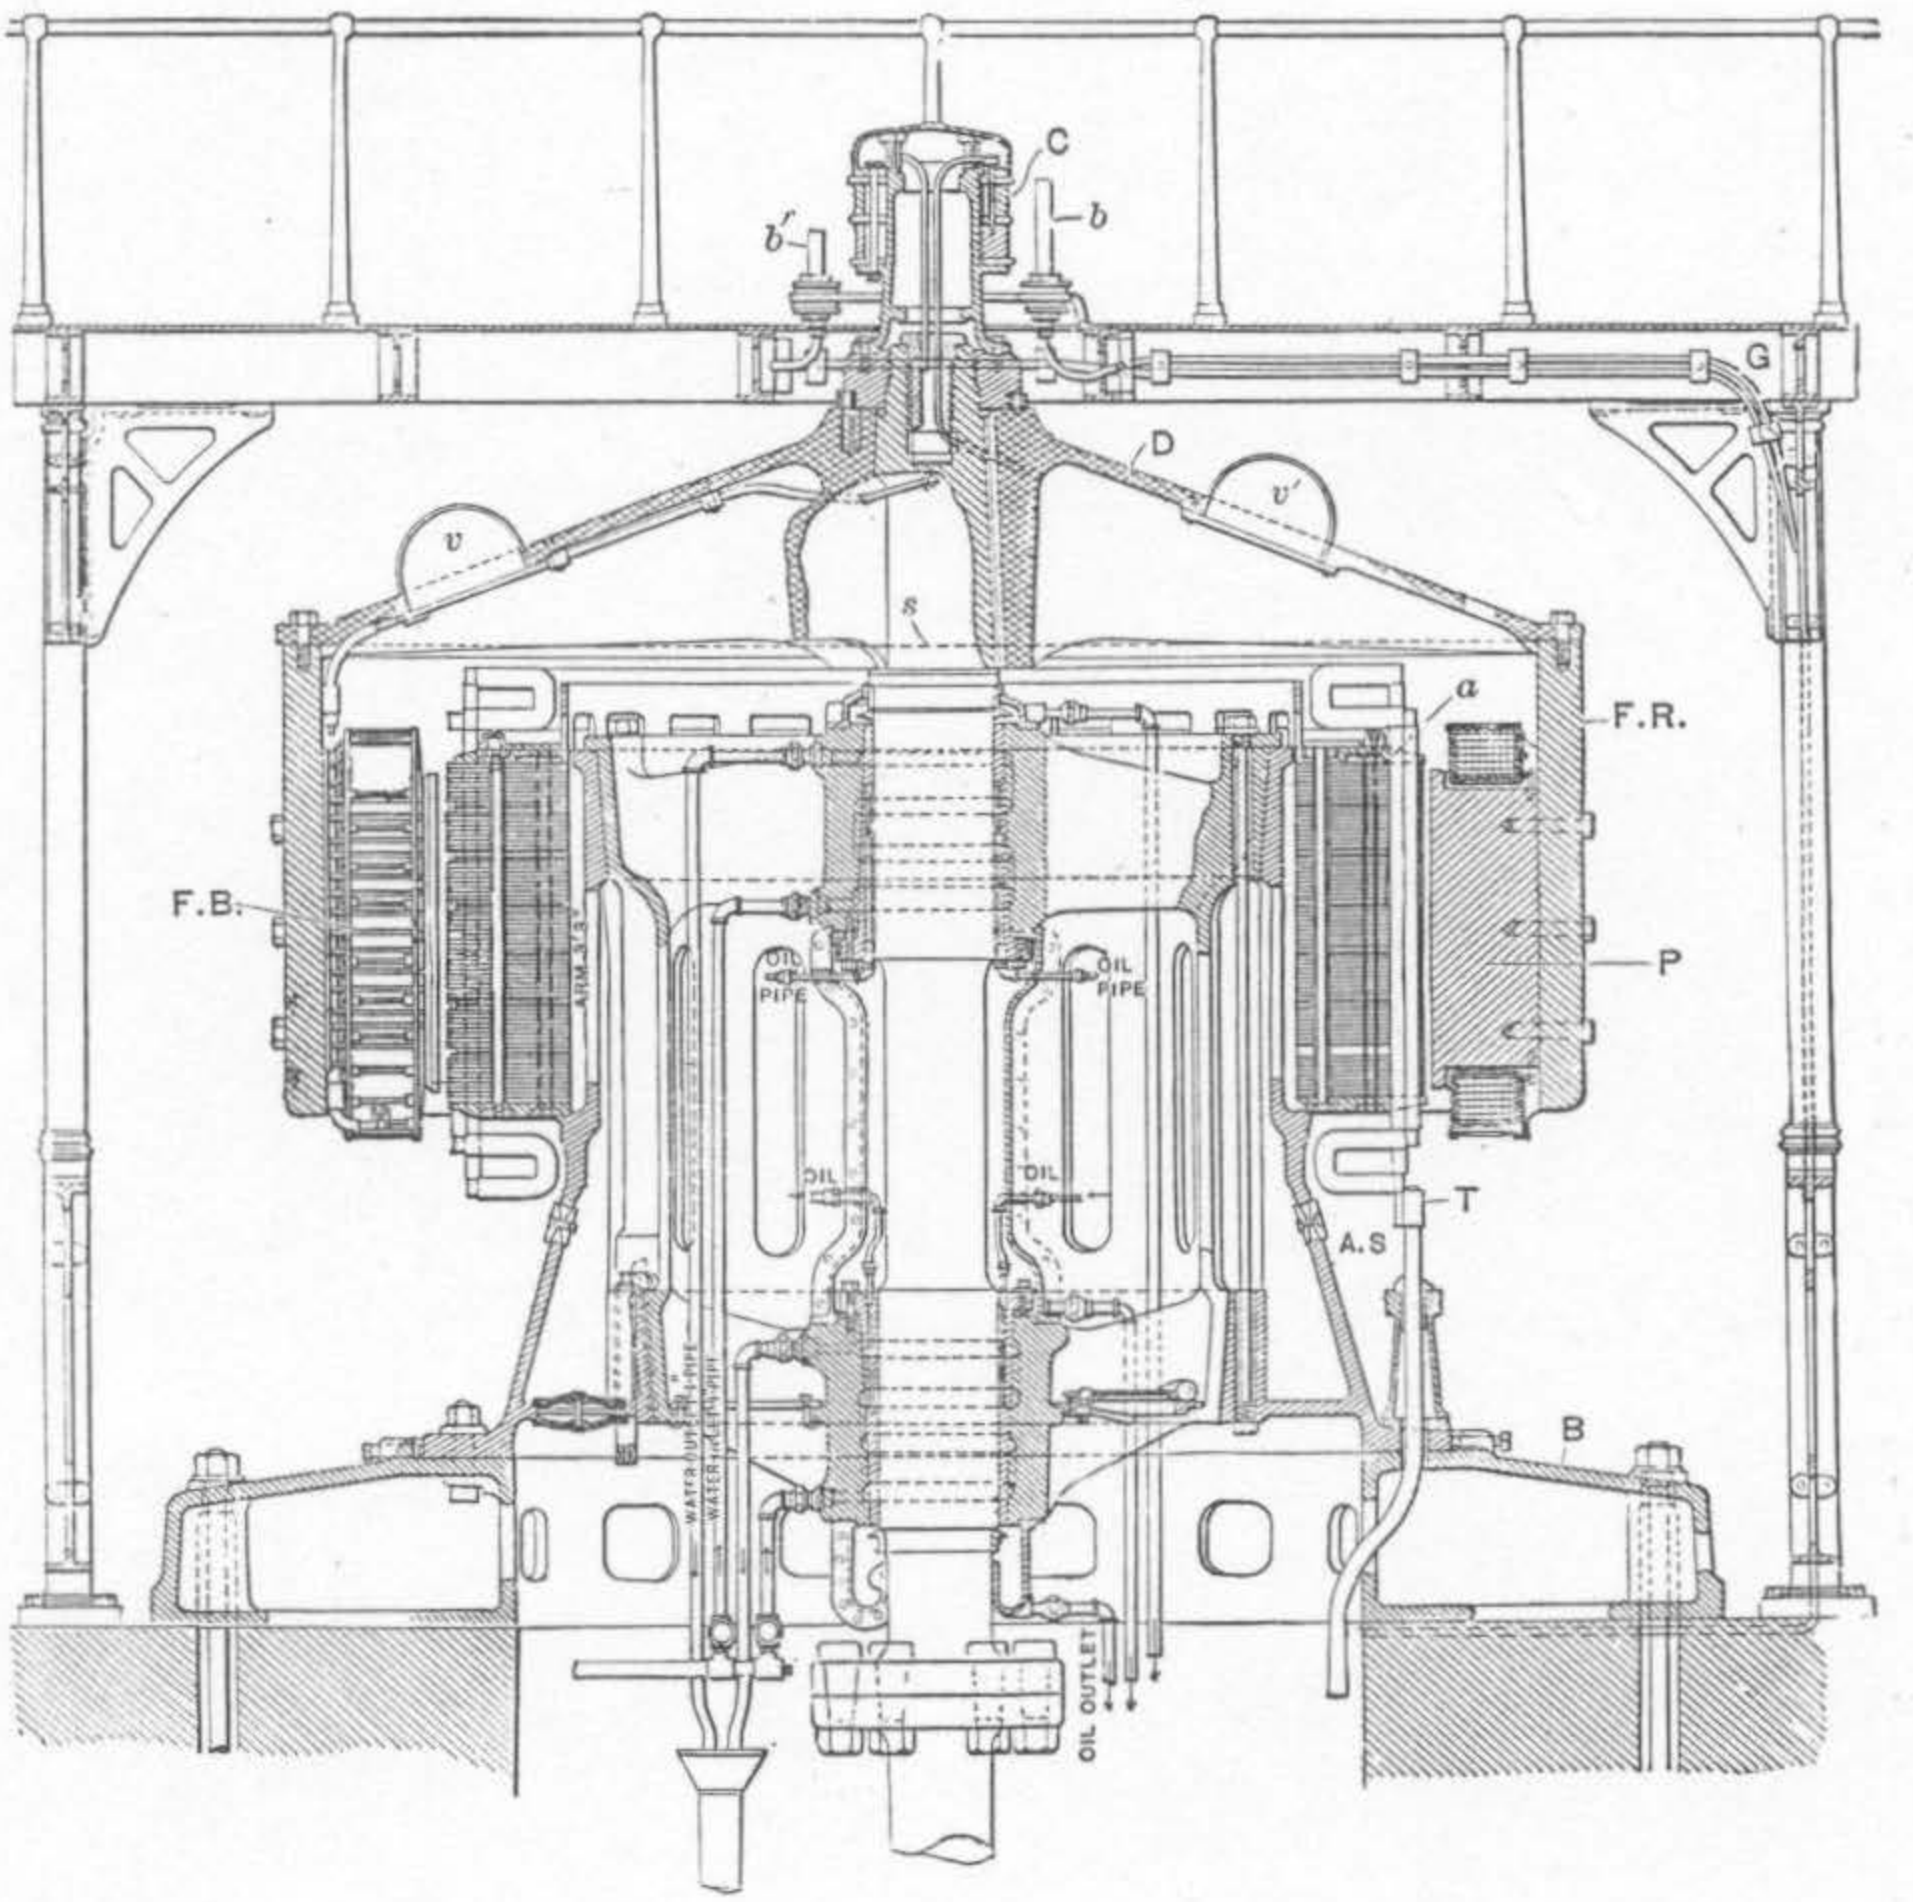
field ring with its pole pieces and bobbins, and the collecting rings, carried upon an extension of the shaft above the driver. The speed at which the field revolves is normally 250 revolutions per minute, and the fly-wheel effect of the revolving parts of the machine, measured by the pounds multiplied by feet per second squared, is 1,274,000,000.



The conditions to be met in the construction of the generators, as determined by the plans adopted for the hydraulic plant, were such as to impose very considerable difficulty upon the designers and manufacturers. These conditions were, in brief, an output of 5000 electrical horse-power, a speed of 250 revolutions per minute, a weight in

the revolving element of the machine not exceeding 80,000 lbs., and a fly wheel effect of the revolving parts, measured by the pounds multiplied by feet per second squared, of not less than 1,100,000,000.

In saying that the imposition of these conditions involved difficulties, no reflection upon the wisdom of the decision which imposed these conditions is intended. It would be, perhaps, more exact to say that the general specifications laid down were such as called for the highest skill in the designers and builders of the generators. The conditions have been met successfully, and the object which the officers of the Cataract Construction Company had in view is attained. The Niagara generators represent to-day the highest state of the art of design and construction of electrical machinery.



The construction of the generators is illustrated by the reproductions from the general drawings on pages 264 and 265. In the vertical section through the centre line of the shaft on page 264, *a* represents the stationary armature, secured in place by the armature support AS, which, in turn, rests upon the bedplate B. One of the four terminals at which the current from the armature is delivered to the cables leading to the switchboard, is shown at T. Of course, since the armature is stationary, no ring collectors or brushes are needed. The revolving part of the generator consists of the shaft S, carrying the driver D, the field ring FR, the steel pole pieces P, the field bobbins FB (each bobbin surrounding a pole piece), and the collector C, by means of which the current delivered from the exciters to the brush holders *b*, *b'*, is conveyed to the field bobbins. In the horizontal section through the armature and field, *a* is the armature, FR the field ring, P, P', etc., are the pole pieces and B, B', etc., the field bobbins. The clearance between the armature and the field poles is one inch.

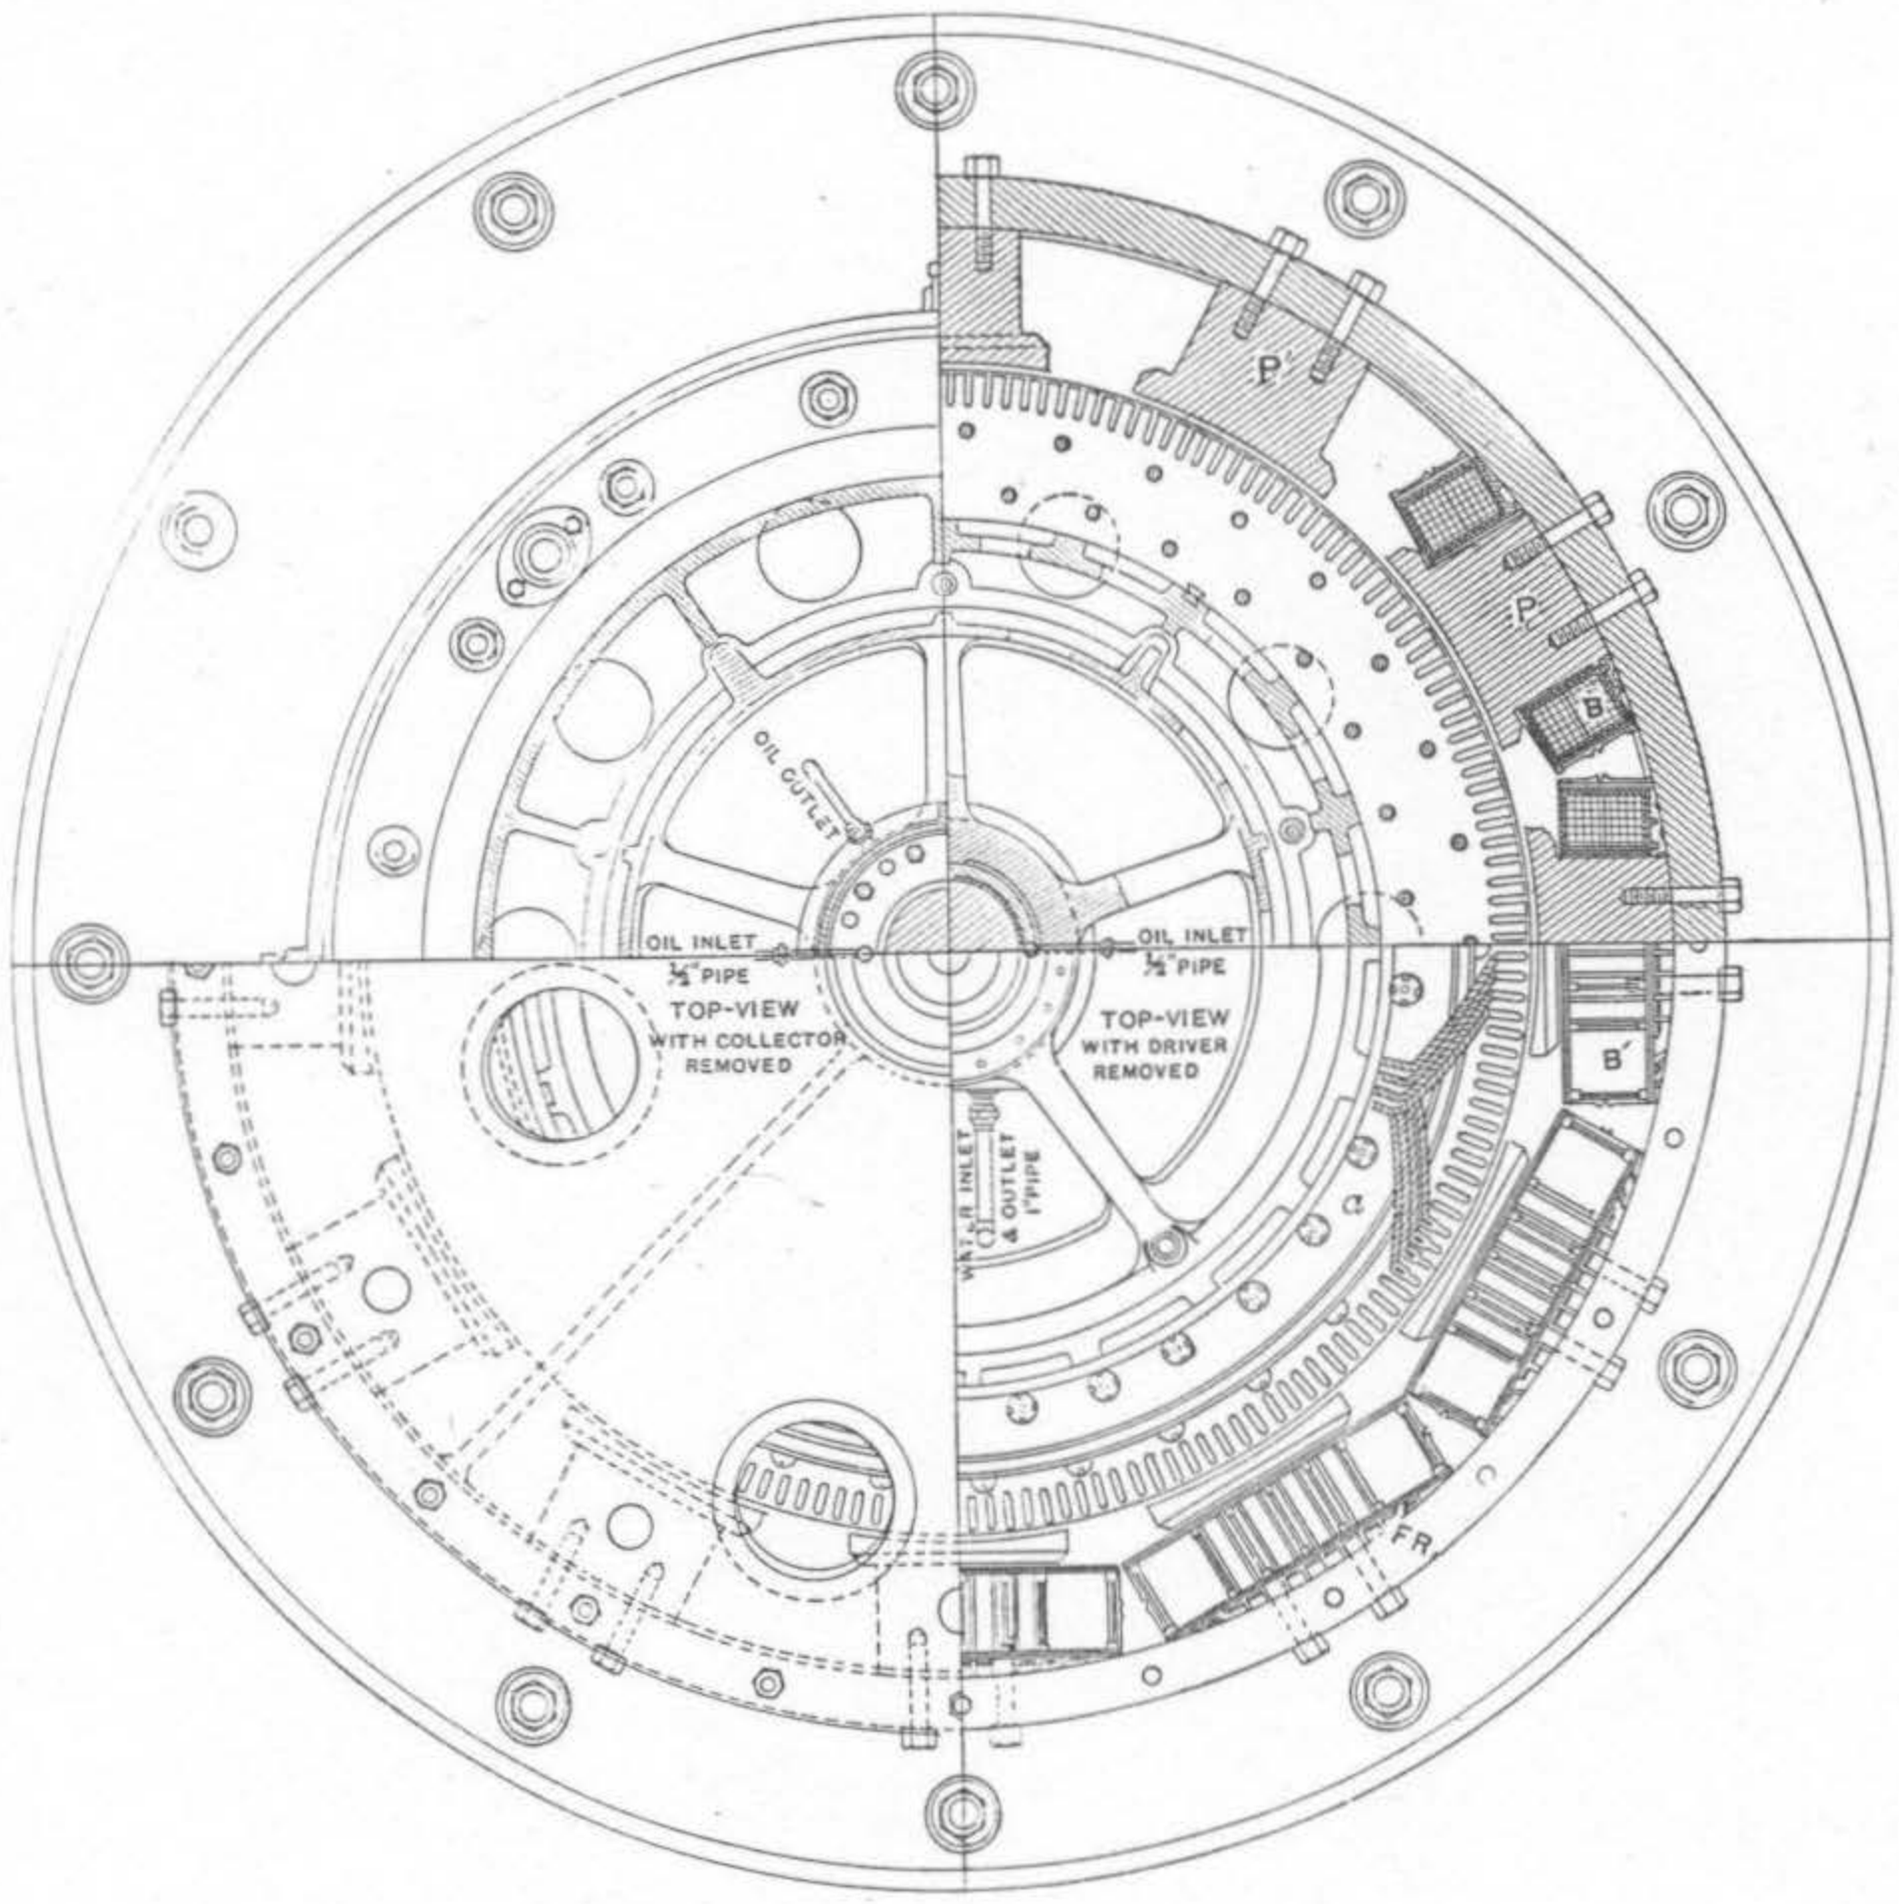
The power house is equipped with a 50-ton electric crane, built by Messrs. Wm. Sellers & Co., of Philadelphia, which is of ample strength to handle

CROSS SECTION OF POWER HOUSE AND WHEELPIT.

any part of the electric or hydraulic machinery, and by means of this the revolving parts of the machines may be removed when necessary. In doing this the collecting rings near the top of the shaft are first removed, and the bridge is taken out of the way. The key which fixes the driver to the shaft is then withdrawn, and a special tool,

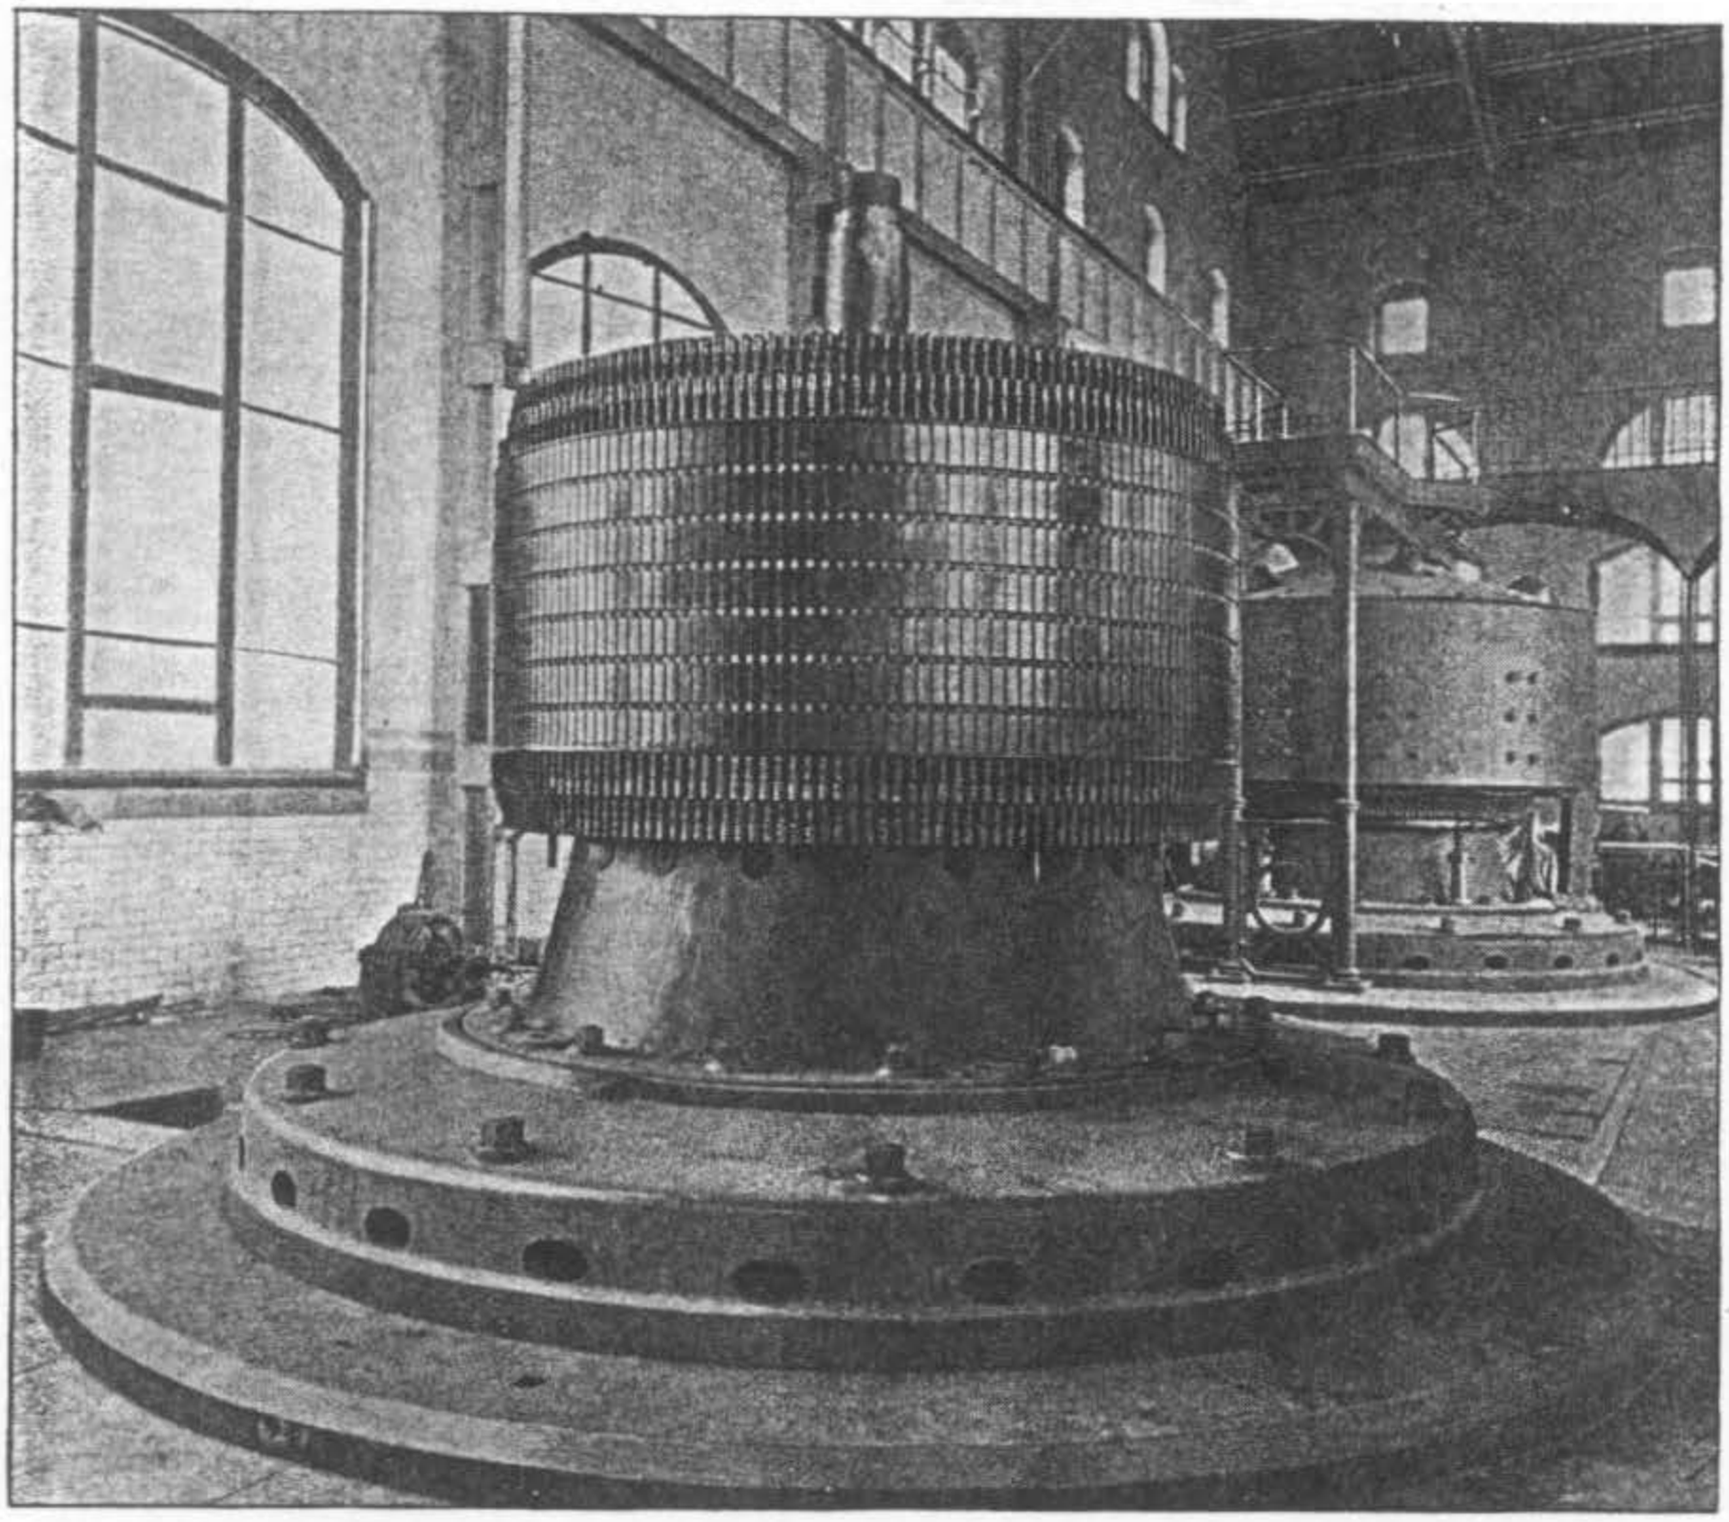
VERTICAL SECTION OF ONE OF THE 5000 HORSE-POWER GENERATORS.

which may be described as a combined eyebolt and hydraulic pump, is attached to the driver by eight heavy tap bolts. The pressure pump is then operated by hand, and, leakage of water being prevented by packing rings, a pressure of many thousand pounds, tending to lift the driver with reference to the shaft, is exerted. In this way the driver is loosened from the shaft, and, with the field, is then raised bodily by the electric crane. The bearings and the castings which support them are next lifted out, and the shaft is removed if necessary. When this has been accomplished, a clear space is left within the fixed part of the machine, that is, within the armature support, five feet in diameter, through which parts of the turbine shaft or other machinery from the wheel pit can be raised.



An attractive feature of the form of construction adopted is the fact that the magnetic attraction between the field poles and the armature acts against the centrifugal force. As compared with the centrifugal force at high speeds at which the ring must still be safe, the magnetic attraction is not very great, and, unless the field is charged, there is, of course, no magnetic pull between armature and field. But with normal conditions, this attraction tends to reduce the strains in the ring, due to centrifugal force, whereas, were the armature revolved inside of the field,

the magnetic pull would be added to the centrifugal force.

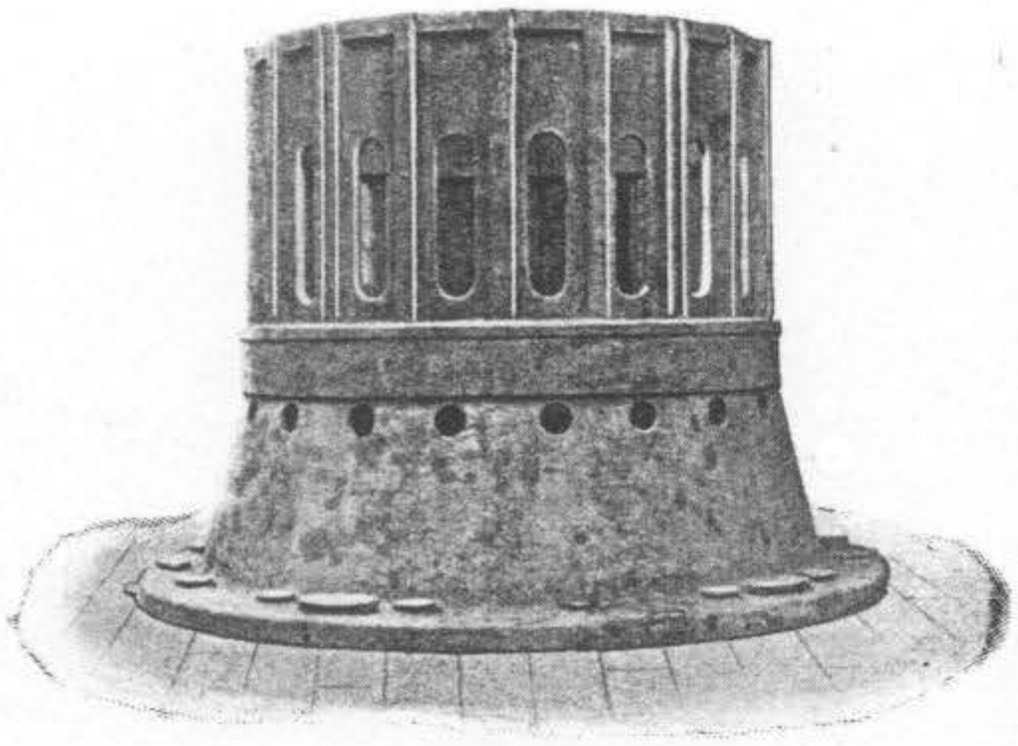


The armature and field are ventilated by means of openings in the driver, provided with special ventilators v, v', so arranged as to draw air up through the machine, and throw it out at the top. A considerable draught is necessary, since, at full load, heat equivalent to about 100 horse-power, representing the loss in the generator due to magnetization of the iron and the resistance encountered by the currents traversing the conductors, must be dissipated.

The sections on pages 260 and 261 show the method of securing the bed plate in place. Eight 2½-inch bolts are used, and, at their lower ends, are securely held by castings buried in the concrete foundation. The masonry is of the highest class, massive blocks of Queenston limestone being used for the capstone and in the construction of the arch. In the latter a cylindrical steel casting takes the place of the keystone, the turbine shaft passing through it to the dynamo shaft above.

The armature support is a single casting of cylindrical form, and is securely bolted to the bedplate, upon which it is adjusted by set screws in a flange around the circular bed, and is afterwards babbitted to secure rigidity. This cylindrical casting has on its outer periphery a series of vertical ribs, which terminate at the lower ends in a flange upon which the armature ring rests. The latter was lowered to this flange

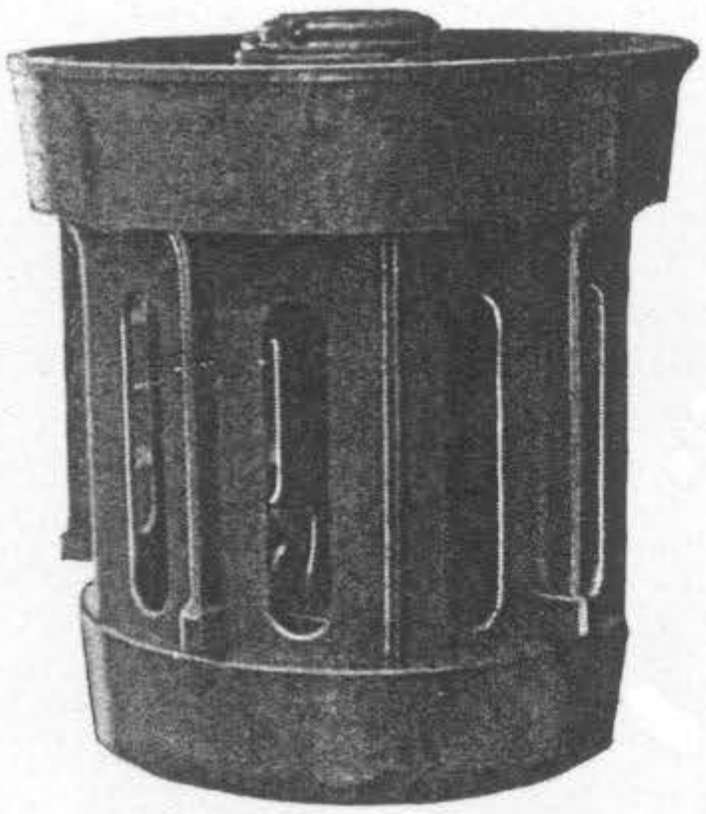
HORIZONTAL SECTION.



THE ARMATURE OF THE SECOND GENERATOR IN PLACE.

while heated, and then shrunk into place against the ribs on the cylindrical support. Five of these ribs are provided with dove-tailed keyways, corresponding with keyways in the armature ring. Into these, after the ring was shrunk into place, metal keys were cast. While the outer surface of this casting which supports the armature is cylindrical, its inner surfaces, at the top and bottom, form sections of two truncated cones into which fits and is securely bolted a second casting carrying two massive, five-arm spiders, which support the upper and lower bearings. The illustration on page 267 shows the armature support and armature core after the latter has been shrunk into place. The vertical slots which will be noted around the periphery of the core, are ready for the reception of the armature conductors.

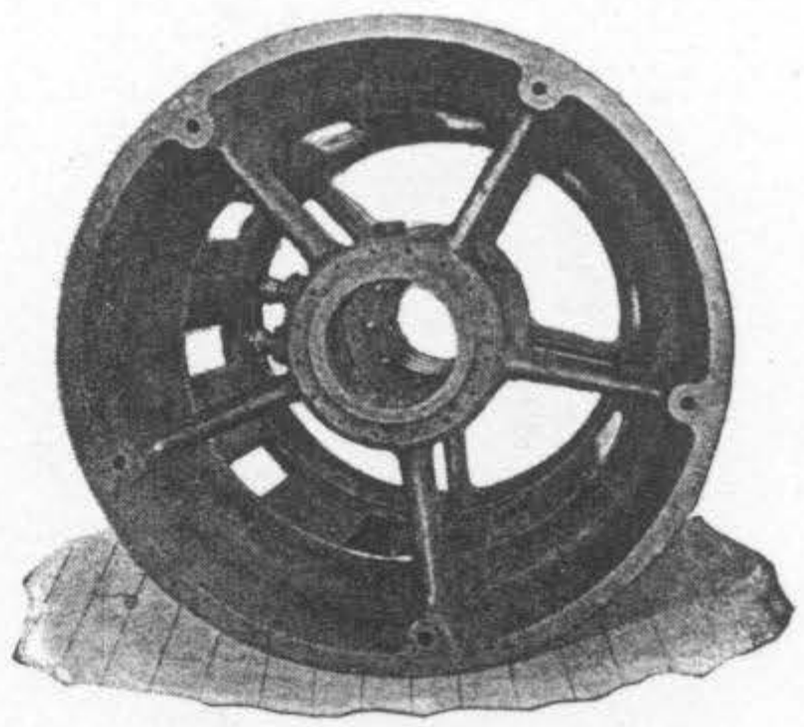
The construction of the casting which carries the spiders supporting the bearings is illustrated on the same page. The end view shows the bushings in place, and these bushings are separately illustrated on page 268. The bearings, which are of the best quality of bearing metal, are in two parts, are fitted into conical bearings of iron surrounding the shaft, and are provided with set screws to assist in withdrawing or tightening when necessary. The bearings are lubricated by oil under pressure, admitted at a point midway between the top and bottom, and also at a point near the top.



Grooves are cast in the hub of each spider, with pipes at each end, permitting the circulation of water to cool the bearings, this water being conveyed to the bearings direct from the city mains at a pressure of 60 pounds per square inch. The oil is supplied from a reservoir placed at an elevation of about 30

ft. above the upper bearing. After having passed through the bearings, it is filtered and pumped back into the reservoir. The pressure at which it is supplied to the machine is that due to gravity.

THE ARMATURE SUPPORT AND CORE.

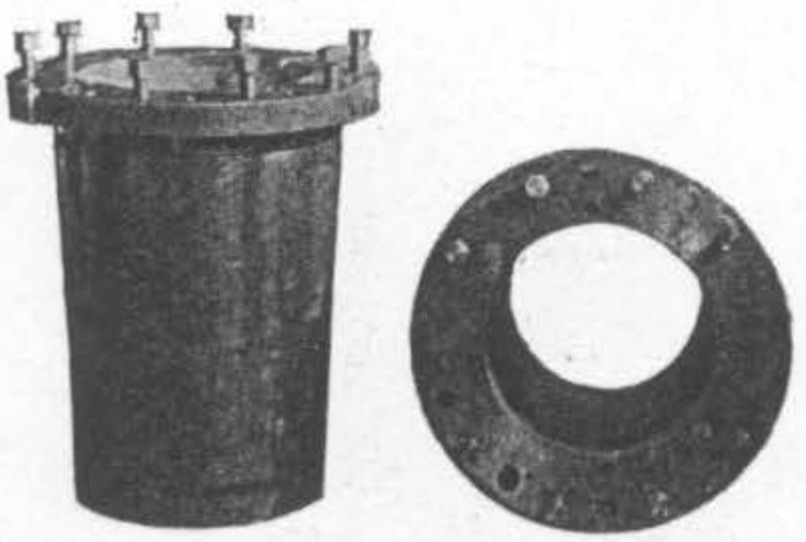


The illustrations on pages 269 and 266 show, respectively, the armature core, or ring, in place upon its support before winding, and the armature complete, with conductors in the grooves or slots around the periphery of the core. The armature core is built up of

SIDE VIEW OF CASTING CARRYING SPIDER FOR BEARINGS.

thin sheets of mild steel, No. 30 B. W., G., and, to secure free circulation of air, is divided horizontally into six equal parts, separated from one another by one-inch spaces. Each layer of the core consists of eleven segments, which are so placed that all joints in each layer are overlapped by the segments of the adjacent layers. One of the sheets of steel is shown on page 268. These pieces are punched out of large sheets of a certain predetermined quality, .015 of an inch thick, by steel dies in powerful presses. They are afterwards thoroughly annealed. In this process of annealing, the surfaces of the segments are oxidized, the oxide serving as insulation to reduce the eddy currents which are set up in the iron of the armature when the machine is in operation.

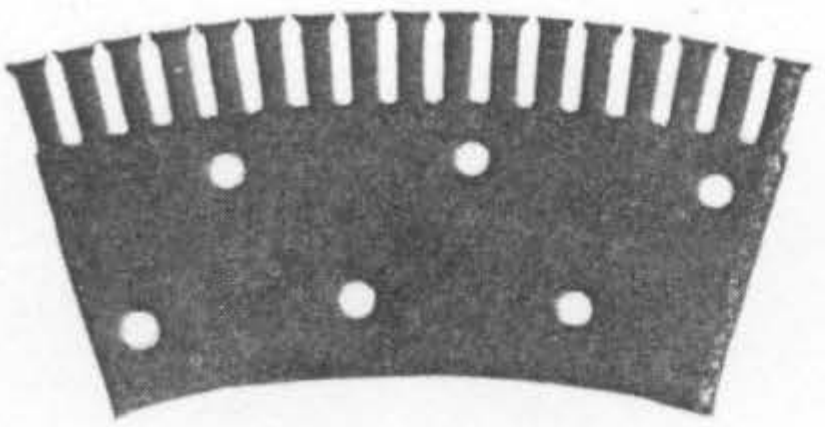
The ring thus built up is securely held together by sixty-six bolts of nickel steel, containing a high percentage of nickel which renders them practically non-magnetic. These bolts are, of course, carefully insulated from the core. The large discs, or end-plates, at the top and bottom of the armature ring are of brass. At the time of tightening the bolts, the steel plates are pressed closely together by



END VIEW OF THE CASTING.

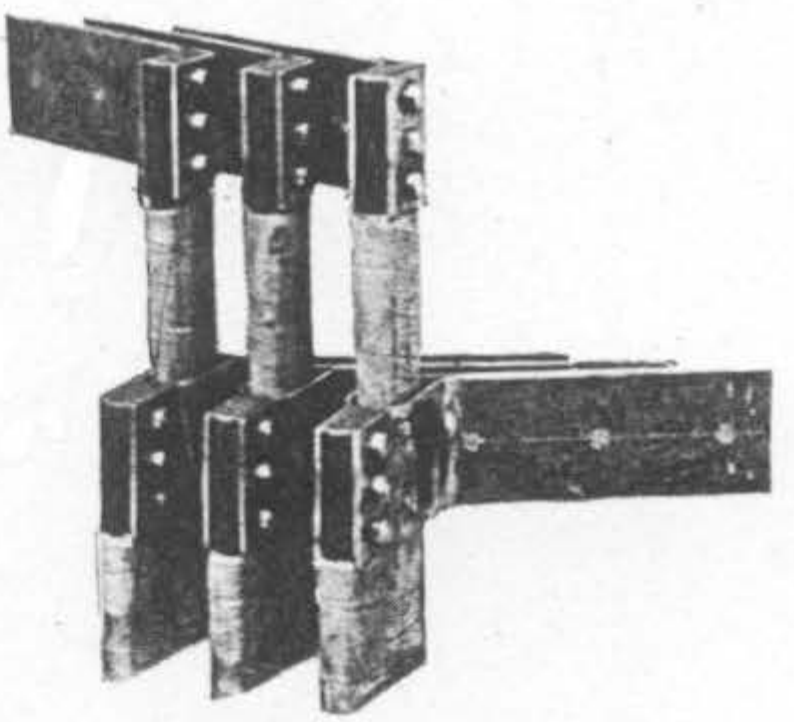
powerful hand-presses. The six equal parts, or layers, into which the core of the armature is divided, are separated from one another by segments of cast brass, these segments being cast in such form that, while they have sufficient strength to withstand the pressure under which the armature core is assembled, the larger part of the spaces between the six adjacent rings or steel plates is left open for the circulation of air.

The armature ring, when finally



built up, is turned on the inner surface so as to accurately fit the ribs of the armature support. It is then heated, and lowered into place against the flange on the support, and, in cooling, shrinks itself tightly into place against the ribs.

The armature conductors consist of copper bars $1\frac{11}{32}$ in. by $\frac{7}{16}$ in. in section, the edges of the bars being rounded to a radius of about one-eighth of an inch to avoid cutting the insulation. Two of these bars, after being insulated, are placed in each of the 187 slots around the periphery of the armature core. The conductivity of the bars used is above 100 per cent., by



DETAILS OF ARMATURE BEARINGS.

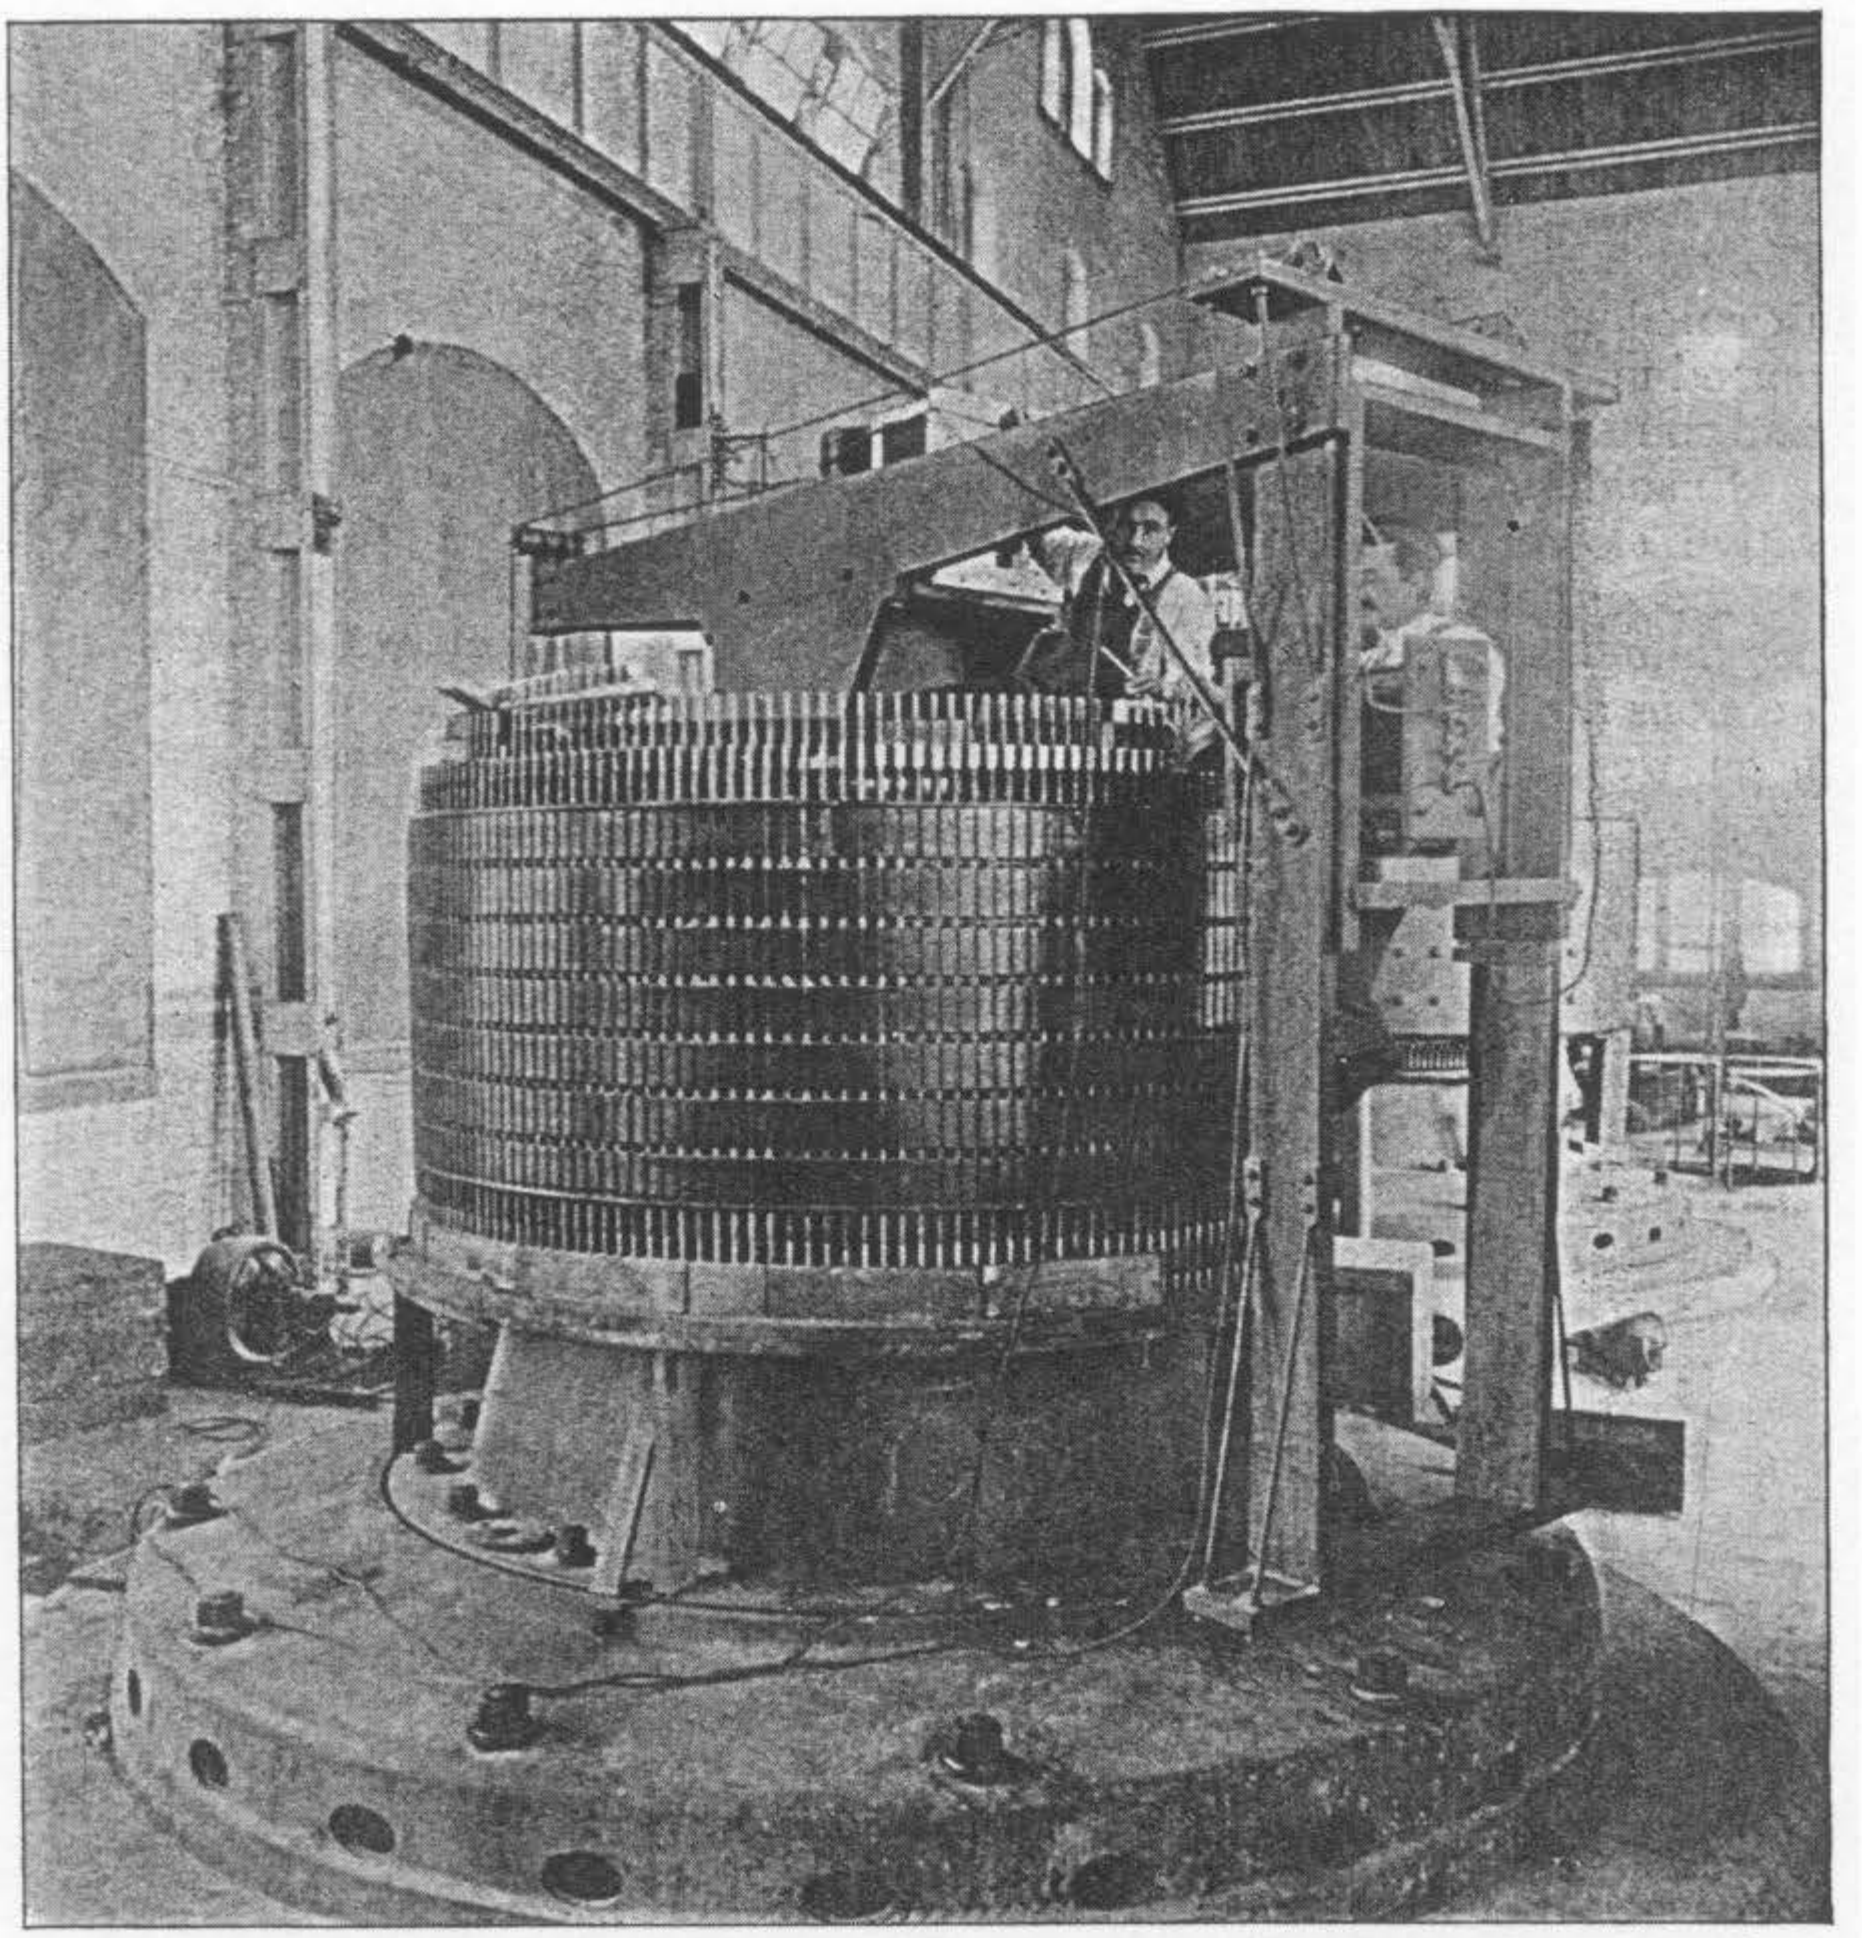
Matthiesen's standard. In the case of the second generator the conductivity of the copper, furnished by the Washburn & Moen Mfg. Co., of Worcester, Mass., is 102.6 per cent., which strikingly illustrates the fact that what was considered pure copper when the standard referred to, and still generally used,

ONE OF THE SHEETS MAKING UP THE ARMATURE CORE.

was determined, is now inferior to certain grades of commercial copper. The proper insulation of these conductors is a matter of the greatest importance. Each conductor must be separated from its neighbors and from the iron of the armature core by insulating material which is abundantly able to withstand the potential to which it will be subjected, and in order to be sure of this, a large factor of safety is allowed; that is, the insulation is tested by apply-

JUNCTION OF ARMATURE BARS AND CONNECTORS BEFORE SOLDERING AND INSULATING.

ing a potential several times as great as any to which it will be subjected in service.



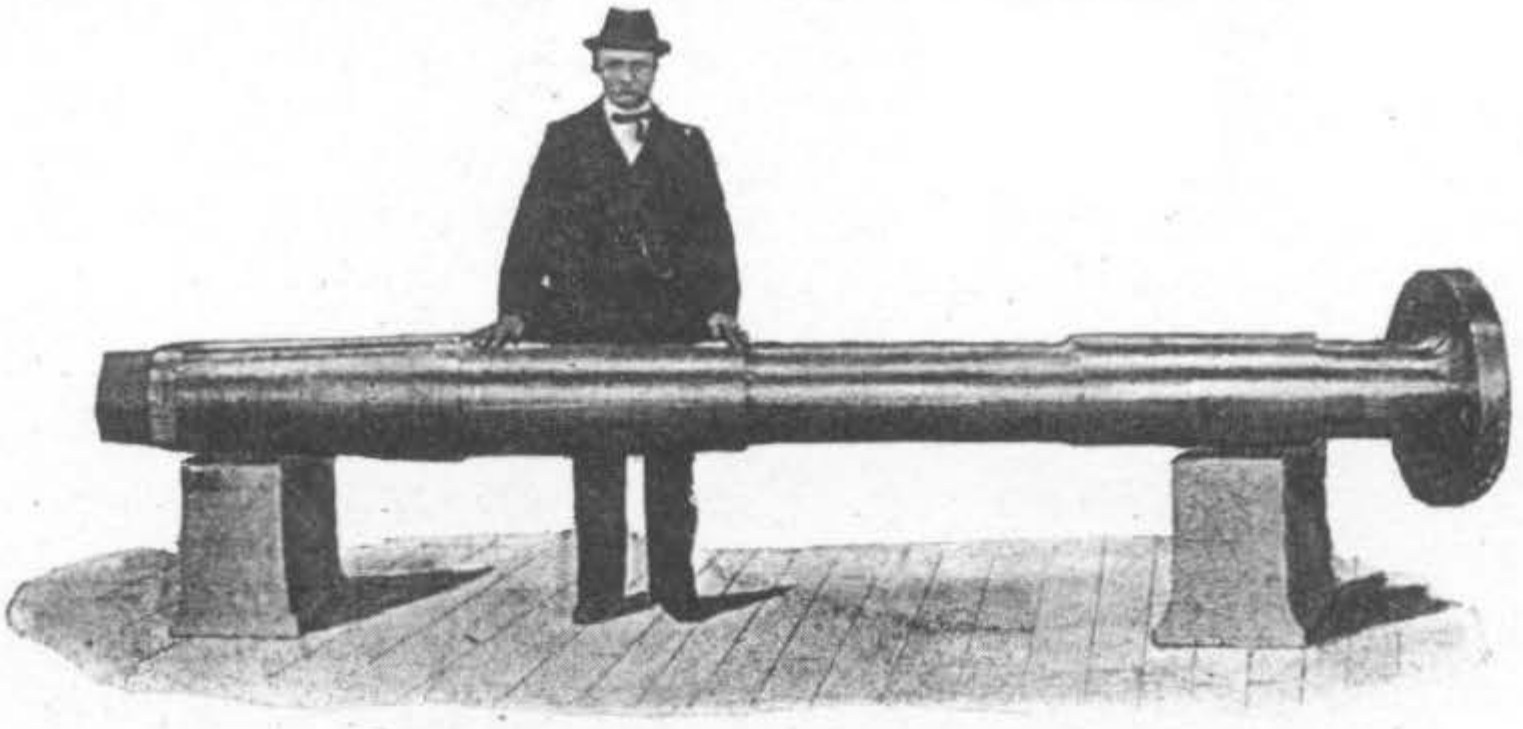
At the factory, the insulation of each bar was tested by applying a potential of 15,000 volts. One terminal of the transformer used in testing was connected to the conductor, and the other terminal was connected to a layer of tinfoil, wrapped about the outside of the insulation. During the erection of the generators at Niagara, the insulation was again tested by applying a potential of 6000 volts, one terminal of the testing transformer being connected to the conductors, while the other was connected to the armature core. An alternating potential was used in both tests, and the values given are in each case the mean or effective potential.

The material used for insulating the bars is principally mica. The armature conductors project above and below the core, as shown in the illustration on page 269, and connections are made by pieces of copper, punched from large sheets and shaped into proper form by presses and iron moulds. These connectors are insulated by mica and rubber insulating tape, the former being used only where connectors conveying

currents of considerable difference of potential are adjacent to each other.

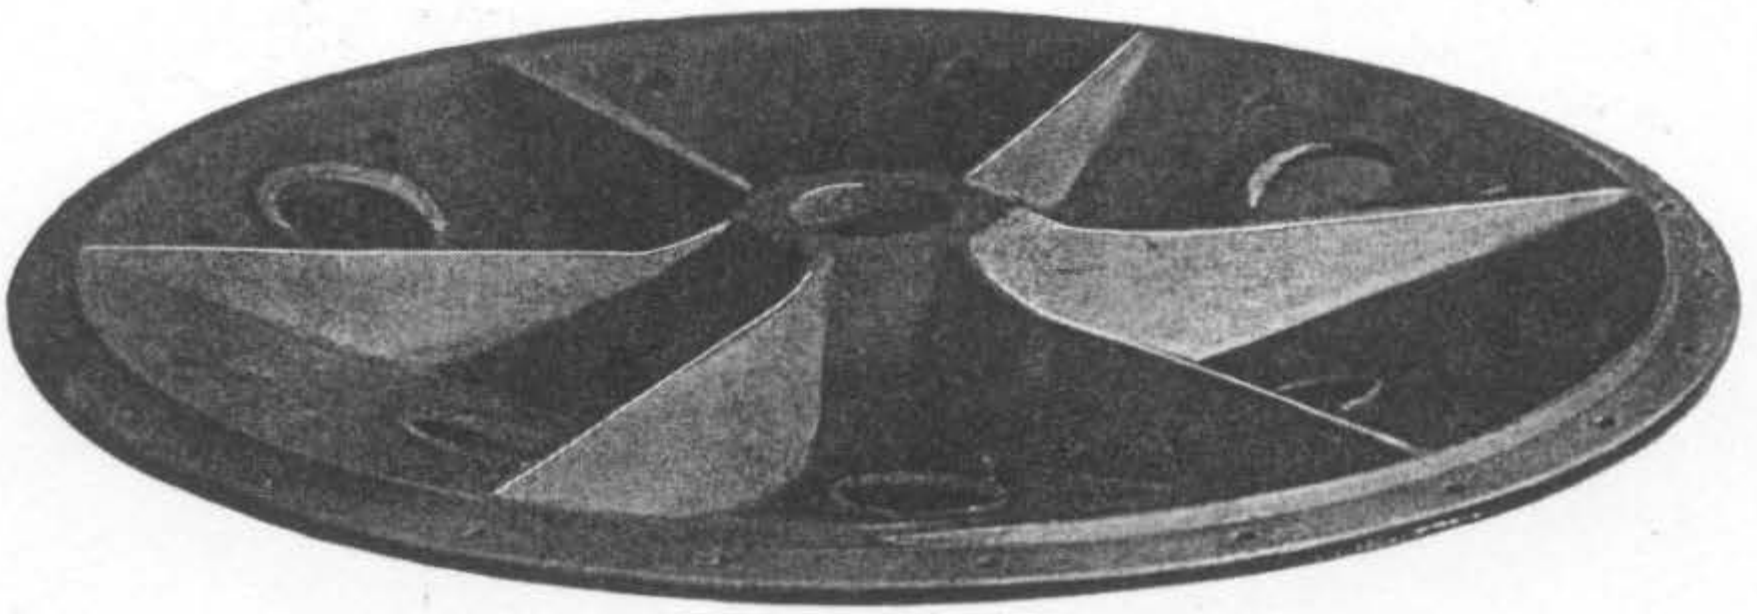
It is very important that good electrical connection be made at the junction of connector and armature bar. The illustration on page 268 illustrates the connection before the solder is applied. Three holes drilled through the split end of the connector correspond to three holes in the end of the armature bar. The split end of the connector is fitted closely to the end of the bar, and when the holes in the connector and bar are properly aligned they are securely fixed in place by three wrought iron bolts, the holes through one side of the connector being reamed out to receive the heads of the bolts. After the nuts are tightened into place, the projecting ends of the bolts are upset; that is to say, they are split and, as it were, riveted to lock the nuts.

The joint is then thoroughly soldered, this work being greatly facilitated by the use of an electrical soldering tool. The process will be best understood by referring to the illustration on this page, which was taken during the erection of the first generator. A transformer, supplied with alternating current at a potential of about 150 volts, is so wound as to deliver a current of very large quantity but low pressure. This current is coveyed through heavy jaws, or terminals, of copper to the point of junction between the armature bar and



ELECTRICALLY SOLDERING THE CONNECTIONS OF AN ARMATURE WINDING.

its connector, and in a few seconds this point is heated to a high temperature. The joint is then readily flooded with solder. This is afterwards dressed up by a file, and the joint is thoroughly insulated.



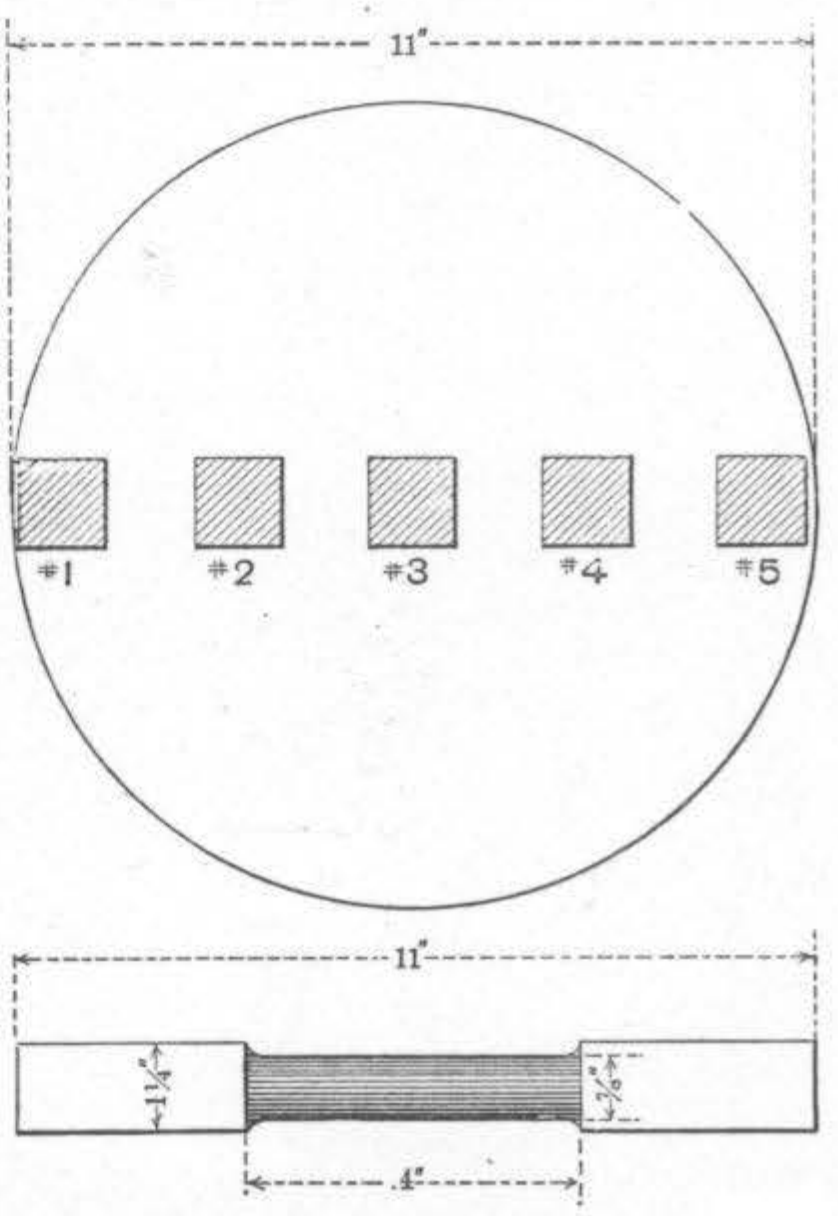
In the illustration the soldering transformer and one of the operatives are seen carried at one end of an oak frame, supported upon the shaft of the generator and counter-weighted at its opposite end. In soldering the connections the operative slowly revolves the frame about the armature. The seat which carries him is adjustable, so that the connections at the bottom of the armature, as well as at the top, can be reached, and it is provided with rails upon which the transformer is pushed forward until the copper jaws grasp the connection, or withdrawn after the soldering is completed.

When the armature is completely wound, as shown in the illustration on page 266, the conductors are so connected as to form two complete circuits, each thoroughly insulated from the other and from the steel core, and so related to each other that the electromotive forces induced in them by the revolving magnetic field are ninety degrees apart.

THE GENERATOR SHAFT.

Coming now to the revolving parts of the generator, we begin with the shaft, which is shown on this page. It is of open-hearth steel, and was forged and rough-turned by the Cleveland City Forge and Iron Company of Cleveland, Ohio. The diameter of the shaft in the bearings is $12\frac{15}{16}$ in. It is tapered at the upper end to receive the driver, and a flange, 27 in. in diameter, is forged at the lower end to provide means for connection to the flange at the top of the turbine shaft. These flanges are bolted together by eight tapered steel bolts. At its extreme upper end the shaft is threaded to provide means for securing

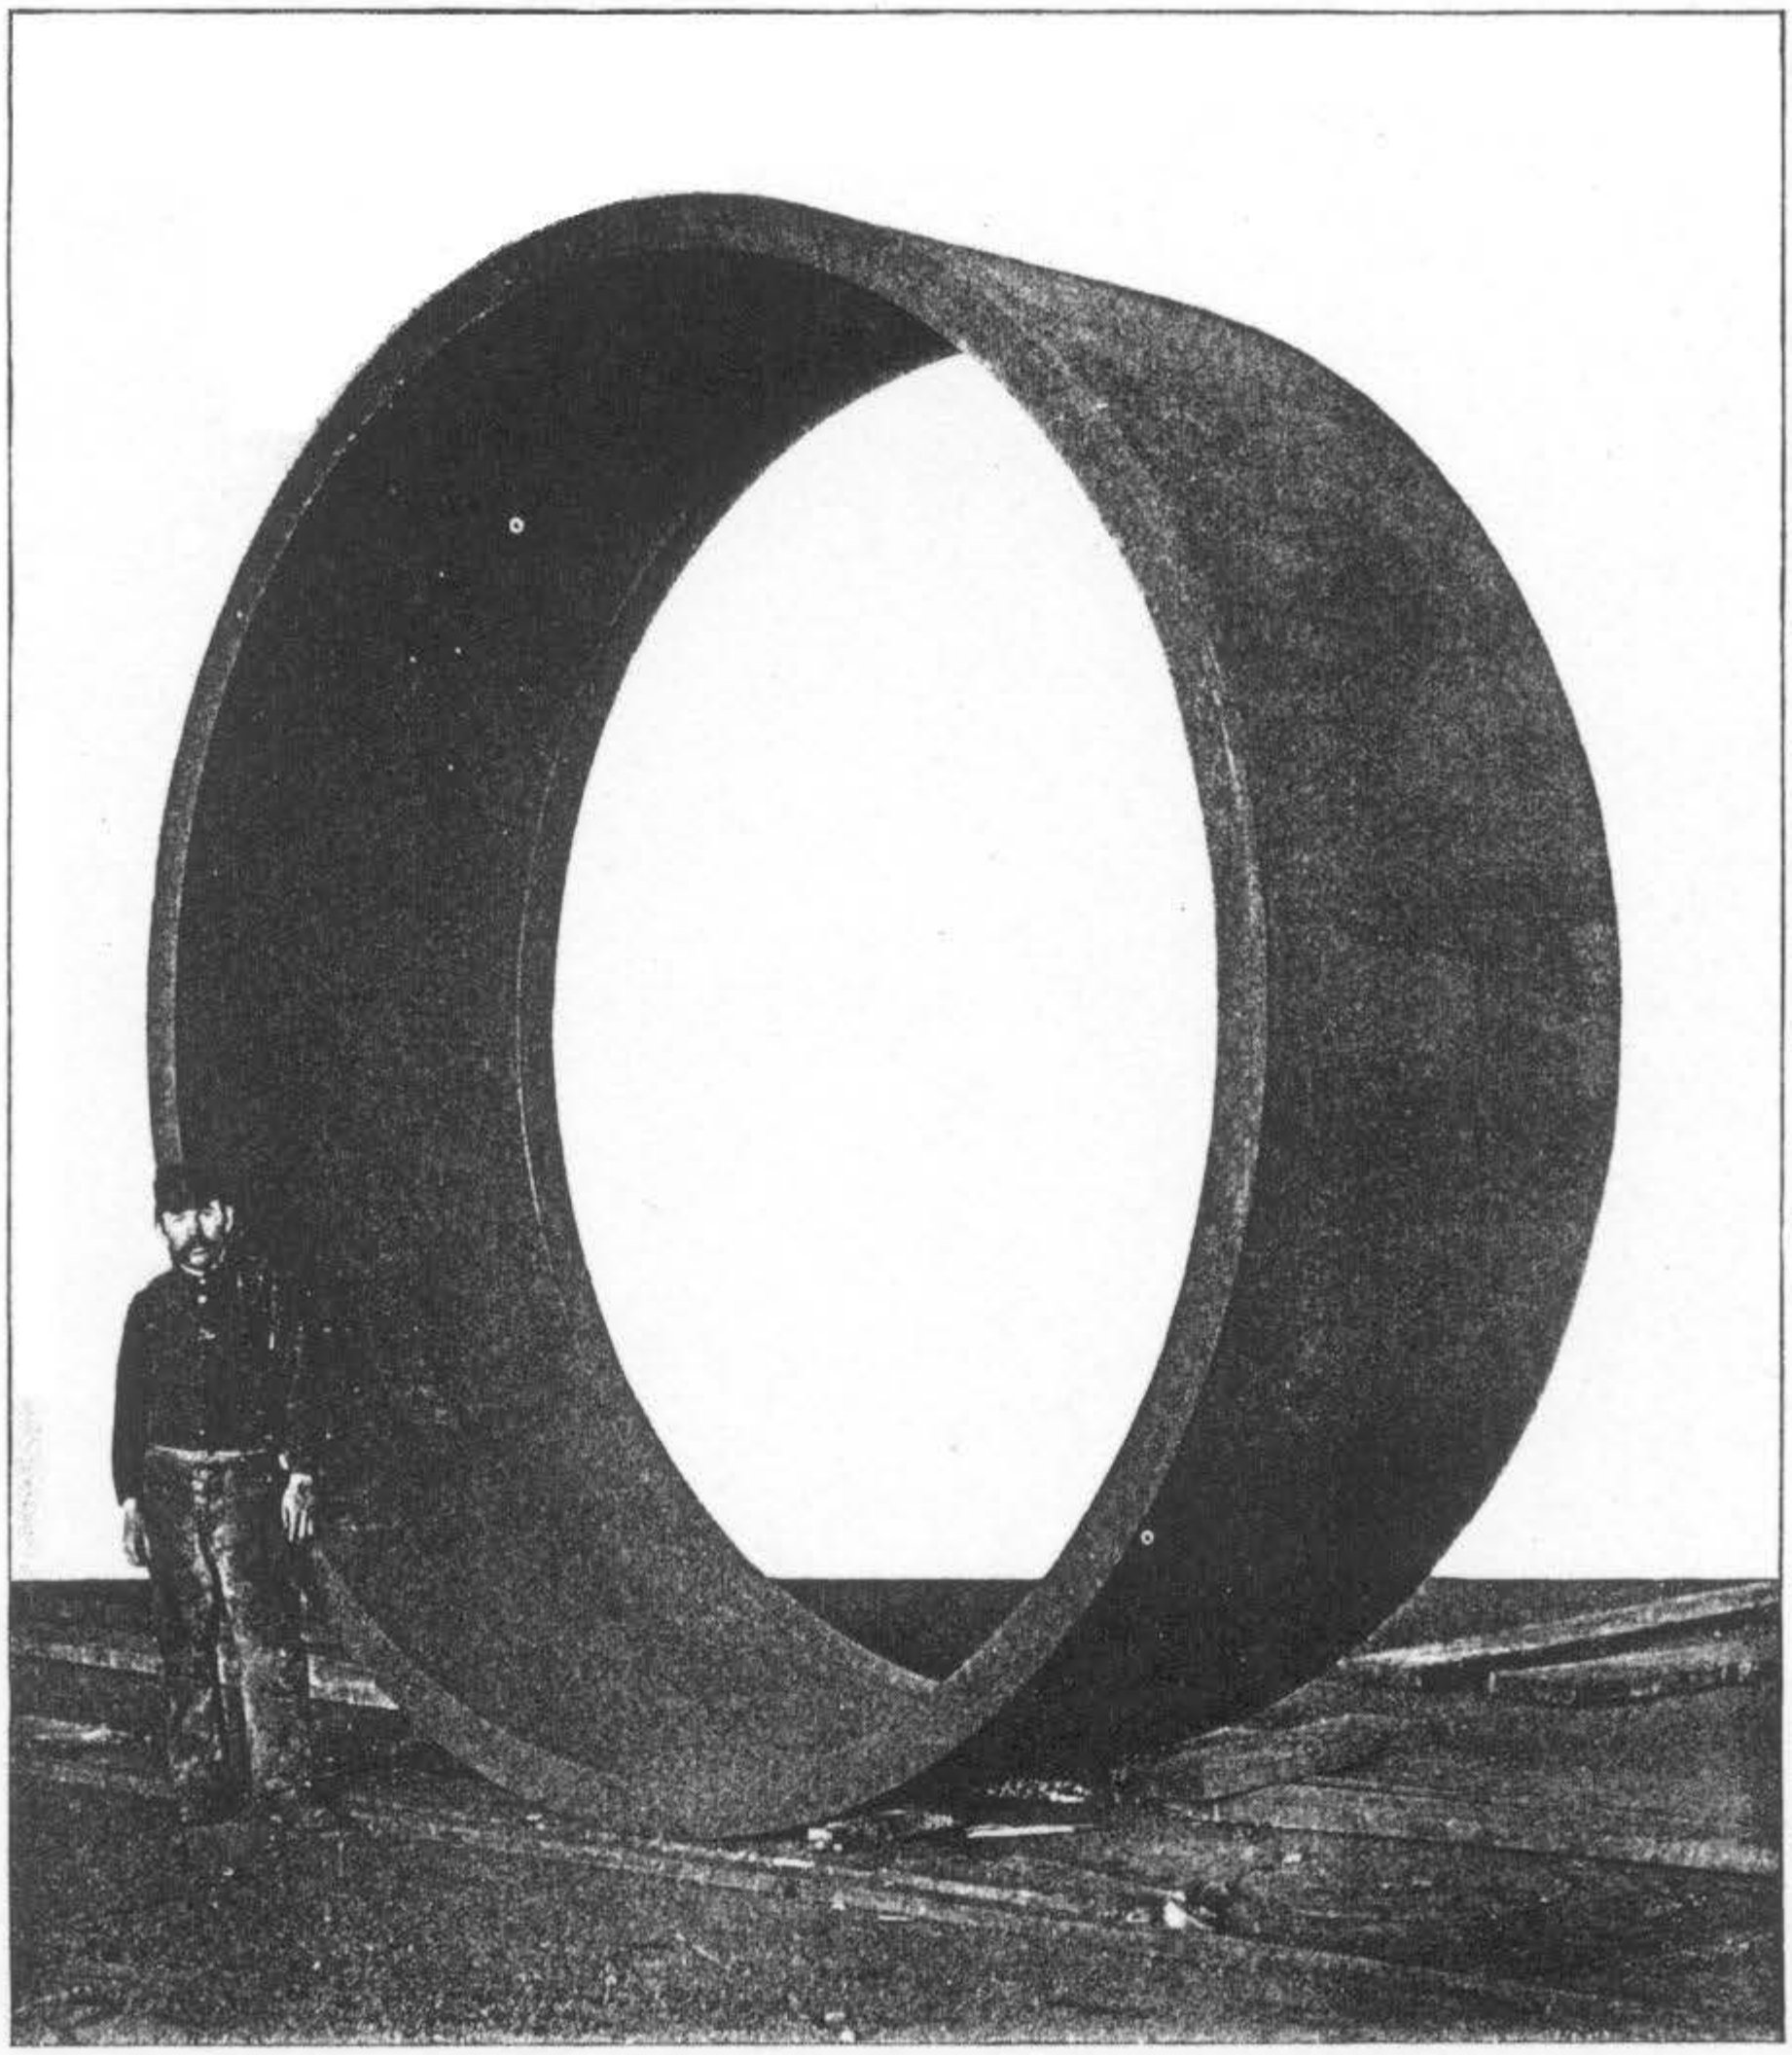
THE DRIVER FOR THE FIELD RING.



in place the revolving parts which project above the driver and carry the collecting rings.

For the purpose of securing information as to the physical properties of the steel used for the shaft, it was originally forged of extra length ; an end, several inches in length, was then cut off, and from this five samples were taken, two being cut from the periphery of the shaft at opposite ends of a diameter; one, from the centre of the shaft; and two, from points midway between the periphery and the centre, as illustrated in the cut on this page, where the numbers 1, 2, 3, 4 and 5 indicate the places in the section of the shaft from which the test samples were taken. These samples were tested by the Pittsburgh Testing Laboratory at Pittsburgh, and the fact that forged shafts are stronger near their outer surface than elsewhere is shown in an interesting manner by the results, which are set forth in the following table :

Sample No.	Tensile Strength in Pounds Per sq. in.	Elastic Limit in Pounds Per sq. in.	Reduction of Area in Percentage of Area Before Test.	Elongation in Percentage of Length Before Test.
1	63,000	35,500	53	37.5
2	59,000	29,500	51	38
3	56,000	28,500	37 5	31
4	58,500	31,500	41.5	38
5	62,500	35,000	55.5	35



A view of the driver is given on page 270. It is 11 ft. 8 in. in diameter. As has been noted in describing the shaft, the latter is tapered at its upper end, and by referring to the illustration on page 270 it will be seen that a heavy key-way is cut into the tapered portion. The bearing in the driver which fits over this tapered end of the shaft is also provided with a key-way, and the driver and shaft are held together by a long and massive steel key. The driver is of mild cast steel, and was turned out by the Midvale Steel Company, of Philadelphia. It was guaranteed to have a tensile strength of about 60,000 lbs. per sq. in., but the tests of samples of steel, taken from the casting near the periphery of the first driver, showed a tensile strength of 74,700 lbs. per sq. in., an elastic limit of 44,590 lbs. per sq. in., an elongation of 30 per cent. in 3 in., and a reduction of area of 43 per cent. The surface of the fracture was silky and fine-grained. The drivers are turned on their outside surfaces and are strengthened by six deep ribs on the inside.

Perhaps the most interesting part of each generator is the field magnet ring, which not only illustrates the wonderful physical properties of nickel steel, but demonstrates in a most striking manner the perfection of modern forging ma-

TEST PIECES FROM THE GENERATOR SHAFT.

chinery and the skill of those who use it in the great plant of the Bethlehem Iron Company, at South Bethiehem, Pa. The ring is forged in one piece without weld, and is shown in the photographic reproduction on the following page. The Bethlehem Iron Company guaranteed that the rings for the first three generators should have a tensile strength of not less than 70,000 lbs. per sq. in., an elastic limit of 38,000 lbs. per sq. in., and an elongation of about 25 per cent. in 2 in.; but they have done much better. Three samples, cut from the first ring before

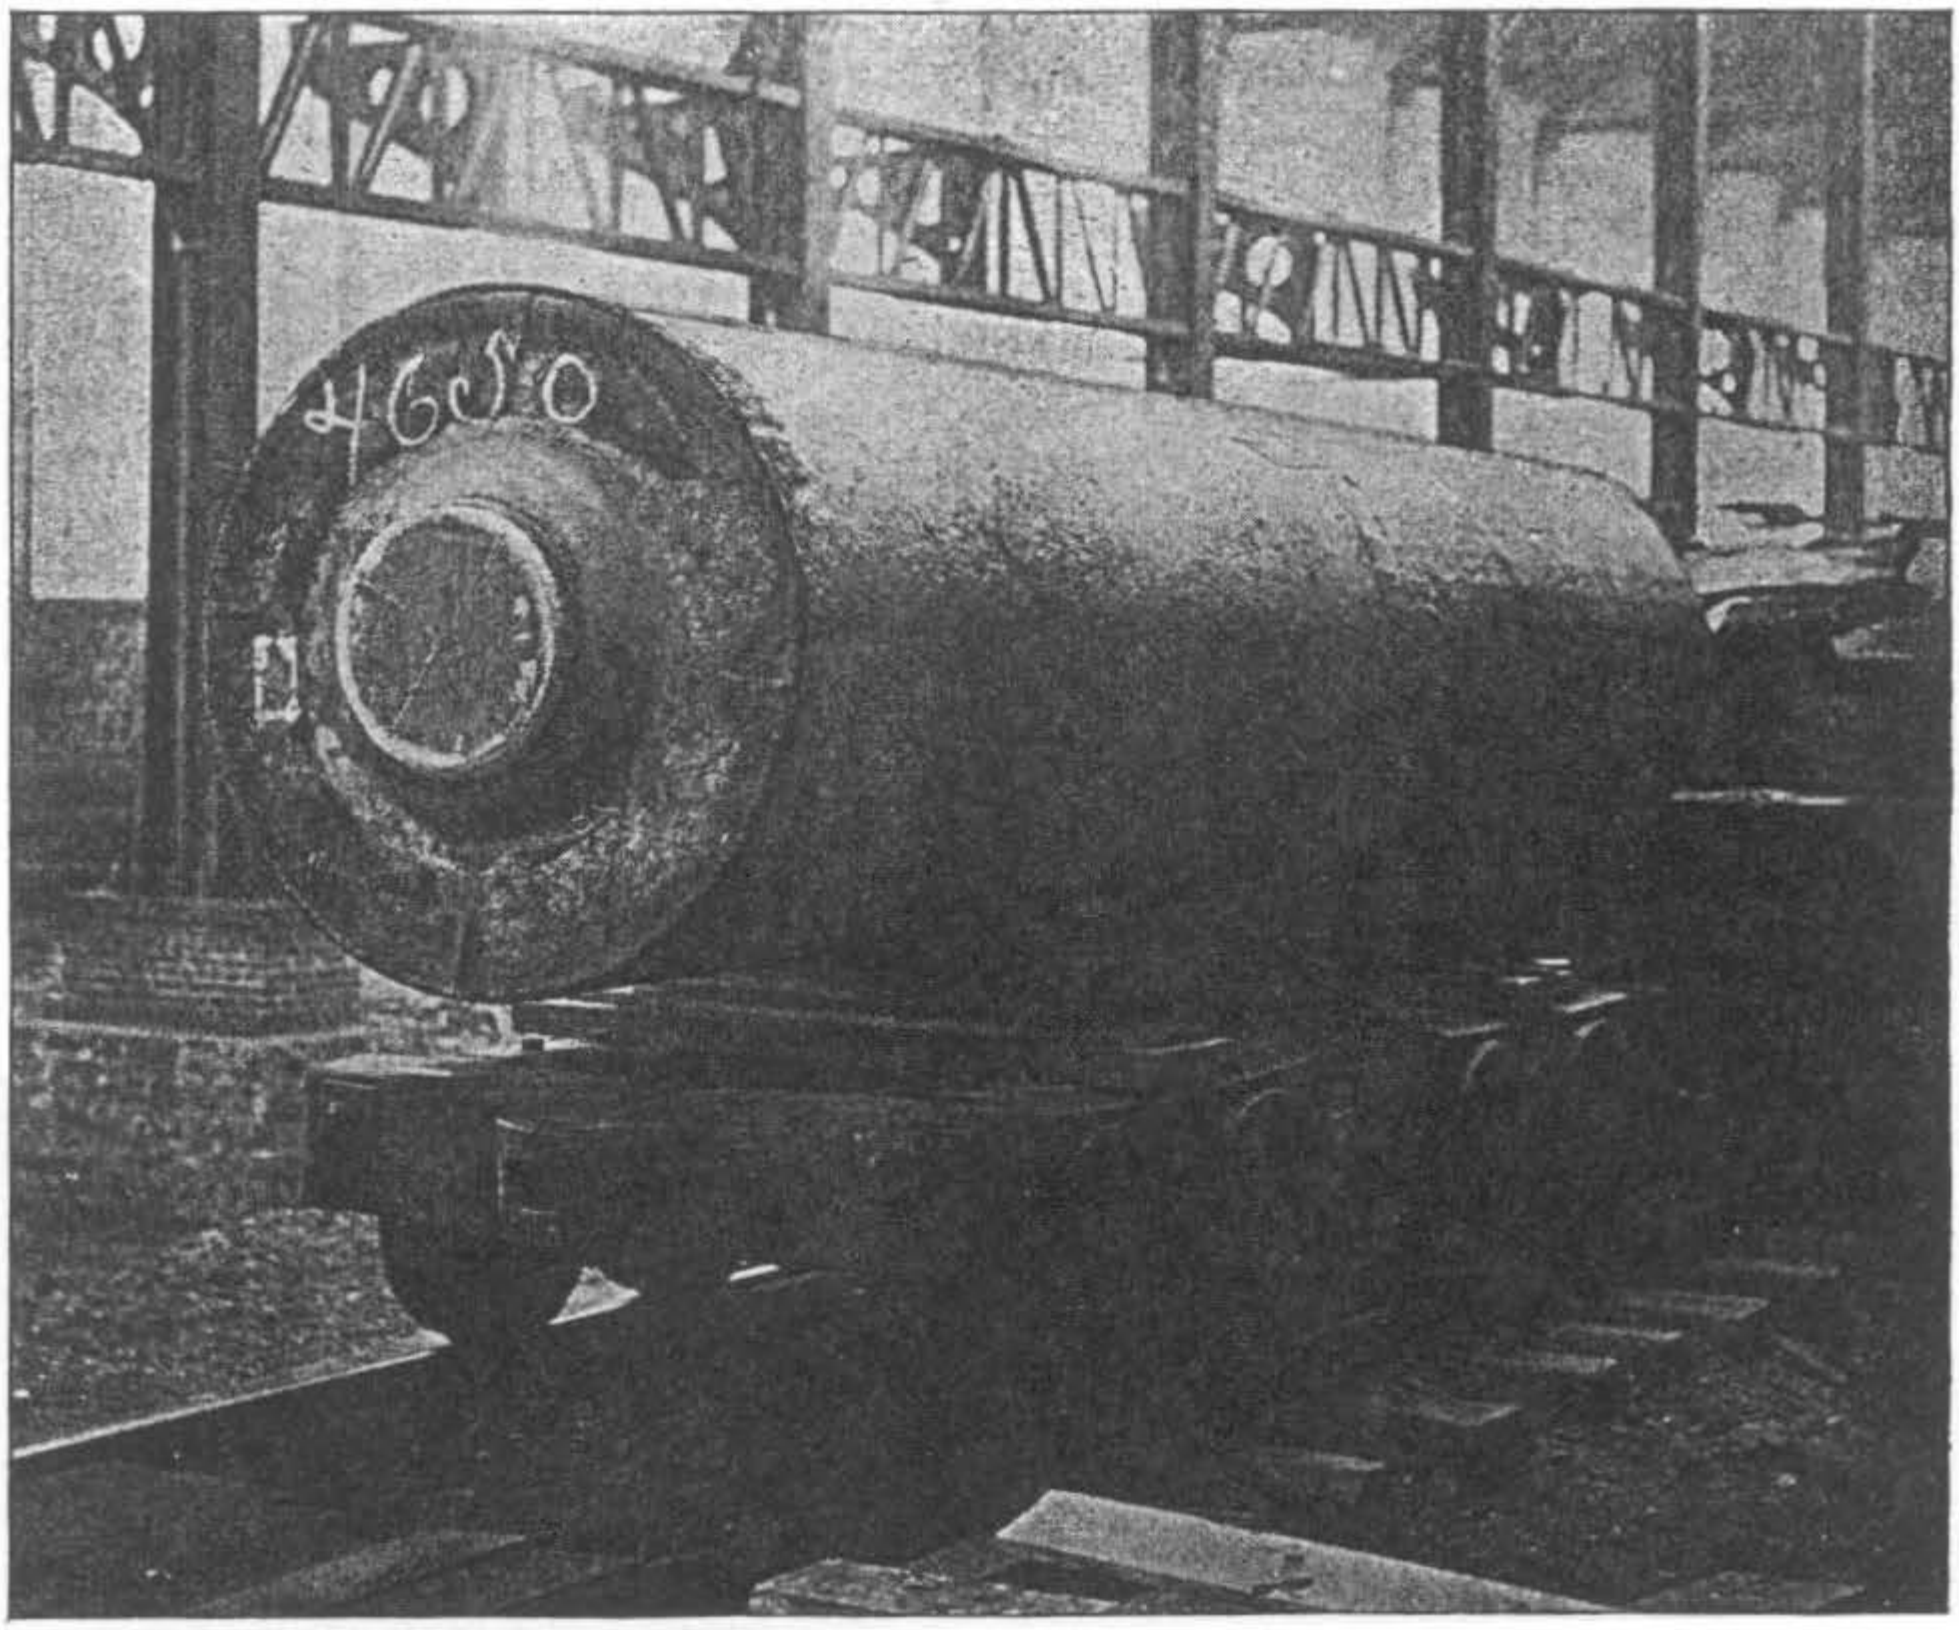
NICKEL STEEL FIELD RING, FORGED WITHOUT A WELD BY THE BETHLEHEM IRON COMPANY. DIAMETER, 11 FT. 7⅛ IN.

turning were tested with the following results :

Sample No.	Tensile Strength Measured in Pounds Per sq. in.	Elastic Limit Measured in Pounds Per sq. in	Elongation in 2" Measured in Percentage of Original Length.
1	82,915	53,560	27.05
2	81,110	47,230	25.75
3	82,140	49,280	22.5

The following brief account of the method of making the field rings is based upon notes furnished by Mr. R. W. Davenport, second vice-president of the Bethlehem Iron Company. A nickel steel ingot, 54 inches in diameter at the bottom, 197 inches long, and weighing about 120,000 lbs., was cast solid, and compressed by hydraulic pressure when fluid and during solidification. This ingot is shown in the illustration on page 274. A hole was bored through its longitudinal axis, as shown on page 275, and a block of proper weight was then cut from the ingot. The cylinder thus formed was brought

to a forging heat, and expanded on a mandril under a 14,000 ton hydraulic press. The high degree of skill, and the perfection of mechanical appliances required to expand part of the cylinder, shown on page 275, to the ring, illustrated on page 272, are evident, and reflect much credit upon the Bethlehem Iron Company. After forging, the ring was carefully treated to obtain the physical qualities desired, and was then bored and rough-turned on a large boring mill. It was finally turned true in the shops of the Westinghouse Electric & Manufacturing Company, at Pittsburg, Pa.



Not only are the physical properties of the ring extraordinary; in size it is without precedent, and to those interested in the recent remarkable improvement in the quality of steel, and in the methods of working it, the interest which attaches to this ring, as an example of the finished product of the Bethlehem Iron Company, is not less than that which it derives from the important part which it sustains in the Niagara installation.

Why it is necessary that these rings should be so strong, and that they should be so forged as to eliminate the possibility of weakness in any part, will be better understood when we consider the speed at which they revolve, and the weight of the pole pieces and field bobbins which they carry. The illustrations on page 276 show one of the field poles without its winding, and one of the field poles with bobbin in place. The poles are of mild open-hearth steel, and were cast by the Midvale Steel Company. Their magnetic qualities have been carefully tested by sample, and are excellent.

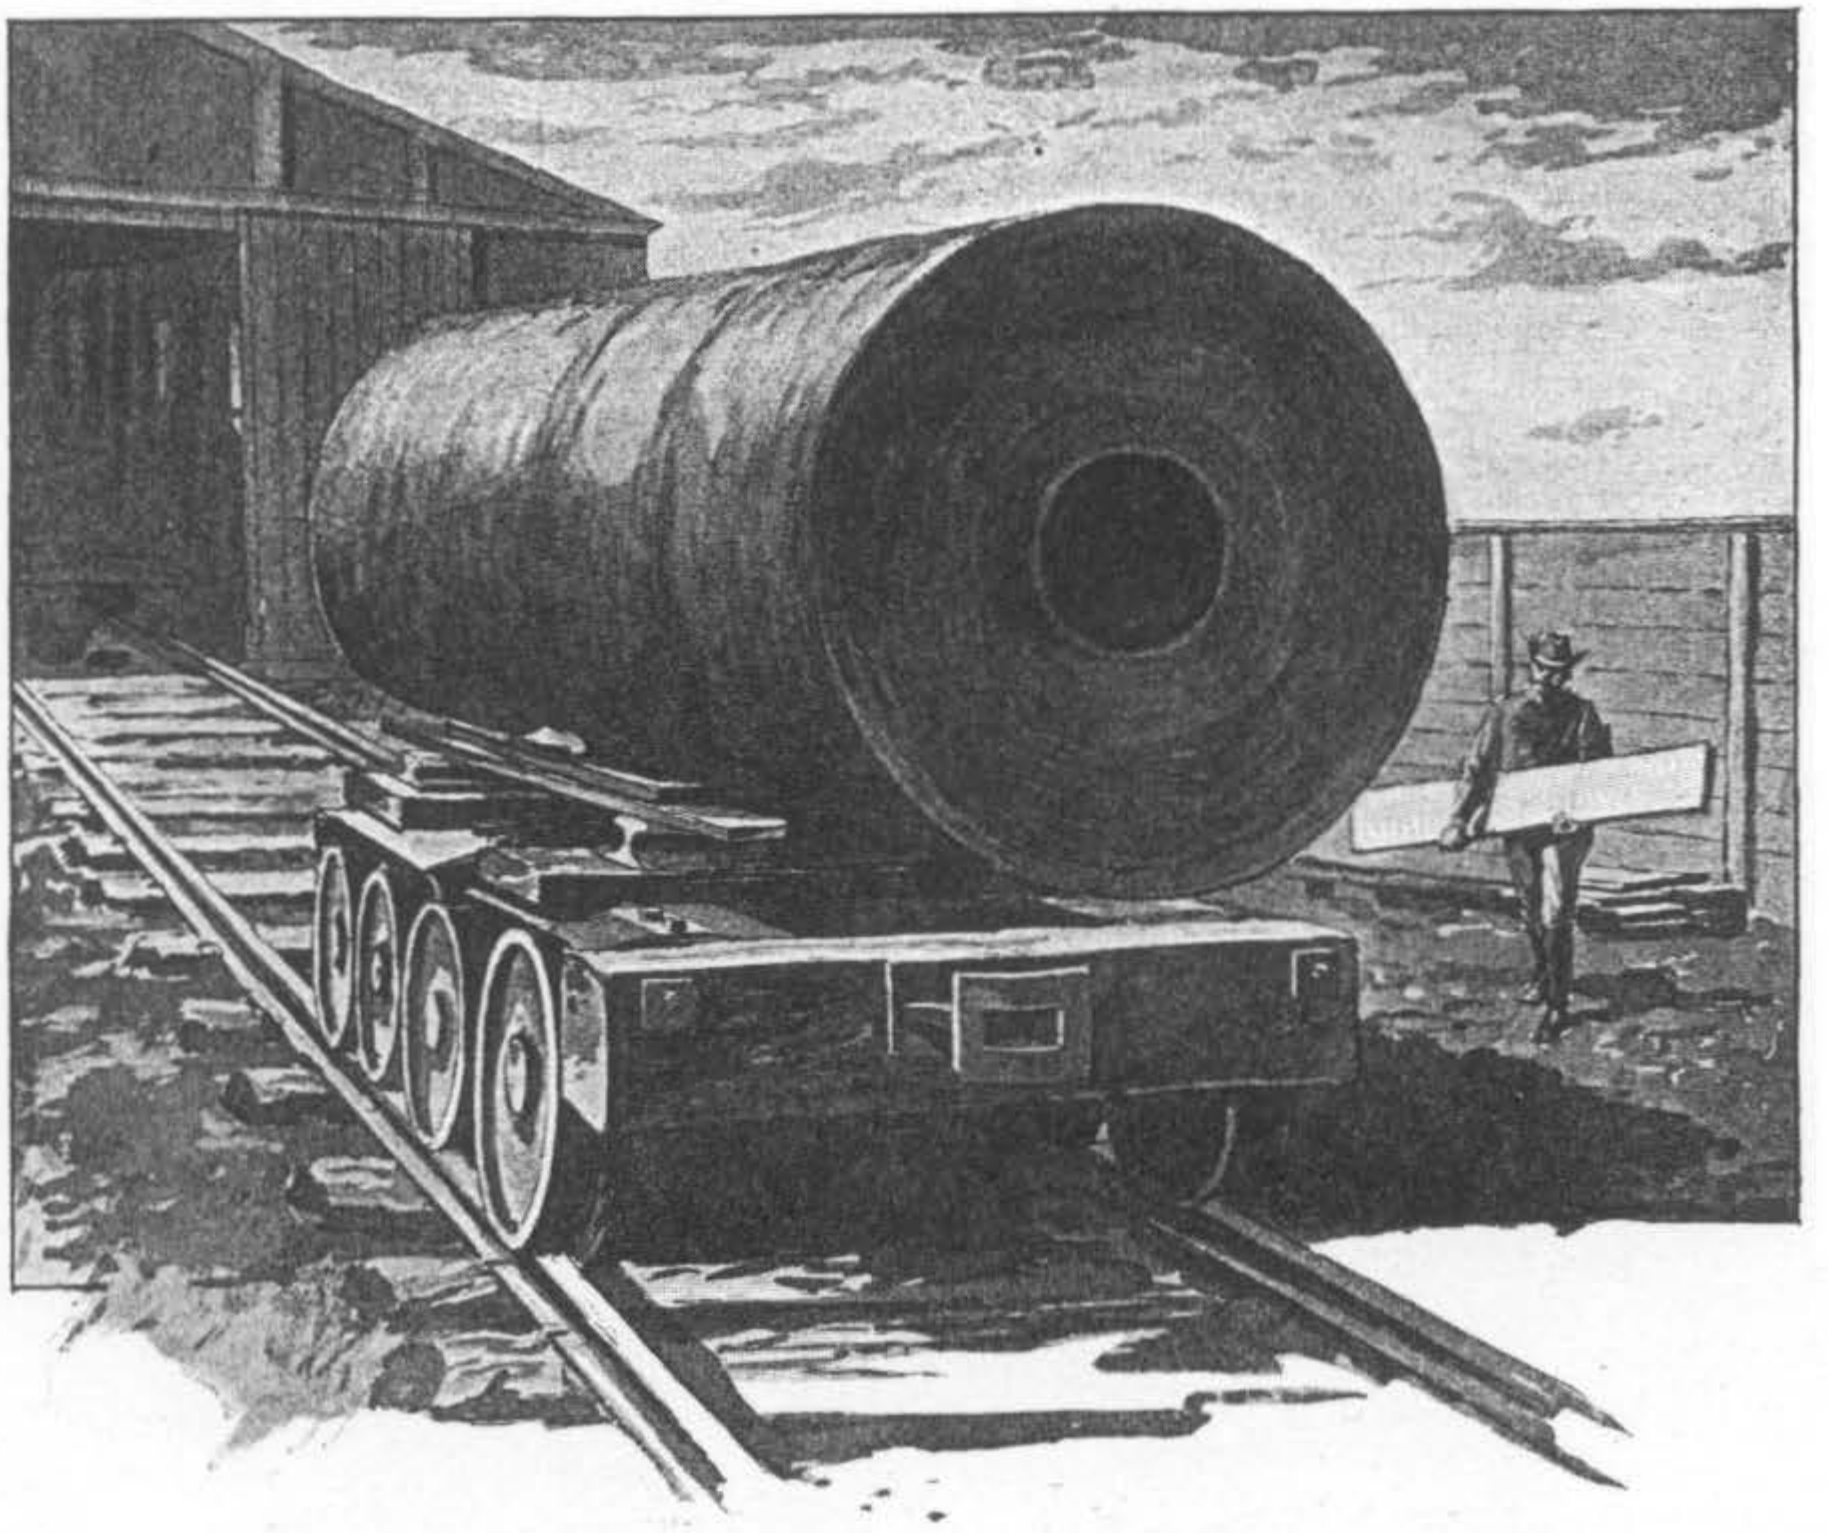
The field winding, which consists of copper conductor of rectangular section, thoroughly insulated, is contained in ribbed brass boxes or covers, one of which is well illustrated on page 276. The weight of each pole piece with its bobbin is 2800 lbs. The relation of the pole pieces and bobbins to the ring is shown in the illustration on page 277. The speed of the ring at its periphery is 9300 ft. per minute when making 250 revolutions per minute, and at this speed the centrifugal force, due to each field pole and bobbin, is 2727 lbs. The strain is, of course, a maximum at a point in the ring midway between each pair of adjacent poles. The strain due to the mass of the ring itself is 2325 lbs. The total maximum strain in the ring at 250 revolutions per minute is, therefore, by calculation, 5052 lbs.

It is not sufficient that the ring should be simply strong enough to withstand the centrifugal force due to the field poles, bobbins and its own mass when revolving at 250 revolutions per minute; it must be able to run safely at a much higher speed, for it is conceivable that, should anything happen to the apparatus which governs the turbines, a much higher speed may be attained. It was judged necessary, therefore, to so design the machine that it should be safe when running at a speed of 400 revolutions per minute, and at this speed the centrifugal force due to each pole piece and bobbin becomes 6500 lbs. The strains in the ring have been, as may be supposed, calculated with great care, and even at 400 revolutions per minute, equivalent to 241 feet per second at the periphery, the total strain will not exceed 13,000 lbs. per sq. in. As the elastic limit of the material used in the rings is 48,000 pounds, the factor of safety at this speed, which will probably never be realised in practice, is nearly four. At a speed of 800 revolutions per minute, which means 482 feet per second, or nearly six miles per minute at the periphery, the ring would burst. But it is, of course, impossible that any such speed could, under any circumstances, be attained; in fact, the calculations of the designers of the hydraulic machinery show that the speed could in no case exceed 400 revolutions per minute.

Above the driver in the illustration on page 254 are the collector and brushes by which the current is conveyed from the exciters to the revolving field of the generator. The conductor conveying the field current comes from the exciters through covered conduits beneath the level of the floor, passes

SOLID INGOT OF FLUID COMPRESSED STEEL USED FOR MAKING THE FORGED FIELD RING. LENGTH, 197 IN. DIAMETER, 54 IN. WEIGHT, 120,000 LBS.

through an iron pipe concealed in the capstone of the foundation, up one of the hollow iron columns supporting the bridge or platform across the machine, and thence, along the bridge, to the brushes. From the collector rings it passes under the driver through the shaft, and thence, along one of the ribs inside of the driver, to the field bobbins. The collector rings are built upon a separate cylindrical casting placed above the driver, and securely fixed to the hub of the latter by heavy screws through a flange at its base. The brush-holder rods are held in place by a heavy iron bracket encircling the casting below the collector rings. This bracket rests upon the bridge which spans the machine.



Balancing the Revolving Field.

The longitudinal and transverse sections of the power house and wheel-pit, showing turbines, shafts and generators in place, reproduced on pages 262 and 263, illustrate the relation of these elements in the plant more graphically and exactly than is possible in a mere verbal description. The turbines are so designed that they and the shaft and the revolving part of the dynamo above them are supported upon the water passing through the wheels. By calculation, the force of the water tending to lift the shaft and generator varies from about 149,000 lbs. to about 155,000 lbs., depending upon the amount of water passing through the turbines, which, in turn, depends upon the amount of current which the generator is delivering to the circuits. The weight of the shaft and revolving part of the generator is very nearly 152,000 lbs. The difference between this weight and the upward

thrust of the water is taken care of by the thrust bearing located on the third gallery above the turbines. When the upward thrust of the water exceeds 152,000 lbs., the collars on the steel shaft are pressed upward against the grooves in the bearing in which they revolve, and when the upward pressure is less than 152,000 lbs. the collars are drawn downward by gravity against the grooves in the bearing. This pressure, however, whether upward or downward, in direction, never exceeds 3500 lbs. in amount, and this, of course, puts very little work upon the bearing.

The entire revolving parts of each unit of the plant, therefore, consisting of the turbines, the dynamo field and the shaft, 166 feet in length, constitute a huge top, the weight of which is practically carried upon the water in the turbines. The bearings on the first and second galleries of the wheel pit, and the upper and lower bearings in the generator, are simply guides for the shaft, to keep it in a vertical position, while the thrust bearing on the third gallery acts as a guide, and also carries the relatively small difference between the weight of the revolving mechanism and the upward thrust of the water. The turbines, shaft, and generator field revolve at the high speed of 250 revolutions per minute, and it is obvious that all of the revolving parts, especially the heavy generator field, weighing about 70,000 lbs. and measuring nearly 12 feet in diameter, must be balanced with the utmost accuracy to prevent vibrations which might become dangerous.

The method employed in balancing the revolving element of the generators is illustrated on page 278. A special shaft was placed in the bearings of the machine, and supported at its lower end by a thrust bearing into which oil was pumped at a pressure of about 1000 lbs. per sq. in. This pressure was sufficient to lift the weight of the revolving parts,

COMPRESSED STEEL INGOT WITH HOLE THROUGH CENTER, PREPARATORY TO FORGING.

and the collars on the shaft were separated from the grooves of the thrust bearing by a thin layer or film of oil. A small piece of tool steel was set into the upper end of the shaft, a half sphere or cup being cut in its upper surface, and in this was placed a tempered steel ball,

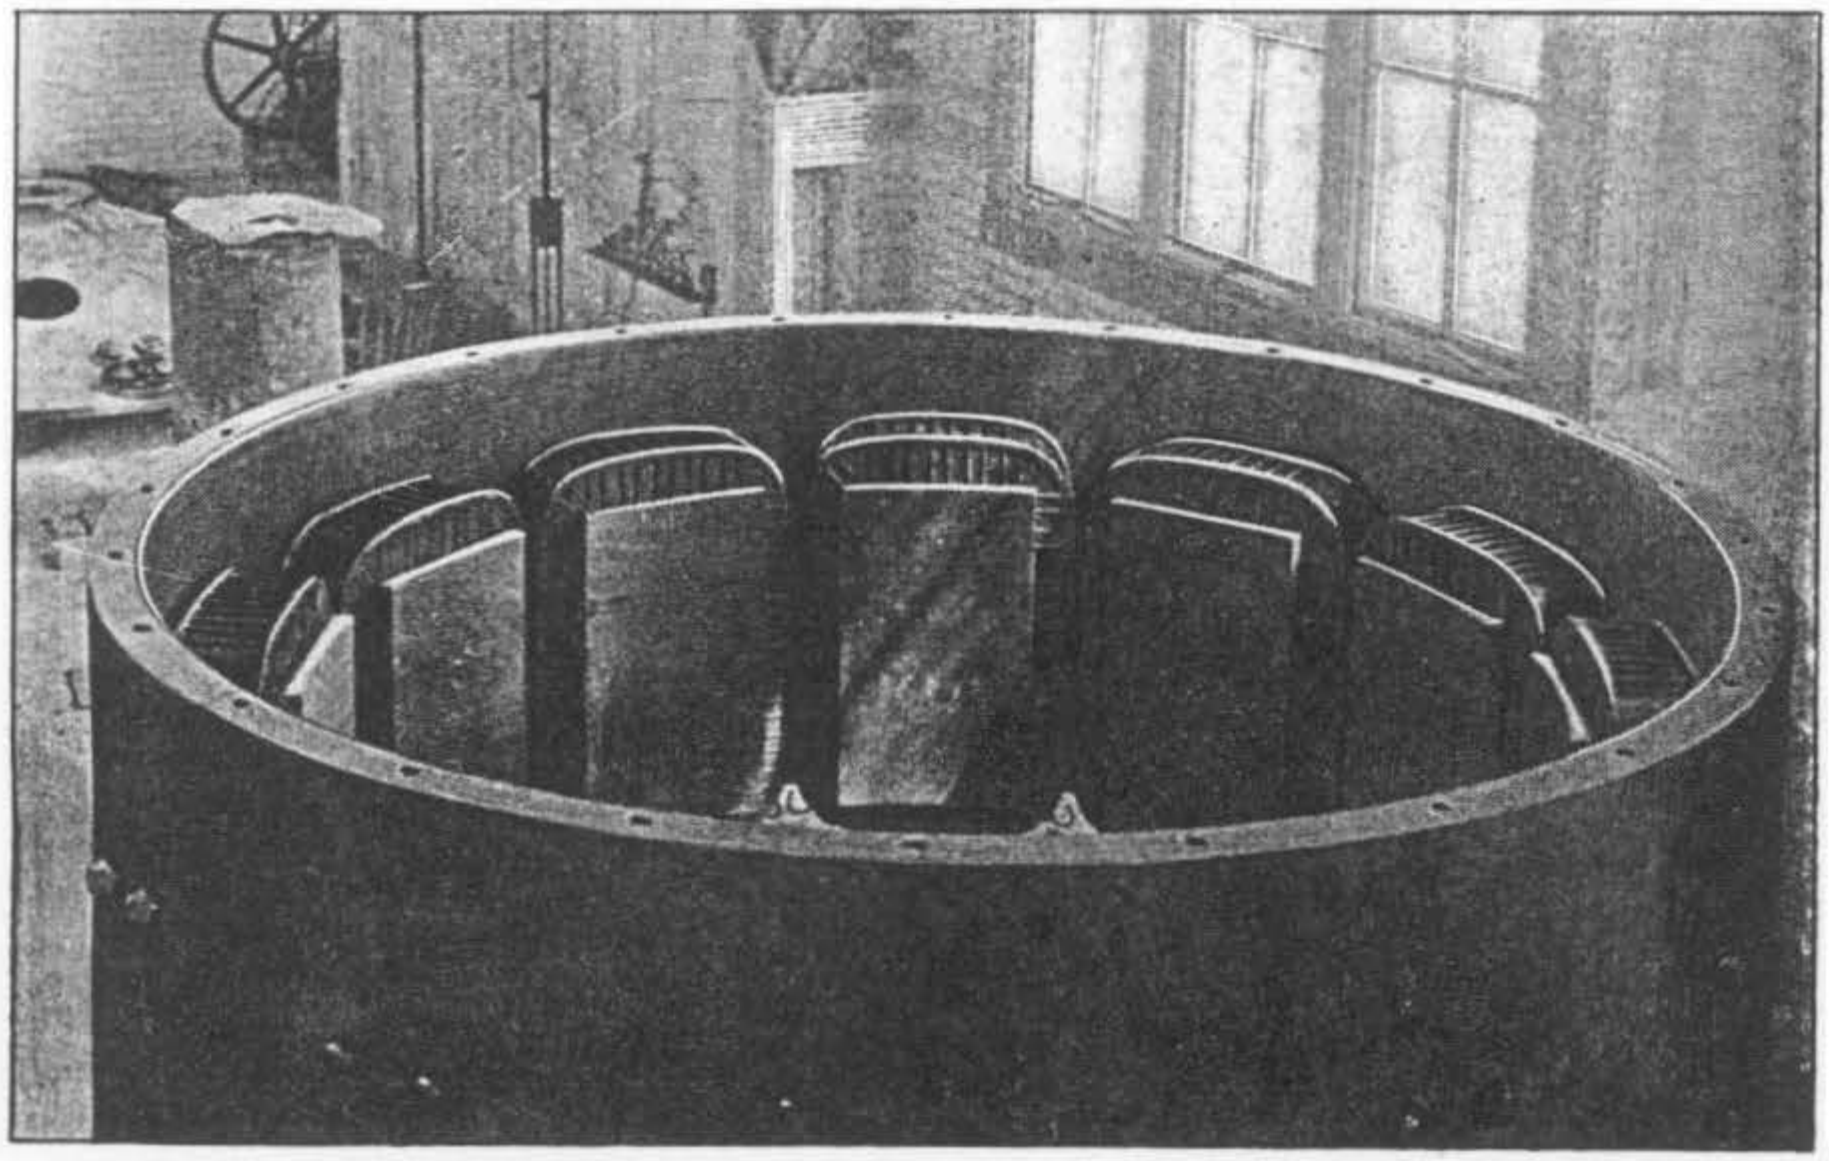
A FIELD POLE WITH WINDING IN PLACE.
WEIGHT, 2800 LBS.

⅜ in. in diameter. A large eyebolt with a similar piece of tool steel, having in its lower surface a cup bearing similar to that at the top of the shaft, was secured in the tapered bearing of the umbrella-shaped driver, to the periphery of which the field ring is bolted. The entire weight of the driver and the ring was thus supported upon the small steel ball.

A casting, clamped to the shaft, served to rotate the driver and ring with the shaft. A section of this casting and of one of the ribs of the driver is shown in the illustration. The steel ball, as will be noted, was placed a very short distance above the centre of gravity of the field and driver, and under these conditions, the driver and ring being free to rock while rotated, a defect in balance was quickly shown. As a matter of fact, in the case of the first generator the driver at first assumed the position indicated by the dotted lines. This was corrected by riveting to the driver a wrought iron plate, the weight of this plate and the distance from the axle of rotation being experimentally determined to obtain not only exact static balance, but also exact running balance.

The driver was first balanced in this manner, independently. The ring was then bolted to the driver, and the two were balanced together as shown in the illustration. It was unnecessary to balance the combination of the driver, ring and field poles since the field poles and bobbins were separately weighed, and their weights adjusted to exact equality, while the positions in which they are bolted to the ring are exactly symmetrical with reference to each other and to the axis of rotation.

Organization of Apparatus in the Power House.

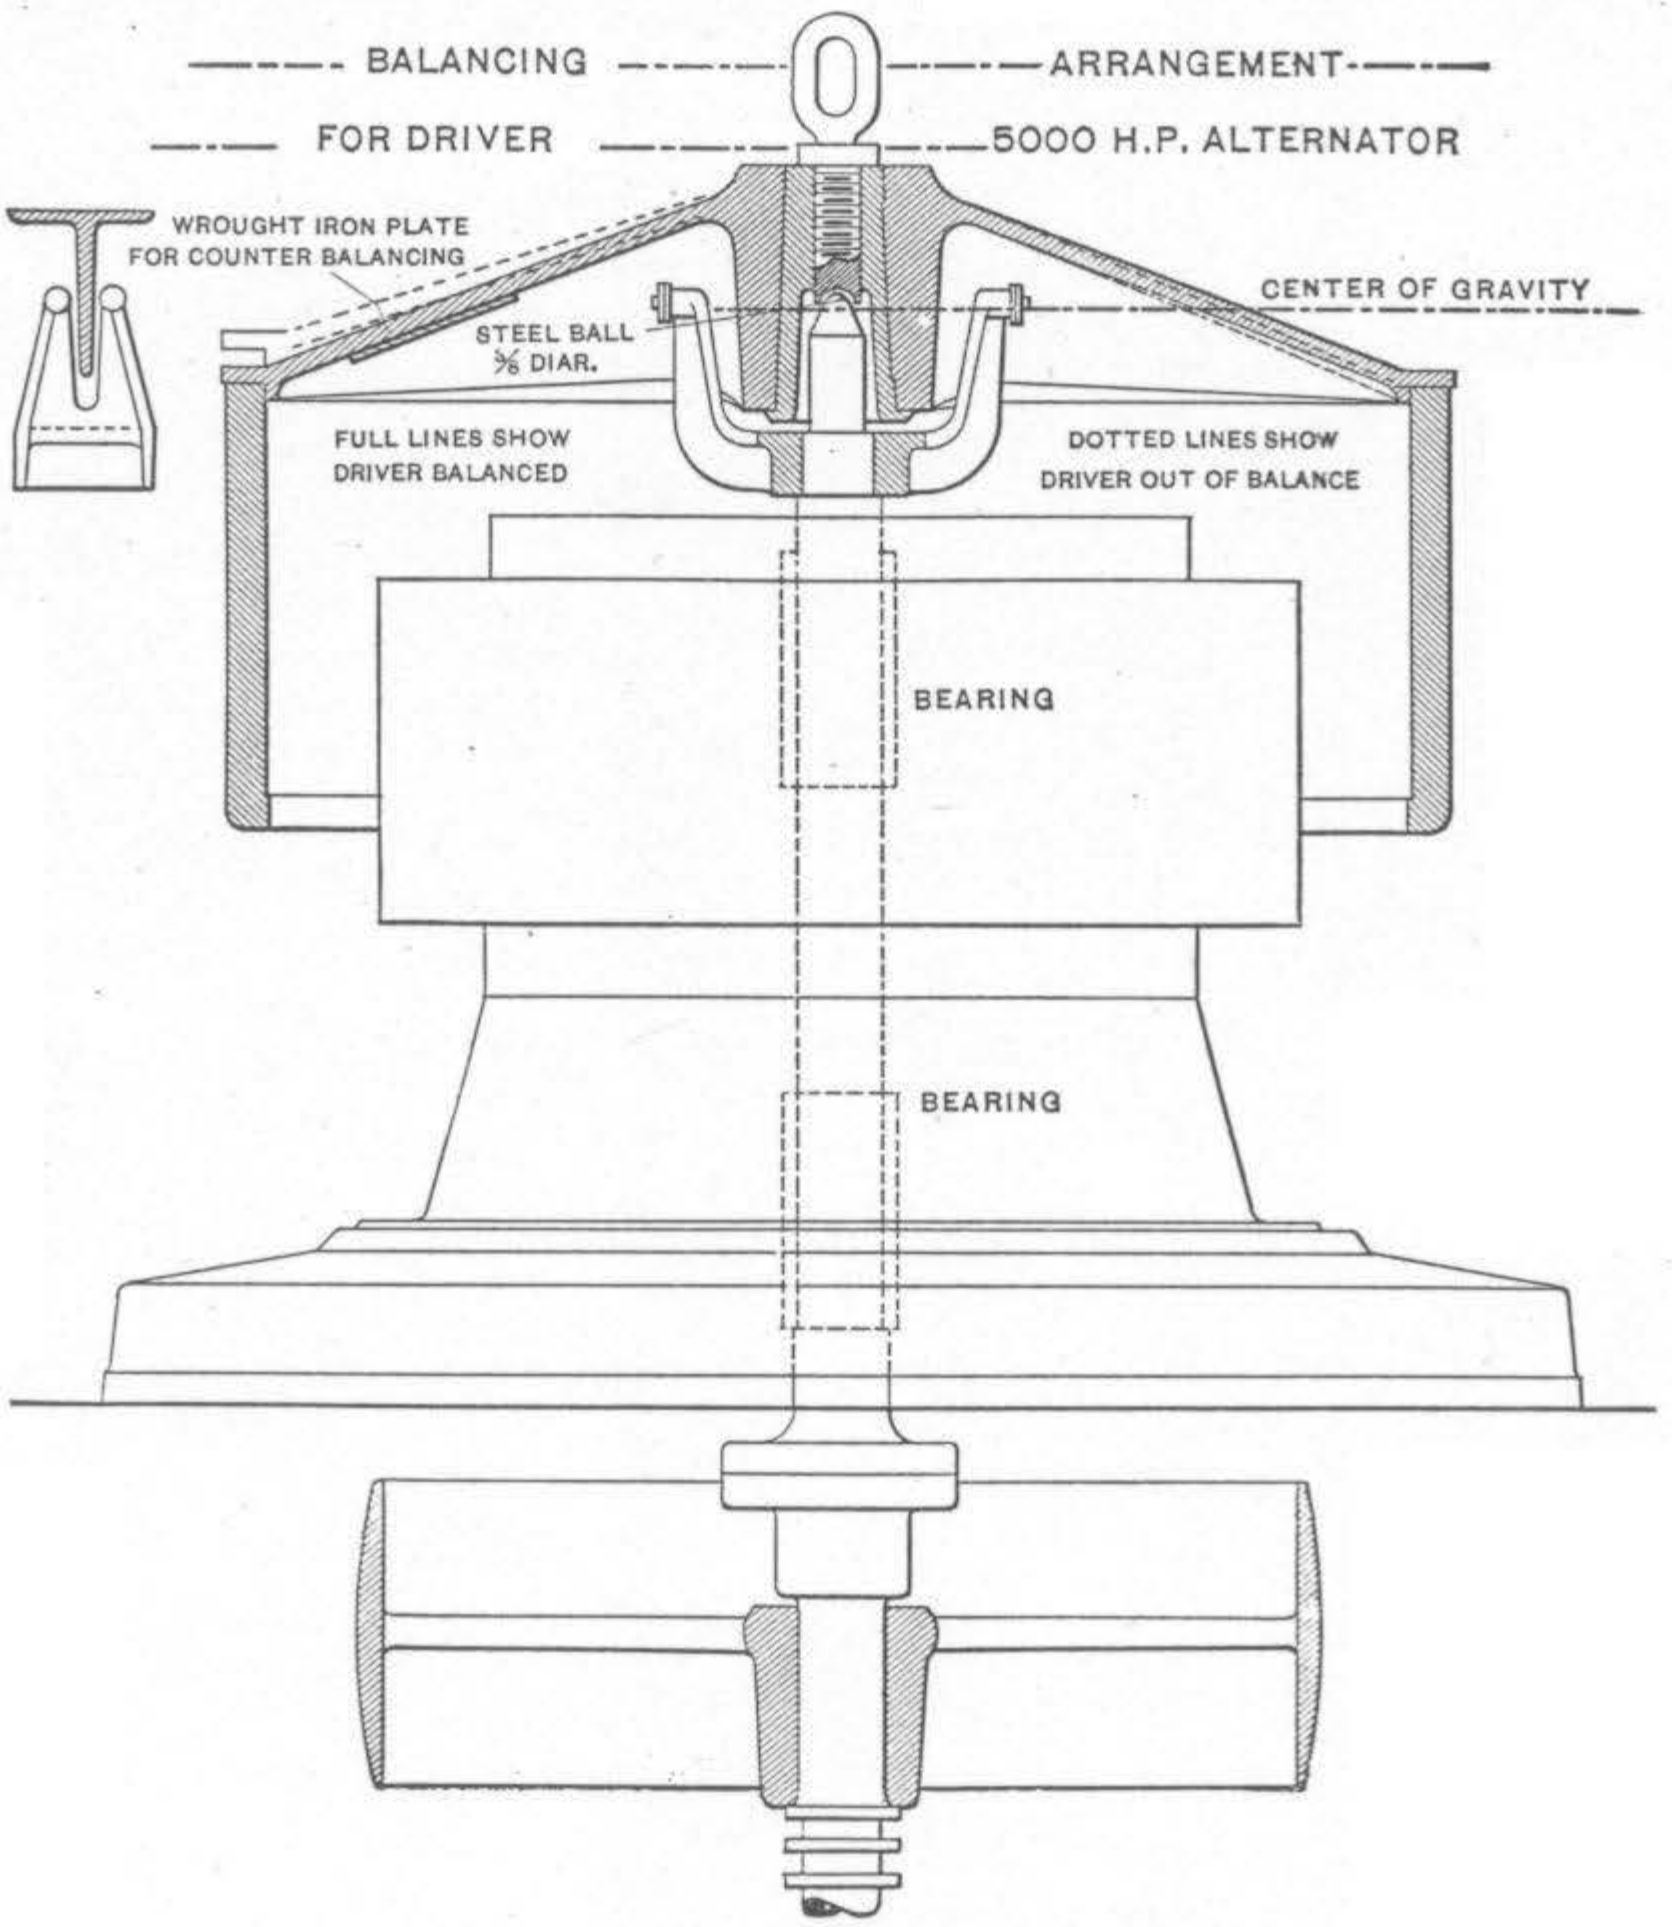


The organization of apparatus constituting the system adopted, that is,

A FIELD POLE.

the inter-relation and the functions of the generators, step-up transformers, step-down transformers, motors, commutating machines and other appa-

ratus, has been described in a general way in the early part of this article. I have also explained the construction of the generators,—the most important unit of apparatus in the plant. It remains now to describe the means adopted for controlling the heavy currents delivered by the generators, and for delivering these currents to the supply circuits which convey them from the power house to the premises of the users of power.

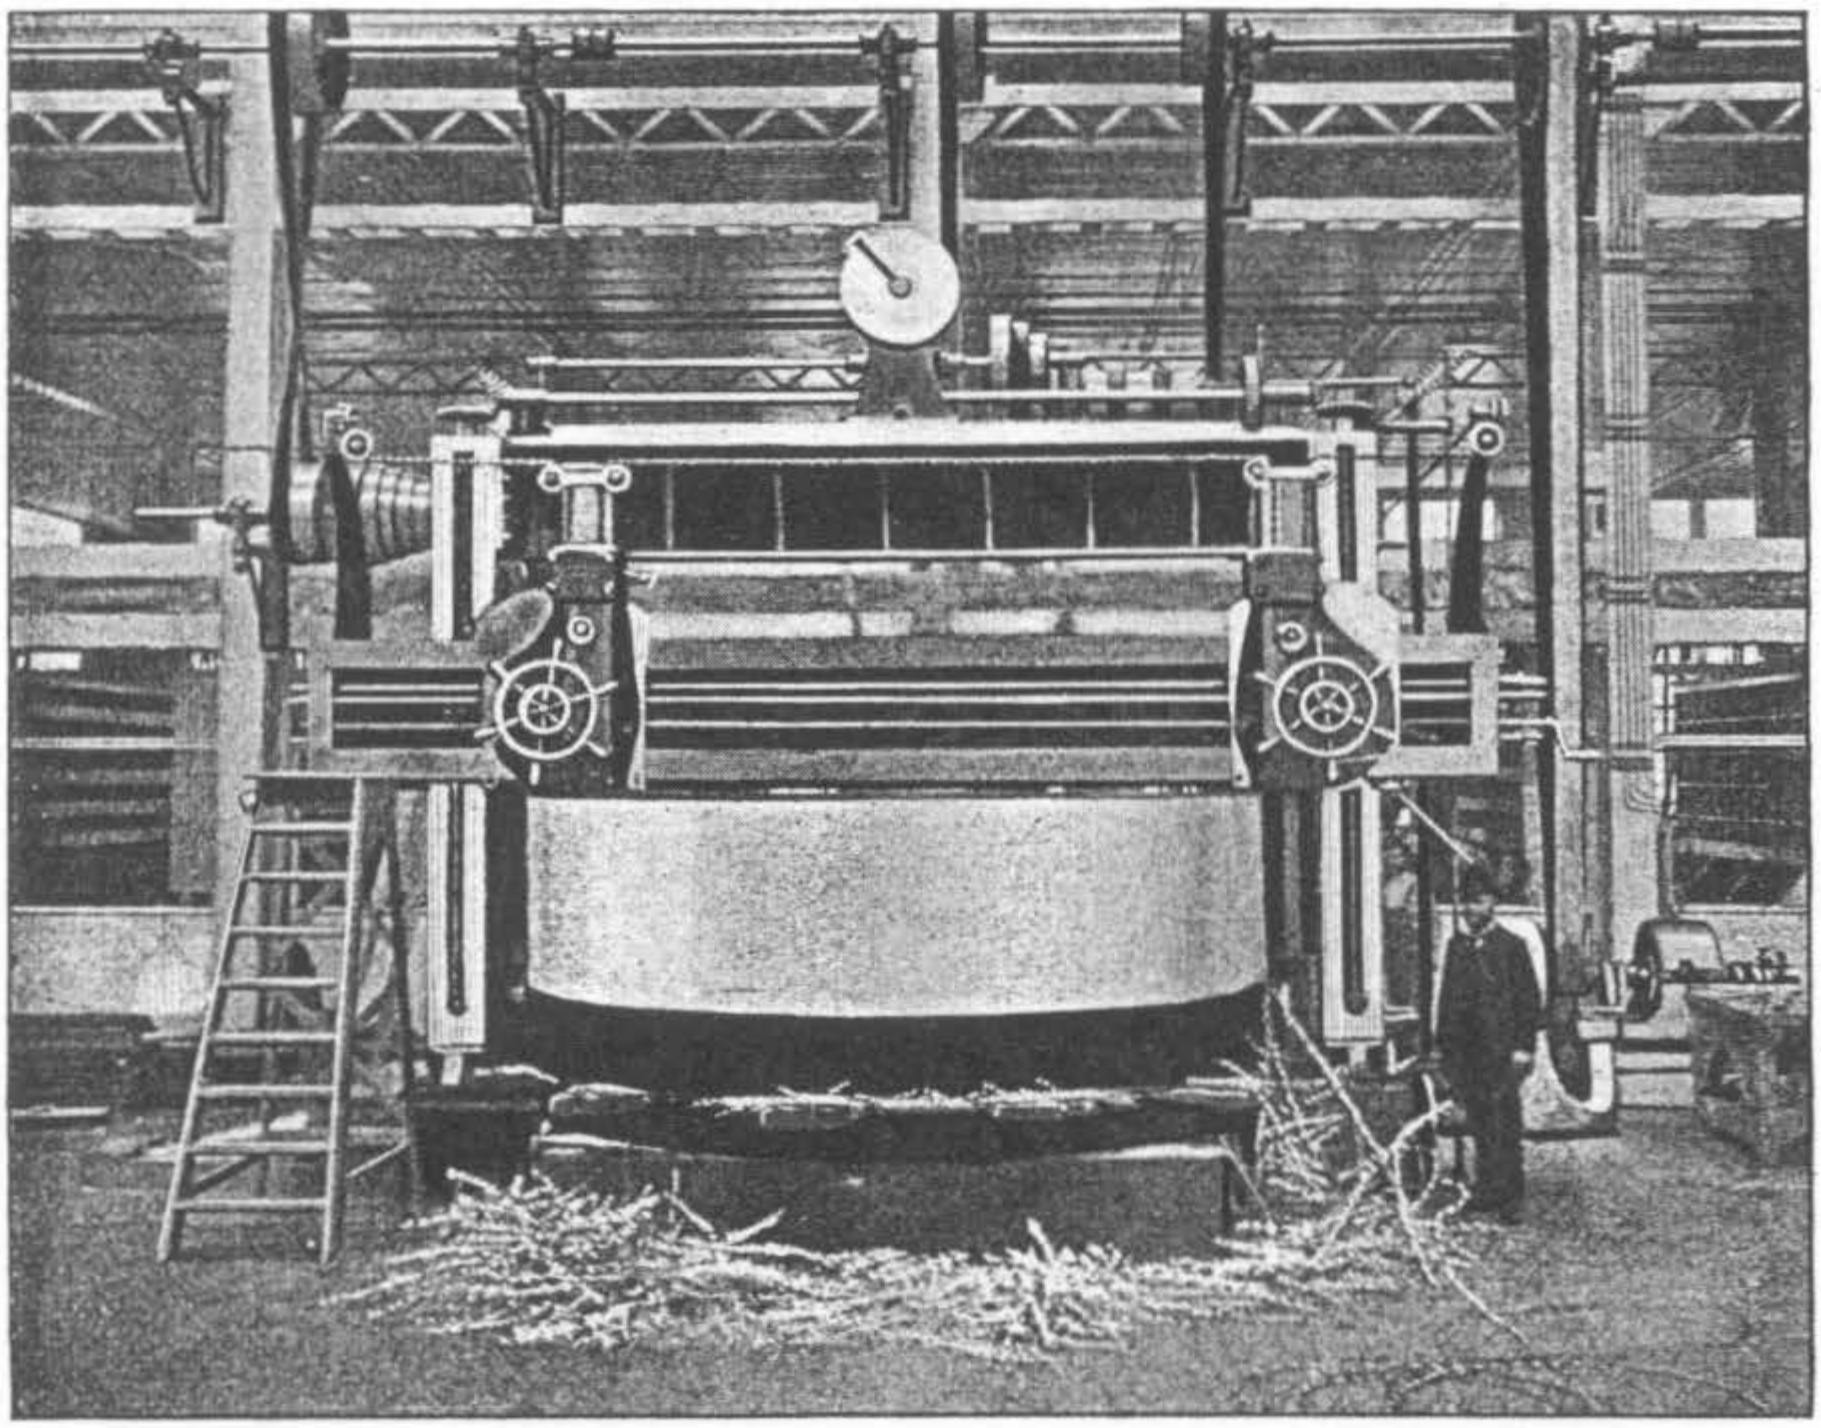


FIELD RING WITH POLES AND BOBBINS IN PLACE.

In deciding upon a plan of station organization, we face, at the outstart, two very serious conditions :—First :—The forces with which we are dealing are, in amount, far beyond the range of experience. Second :—The plan adopted must be capable of almost indefinite extension without radical modification, and without involving loss of symmetry.

We are dealing with energy in units of 5000 horse-power, developed under conditions which are, in many respects, without precedent ; and while, at the outstart, there are to be installed but three generators, the fact must be kept in mind that others will be added to the installation, and that, when the number of generators shall have increased from three to thirty or twice thirty, the organization and means provided for operating them must still be symmetrical and consistent in all its parts. The plan adopted contemplates an arrangement in groups of five generators each. The switching and regulating apparatus, and the indicating and measuring instruments, are concentrated in a swithboard centrally located with reference to each group. Provision is made for cross-connecting the several groups to be ultimately installed in this power house and in other power houses which may be erected on both the American and Canadian sides of the river in order that continuity of service may be doubly assured.

The switchboard is the centre from which the brain and hand of the operator control the mighty forces of Nature which are here compelled to do work,—it is the bridge of the ship. From it, imprisoned energy, aggregating 25,000 horse-power,—electric energy, eager to escape, seeking for the smallest pinhole in insulation, and concentrating instantly at that pinhole, if

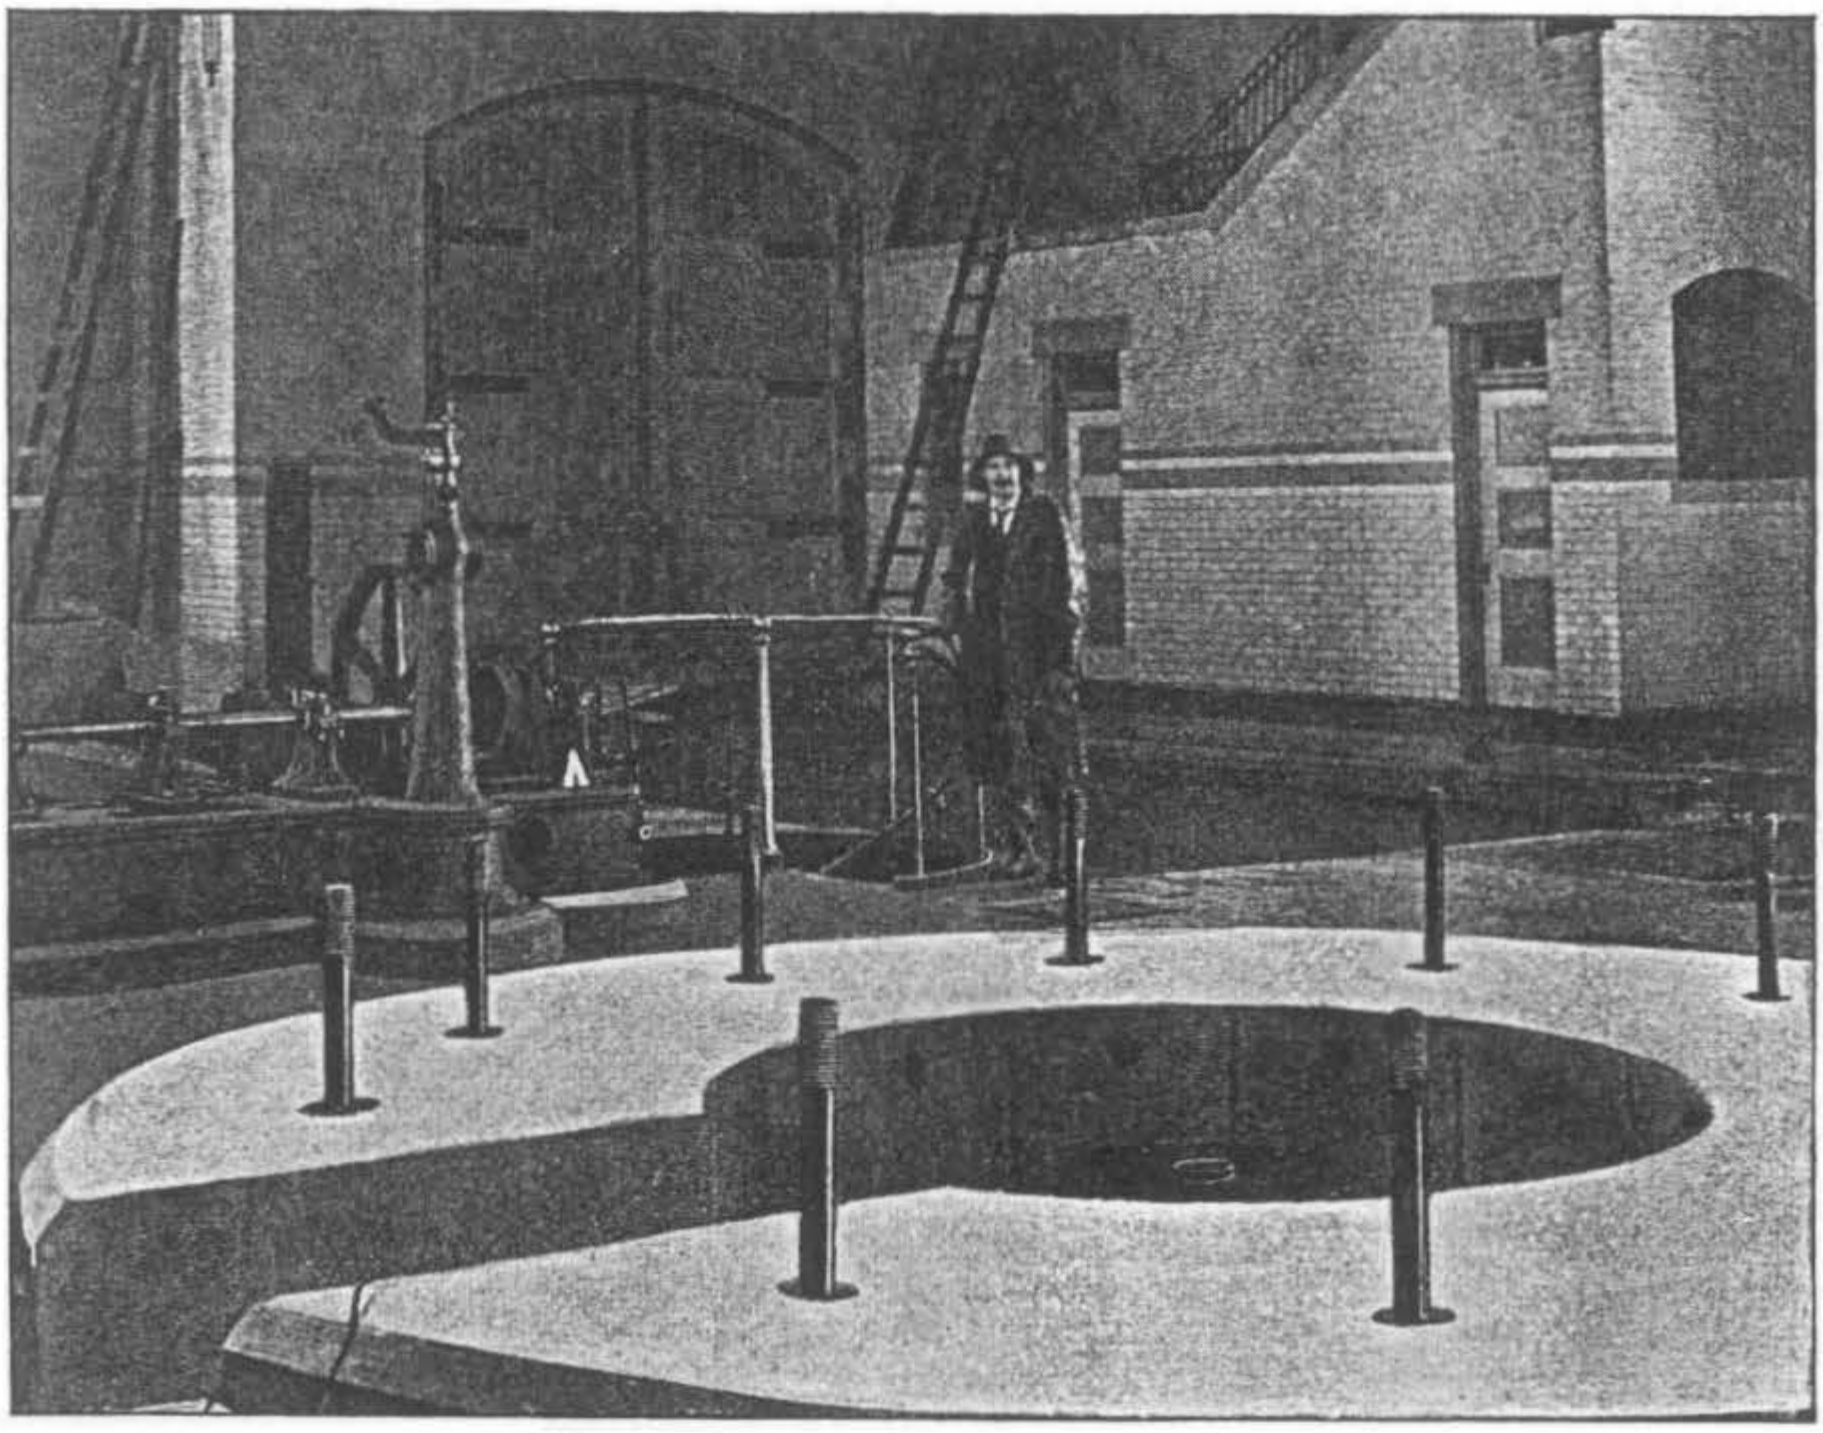


found,—must be controlled, combined, subdivided and directed. It is evidently desirable to operate the generators in parallel, this method tending to improve regulation of speed and potential, insuring continuity in the delivery of current to the users of power, and house, and the latter referring to the service which will supply consumers in Buffalo and other distant places. This consideration makes it probable that it will prove convenient and desirable to operate the generators in two sets, for the following reason :—

METHOD OF BALANCING THE DRIVER AND FIELD RING.

minimizing the necessity of opening switches conveying heavy currents of high potential in circuits of very considerable inductance and capacity. But it is also evident that the service will, in the near future, divide itself into two classes, which we may call "local service" and "long-distance service," the former referring to the service which will supply consumers within a radius of a few miles from the power

Distribution of electricity at constant potential is strictly analogous to the methods commonly employed in supplying gas and water. Each consumer has a small, independent circuit through which he draws his supply from the distributing mains, and he may open or close this circuit without in any way interfering with the supply to his neighbours, provided the potential or pressure in the network of mains is kept



TURNING THE FIELD RING IN THE WESTINGHOUSE SHOPS.

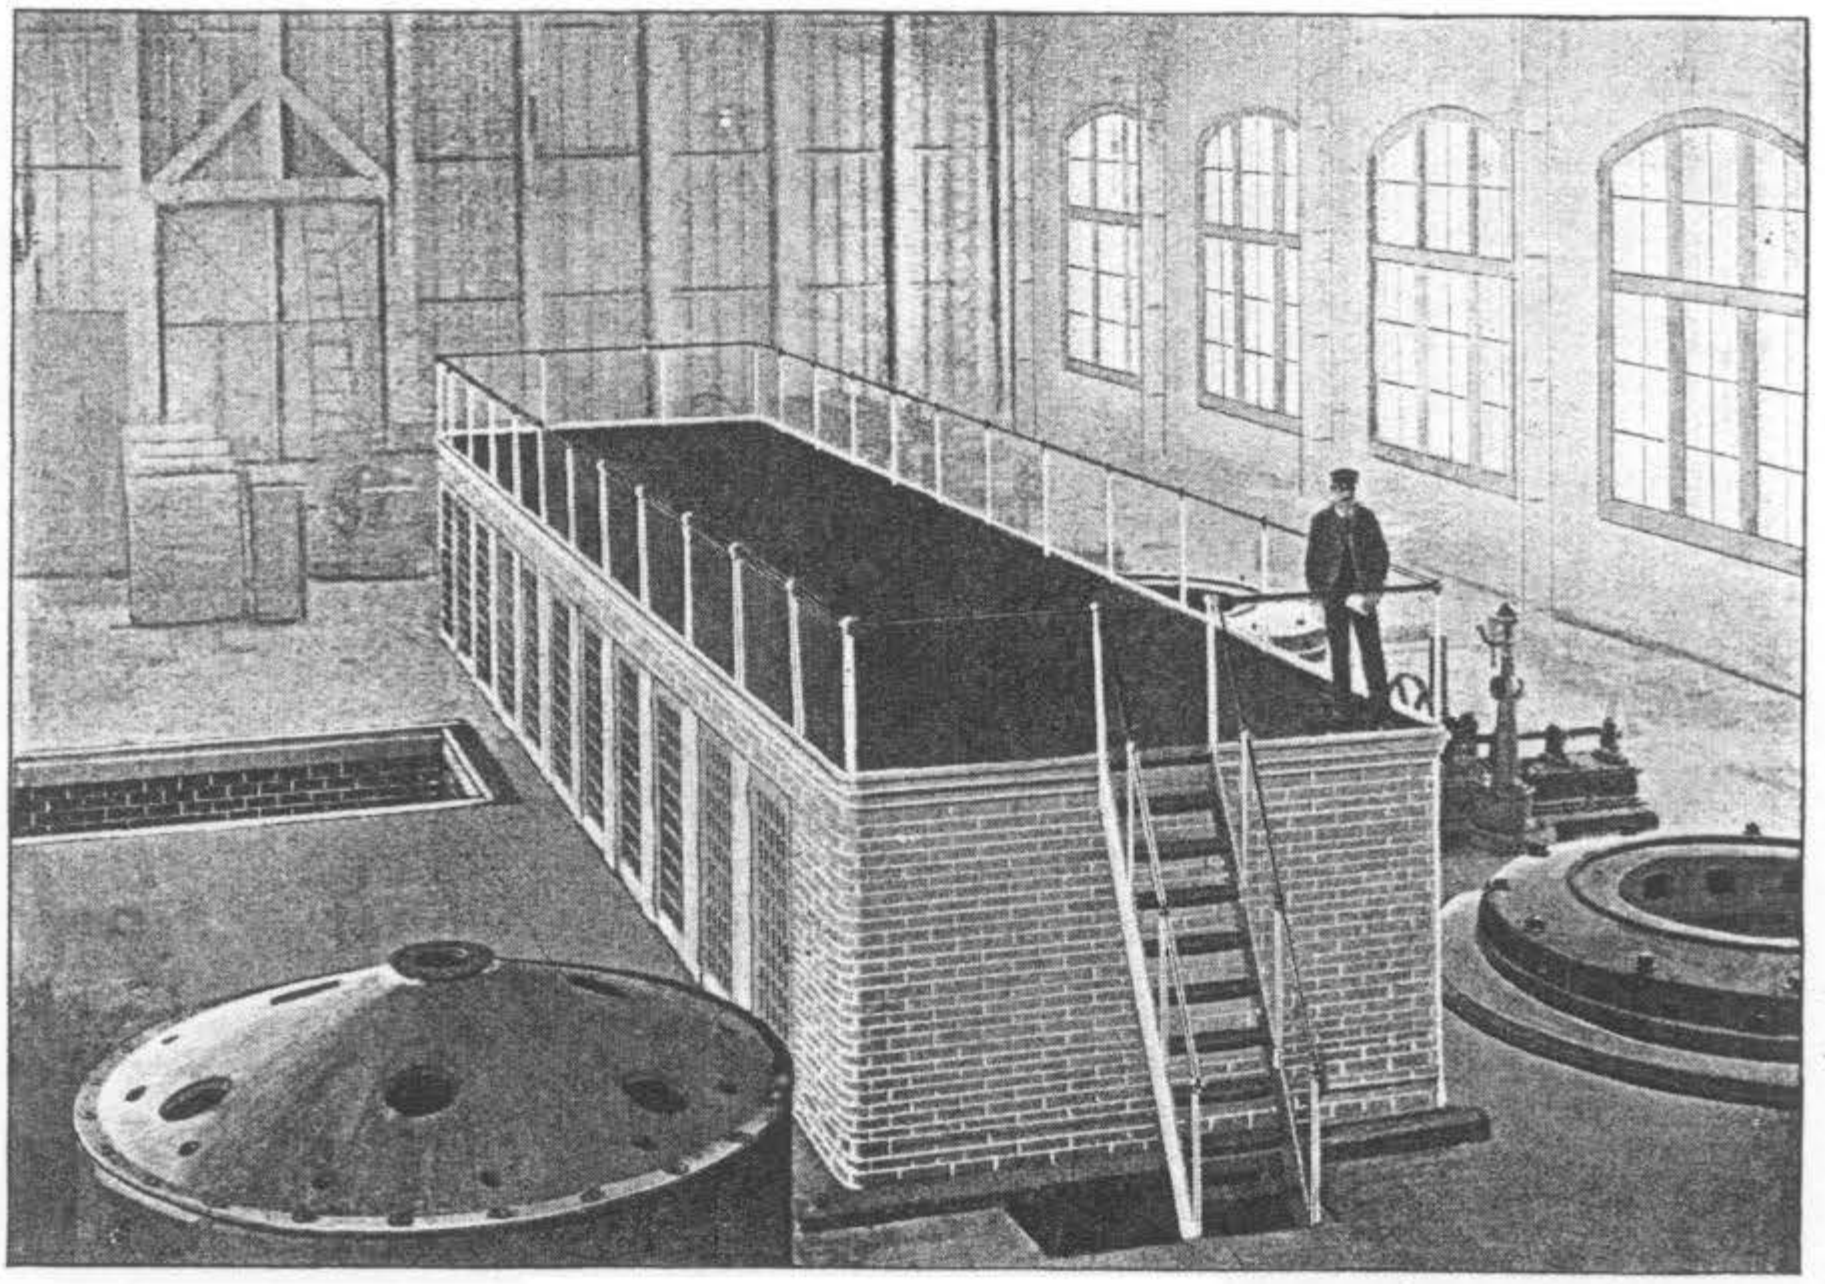
constant. For satisfactory service, this last provision is a necessity,—the potential in the distributing mains must be constant. The local circuits at Niagara are supplied direct from the power house, through feeder or supply circuits of comparatively short length, and, consequently, the loss of potential, or drop, as it is technically called, will, in these circuits, not exceed one or two per cent.

The distributing mains in Buffalo, however, will be necessarily supplied from feeders extending from the power house, a distance of about twenty miles, and in these feeders, unless a very high potential be used, the drop will vary from a maximum of, say, five or possibly ten per cent., depending upon the amount of copper in the circuits, down to one-half, one-fourth or one-tenth of these percentages, depending upon whether the current transmitted along the feeders is the full load current for which these feeders are designed, or one-half, one-fourth or one-tenth of the full load current. It follows that at certain times during each day the potential delivered to the long-distance feeders must exceed that delivered to the local feeders by a not inconsiderable percentage, and the readiest means to meet this condition is to operate the generators in two sets or groups, the units constituting each set working in parallel.

When two or more generators work "in parallel," they are so connected that their currents are delivered to a set of large conductors, called "bus bars," just as two engines, belted to the same line shaft, deliver the power which they develop to that shaft. By suitable devices, such as friction clutches or fast and loose pulleys, either engine may be put into service, or shut down without stopping the line shaft; and, in a similar manner, any electric generator of a group may be made to add its current to that of another generator or group operating in parallel with it, or may be shut down without interfering with the

ONE OF THE GENERATOR FOUNDATIONS.

continuity of the supply of energy delivered by the group.



As an alternative to the plan of operating the generators in two groups, they may all be operated in one group, provision being made for adjusting the potential in either the local mains at Niagara, or the distant mains in Buffalo, by special regulating devices. For a limited number of generators this latter plan offers some advantages, but, looking forward to the time when a dozen or a score of generators will be installed, the method of operating in two groups appears preferable.

In the case of transmission to places more remote than Buffalo, it will be necessary to adopt special means for regulating potential in the distributing mains, at least until the time when improved methods of insulating circuits shall make it practicable to employ very high potentials. When that time comes, the drop in the circuits between the power house and the city of Buffalo will become so small that we may treat the Buffalo feeders as local circuits and can supply them with current from the same bus bars that are used in supplying power in the immediate vicinity of the power house; and when the practicability of commercially employing these very high patentials, *e. g.* 25,000 or even 50.000 volts, is demonstrated, transmission to places more distant than Buffalo will naturally be undertaken. Here again the second set of bus bars will be useful. The diagram on page 282 illustrates the connections of generators, generator switches, bus bars, feeder switches and local and long-distance feeder or supply circuits. To avoid complication but two generators and one long-distance and one local feeder are shown. The currents are conveyed from the generators 1 and 2, to the generator switches, S, S″, through insulated cables, each made up of 427 tinned wires. The aggregate section of copper in each cable is 1 sq. in. Through the generator switches the currents from the respective generators pass at the

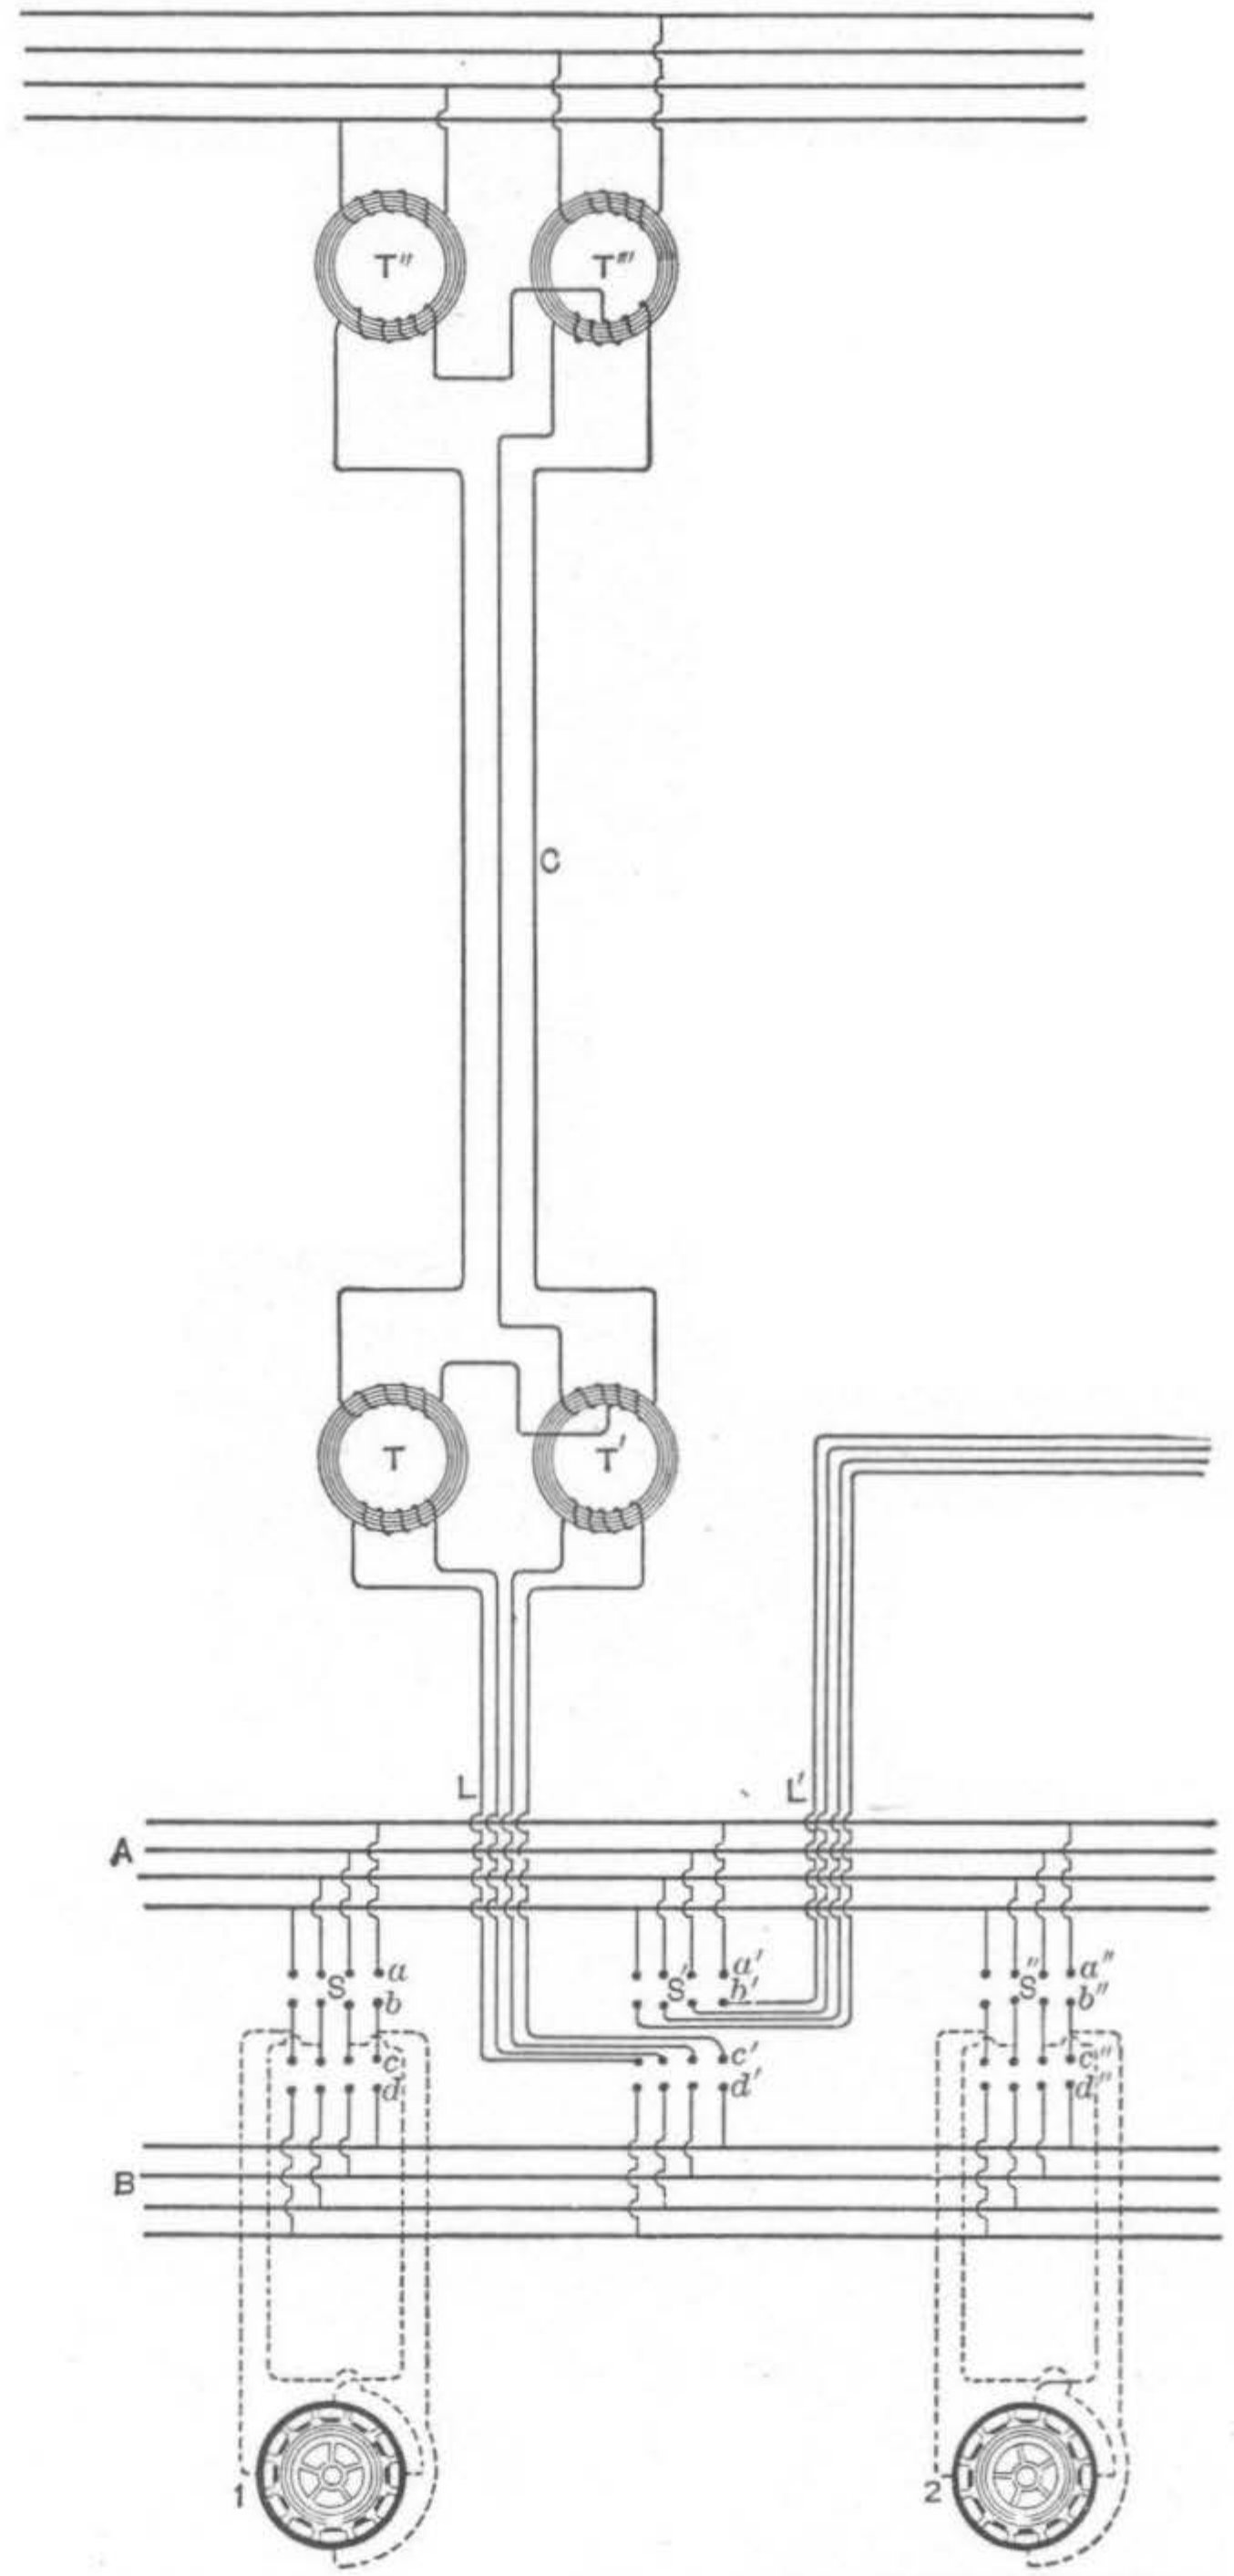
will of the engineer in charge, to either of the two sets of bus bars A, B. Each set consists of four thoroughly insulated copper conductors, the construction of which will be again referred to. The switches are operated by compressed air, controlled by levers mounted on iron stands placed upon the platform above the switchboard structure within which the switches are located. By them any one of the generators, or any combination of the five generators constituting the group, may be connected to either set of bus bars.

Each switch has two separate and independent air cylinders, by which the two ends of the switch are independently controlled. The construction of the switch is shown in the illustration on page 292. To charge the bus bars A with current from the dynamo, 1, the switch is closed at one end, establishing connections between four points in the horizontal row of terminals, marked *a*, and the four points *b*. To connect the dynamo to the bus bars B, the switch is closed at the other end, establishing metallic connection between the four terminals in the row *c*, and the four terminals in the row *d*. If the two sets of bus bars are to be charged with the same potential we may supply both from the generator, 1, by closing both ends of the switch simultaneously. Similar connections are, of course, possible in the case of the other generators and the bus bars.

The feeder switch S′ is similar in

THE SWITCHBOARD STRUCTURE.

construction to the dynamo switches, but the connections are different. So far as the feeders are concerned, it is not necessary that we should be able to connect them to more than one set of bus bars. Until long-distance transmission is begun, either set of bus bars may be used, or both may be charged from the same generator or generators, in which case they will, of course, be charged with the same potential. When additional generators are installed, and long-distance as well as local service is undertaken, as I have said, it will probably be advantageous to operate the



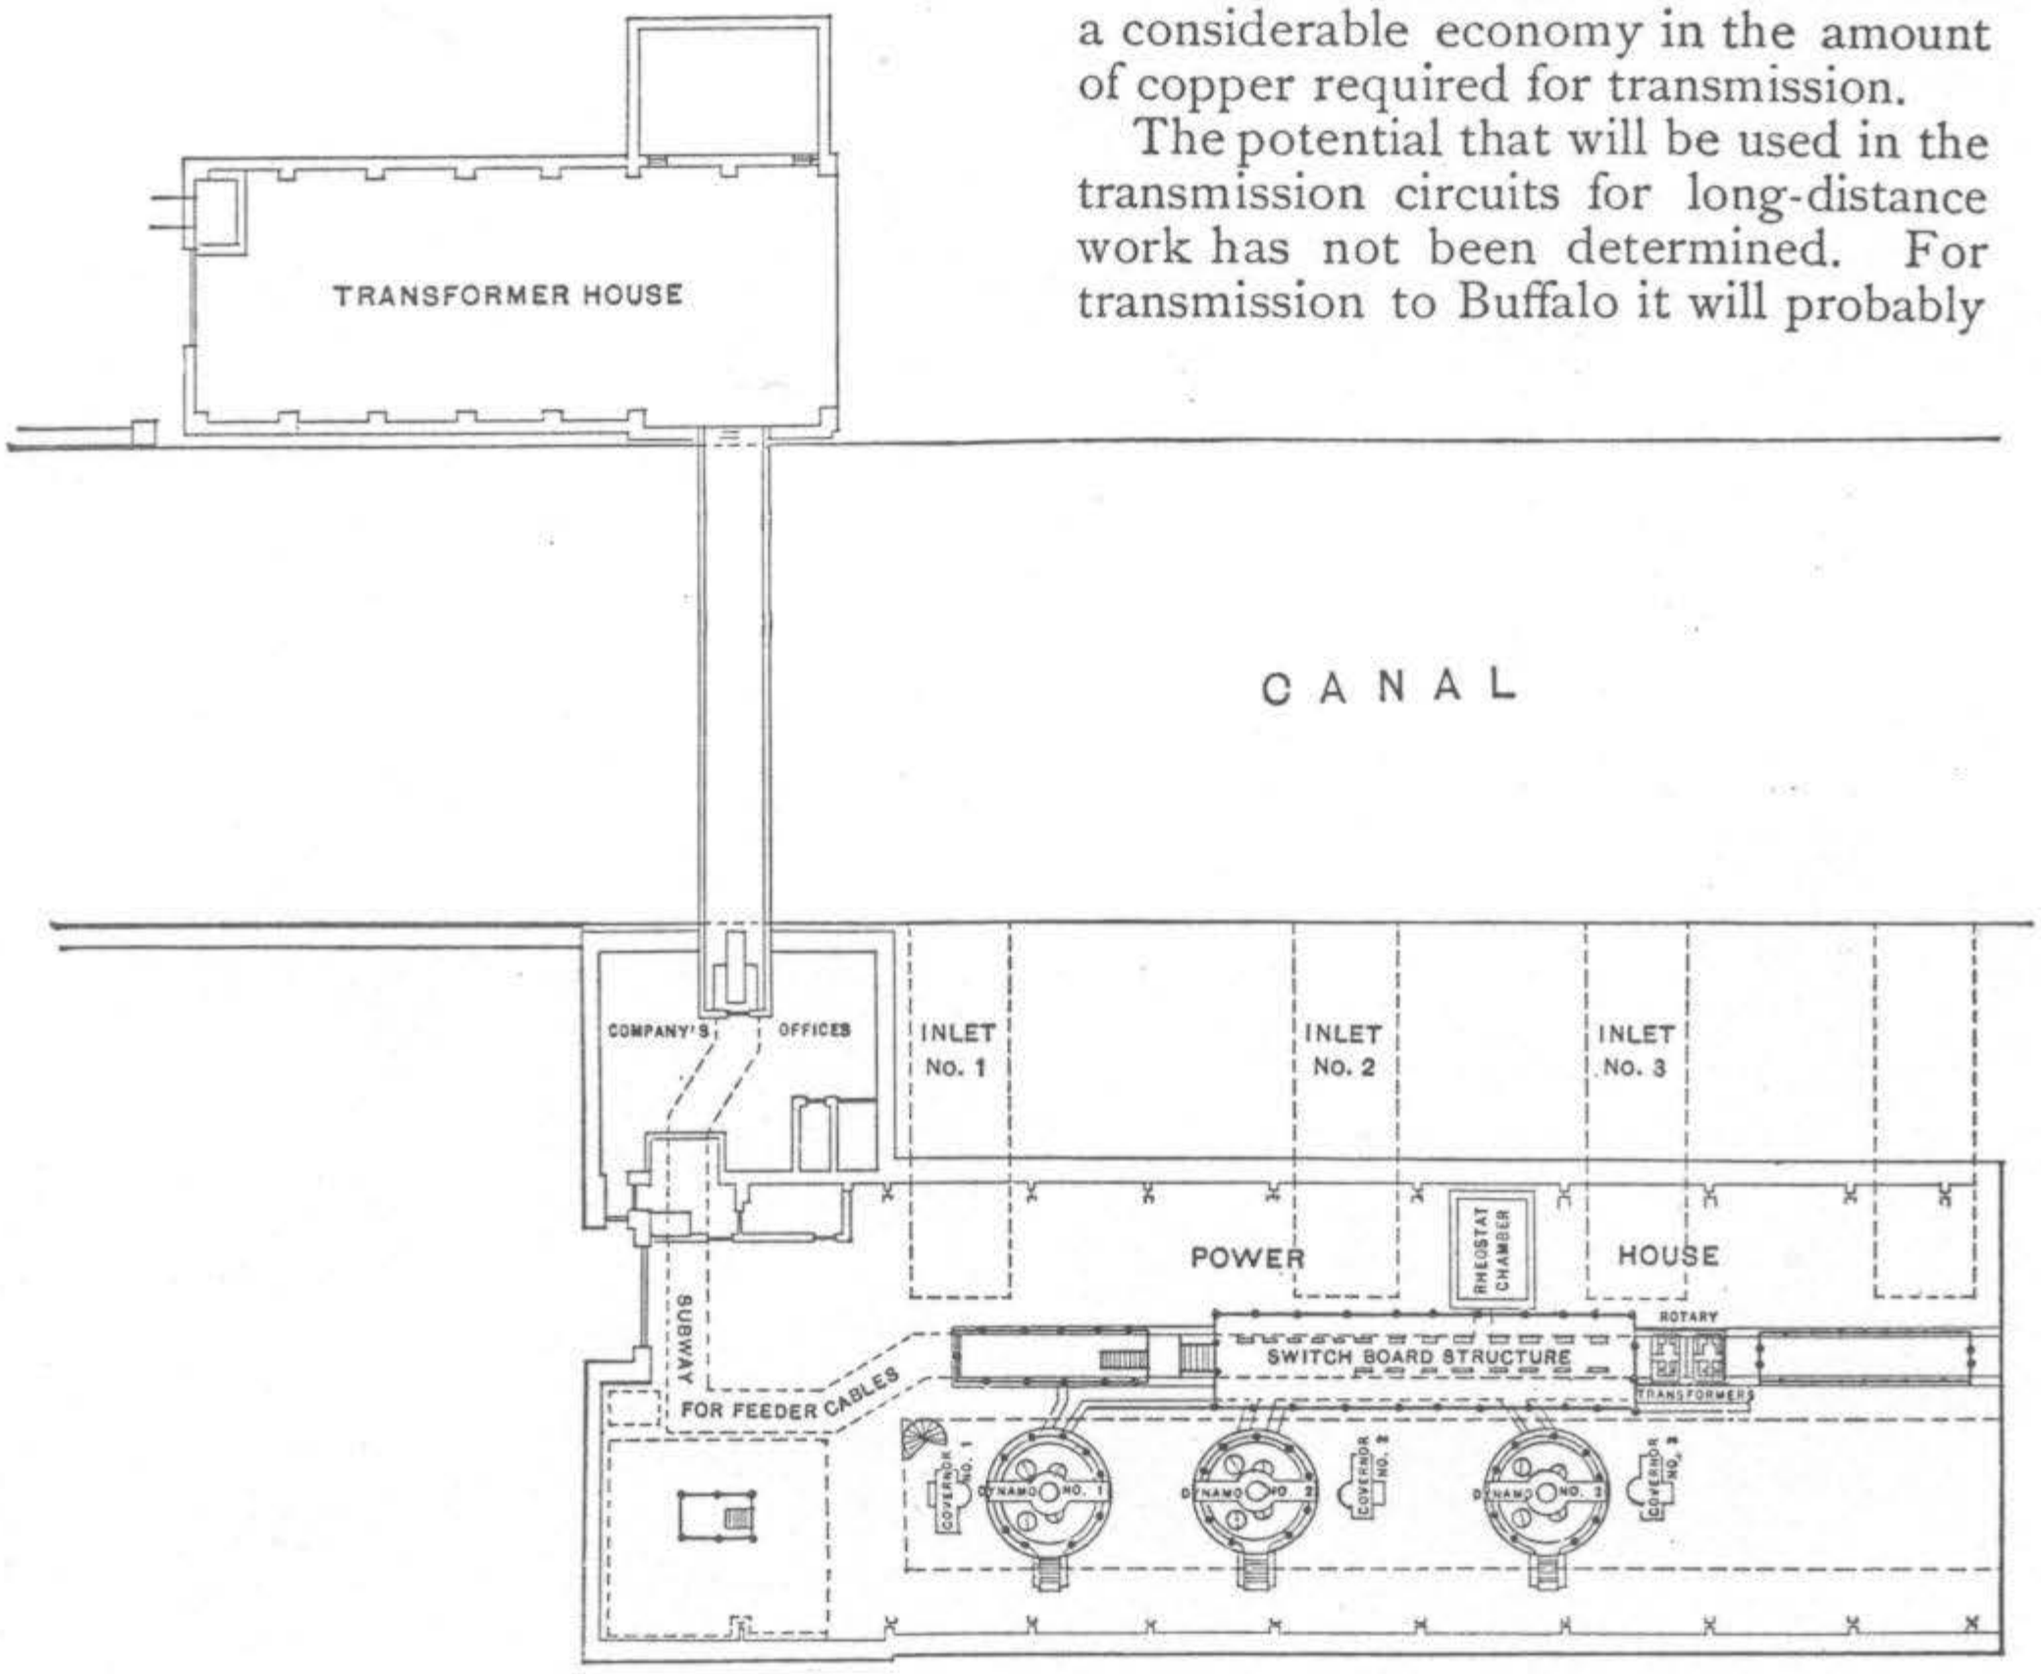


DIAGRAM SHOWING THE CONNECTIONS OF THE GENERATORS WITH LOCAL AND LONG-DISTANCE FEEDERS.

generators in two sets to permit adjustment of potential to compensate for losses in transmission. The respective local and long-distance supply circuits will then be simply arranged for connection through their switches to the local or long-distance bus bars, as desired.

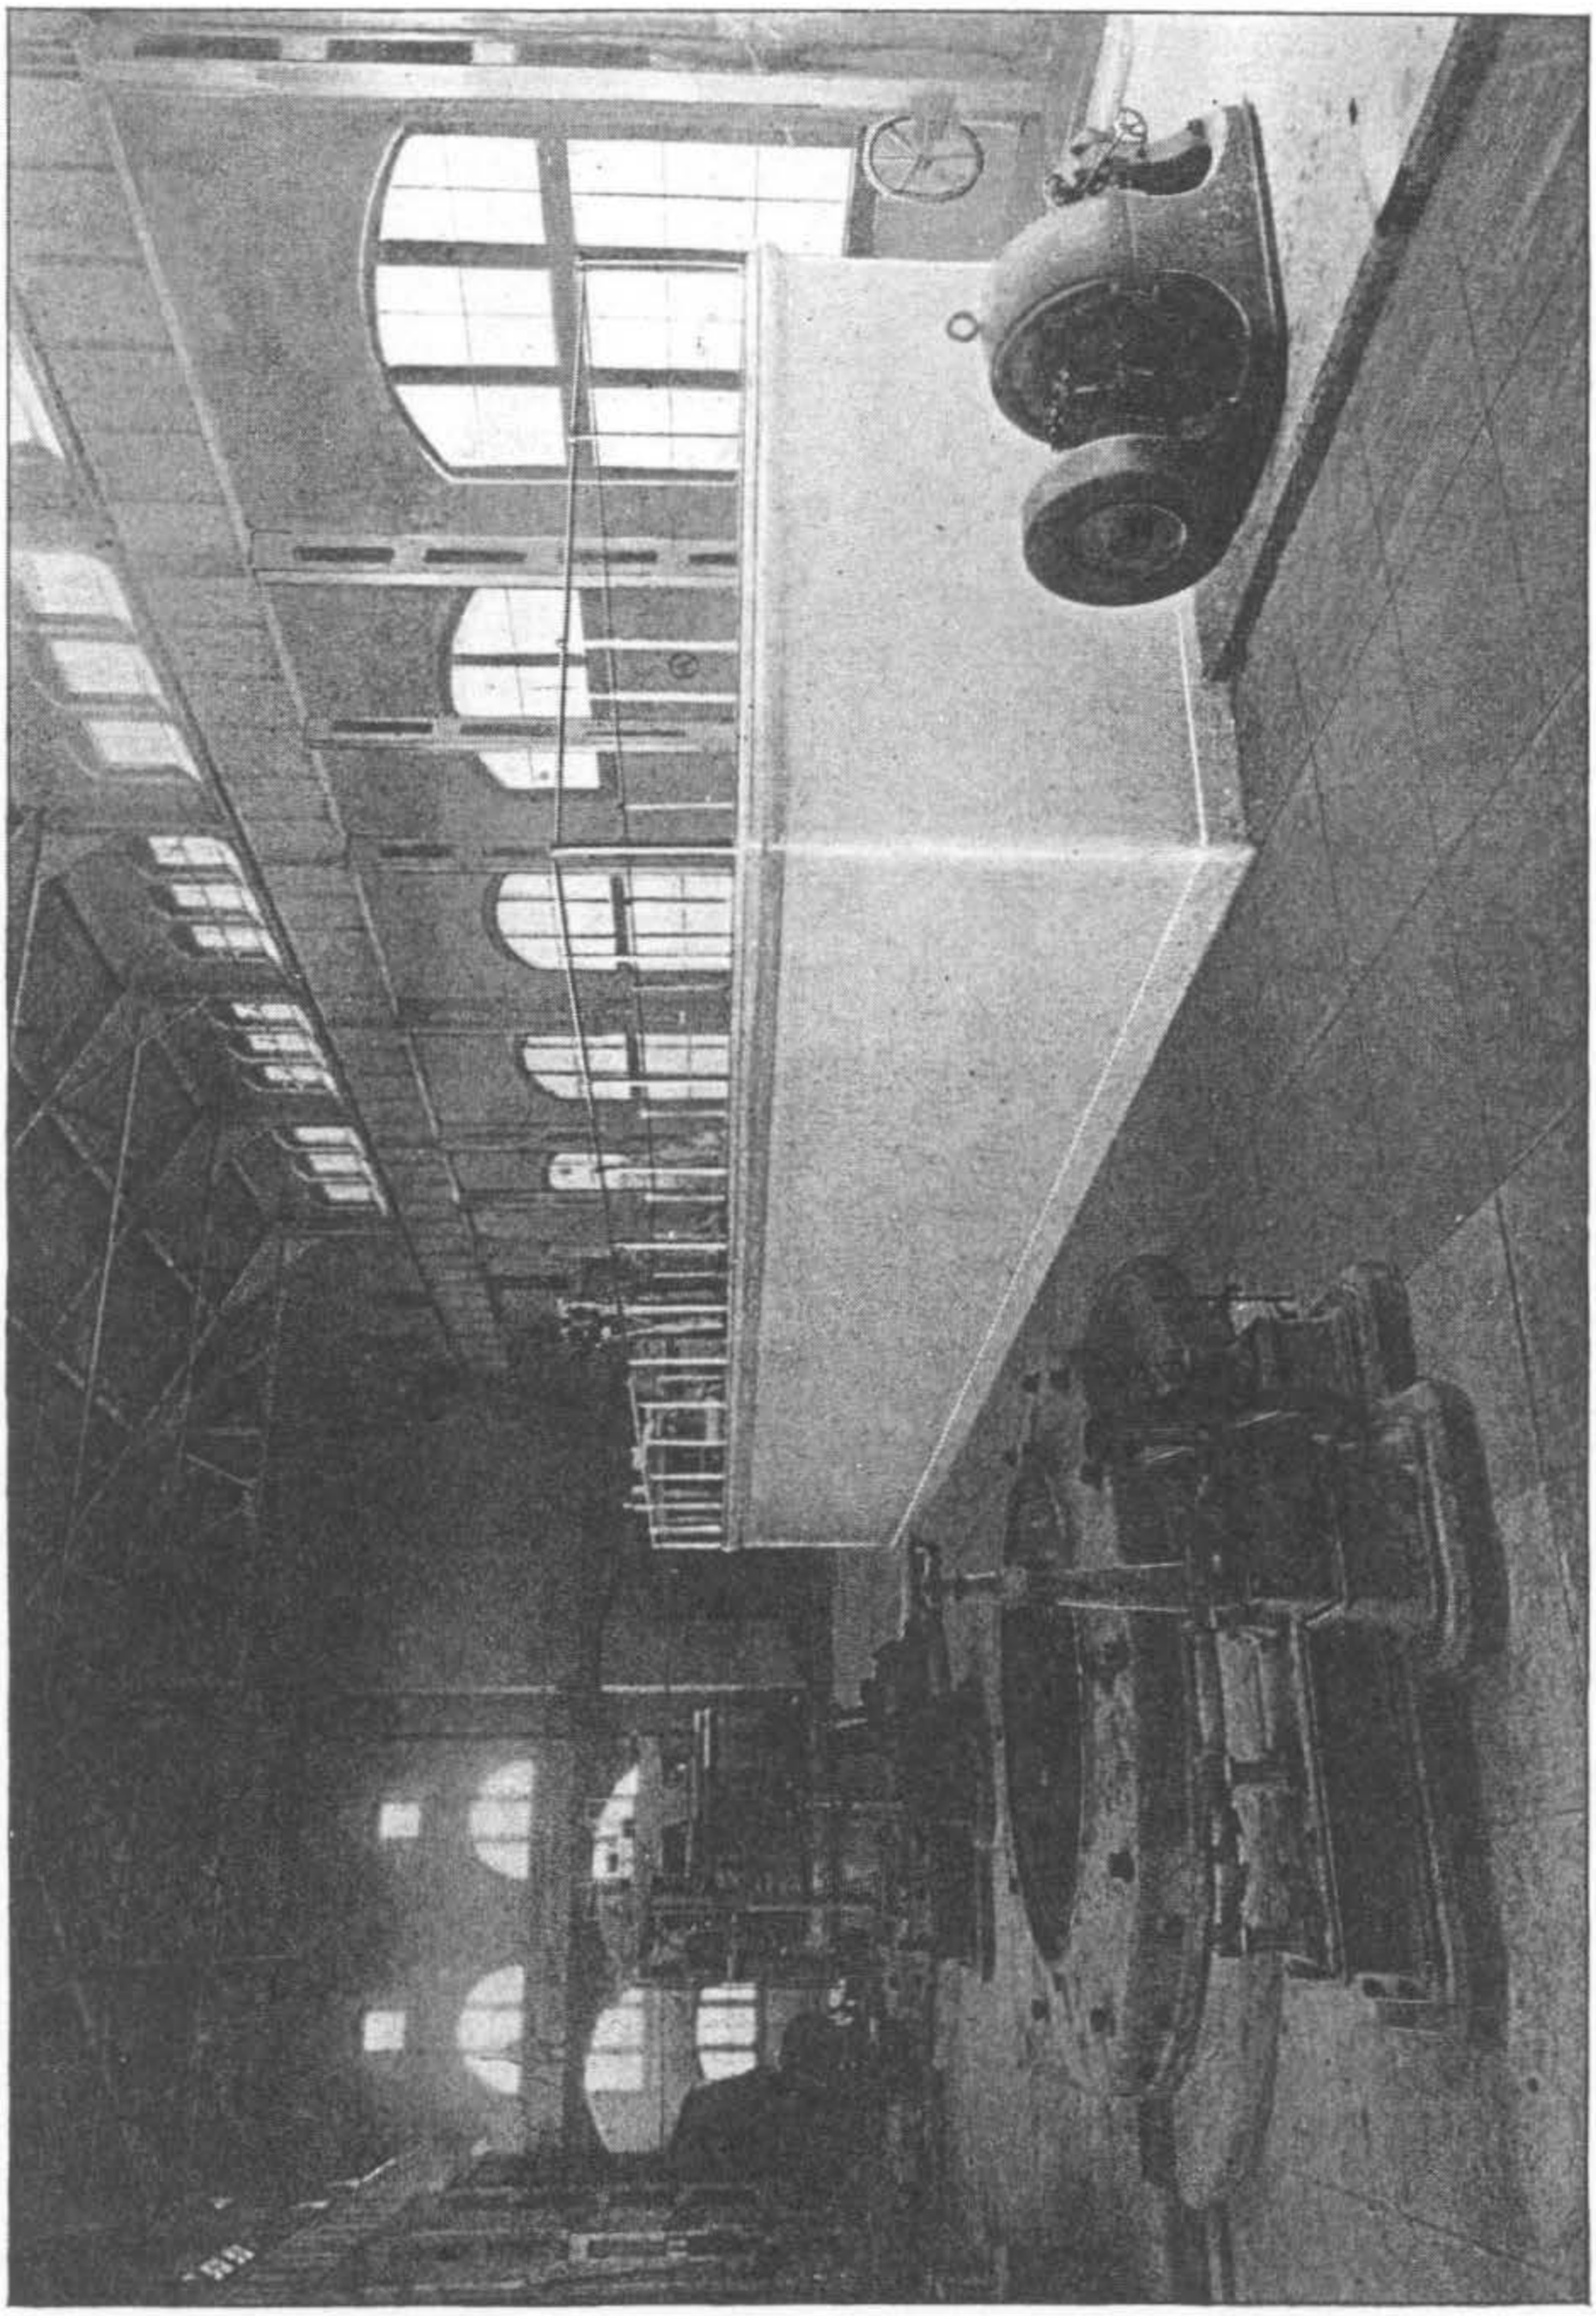
In the diagram on page 282, L represents a supply circuit used for long-distance service, and L′ represents a similar circuit used for local service. In the diagram of the long-distance circuit, T and T′ are step-up transformers, used to increase the potential for transmission, while T″ and T‴ are step-down transformers, located at the distant end of the transmission circuit, for example, at Buffalo or Tonawanda. In the general diagram on page 256 is illustrated the arrangement of circuits in the case of simple two-phase transmission by four wires. The diagram on page 282 shows an arrangement of transformers by which the two-phase currents, delivered by the generators, are changed to three-phase currents in the transmitting circuits, and then changed back to two-phase currents in the local distributing circuits at a distance. This method effects a considerable economy in the amount of copper required for transmission.

The potential that will be used in the transmission circuits for long-distance work has not been determined. For transmission to Buffalo it will probably not be less than 10,000 volts, and not more than 25,000 volts. For transmission to greater distances, still higher potentials are contemplated.

PLAN OF POWER AND TRANSFORMER HOUSES.

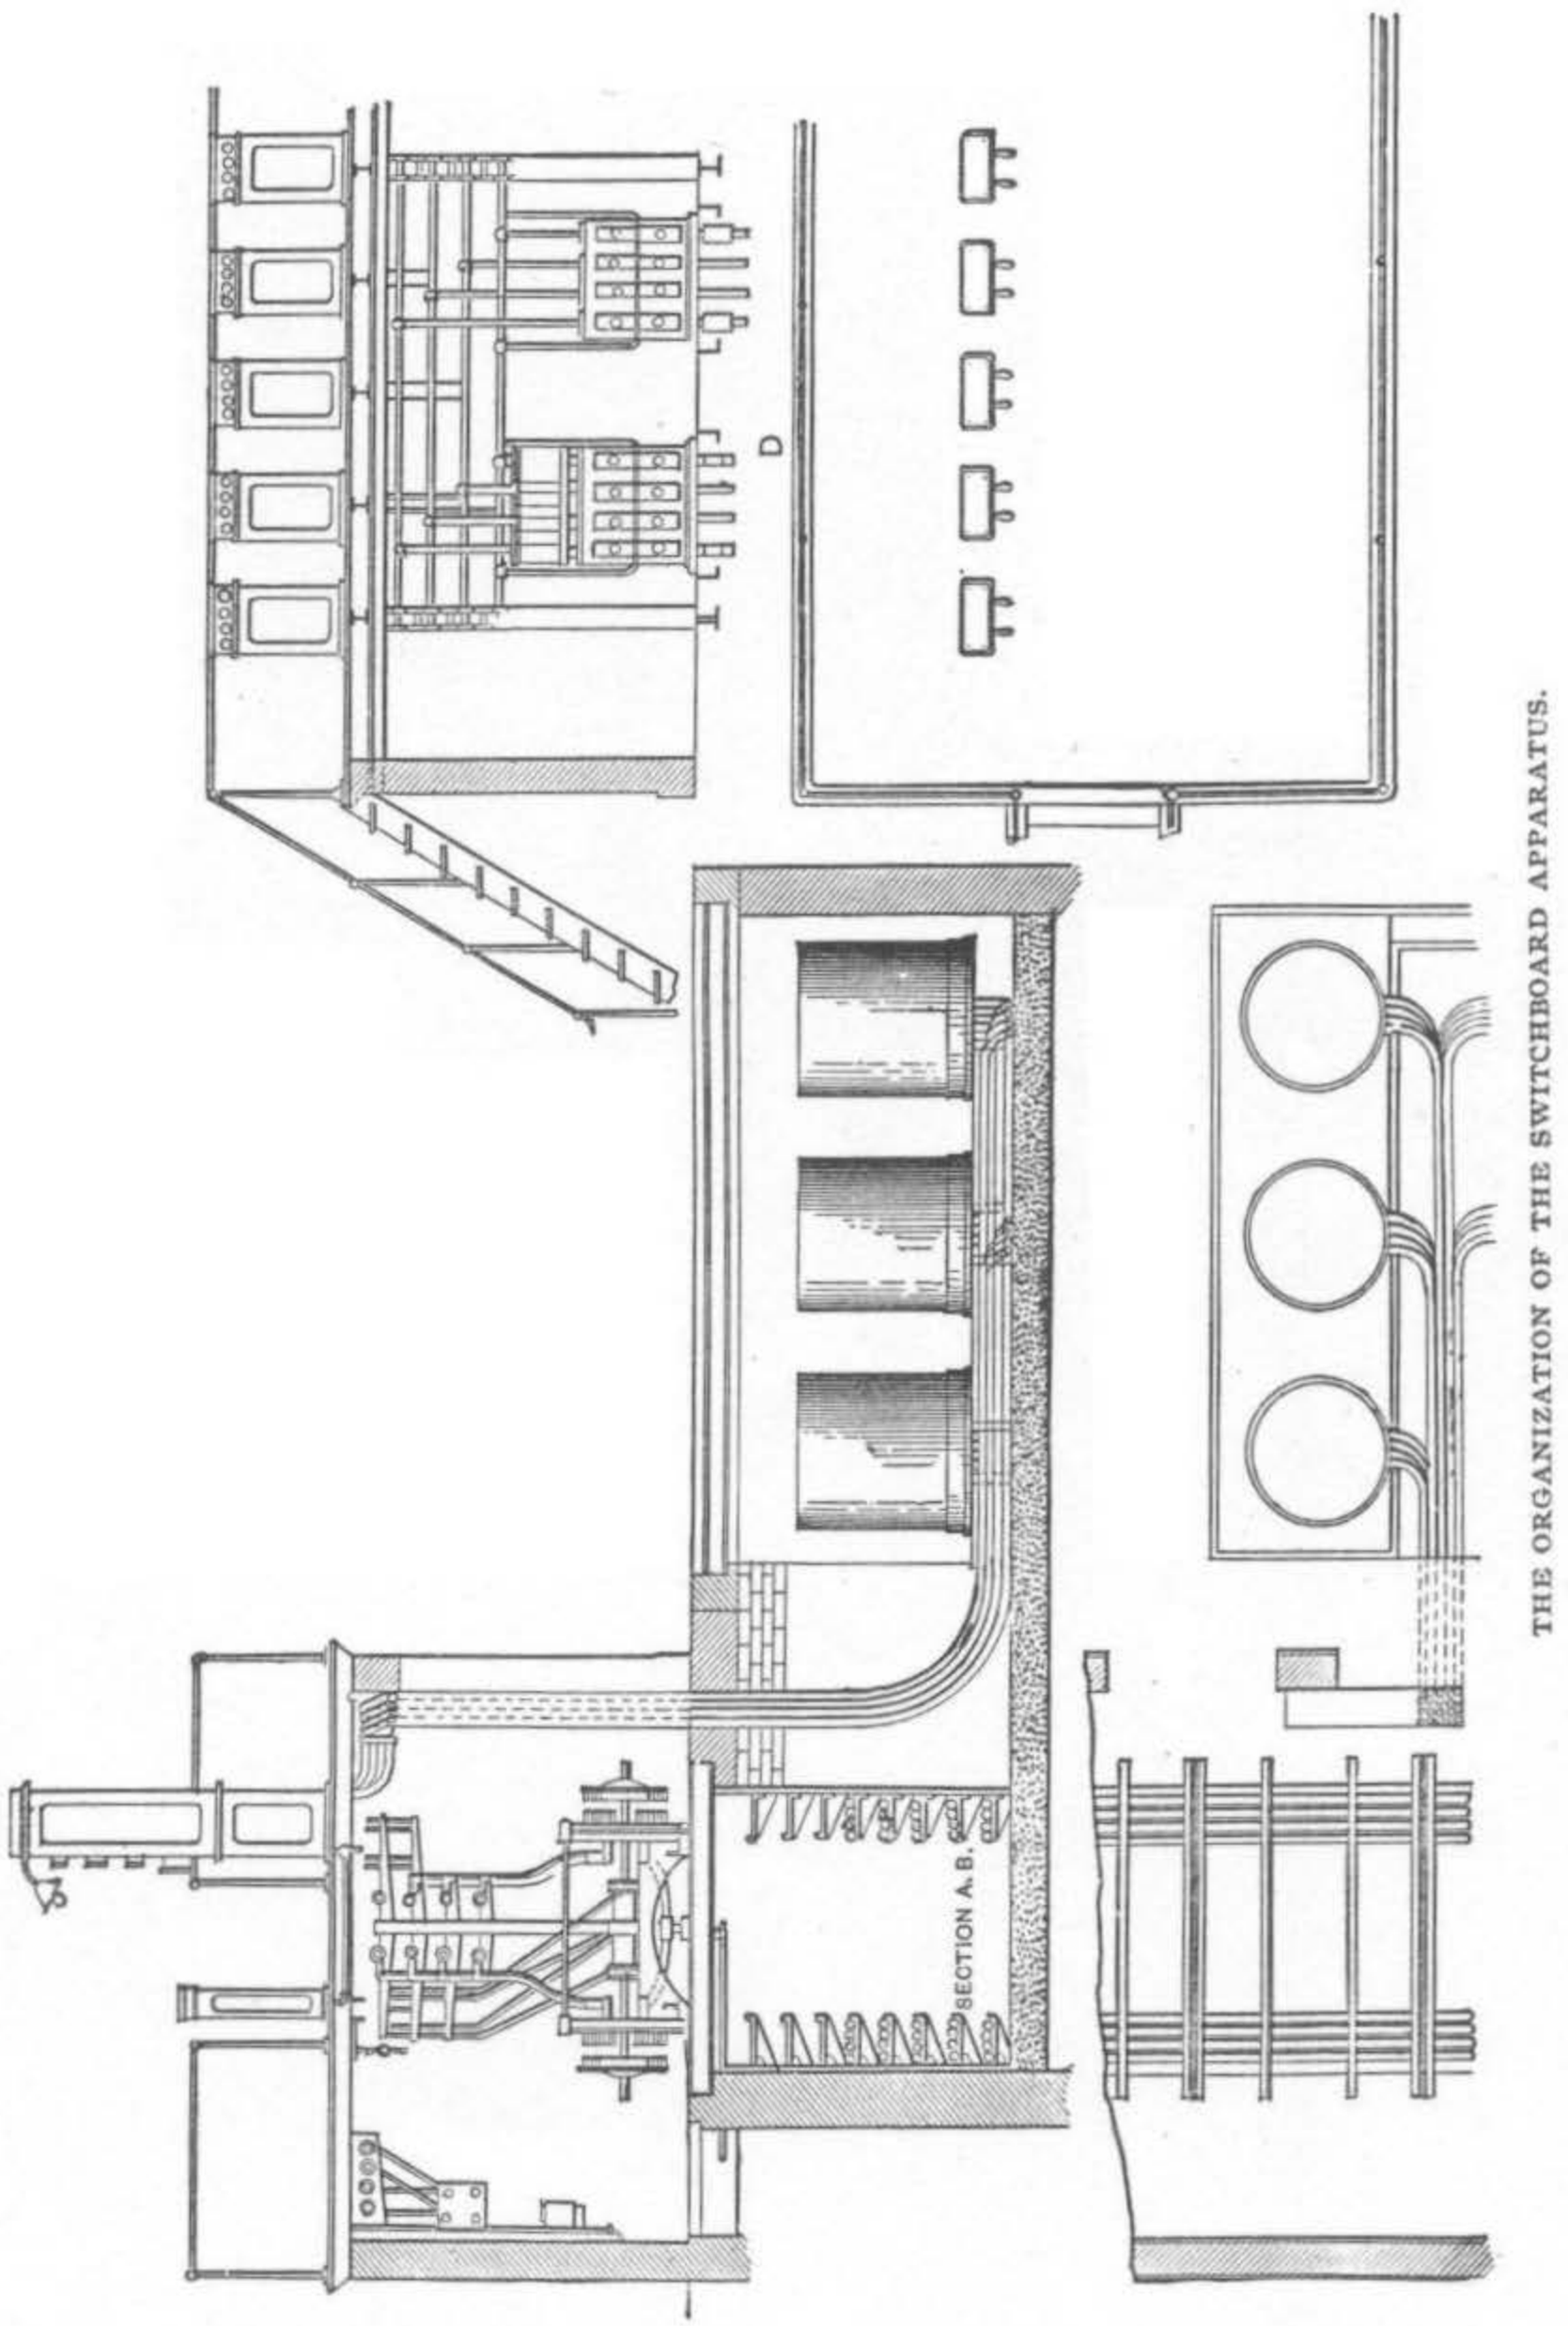
The illustration on page 281 shows the structure erected for the switchboard apparatus. It is of white enameled brick, and is 57 ft. 10 in. long, 13 ft. wide and a little less than 8 ft. in height. It is erected directly over the sub-way, as shown in the floor plan on page 283. The top of the structure is of slate sup-

ported upon iron I-beams, and the platform thus formed is surrounded by a neat brass hand-rail. The sub-way beneath the switchboard is spanned at suitable distances by iron I-beams, to which the dynamo and feeder switches are bolted in place. The cables passing from the generators through ducts beneath the floor line are connected to the generator switches, while the outgoing cables, constituting the feeder or supply circuits, drop directly from the feeder switches into the subway. Iron standards are secured to each side of the subway by expansion bolts. They are placed at intervals of about 4 ft., and adjustable iron brackets set into these standards support the lead-sheathed cables passing through the sub-way and bridge to the transformer house on the east bank of the canal.



The drawing on page 283, showing the floor plan of the power house, bridge and the transformer house, will make clear the position of the switchboard structure with reference to the first three generators and the sub-way. Additional generators will, in due time, be erected in line beyond the generator marked "Dynamo, No. 3," and the switchboard structure is designed to accommodate all instruments and switches needed in connection with the first five generators.

The organization of the switchboard apparatus and the general features of the construction of the essential elements will be best understood by reference to the illustration on page 286, which is reproduced from the official drawing. The upper part of the illustration at the reader's right hand is a front elevation of the stands which carry the instruments for the several generators and for the exciters, and also shows one of the lever stands for the feeder circuits. Beneath the floor line of the switchboard platform is seen one set of bus bars in connection with an end elevation of the generator and feeder switches. A plan of the switchboard platform is also given in the illustration on page 288, a part of the platform being cut away to show a plan of one generator switch and one feeder switch. On page 286, again, is shown a plan of the rheostat chamber and sub-way for the cables, and just above this, a section through the switchboard, sub-way and rheostat chamber, at right angles to the direction of the sub-way, is given.



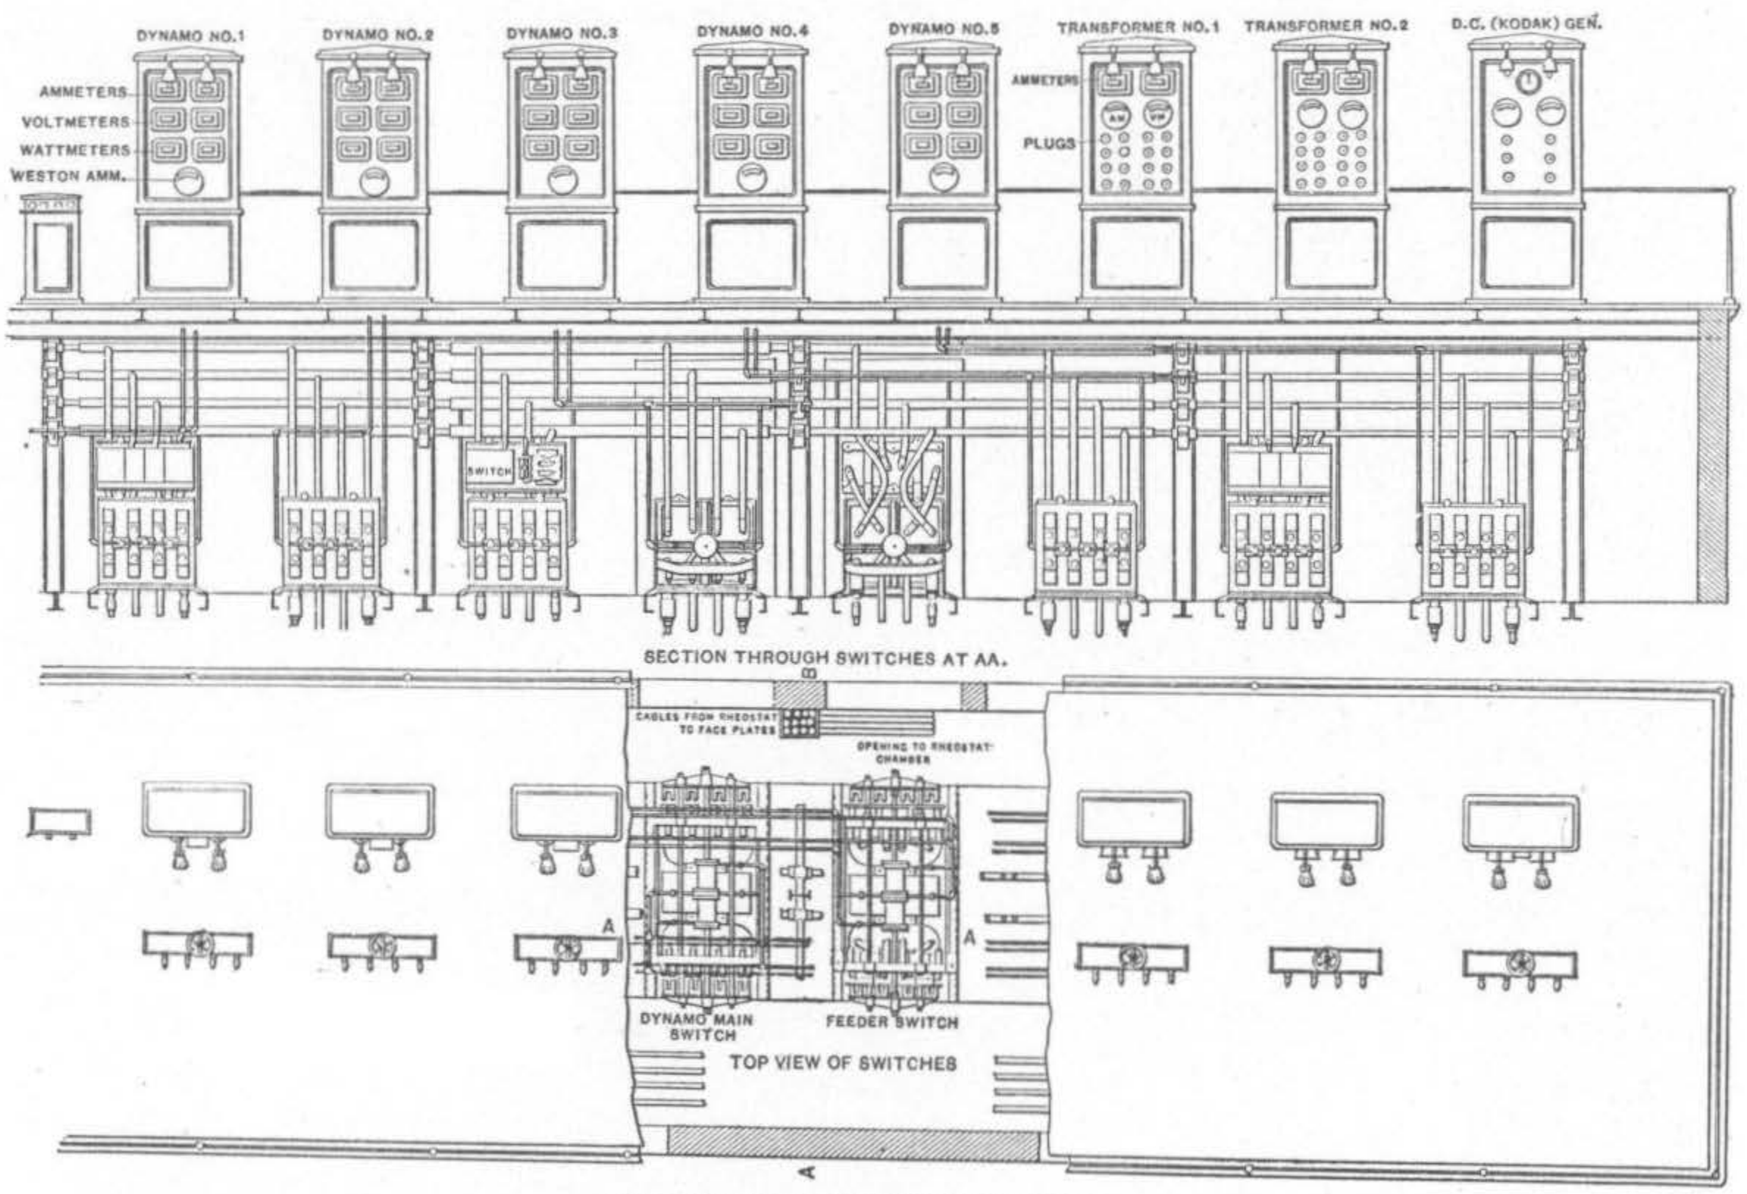
The essential elements of the switchboard apparatus are,—the generator and feeder switches, the bus bars, the switching and safety devices for the exciting currents, the rheostats for controlling the generator fields, and the indicating and measuring instruments. As shown by the plans, the switches and bus bars are located within the switchboard structure. Upon the switchboard platform are erected the instrument stands, one for each generator, two for the rotary transformers, and one for the engine-driven generator, temporarily used as an exciter, and in front of each instrument stand is placed a cast-iron stand, about 30 inches in height, carrying the levers which control the admission of air to the switch cylinders, and a wheel by means of which the rheostats are controlled.

Each of the lever stands used for controlling the large generator switches carries also levers for opening and closing the field circuit of the corresponding generator, and a hand wheel by which the rheostat resistance in the field of the generator is adjusted. The rheostats are located in a special chamber below the floor line of power house, the face-plates being located in the bases of the instrument stands. Connection between the face-plates and resistance coils of the rheostats is secured by insulated cables of suitable section. The compressed air used in operating the switches comes from a compressor direct, driven by a Worthington water motor. This compressor is located at the bottom of the wheel pit, and supplies air to a large cylindrical reservoir from which pipes are led to the various switches. The pressure used is 125 pounds per square inch.

Engineers, not familiar with the possibilities of electricity, will be impressed by the fact that the currents actually measured are not the heavy currents traversing the cables within the switch-

ONE END OF THE POWER HOUSE.

THE ORGANIZATION OF THE SWITCHBOARD APPARATUS.



board structure, but are derived currents, bearing a known relation to the heavy currents delivered by the generators. They are small in quantity and absolutely harmless. The operator, standing upon the switchboard platform, cannot possibly touch a circuit which is in the slightest degree dangerous. The currents measured are obtained by means of transformers located inside the switchboard structure, the ratio of their winding being such that for every 50 ampères flowing in the main circuit, a current of 1 ampère is supplied from the secondary of the transformer to the measuring instruments. Currents to the respective voltmeters are supplied from transformers, the primaries of which are connected across the generator circuits. For the wattmeters both series and shunt connections from the generator circuits are needed, and these are obtained from the transformers used for the voltmeters and ammeters.

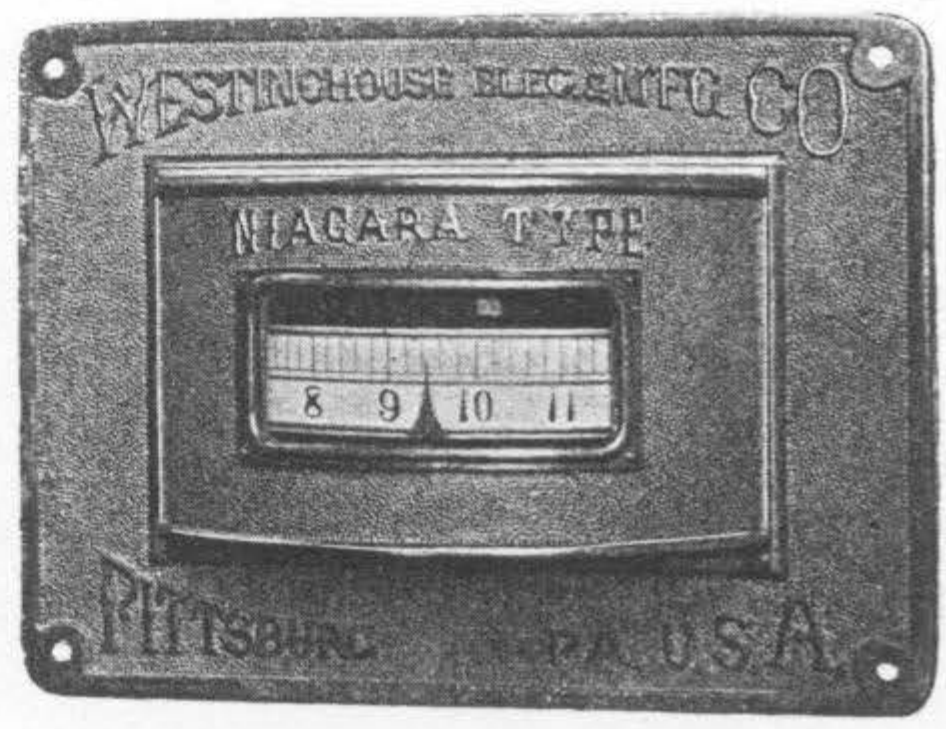
To measure energy, current and potential in each phase of each generator, two converters, an indicating wattmeter, an ammeter and a voltmeter are employed. The energy required by these devices amounts, as a maximum, to about 30 watts—that is, $\frac{1}{25}$ horse-power. It is an extraordinary illustration of the facility with which electricity is accurately measured that we should be able thus to determine energy varying from 25 horse-power to 2500 horse-power by means of measuring devices, accurate throughout their range within one per cent., and requiring for their operation not more than $\frac{1}{30}$ horse-power.

The instrument stands are boxes or cabinets, constructed of iron and marble, the front of each, above the pedestal, being formed of a single slab of polished Italian marble, 1¾ inches thick, 30 inches in width and 45 inches in height. Each stand occupies a floor space of 38 inches by 20 inches and is 7 feet in height. Sliding doors at the back give access to the measuring instruments. The marble front of the stand is pierced by six rectangular openings, and the instruments are secured to the marble in such a way that the front of each, with its scale and index, projects through the marble to the front of the stand.

The engraving on page 289 illustrates one of the alternating current ammeters, as viewed from the front. The indicating wattmeter and the voltmeter are similar in appearance. The fronts are finished in oxidised brass. These instruments, and the integrating wattmeters, used in connection with feeder circuits (not located upon the switchboard platform), comprise a remarkable group of measuring instruments recently invented and designed by Mr. Oliver B. Shallenberger, Consulting Electrician of the Westinghouse Company. As they were primarily designed with special reference to the Niagara installation, they are designated the "Niagara type" by the Westinghouse Company. Their sphere of usefulness, however, will be as wide as the applications of alternating currents. They depend for their action upon the induction of currents in a movable closed secondary circuit, and all operate to a certain extent upon the same general principles, specifically developed in each case to attain the object desired. They are extremely simple in construction, the parts are few and comparatively massive, and yet the instruments are capable of giving very accurate results. They are guaranteed by the Westinghouse Company to be correct within one per cent.

In each instrument a thin aluminium disc, stiffened by a flange around its edge, constitutes the movable element, in which eddy currents are induced by currents traversing coils placed above and below it. The relation of the induced currents in the disc and the inducing currents in the coils is such that the disc tends to rotate. In the wattmeter the tendency is proportional to a function of the energy traversing the inducing circuits, and these currents come from a converter located beneath the platform, and, in turn, are proportional to the energy in one of the gen-

SOME DETAILS OF THE SWITCHBOARD.



erator circuits, which is the energy to be measured. The tendency to rotate is resisted by a torsion spring, and the currents turn the disc, overcoming the resistance of the spring through a certain angle. This angle depends upon the relative strength of the twisting moment, due to the currents and the resisting force of the spring, and the position of the disc, with reference to its position when no current traverses the coils, becomes a measure of the energy. The scale is attached to the circumference of the disc, and depends from it much as the field ring of the generator depends from the driver. This scale is carried with the disc, from its zero position, through an angle depending upon the current measured, and the instrument being once carefully compared with a standard and the scale properly marked, the energy can be determined by taking the reading of this scale opposite the index, which is always fixed in position. In the illustration on this page the index will be seen in the centre of the rectangular glass window, and, immediately behind it, an arc of the circular scale.

The ammeter, which measures the strength of the current, and the voltmeter, which measures the potential, resemble the indicating wattmeter in the fact that they are based upon the same principles, and they are also similar in general features of construction. The methods employed to obtain the proper phase relations of the currents in the inducing circuits and in the disc are very ingenious and, to the electrician, interesting. But this is not the place to describe them in detail.

The ammeters, which measure the currents in the fields of the generators, were furnished by the Weston Instrument Company, of Newark, N. J., and are of their well-known type, in which the current actually measured by the instrument is that which flows through a circuit connected in shunt to a resistance which is placed in the circuit traversed by the current to be measured.

All of the currents measured by the instruments located in the instrument stand are supplied through insulated conductors of small section, which convey the small derived currents from converters or from the terminals of resistances placed beneath the switchboard platform. Each generator instrument stand carries, in addition to the instruments already described, a phase indicator, by means of which the attendant or the engineer in charge, who desires to connect a generator in parallel with another generator or group of generators, determines the proper time for closing the switch.

The instruments provided for the stands belonging to the rotary transformers used as exciters, are not the same as those provided for the generator instrument stands, and they also differ from the instruments provided for the stand belonging to the temporary engine-driven exciter. They comprise two Shallenberger alternating-current ammeters of the Niagara type and a direct-current ammeter and voltmeter made by the Weston Instrument Company. A number of plug contacts are provided, by means of which the ratio of conversion of the static transformers which supply current to the rotary transformers may be adjusted.

AN ALTERNATING CURRENT AMMETER, NIAGARA TYPE.

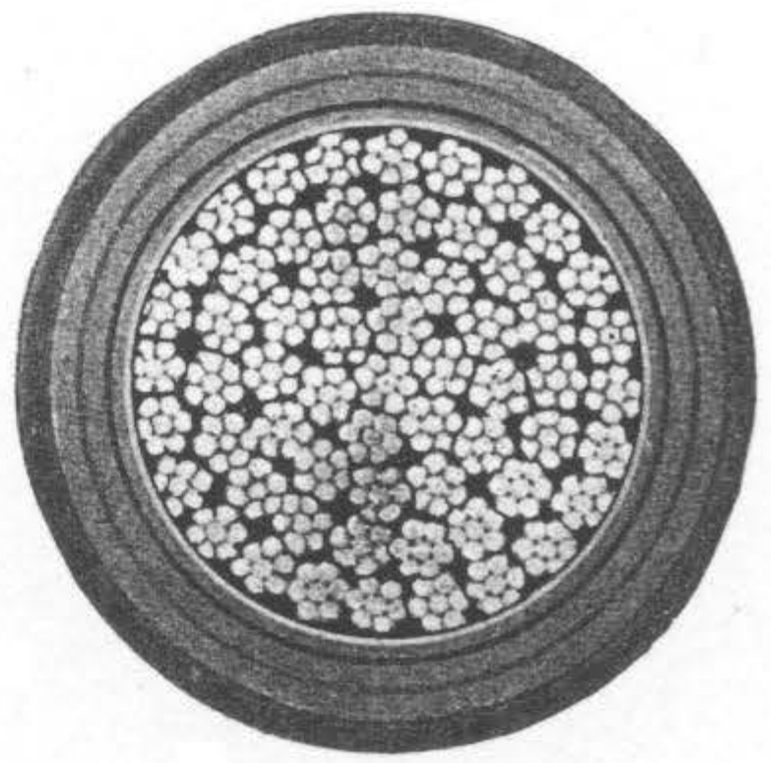
The construction of the bus bars is, in several respects, remarkable, the magnitude of the quantities dealt with again making it necessary to devise methods of construction outside the range of experience. As has been said, two sets of bus bars are provided, but it

is, of course, conceivable that under certain circumstances it may be desirable to cut one set out of service and control the output of five generators through the other set. By arranging the generator switches and feeder switches as shown in the illustration, in such a way that the former, through which current is delivered to the bus bars, alternate with the latter, through which current is drawn from the bus bars, the maximum current which it is necessary to convey through any section of the bus bars becomes that supplied by three generators. This is equivalent in each bar to about 3000 ampères, and, assuming a current density of 1000 ampères per sq. in., would require a section of about 3 sq. in. in the bus bar. The potential of the currents may be as high as 2400 volts.

A short-circuit might obviously be very dangerous, and this fact, in connection with the fact that at certain times the atmosphere of the power house is liable to carry a considerable amount of moisture, ready to be precipitated upon metallic surfaces, points to the desirability of insulating the bars. To insulate them in the most satisfactory manner, rounded surfaces are necessary, but in a round solid conductor, 3 square inches in section, nearly 2 inches in diameter, two other difficulties must be faced: First, the surface from which the heat, due to resistance, must be radiated, is small as compared with that obtained by using flat bars or straps of equal section; and, second, an alternating current in such a conductor will not distribute itself uniformly, but will seek the surface, leaving the copper at the centre relatively idle and ineffective.

These difficulties have been successfully overcome by the construction adopted. From the middle each bar tapers toward the ends. The middle section consists of a copper tube of about 3 inches outside diameter and 2 inches inside diameter. Into this, at either end is screwed a tube, the outside diameter of which is approximately 2 inches, while its inside diameter is about $1\frac{1}{8}$ in. Into the other ends of each of these tubes, in like manner, a copper rod $1\frac{1}{8}$ inch in diameter is screwed. The offsets or connections from which short lengths of cable convey current to or from the several switches, are clamped to the bar thus formed, all surfaces being rounded. The entire bar with offsets is then insulated with very high-class rubber insulation. These bars were constructed by the Brown & Sharpe Manufacturing Company, of Providence, R. I., U. S. A., according to the designs of the Westinghouse Company, and were insulated by the India Rubber and Gutta-Percha Insulating Company, of New York, the method employed being that covered by the Habirshaw patents. The insulation consists of alternate layers of pure Para gum and vulcanized rubber, two layers of each being used, and the outer layer of vulcanized rubber protected by a special braided covering chemically treated to make it non-combustible. Similar insulation is used for the cables between the generators and the switches and for the connections between the bus bars and switches.

A section of the Habirshaw cable is reproduced on the opposite page. The illustration is very nearly the exact size of the cable. The makers guarantee that the insulation of cables and bus bars, erected in place, shall stand an alternating current potential of 10,000 effective volts between copper and earth. Samples submitted and tested in the laboratory of the Westinghouse Company successfully resisted the application of potentials exceeding 40,000 volts.

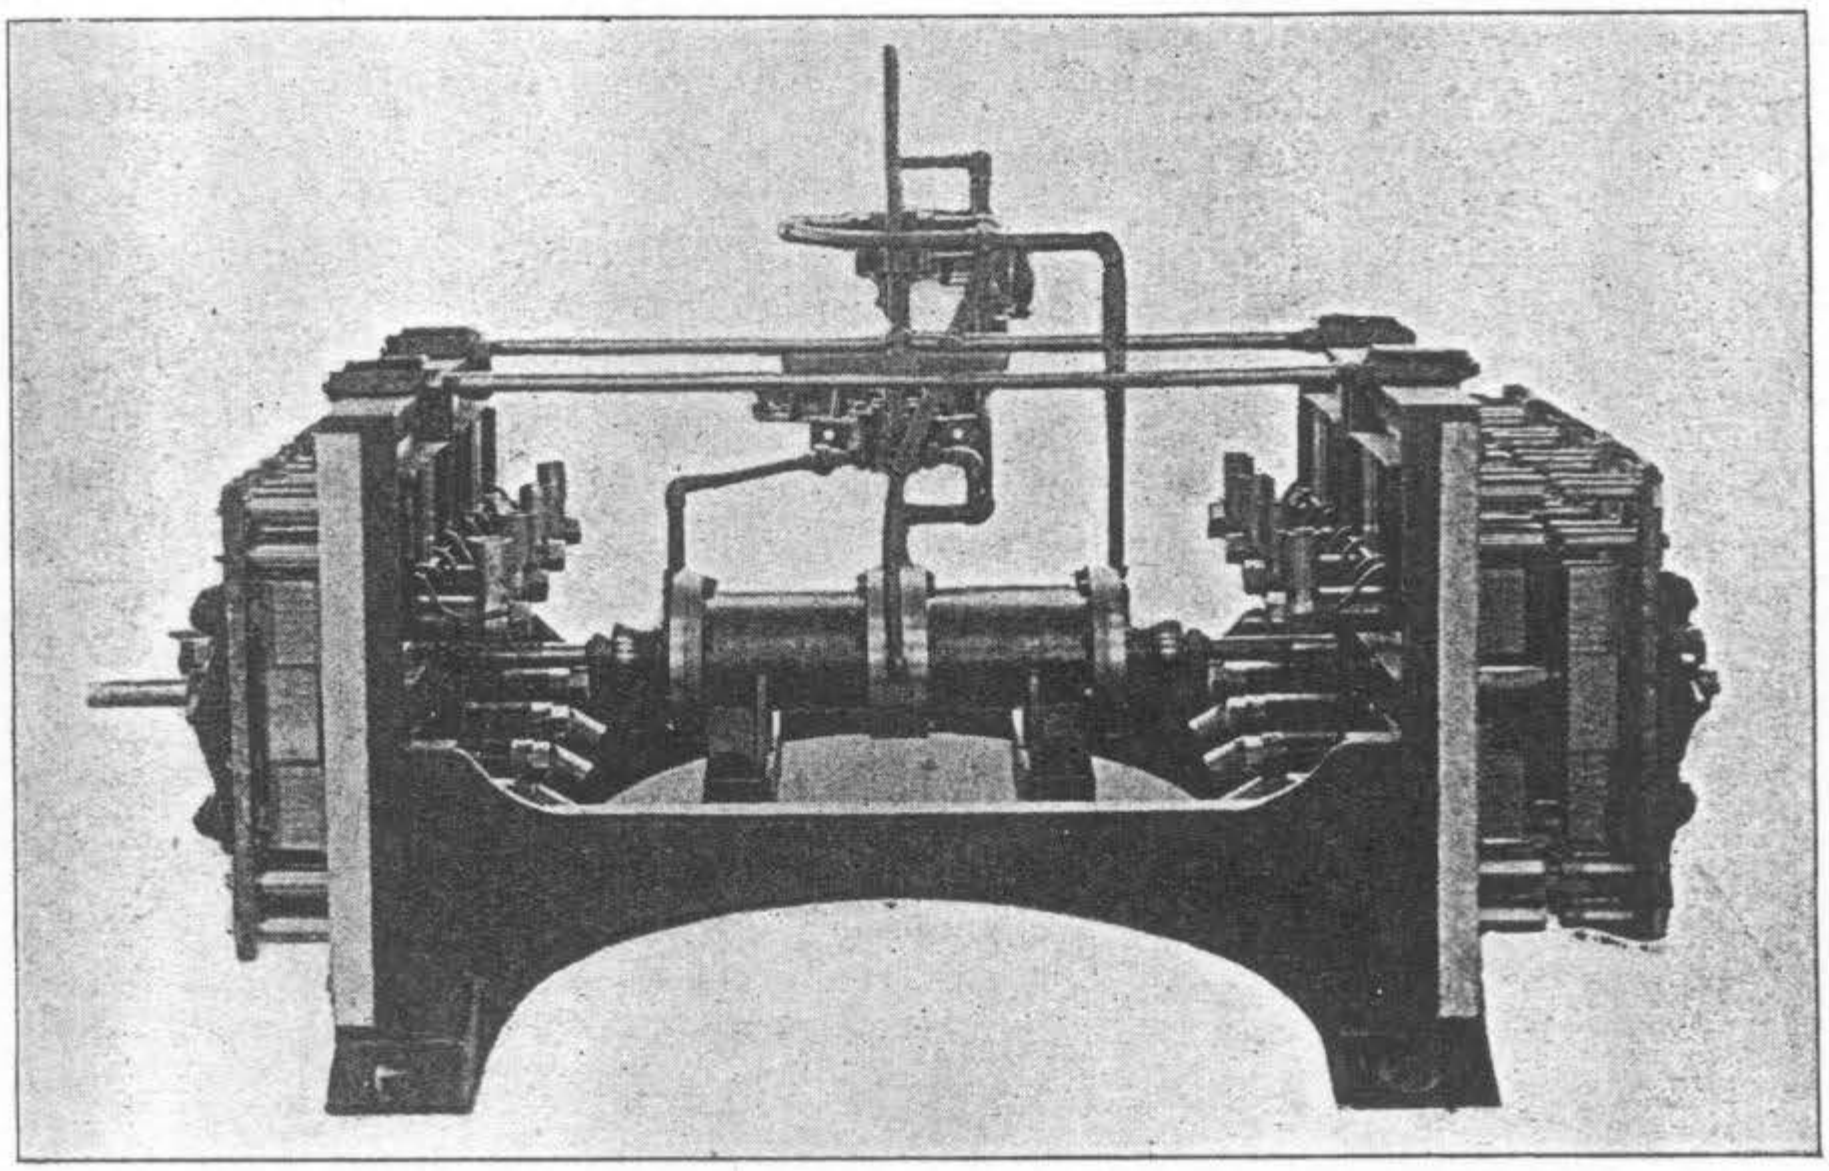


The calculated losses in a set of four bus bars conveying the full output of five generators, 25,000 electrical horse-power, are less than 10 horse-power. The radiating surface is, of course, considerably greater than it would be in the case of solid circular bars of equal section. At the ends of the bars, where the section is about 1 sq. in., the current is that coming from one generator only, and in a bar of this section the tendency of the current to seek the surface is negligible. In that part of the bar which has an outside diameter of 2 inches the current con-

veyed may be that coming from two generators, and the tendency to seek the surface would be appreciable in a solid circular conductor of equal section, while in that part of the bar which is 3 inches in diameter and which may be called upon to convey current from three dynamos, it would be very considerable. The use of the tubes instead of solid bars gets rid of the idle copper at the centre of the latter, and at the same time increases the ratio of radiating surface to section of conductor.

The construction of suitable switching devices for circuits conveying 5000 horse-power at a potential of 2000 volts is a serious problem. To be sure, the dynamos will be operated in parallel, and by proper adjustment of the field charges of the generators and the gates controlling the turbines, the current traversing the dynamo switch at the moment of opening or closing the circuit can be reduced within moderate limits. But there is always the chance that something may go wrong; the operative may make a mistake, or something else may happen, and it was, therefore, deemed necessary to construct a switch capable of opening without damage to itself or other apparatus, circuits conveying 5000 horse-power. The Westinghouse Company accordingly inaugurated a series of experiments, and detailed several expert engineers to thoroughly study the subject. The result of their work is illustrated on page 292. The opportunity has not yet been afforded to thoroughly test this switch in commercial service, but shop tests, carried out under conditions approximating to those which will be met in practical operation of the plant at Niagara, indicate that it is capable of switching very heavy currents without damage to itself, and without dangerous rise of potential.

Current for exciting the fields of the generators is obtained directly from rotary transformers, which, in turn, are supplied with alternating current from the generators, static transformers being interposed to reduce the potential. During the period of construction exciting current is also derived, when necessary, from a 75 kilowatt direct current generator driven direct by a Westinghouse compound engine. This generator and engine, together with the boiler plant for the latter, are located in a small temporary building at a distance of about 200 yards from the power house. The engraving on page 293 illustrates one of the two rotary transformers installed, and their location in the power house is indicated in the floor plan on page 283. These transformers are of 200 kilowatts output each.

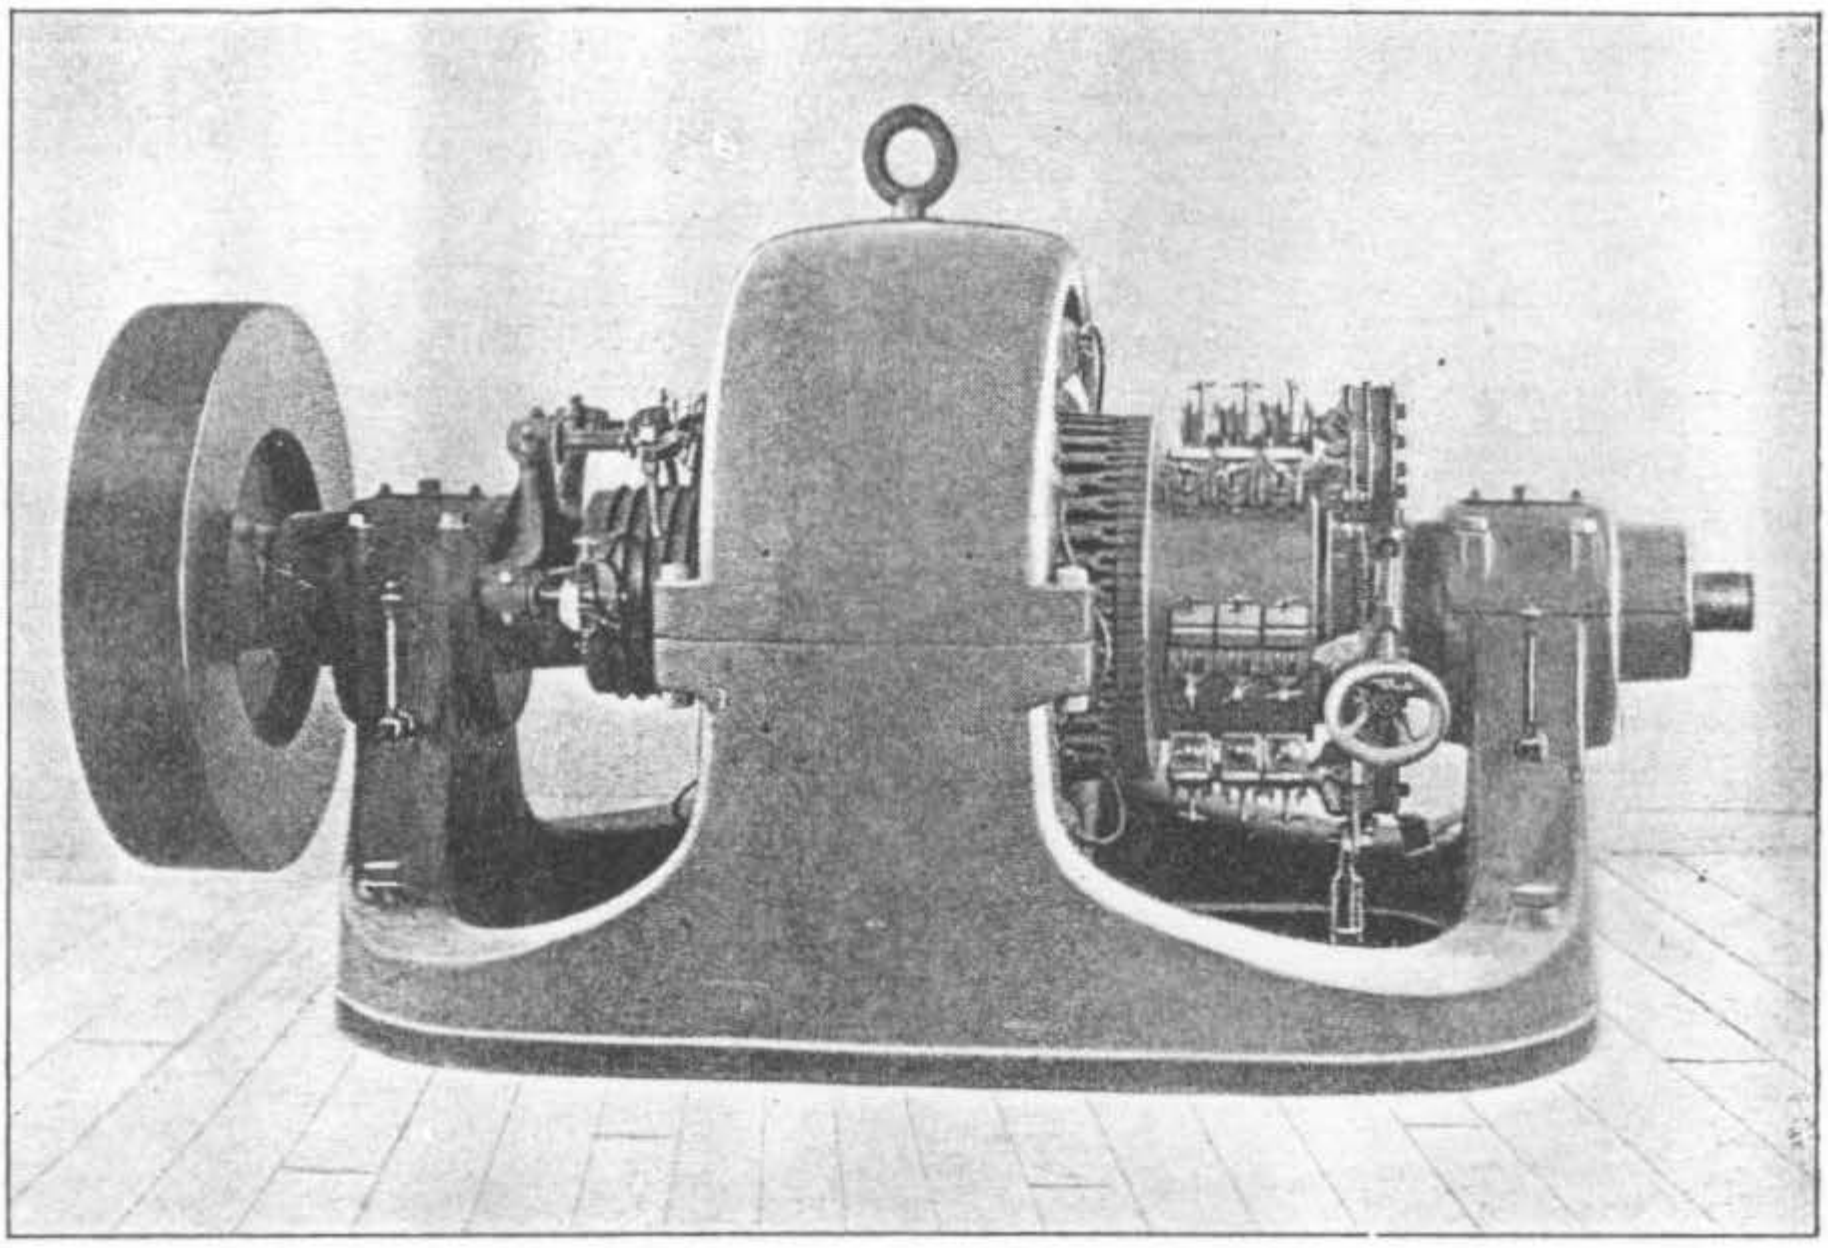


As will be seen in the illustration of the complete machine, on page 259, the shaft carries a commutator at one end of the armature and a four-ring collector at the opposite end. Alternating current, at about 125 volts potential, is delivered to the collector from the secondary terminals of the static transformers, one of which is illustrated on page 294. From the commutator end of the rotary transformer, direct current, at a potential approximating 175 volts, is delivered to the fields of the generators, the field rheostats being interposed in these circuits to permit adjustment of the current flowing in each field.

A SECTION OF THE HABIRSHAW CABLE.

The armature winding is of the closed circuit type, and each of the ring collectors is connected to a certain point in the same winding from which current is delivered to the commutator. The machine, in operation, runs as a

synchronous motor, driven by the two-phase alternating current, and delivers from the commutator continuous current, just as it would do were it driven as a generaror by a turbine or an engine. The fly-wheel at the end of the shaft is used to give steadiness of speed and to prevent what is sometimes called "pumping;" that is to say, unequal angular velocity at successive stages in a revolution of the armature, caused by the flow of idle current between the generator and the rotary transformer.



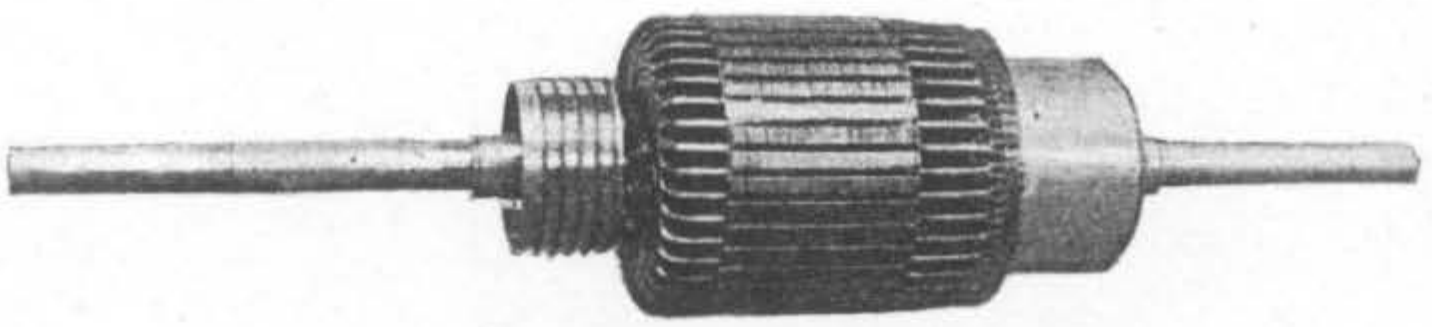
ONE OF THE MAIN SWITCHES.

Two static transformers, each capable of delivering 100 kilowatts each, are used to supply alternating current to each rotary transformer. They are placed in cylindrical boxes of boiler iron, and are immersed in oil. This secures an extremely thorough insulation. The oil is kept cool by water, which circulates through a spiral of galvanized iron pipe, fitting closely to the inside of the cylindrical box. Each box is provided with an oil gauge by which the height of oil may be determined. Provision is made for readily drawing off the oil at the bottom of the box in case of necessity. The transformer, the box, and the spiral of pipe through which the water circulates are shown on page 295.

Before the generators were erected in the shops of the Westinghouse Electric and Manufacturing Company, at Pittsburgh, careful tests were made of the materials used in the construction of the various elements of the machines. Of these, the tests of the physical properties of the shaft, field ring and driver have been referred to. The special means adopted for balancing the revolving parts of the generator have also been described. Among other tests, the following are of especial interest:

TESTS OF THE MAGNETIC QUALITIES OF THE FIELD RING.

Two samples of steel, cut from the edge of the rough-forged ring before it was turned, were tested by the permeameter method to obtain what is technically known as the B-H curve; that is, the ratio of induction to magnetizing force for various values of the latter. The B-H curve was also determined by a modification of the so-called "ring method," the entire field ring being used for this purpose. This very beautiful and interesting experiment

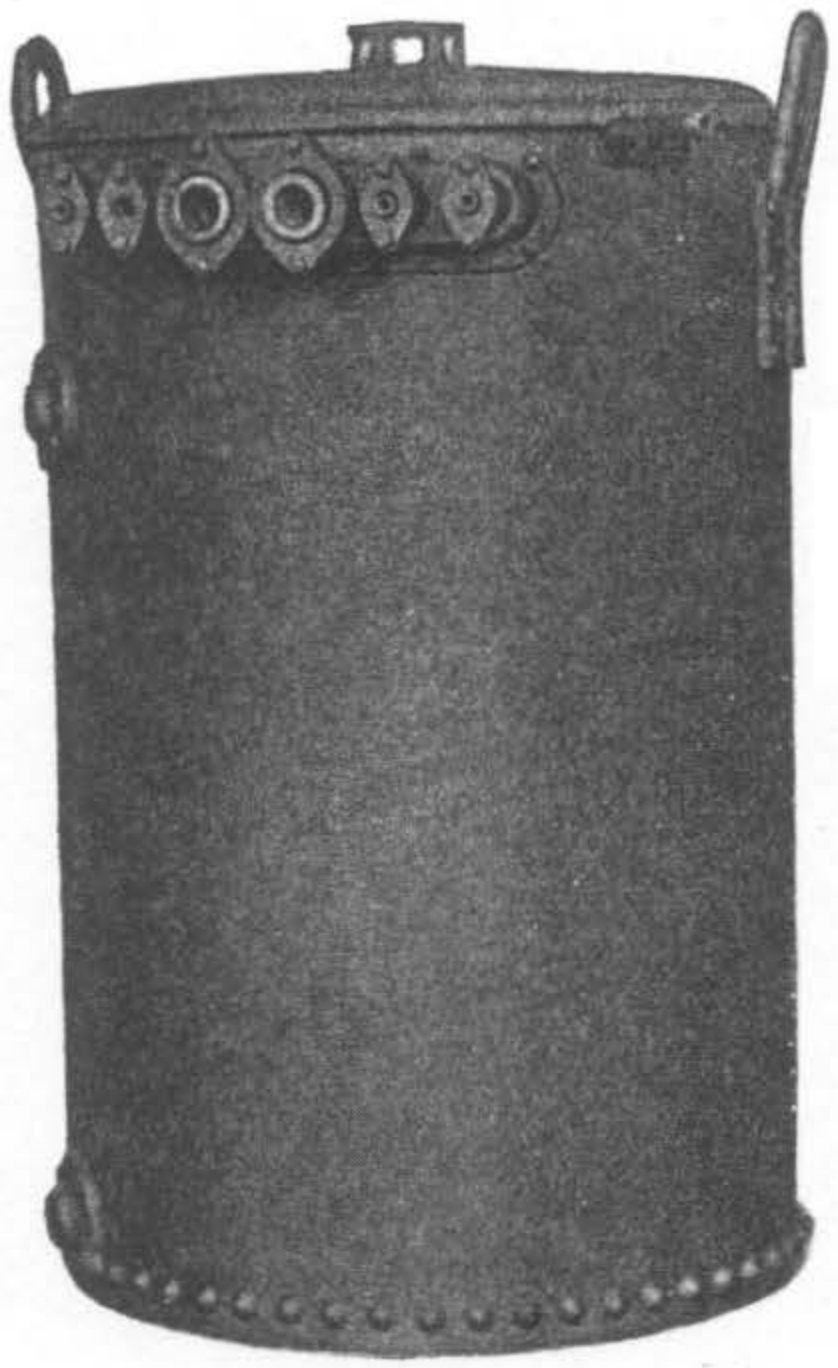


A 200 KILOWATT ROTARY TRANSFORMER USED AS AN EXCITER.

was suggested by Mr. Chas. F. Scott, electrician of the Westinghouse Electric and Manufacturing Company, and carried out under his direction.

All the measurements are illustrated graphically in the chart on page 297. Curves A and B are respectively the B-H curves for wrought-iron and cast-iron, as determined by Dr. John Hopkinson of London, and are here given for purposes of comparison. Curve C is the B-H curve for nickel, as determined by Prof. J. A. Ewing. Curves D and E are determined by permeameter from samples cut from the edge of the ring. Curve F was determined by the ring method, using the entire field ring. The very high values of the induction, for all except very low magnetizing forces, are remarkable.

The tests by the ring method indicate higher values of the induction for moderate magnetizing forces than were obtained by the permeameter. The former is the more reliable method, and curve H undoubtedly represents very closely the true relation of induction and magnetizing force in the field ring of the first generator. The permeability of the field ring is, therefore, considerably higher than that of standard wrought iron.



ARMATURE OF THE ROTARY TRANSFORMER.

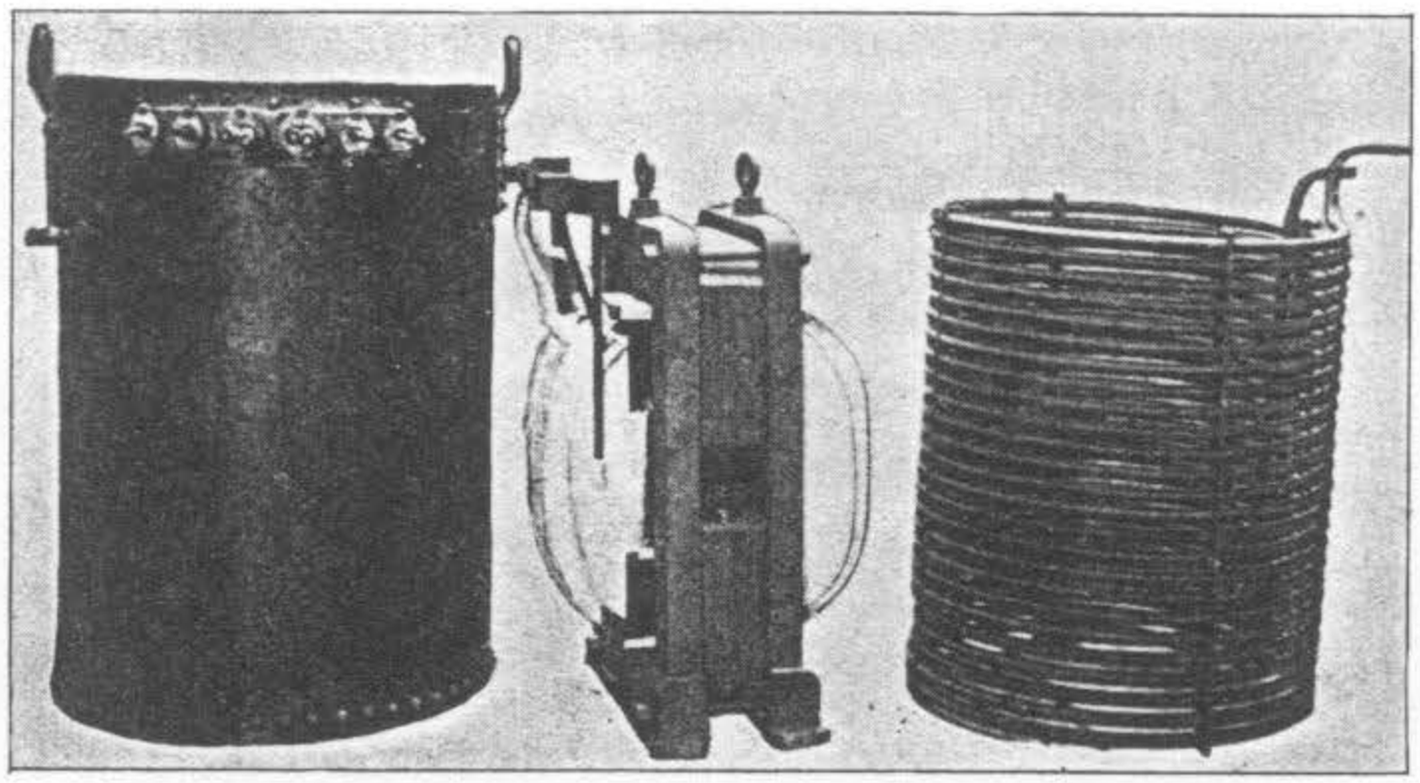
For the purpose of balancing the driver and field ring, and to make mechanical and electrical tests as complete as was practicable in the shops where no 5000 horse-power engine was available to drive the generators under full load, each machine was erected in such a manner that the weight of the

revolving element was carried upon a collar or thrust bearing at the bottom of the shaft. Into this bearing oil was forced by a pump, at a pressure approximating 1000 pounds per square inch, the result being that the collars on the shaft and the corresponding grooves in the bearing were thoroughly lubricated. The oil was kept in circulation so that it might not become excessively heated.

That the friction in the bearing was reduced within very moderate limits was demonstrated during some of the later tests, when, the driving belt coming off the pulley suddenly when the machine was running at about 250

A 100 KILOWATT TRANSFORMER.

revolutions per minute, the field continued to revolve for thirty-nine minutes by reason of its own inertia.



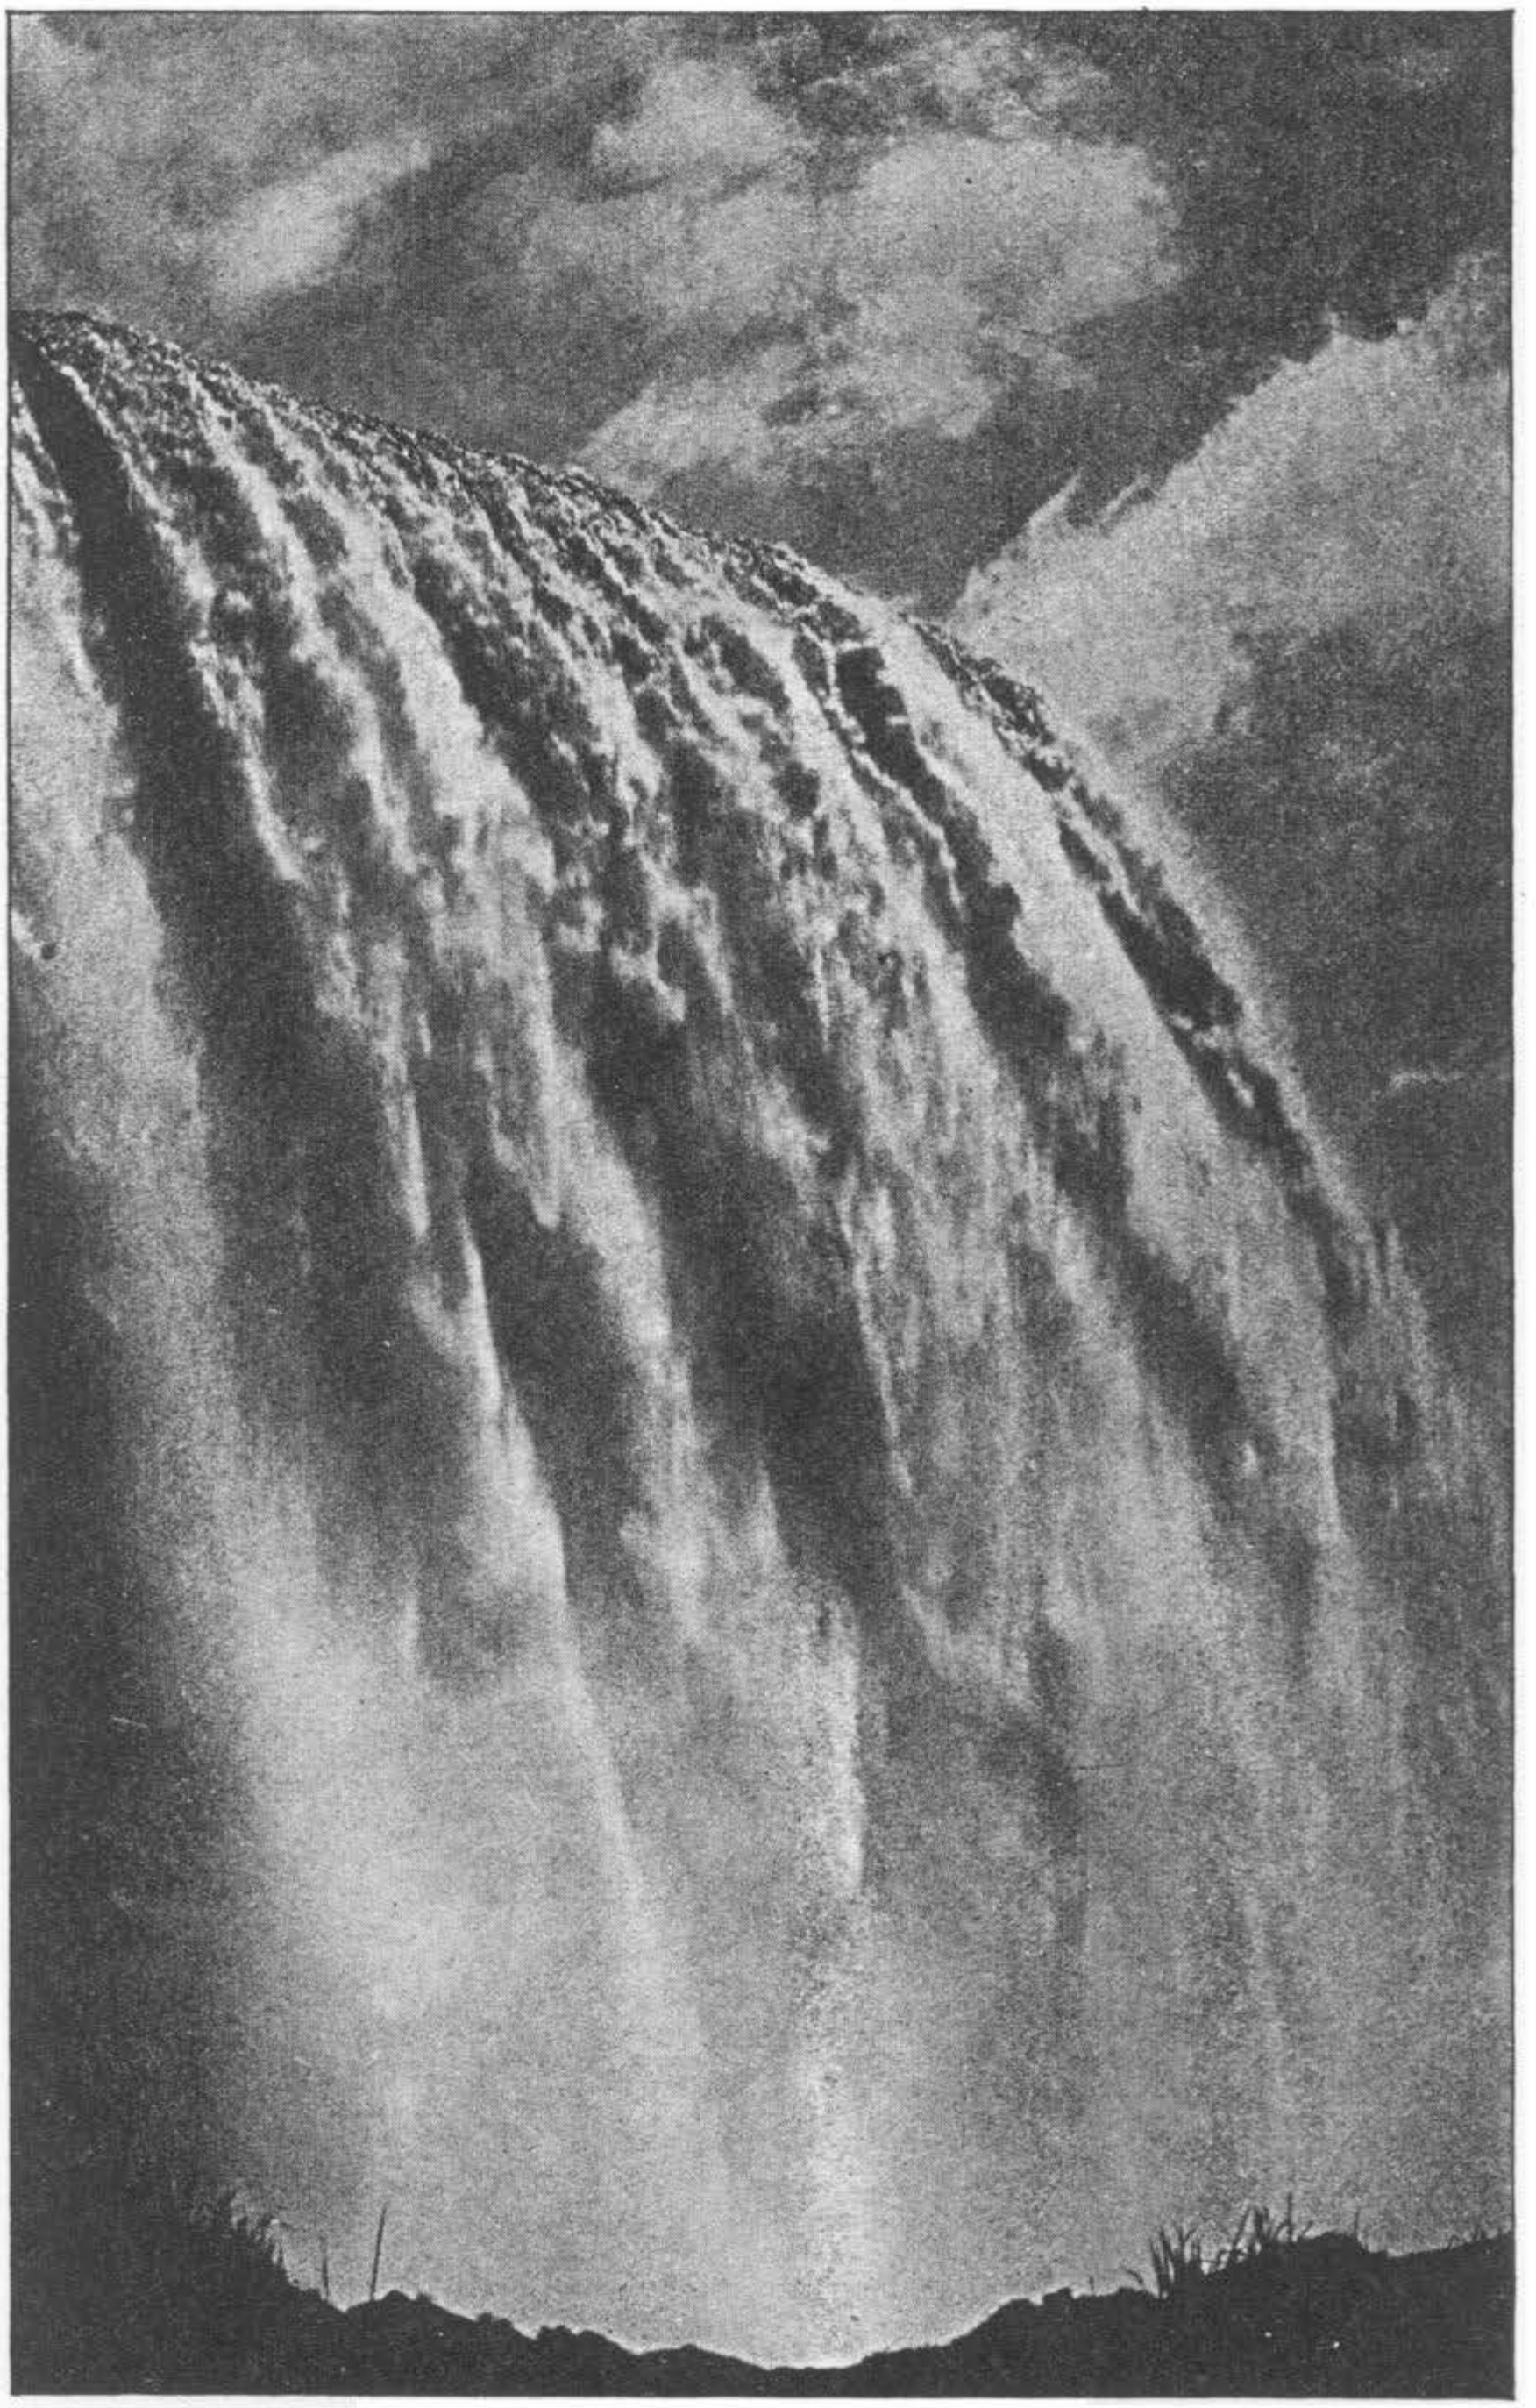
Determination of the Potential Curve.

As is now pretty well understood by those who are in any way interested in engineering, the potential at the terminals of an alternating current generator varies from zero to a positive maximum value, then to zero, then to a negative maximum value, and then to zero again, this cycle being continuously and rapidly repeated, in the case of the Niagara generators twenty-five times per second. One half of such a cycle is graphically represented by the chart on page 298, in which the solid line is the curve of potential at the terminals of the first generator, as experimentally determined. The dotted line is a sine curve, representing an electro-motive force of equal effective value. Horizontal distances, measured along the base or zero line, represent time, while the vertical distances, measured from the base line to the potential curve B, represent difference of potential at the generator terminals. At any given instant, represented by a certain point on the base line, the difference of potential is proportional to the vertical distance from that point to the curve.

In the determination of the form of the potential curve at the terminals of the first Niagara generator, a method, suggested by Mr. B. G. Lamme, of the engineering staff of the Westinghouse Electric and Manufacturing Company, was adopted, and carried out as follows: The machine being set up, as above described, a steel cable was secured to the outside of the field ring, about which it was wound to the extent of a half-dozen turns. The free end of the cable was then secured to a vertical shaft placed in a boring mill. The latter, being revolved at slow speed, the cable was wound upon the shaft, and the field of the generator was slowly revolved as the cable unwound from the field ring. In this way an extremely slow speed (about one revolution in five minutes, or one cycle in fifty seconds) was obtained.

A field charge which, at 250 revolutions per minute, would induce an electro-motive force of 2500 volts in the armature, would, at this speed, induce about 2 volts in the armature circuits. Voltmeters, capable of reading accurately to $\frac{1}{100}$ of a volt, were connected directly across the terminals of the armature, and, as the field revolved, readings were taken at intervals of three

seconds, these intervals being timed by an observer, while two others read the voltmeters, and two assistants recorded the readings. This test was repeated many times with very close agreement in the results. It is due to Mr. Scott, Mr. Lamme and Mr. McLaren, of the technical staff of the Westinghouse Company, to say that the results, when plotted to the same scale as the theo-



DETAILS OF THE 100 KILOWATT STEP-DOWN TRANSFORMER.

retical curve which they calculated before the test was made, can scarcely be distinguished from the actual curve determined by experiment.

By the efficiency of the generator we mean the ratio of electrical output to mechanical input; that is to say, the quotient obtained by dividing the amount of energy delivered to the circuits by the generator, by the energy delivered to the shaft of the generator at the top of the long shaft which connects the generator and the turbine. This quotient is expressed as a percentage of the input. The difierence between the input and output of energy is represented by the various losses in the generator.

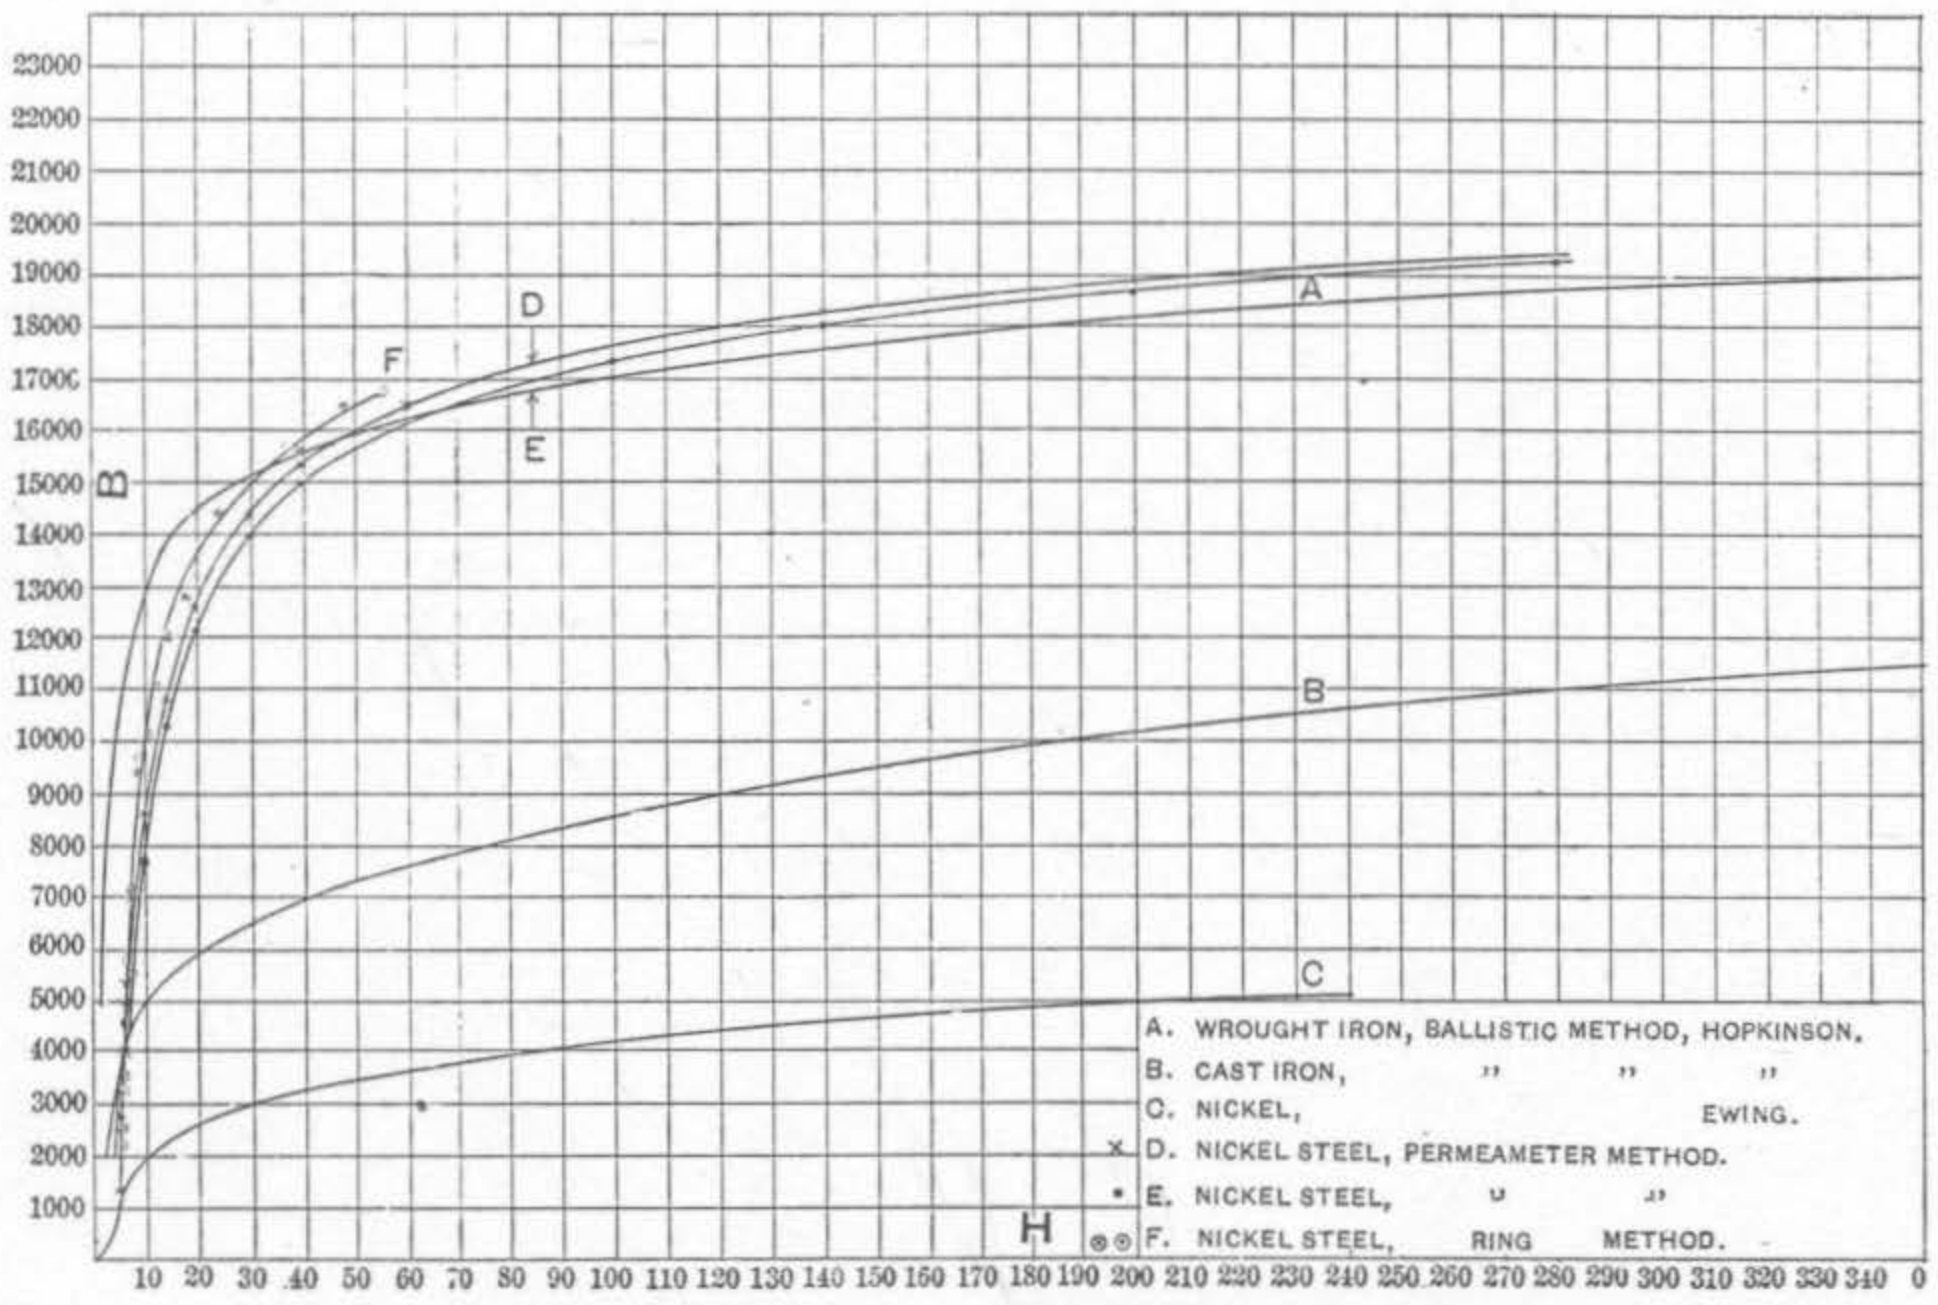
These losses are mechanical, electrical and magnetic. The mechanical losses are those due to air friction of the revolving parts of the generator, and the friction of the two bearings which guide the generator shaft. The electrical losses are those due to the main or primary current traversing the armature conductors, the exciting current in the field winding, and eddy currents which may be set up in the armature conductors, in the core of the armature, in the field poles and in the field bobbins. The magnetic losses are those due to the magnetization of the core of the armature, which is, of course, alternating in sign, and to fluctuations in the magnetization of the field. Not all of these various losses can with convenience or accuracy be segregated, but fortunately, practically all that are of special importance can be measured. Tests were, therefore, made at the Westinghouse factory which determined the efficiency of each machine with a very fair degree of accuracy. They were made with great care, and in the case of the first generator all important measurements were repeated many times. This is not the place for a complete statement and discussion of the tests made, which, in itself, would be as long as this entire article, but the methods employed and the results obtained may be briefly summarized.

As the generator was erected in the shops, the revolving element was sustained, as already stated, by a collar or thrust bearing. A direct current motor, capable of delivering 200 horse-power, was used to drive the generator, the motor being turned upon its side, so that the shaft, supported upon a thrust bearing, was vertical, and, therefore,

THE AMERICAN FALLS AT NIAGARA.

parallel to the shaft of the generator. The field of the direct current motor was independently excited, and readings of the current and potential, delivered to its armature from a direct current generator, driven by an engine, were taken in a series of tests, which were repeated several times during a period of about two weeks. The results show that when the field of the generator was not charged by exciting current, it was necessary to deliver to the motor 76 horse-power to drive the generator field at a speed of 250 revolutions per minute. The belt connecting motor and generator being taken off, 26 electrical horse-power were required to drive the motor at the same speed as before. The difference between these two quantities, or 50 horse-power, represents the mechanical friction in the generator, made up of air friction, the friction of the two bearings which guide the shaft, the friction of the step-up or thrust bearing at the bottom of the shaft, and also the loss in the belt, which was necessarily kept very tight. Just what this belt friction, and the increased friction in the bearings, due to tightness of the belt, amounted to could not be easily determined, nor was any attempt made to segregate the loss in the thrust bearing from the other losses.

This loss in the thrust bearing is not properly chargeable to the generator, since the machines, as erected at Niagara, have no thrust bearing above the point in the shaft where the power is delivered to the generator. It can safely be said, therefore, that at Niagara the total mechanical losses in the generator will be less than 50 horse-power, —that is, less than one per cent. of the power required to drive them.



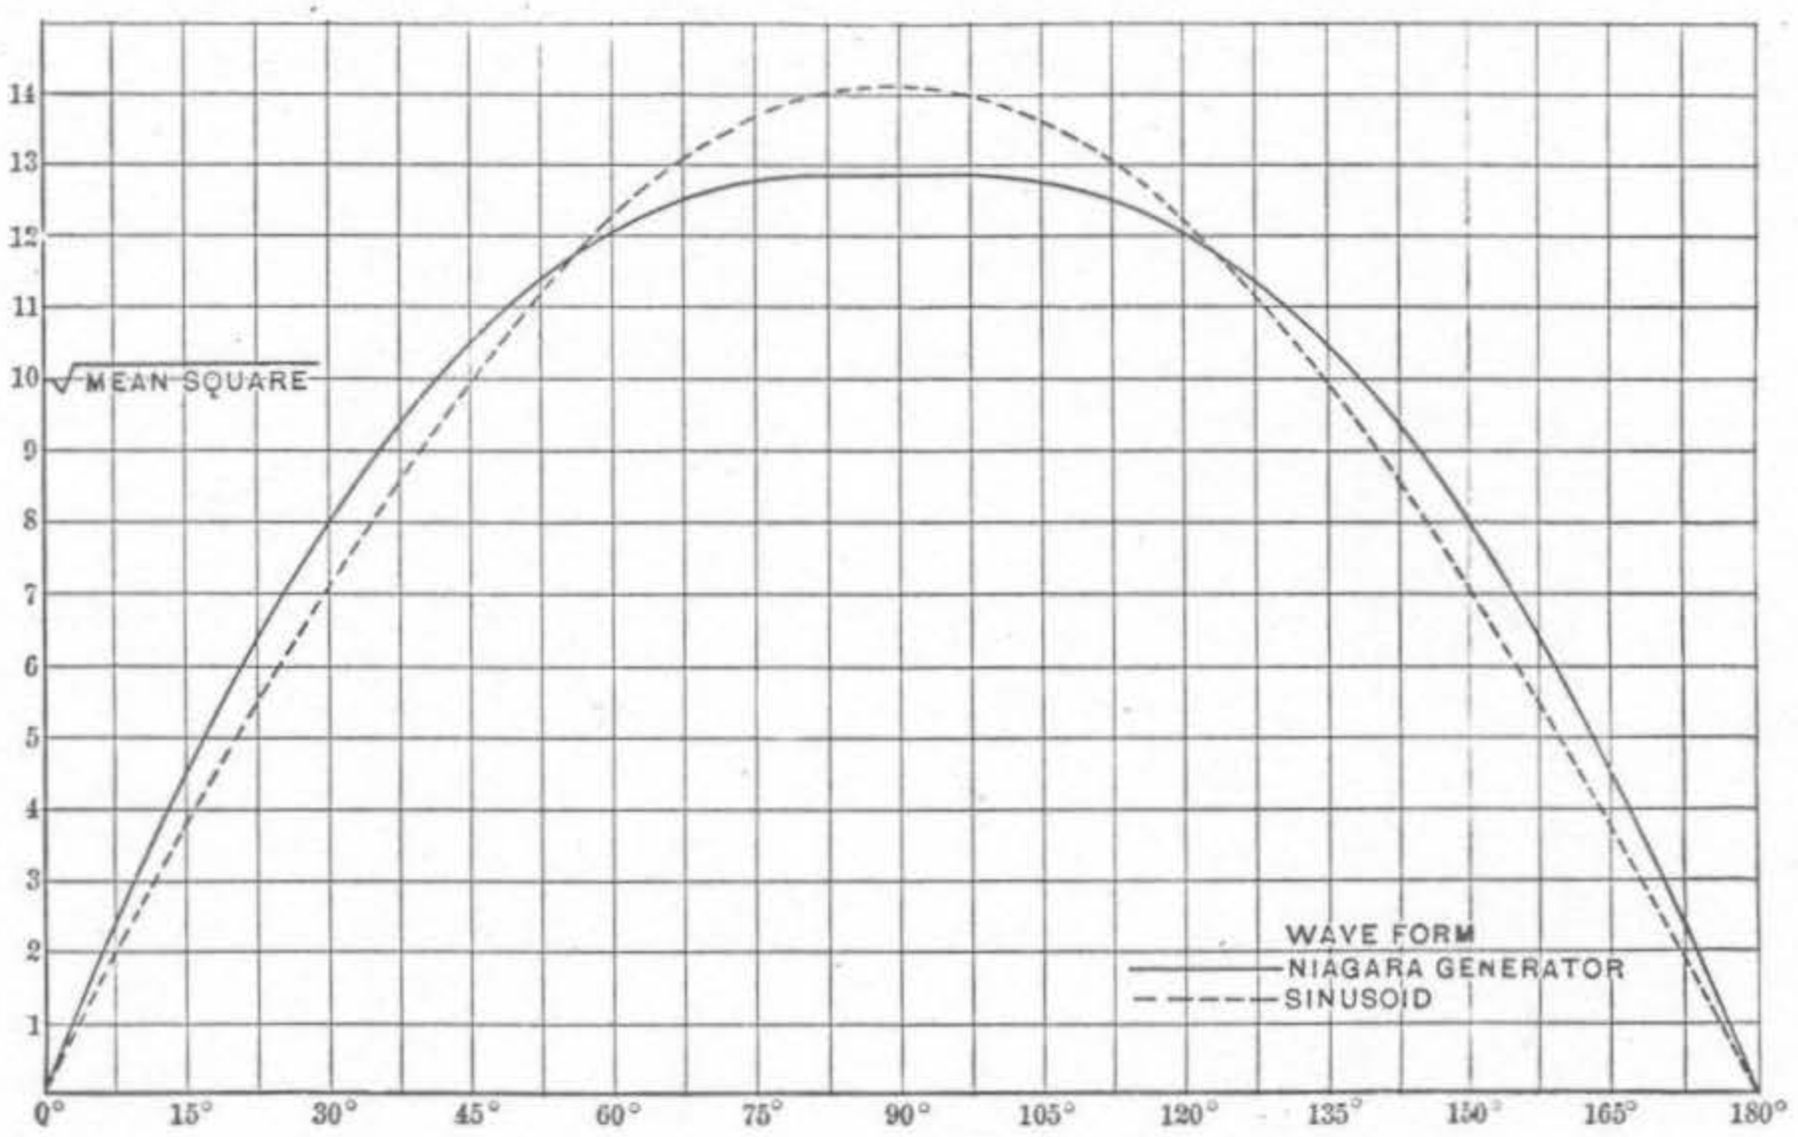


CHART SHOWING THE MAGNETIC QUALITIES OF THE FIELD RING.

The determination of the amount of energy represented by the current which excites the field of the generator is easily made. The method employed was to charge the field, beginning with a very small current, and increase this by successive steps until the potential at the terminals of the armature, at a speed of 250 revolutions per minute, approximated 3000 volts, taking at each

step simultaneous reachings of the current in the field, the potential at the field terminals, and the potential at the armature terminals. The field current was then gradually reduced, simultaneous measurements being taken as before of the current in the field, the potential at the field terminals, and the potential at the armature terminals. In this way the field current required to induce in the armature, without load, any given electromotive force not less than 500 volts and not greater than 3000 volts, was determined. From this the field current which corresponds to any armature potential when the generator is loaded,—that is, when the armature is delivering current,—can be determined with close accuracy by calculation.

With some types of machines this would not be so easily done, but in these generators the relations existing between the armature and field are similar to those which exist in many of the large generators employed in street railway service, and in making the calculation, therefore, we are not far removed from the safe basis of experimental fact. In this way it was determined that under conditions which will exist at Niagara, the field current in each generator under full load will in no case exceed 15 horsepower.

The next loss to be determined is that due to the magnetization of the armature core. This is made up of two factors, but for our purpose, these need not be differentiated from each other. The test was made as follows: The generator being driven at a speed of 250 revolutions per minute by the direct current motor, measurements of the electric energy delivered to the

THE POTENTIAL CURVE FOR ONE OF THE GENERATORS.

latter were made coincidently with measurements of the potential at the terminals of the generator armature. As the current in the field of the generator is varied, by adjusting resistance in its circuit, the magnetization of the armature, of course, varies, and the potential at its terminals is a measure of the magnetization, or, more strictly, induction in the armature core.

As the magnetization increases, more power is required to revolve the field, the difference in the power delivered by the motor to the generator for any given potential at the armature terminals (that is, for any given degree of magnetization), and the power required to drive the field at the same speed with

no magnetization being accounted for by the core loss. As already stated, the energy required to drive motor and generator, as determined in the case of the first machine, is 76 horse-power, and by subtracting this amount from the amounts required to drive the generator with any given magnetization in the core, we have a closely accurate measure of the loss.

In this way it was determined that the amounts of power delivered to the motor, corresponding to potentials at the armature terminals varying from 2000 to 2400 volts, were as follows :

2000 volts	121 − 76 = 45	horse-power
2200 "	130 − 76 = 54	"
2400 "	141 − 76 = 65	"

Were the armature in service, delivering currents representing the full output of the machine, the distribution of the magnetic lines in the armature core would be somewhat, but not very radically different, and consequently these measurements do not tell us exactly what the loss in the core will be under conditions of actual service. But, making a fair allowance for an increased loss due to this and other minor causes which may make themselves felt in the commercial operation of the generator, it would seem safe to say that the loss in the armature core, operating at 2100 volts, which is about the voltage at which those generators supplying local service will be operated, will not exceed 60 horse-power.

The loss due to the current in the armature conductors could not be accurately determined from tests in the shop. This loss, however, is easily calculated with close accuracy from measurements of the resistance of the armature conductors and the known value of the full load currents which they will carry in service. Disregarding possible eddy currents in the conductors, which, from the construction, should be almost negligible, calculations show that the loss in the armature conductors under full load will not exceed 30 horse-power. Theory indicates that other losses, with the possible exception of eddy currents in the field poles, will be so small as to be practically negligible, and including the loss in the field poles, which could not be readily determined, their amount will not be sufficient to materially affect the efficiency of the generator.

To sum up the mechanical, electric and magnetic losses, when the generator is delivering current at 2100 volts, we have roughly the following:

Maximum loss in field copper	15	horse-power
Loss in armature core	60	"
Loss in armature conductors	30	"
Total	105	"

To arrive at the actual efficiency of the generator we must add to this the losses due to air friction and friction of the bearings, but the tests do not indicate to what these amount, except that with the loss in the thrust bearing used during the shop tests they did not exceed 50 horse-power. With the losses in the thrust bearing charged against the generator (which is, of course, unfair to the machine) we have for the total mechanical, electric and magnetic losses 155 horse-power. In order that the generator shall deliver 5000 horse-power to the circuits it is, therefore, necessary that 5155 horse-power be transmitted to it through the shaft. Dividing 5000 horse-power, the output, by 5155 horse-power, the assumed input, we have almost exactly 97 per cent. From all this it appears perfectly safe to say that the generators, under the conditions of commercial service, will, at full load, operate at an efficiency exceeding 97 per cent. At the time of writing this, the tests of the generators as erected in the power house at Niagara are not yet completed.

The description of the electric generating plant in the foregoing pages is necessarily incomplete. Much that would interest scientific specialists is omitted or merely glanced at, and on the other hand, space and time have not permitted the attempt to elucidate statements which, to those not familiar with electric work, must appear more or less obscured by technical phraseology. This I cannot hope to amend.

The tests of the first 5000 horse-power unit are now in progress, and success is assured. When, on the

morning of April 4th, 1895, Mr. Rudolphe Baumann, the Swiss engineer, who has for several years devoted his skill and energy to perfect the hydraulic plant, gently moved the hand wheel which controls the first turbine, the field of the generator began to revolve, noiselessly, irresistibly, testifying to the skill and painstaking effort of the civil, hydraulic, mechanical and electrical engineers, whose combined efforts, directed by the splendid enterprise of the Cataract Construction Company, have united in producing a 5000 horse-power unit of machinery, capable of transforming the energy of falling water to electric energy, live, vibrant, needing only suitable conductors to guide it across miles of country, to places where it may turn the wheels of a thousand mills and factories.

The Niagara generators were constructed by the Westinghouse Company, following, as regards mechanical form, the type of machine proposed by the engineers of the Cataract Construction Company. This was fully described by Prof. George Forbes in a paper read in November, 1893, before the British Institution of Electrical Engineers. The auxiliary electric apparatus, including exciters, switching devices, measuring instruments, etc., were designed and constructed by the Westinghouse Company, assisted, as to the bus bars, by the Brown & Sharpe Manufacturing Company, of Providence, R. I., U. S. A., and the India Rubber and Gutta Percha Insulating Company, of New York.

Among those who have been particularly prominent in the work are: Mr. Albert Schmid, general superintendent; Mr. C. F. Scott, electrician; Mr. Philip Lange, superintendent; Mr. O. B. Shallenberger, consulting electrician; Mr. B. C. Lamme, Mr. E. C. Means, Mr. H. P. Davis; Messrs. Sigfried, Wright, Boegel, W. F. Lamme, Beinitz, Alberger, Mirault, Friedlander, Strauss, Mould and Parks. To Dr. Coleman Sellers, president and chief engineer of the Niagara Falls Power Company, and Mr. De Courcy May, late superintendent and engineer of the Cataract Construction Company, who, in consultation with Mr. Schmid and his assistants, made many valuable suggestions, the thanks of the Westinghouse Company are also due.

THE DOGMATISM OF SCIENCE.

By Mrs. Bloomfield Moore.

Henry Thomas Buckle, in a paper read at the weekly evening meeting of the Royal Institution of Great Britain, Friday, March 19th, 1858, said that "an exclusive employment of the inductive philosophy was contracting the minds of physical inquirers and gradually shutting out speculations respecting causes and entities; limiting the student to questions of distribution, and forbidding to him questions of origin; making everything hang on two sets of laws, namely, those of co-existence and of sequence; and declaring beforehand how far future knowledge can carry us. But," added this great man, "we shall not always be satisfied with seeing the laws of nature rest on this empirical basis; and the most advanced thinkers are looking to a period when we shall deal with problems of a much higher kind than any yet solved; when we shall incorporate mind and matter into a single study; when we shall seek to raise the veil and penetrate into the secret of things."

No man nor woman of intelligence, who is conversant with the writings of "the most advanced thinkers" of our age, can fail to see that this time is near at hand; and yet dogmatic science refuses to put itself in a position where it could announce that the veil is already raised, and, to quote the words of Prof. Lascelles-Scott[1], that "the door which

[1] Physicist at the Government Physical and Chemical Laboratories, Forest Gate, Essex.

prejudice has declared to be shut and bolted is even now ajar, and gleams of light are struggling over the threshold from Keely's discoveries."

Of course, new hypotheses should not meet with too ready an acceptance, and the professor, with admirable caution, takes the text of his review of "Keely and His Discoveries," from the Syracuse philosopher—Epicharnus—"The very nerves and sinews of knowledge consist in believing nothing rashly." But with such evidence as he sets before his readers (in the October number of THE NEW SCIENCE REVIEW), the determined blindness of dogmatic science should not be permitted to delay, to another century, the general promulgation of truths which have been already established by the testimony of some of the most distinguished American men of science of this age. The fact that there are, as yet, no commercial profits from Keely's discoveries is all that retards the promulgation of these truths; but the law allows no patents on new truths nor on a principle of nature. Until the vibratory circuit, operated by this costless current of force drawn direct from space, is connected with some patentable device, Keely's discovery has no more commercial value than Newton's discovery of gravity. Therefore, as science still denies the fundamental doctrines on which this new system of physics is based, the only hope lies in the prolongation of Keely's life until commerce, instead of science, is able to make the announcement; unless the press, with its gigantic power, lends itself to the efforts now being made to bring before the public the present position of Keely in his great work of evolution. Of another discoverer of unknown truths the poet Cowley wrote:

"Bacon, like Moses, led us forth at last;
The barren wilderness he passed;
Did on the very border stand
Of the blest, promised land;
And from the mountain's top of his exalted wit,
Saw it himself, and showed us it.
But life did never to one man allow
Time to discover worlds and conquer too."

Scientific caution is necessary at all times, and more especially so with discoveries which antagonize the established order of what is supposed to be scientific truth. But of quite a different nature is that stolid and contemptuous indifference manifested by those "lights of science," who consider it derogatory to their dignity to interest themselves in an examination of claims that, if proved to be true, would revolutionize the accepted dogmas of science. When Italy was disturbed by Galileo's discovery, the same thing occurred. It was a professor of the University at Padua who refused Galileo's invitation to look through his telescope and obtain proof of his assertion that "the world moves."

The world of thought moves faster than in the days of Galileo. Under the pressure of outside opinion and the gradual infiltration of new truths, men of science will, in the end, be awakened into honest and serious attention to Keely's claims. New truths pass more quickly, now than formerly, through stages of blind, unreasoning opposition. This improvement does not spring out of any change in human nature in scientific men, for their "good-fellowship," among themselves, is never extended beyond those researchers who maintain orthodox views and support each other in their claims.

The hope of Keely's life being prolonged "to conquer too" (nearly three score years and ten as he is now), would be much more likely to be realized if the certainties of the scientific value of his discoveries were made known more widely, together with the *uncertainties* of his living to complete all that is necessary before there can be any financial gain therein.

Notwithstanding the persistent denial of physicists, who have not examined into Keely's claims, the advancing wave of interest in his work cannot be kept back, for it will be sustained in its course by the ever-increasing pressure of a larger outside public of intelligent and interested minds, not wedded by long association of thought to special systems, and having no motives of self-preservation prompting them to repel what appeals to their intellectual capacity of

comprehension with much greater force than to minds educated on rigid lines of thought, as is the mind of the physicist. Such minds, says Hovenden, from the necessities of the case, are the least capable of solving a problem which can only be solved by views that are foreign to the fundamental ideas in which the physicist has been educated.

The distinguished men of science, Profs. Leidy, Brinton and Koenig, who investigated Keely's work in 1889–90, testing the current of force produced with the most sensitive galvanometer of the University of Pennsylvania, publicly asserted that it was free of electricity, magnetism or any known force—scoffing at the less than school-boy knowledge, which had, in 1876, pronounced it to be compressed air.

Ricarde-Seaver, an European electrician, who, after investigating, returned to London and gave testimony in favor of the discoverer, was asked to withdraw his name, when the balloting was about to take place for membership at the Athenæum Club, by the very man of science[1] who had proposed him sixteen years before, the only reason given being his espousal of Keely's claims as a discoverer.

Such an experience (and more notably the recent experience of Prof. Oliver J. Lodge) proves that the founder of new systems must look to the power of the press, which is greater than that of the sword, when help is needed in making known to the world the importance of newly-discovered truths not accepted in general by those whose canons they controvert.

One of the most widely-known English physicists,[2] who for more than ten years has followed Keely's progress in his experimental researches, when asked in 1891 why he was not willing to make public his views of their nature, replied: "If I am called before a bar of justice to give testimony, I am cross-questioned by judge and counsel. It is the same at the bar of science. I cannot say what I think. I must say what I know, what I believe, what I have seen."

[1] Lord Kelvin.

[2] Prof. Dewar, of The Royal Institution of Great Britain.

As long as the so-called "Lights of Science" hold the attitude that they take toward lesser lights, who are interested in Keely's work, no physicists of note can be expected to interest themselves in Keely's claims publicly.

Prof. Lodge, in closing a recent article, "Unusual Physical Phenomena," writes: "And now, finally, let me disclaim all missionary spirit in this long exposition. The business of a scientific man is the pursuit of natural knowledge and the imparting of such portion of it as has by long trial become recognized and orthodox—*i. e.*, such portion as people are willing to receive. For I need hardly remind the reader that at one time the science of nature, or physics itself, was very far from being orthodox, and that in past days promulgators of any new truth had to pass, not through the fire of a little friendly badinage and ridicule, but through fire of a much fiercer and more searching character; unless, indeed, they recanted their 'errors.' Instruction in orthodox branches of science is now permitted to youth; an unorthodox department of knowledge may have to wait many years before instruction in it can be willingly received, even by adult and experienced minds. Let it wait! The instinct of an investigator and teacher is to set forth, as best he may, such natural truth as he is able to perceive—such truth as the interworking of his era and his opportunities have revealed to him—and there he must leave it. For its reception by the human race, he is not responsible.

"The universe is not so simple a matter as men in this century have been apt to think. *All we ask for on the part of our contemporaries is an attitude of mind willing to give to new truths a chance of life. If it be of God, they cannot indeed ultimately overthrow it; but they may, by determined blindness, seriously delay its coming, and entirely prevent its reception in their own age.*

"I ask for no hasty belief. No one can usefully believe things of which he has had no experience. He may say that the statements of those who support them are or are not entitled to respect, and that, if he were forced by a pistol at his head to take sides prematurely, he would range himself

on one side or the other; but till he has had some sort of first-hand experience his belief and his disbelief are equally worthless, except in so far as they may lead him to devote some portion of his time to a study of what has been recorded on the subject, and to an unprejudiced, critical contemplation of whatever phenomena may in the progress of events unfold themselves before him."

The public is now asked in the same spirit to give attention to Keely's present position in an unorthodox department of true scientific research. The long course of experiments made by English and Continental physicists in the case of the medium Eusebia, seems to have proved nothing more than that obsession did not cease with the days of the Apostles. In fact, Mr. Keely is opposed to these mediumistic experiments with subjects possessing abnormal will power. Hypnotism, animal magnetism, suggestion, etc., he considers are so little understood in their workings, that it is like an obstruction placed on a railway track: the engine may dash it aside, or it may wreck the train. The experimental researching of Keely, in manifestations of will power, is of an entirely safe nature, made with dynamic apparatus instead of on the human brain and the physical organism.

Since the insults to which he was subjected several years ago by a professor of physics who visited his work-shop, Mr. Keely has refused to make explanations of the operations of his instruments to those physicists who have reluctantly condescended to inspect his aerial navigation machinery, preferring to wait until the propellor is able to speak for itself. At present, however, for certain business reasons, it has become necessary for him to explain the operation of the machine, and Dr. Tuttle, physicist at the U. S. Mint in Philadelphia, has been chosen to receive this instruction. The series of experiments which Mr. Keely was preparing to give (as set down on page 464 of the April number of THE NEW SCIENCE REVIEW) before an expert committee, will therefore be made before Dr. Tuttle; but no public announcement will follow on account of the business complications alluded to.

It has become evident that an authoritative public announcement of the completion of Keely's long work of evolution, in a machine adapted to navigation of the air, would facilitate stock jobbing operations. That such undesirable results may be avoided, this statement must be delayed until Mr. Keely's plan of reorganization of the old Keely Motor Company has been accepted by the shareholders of its stock, and a settlement made with them, as set down in his circular No. 1. (The circular will be found in the advertisement pages of this number of THE NEW SCIENCE REVIEW). When Mr. Keely has effected this settlement and completed his railway traction engine, then, and not before, will the stock of the Keely Motor Company possess marketable value. The expert American electricians and engineers, who were to have formed the committee of investigation, prefer to wait until this is accomplished, lest their names be used to facilitate Wall street operations in Keely Motor stock.

Mr. C. W. Baker, of *Engineering News*, upon withdrawal of the invitation that had been extended to him (in accordance with an intimation from him that he would like to pursue the subject farther than he had been able to do), expressed his regret that the plans formed for giving a wide publicity to the result of the demonstrations had been frustrated from want of coöperation on the part of the Board of Directors of the Keely Motor Company. Nikola Tesla, for reasons that need not be explained, would not have been able to serve on the committee. It is well known that he is striving to draw power from space by purely scientific methods, which Keely succeeded in doing in 1893 by "unscientific methods." An earnest effort has been put forth to induce this distinguished man of genius to acquaint himself with Keely's system of aerial navigation, in order that he may more quickly attain one of the goals he is aiming to reach—that of producing light devoid of heat.

It is now a number of years since Mr. Tesla crossed the border line of the circle in which all other electricians are working, on their treadmill round, but he still remains in the interatomic field of research, apparently unmindful of

the triple conditions that govern electricity in the relation which it sustains, in that field, to the first order of the luminous.

Tesla's great penetration may enable him eventually to attain his aims on orthodox lines of research; but, in the writer's opinion, were he to acquaint himself with Keely's system of resonance, it would be but a short time before he could induce electrical alternation of such an intense degree as to produce a light as susceptible to the retina as is solar light. Even should Tesla succeed in drawing power from space, on his own line of research, his position would still be remote from all the conditions governing magnetic and electric phenomena in the sympathetic field, where Keely has solved the problem of navigation of the air. Keely calls this realm the interetheric or celestial, in contradistinction to the terrestrial or interatomic realm, which Tesla is researching. The terrestrial sympathetic forces are subservient to the celestial sympathetic. Tesla stands as it were on the bridge which connects the primary two-thirds of the electric stream—the subdominant current with the dominant. Even should he hook on to the dominant, he would still be subserved to the terrestrial neutral; far in the rear of sympathetic union to radiating celestial outreach,[1] the connecting link of which exists in the interluminous, and remote from all the conditions that govern electricity sympathetically. Therefore Tesla is wrong when he says that "electric phenomena and ether phenomena are identical;" nor will he arrive at a true conclusion, as to the relation or association of the two, until he has brought about an alter-

[1] The sympathetic outreach of negative attraction is born of the celestial and impregnates every mass that floats in space, seeking out all magnetic or electric conditions. All these masses are subservient to celestial outreach It is the power that holds the planetary masses in their orbital ranges of oscillatory action. Magnetism is static. Sympathetic negative attraction reaches from planet to planet, but electricity does not, nor does magnetism.

All the magnets in the world could not induce rotation, no matter how differentiated, but polar negative attraction induces rotation, as exemplified scores of times in an insulated compass-needle before the professors of the Pennsylvania University in 1890. (See page 279, "Keely and his Discoveries.", The Transatlantic Publishing Company, 63 Fifth avenue, New York.)

nation of that intensity which induces light visible to the eye. Even then he will not have reached the compound interetheric—the border line to the introductory luminous.

It is evident that Tesla already comprehends the law governing transmission and dissociation in electrical alternation with regard to its reception by the physical organism, whereby an increase of the number of volts that prove fatal to life are harmless, and given without any risk to the subject. The ear is not susceptible to the vibrations of inaudible sounds; nor the eye to those of light beyond the number necessary for sight. A wheel having five spokes and making ten revolutions per minute gives fifty alternations on the spokes, which are readily counted by the eye; whereas an increase in the revolutions, to five hundred in ten minutes, increases the alternations of the spokes beyond the power of the retina to receive and count.

It is the same with electrical alternation in regard to its receptiveness by the physical organism. Phenomenal as it may seem to those ignorant of the fact, this is a standard truth in sympathetic physics, which Tesla's penetration did not fail to discover. The plane of research that he occupies in regard to electrical phenomena, is as much above that of his fellow electricians as is the plane occupied by Keely (in researching the problem of aerial navigation) beyond the realm in which those inventors are working, who are constructing balloons and flying machines on various principles, while still ignorant of a force in nature that is antagonistic to gravity and overcomes it; thus making navigation of the air, with ships of thousands of tons burthen, both possible and perfectly safe.

Electricians will no longer remain captive in their domain when Keely's system is published to the world; as it will be when he has effected the settlement that he seeks. If this settlement is not effected, without the delay of litigation, his secrets will die with him, in all probability, for no one but himself knows the process by which dead metal is sensitized so as to be operated upon, as the brain is operated upon by celestial radiation.

Were Tesla and Edison brought to a proper appreciation of Keely's methods, were they to make themselves acquainted with his system of sympathetic physics, what might not be expected of them in view of their brilliant achievements on a lower plane of research? The march of science would then be a triumphal one indeed.

Let Keely be known to Tesla and Edison as the "great discoverer" which Professor Koenig called him in 1891, and the press will then be ready to publish what has already been accomplished for science. This can be done without affecting the stock market, as long as there is no engine to base speculation upon. Why should science wait upon commerce? Is it not enough that "the whole world problem" is solved by this new system of physics, demonstrating, as it does by dynamic apparatus, the truth of Professor Ladd's words in his recent work, "Body and Mind," when he says, "The Being of the world, of which all particular beings are parts, must be so conceived of as that in it can be found the One Ground of all interrelated existencies and activities."

The cosmical law of sympathetic association, as set down in Keely's system of Vibratory Spiritual Physics, has solved this greatest of all problems—both psychical and physical—the problem of the human will.

Shall this system, founded upon knowledge known to the ancients, which has been lost out of the world for centuries, only be regained to be lost to this age because of the dogmatism of science? There is a warning in Cowley's words, which men of science will do well to heed:

> "But life did never to one man allow
> Time to discover and to conquer too."

THE TESLA OSCILLATOR.

By Lieut. F. Jarvis Patten.

The fire which, since our last issue went to press, destroyed the laboratory of Nikola Tesla in this city and reduced to ashes all the recent devices of his ingenuity, has again aroused public interest in the work of this world-renowned inventor. By the creation of the rotary field motor, which now, some six or seven years from its birth, is a commercial success, and the brilliant investigations he subsequently made in the direction of high frequency phenomena—not yet so far advanced—Tesla has established his right to be regarded as the most promising inventor in electricity that we have to-day. It is, therefore, only natural that, when without warning all his records and more recent apparatus are suddenly wiped out of existence, the public should be eager to know what he had in preparation for his next surprise.

The so-called "Oscillator" was near to a practical working form when the fire occurred, and as this machine, in a less finished shape, had been exhibited at the Chicago Exposition, and has received a large share of his attention since that time, he has considerately given the public some photographs and details of the more advanced forms of this engine. Tesla's researches and inventions have heretofore been confined to purely electrical problems, and electricians were naturally expecting a continuation of such work, but this inventor appears to delight in surprises, and when the Oscillator was announced for the first time, the general conclusion that Tesla had contrived some way of shaking the earth's electric charge, or had made some other ultra scientific step of a like character, was far from the truth.

Of all things yet produced by him the Oscillator is certainly the most thoroughly mechanical and possibly the most practical. The term "Oscillator," in fact, was evidently selected by him in order to distinguish it from other well-known forms of vibrator, and gives hardly any idea either of the

machine itself or the functions it is designed to perform. There is, indeed, no connection between this machine and his former productions, except through the fact that its purpose is to economize the work of the steam-engine and the dynamo at the same time, and so materially to increase the output of these two essentials of every large electric generating plant, the combined weight and cost of the two being greatly reduced.

The Oscillator, in fact, is an "engine dynamo," consisting of a novel form of steam engine combined with and operating on the same bed plate a novel form of dynamo. To understand how such a contrivance can have any practical value in electric generation it is necessary first to consider the essential features of any ordinary electric plant, their relations to each other, and where any losses of power seem unavoidably to enter. In plain terms, all such plants at the present time consist of two independent parts, the steam-engine and the dynamo. This the engine drives generally by indirect methods, as it would any other piece of machinery, as a lathe or a planer, through a system of shafting and belting. True, in modern plants, where large units are employed of five hundred horse-power or upward, the moving part of the dynamo is secured directly to the driven shaft of the engine. This plan is known as direct coupling, and though it introduces no small degree of economy in operation, it seems, according to Tesla, to be only a step in the right direction. It saves, for instance, at least one unnecessary line of shafting with its attendant friction; also, the work wasted in driving the belt or gearing of some kind between the engine and the dynamo, which is a far greater useless drain upon the steam-power.

Direct coupling is, therefore, all very well, so far as it goes, but we have not saved much, if anything, in floor space, or in weight, for we have still an ordinary engine and an ordinary dynamo as before. Are there not other losses equally easy to eradicate? Every engineer knows how really imperfect the steam-engine itself is in respect to work wasted in the friction of many parts that are purely auxiliary, yet appar-

ently necessary to its operation; and although the dynamo, the much younger machine of the two, is a far less wasteful engine, there is still in every reliable form a large percentage of wire that does no work, the friction resistance of sending current through which has to be overcome. Consider the steam-engine first. Here we have a steam cylinder in which is produced the reciprocating motion of the piston rod, and this motion, which represents the active power of the engine, is next converted into rotary motion through a system of auxiliary parts, namely, the connecting rod, the crank, and the attached fly-wheel. These parts all consume work by friction, but by far the greatest loss lies in the change from the reciprocating, or to and fro, piston motion to the rotary motion of the crank, the actual power of the piston working, as it does, at every point of the circle at a disadvantage, owing to the varying inclination of the crank and piston rod in all positions. Rotary motion once obtained, however, we have to reconvert a portion of it back again through further auxiliary apparatus—the eccentric with its rods and valves—to the reciprocating motion of the valve in the steam chest, which latter by its great friction, due to the steam pressure, wastes no inconsiderable amount of power. Thus we see that in the steam-engine all the apparatus except the piston and steam cylinder are auxiliary to it, and all waste, or use up without doing any work on the shaft of the engine, some of the energy delivered by the expanding steam to the piston head. In fact, it is plain that our conversion of the reciprocating motion of the piston to the rotary one of the fly-wheel is wasteful, and if done away with a considerable saving of power could be effected.

Unfortunately, however, in all the machinery for which the steam-engine has been heretofore used as a motive-power or driver, the rotary motion was required in the apparatus, and was, therefore, made in the steam-engine which drove it; all machinery, in fact, with very few exceptions, being essentially rotary.

On the other hand, if we examine the dynamo we shall find that we have made the dynamo a rotary machine only

because the steam-engine is, and to accommodate it to the latter. The dynamo had to be driven by a steam-engine, and in its evolution was naturally first made rotary in order to adapt it to existing forms of the steam-engine.

It is well known to electrical engineers that the simplest and most economical forms of dynamo have reciprocating parts only, and that the rotary form can only be contrived at a certain loss of efficiency. We may, therefore, state in general terms that the usual form of engine, rotary, is not adapted to the best form of dynamo, while the best type of engine for driving the simplest and most economical form of dynamo, that having a reciprocating motion only, has not yet been contrived or designed; not because of any inherent difficulty in the designing of such an engine, but simply because such a machine has heretofore had no particular sphere of usefulness.

The Tesla Oscillator is revolutionary in this respect, that it reverses the existing forms of engine and dynamo construction by making them both reciprocating in their action, thus coupling an efficient dynamo to a steam-engine, which, being also reciprocating, has no wasteful auxiliary parts, and no wasteful conversion of the original reciprocating motion to the rotary form of motion. Such, in general terms, is the Tesla Oscillator. It aims simply at a higher economic construction of the two essential parts of an electric generating plant, and in formulating this idea Tesla makes one machine of the two on one bed-plate, and thus again makes no little saving of space and weight.

While this construction, as described for sake of simplicity, might seem easy at first glance, a few engineering difficulties of a purely mechanical character soon become evident that render the solution of the problem one of extreme difficulty.

Briefly stated they are as follows: The dynamo to be economical requires an extremely high rate of to-and-fro motion, say at least eighty to one hundred strokes a second, while the steam-engine, on the other hand, owing to its necessarily heavy parts, requires a very slow rate for a dyna-

mo, say ten strokes a second, and these adverse requirements of the two machines must somehow be reconciled.

Again, the conversion to rotary motion in the steam-engine from the reciprocating form through the medium of the crank, serves a very useful purpose, especially in the case of heavy and powerful engines. This connection of the piston to the crank causes the piston to start up slowly under the enormous pressure of the steam, attaining its highest speed only for an instant about midway of the stroke, then slowing gradually down to the end of the stroke, where it is zero. The piston is then ready to resume its backward journey in the same manner without shock or jar to the structure. We thus see that there is at least one compensating feature in our conversion loss, for it would evidently be impossible to send the heavy piston, weighing, perhaps, a thousand pounds, at full speed from one end of the cylinder to the other, then instantly arrest its motion at the exact point and send it back again at the same rate. To do this a few times a second would be certain disaster, but to do it at a high rate of speed would be as certainly impossible. In the Oscillator the piston travels its journey to and fro a hundred times a second, and can go much faster if required, but the mechanical conditions are all different. In the first place, the parts are all small and extremely light, it being claimed that an engine of a given power on this plan can be made about one-fortieth the weight of an ordinary engine of the same power; secondly, the piston stroke is very small, being in no case more than a fraction of an inch; and, finally, automatically operated air cushions, or springs, are used, that serve to check and slow down the motion of the piston gradually at the end of the stroke.

In one form of the Oscillator two pistons are used that go out and in the opposite ends of the same cylinder at the same time, thus balancing the motion and relieving the apparatus from the rapid shock of vibration. Like the engine having two pistons the dynamo is double, or rather there are two, one for each piston, each of which carries a light armature that it rapidly thrusts into and withdraws from a very in-

tense magnetic field. The vibratory form or oscillatory form of dynamo is not essentially new. Several earlier laboratory machines having been made this way, perhaps the most remarkable of which was the Edison tuning-fork dynamo, remarkable chiefly, however, for its utter inapplicability to any use.

Perhaps the most remarkable feature about the Tesla apparatus is a novel system of steam packing introduced, which enables him to use a steam pressure of three hundred and fifty pounds without any perceptible leak. This, taken in conjunction with the very high rate of piston speed used, which, of course, only compensates for the very short stroke, should produce an engine of high economy. As for the dynamo, the type certainly admits of high economy in construction, and it is claimed that in one form there is absolutely no armature wire that is not cutting lines of force and doing work.

While it is too early to predict the eventual outcome of such revolutionary steps in both steam and electrical engineering, the developments thus far seem to have been of the most encouraging sort.

ANNUAL REPORTS.

Westinghouse Electric & Manufacturing Company.

(For the year ending March 31, 1895.)

The report of President George Westinghouse, Jr., says in part :

General.—The all-important feature of the year's business has been the creation of a magnificent workshop, having unequaled facilities for the carrying on of the business in which your company is engaged. These new works are located at East Pittsburg, about twelve miles east of Pittsburg. As was to be expected, such extensive building operations and the removal of materials from the old to the new works reduced the output for the year to about three-quarters of what it would otherwise have been. The directors earnestly invite all holders of the company's stock who may be able and desire so to do to attend in person the annual meeting on July 17 at Pittsburg, where special railway and other arrangements will be made.

So far as ascertained there was expended directly in removing the machinery and material $90,499, after deducting which from the earnings from business and from other sources there is left a net profit of $711,909.

Light and Power Properties.—Your company has for the past six years been interested in the United Electric Light & Power Company, of New York, and the Brush Electric Company, Baltimore, Md. During the past year both of these companies, with the assistance of your company, have carried through financial plans which have put them on a prosperous business basis. Their fields of operation are unusually profitable ones and it is believed by your management that the value of their securities owned by your company will, in the near future, be equal to their par value (amounting to $2,591,100); and that the final profit thereon will be a large one.

The United Electric Light & Power Co., under the plan referred to, has acquired almost all of the stock of the Brush Illuminating Company and of the United States Illuminating Company, both of New York City, and is now completing one of the most comprehensive light and power stations in the United States. It has contracted with your company for ten complete electrical outfits of 1,000 h. p. each, and for all the converters and other needed apparatus, half of these outfits having been used for the World's Fair lighting. On the completion of the above contract your company will have in securities of the United Company: 1st mortgage bonds, $913,000; preferred stock, $550,400; common stock, $411,700.

From its old stations this company is now doing a business of about $800,000 per annum, which should be more than doubled by the revenue from the output of the new station, giving it a net revenue sufficient to pay interest on its bonds and dividends on all of its stocks, there now being a demand for light and power sufficient to absorb the entire capacities of the stations of all existing companies.

Brush Electric Company of Baltimore, Md.—In the reorganization of this company your company subscribed for $40,000 first mortgage 5 per cent bonds and took in payment for machinery $170,000 first mortgage 5 per cent bonds, making your company's total holding $210,000 first mortgage 5 per cent bonds. Your company also was the owner and now holds 5,060 ($100) shares of the common stock out of a total of 7,292 shares outstanding.

The station of the Baltimore Brush Company is new and is one of the finest to be found in the country. It has three of the World's Fair 1,000-horse power engines and generators and has been supplied with a large amount of other electrical apparatus and will be hereafter, as will also the United Company, a constant purchaser of your company's apparatus and supplies.

Collateral Trust Bonds.—Your board, under the powers conferred upon it by the company's charter, has authorized the issue of $1,250,000 ten-year 5 per cent collateral trust bonds, secured by certain bonds and stocks held by the company, provision being made in the deed of trust for the sale of a portion or all of the securities, and for the cancellation of the corresponding amount of the collateral trust bonds secured thereby. It is proposed to fund out of the proceeds of this issue of collateral trust bonds an equal amount of debt, a greater part of which has been created in the building of the new works, the purchase of new machinery and the outlays in connection with the financial plans of the United and Brush Companies.

Westinghouse Electric Company, Limited.—Your company during the past year sold additional patent rights to the above company, and with the proceeds purchased the preferred and common stock of a number of English holders, so that your company now owns $782,500 preferred and $1,397,400 common stock (together $2,079,980) out of $2,332,750 outstanding, and your company will hereafter direct all of its affairs. All apparatus sold by the London company has been purchased from your company at profitable rates, and the business of the London company last year netted nearly five per cent on a valuation of $1,000,000. It is proposed to push the business in Great Britain, Continental Europe and in the various colonies in order to increase the sales of your company's product.

Patents and Litigation.—Your company has been successful in favorably terminating the litigation in respect to incandescent lamps, the feeder and main, and other important patents, and it was especially successful in the celebrated Bate Refrigerator case before the Supreme Court, in which the life of a number of patents, which were being used to influence trade by your adversaries, was finally determined.

In the McKeesport case, argued in the Supreme Court October last, involving the ownership of the carbon burner for incandescent lamps, no decision has yet been handed down, but the long delay on the part of the Court in arriving at a conclusion is regarded as not unfavorable to the sustaining of the claims of our Sawyer Man Patent.

To-day the most important inventions are those relating to the use of alternating currents, and your management believe that, with the exclusive control of the Tesla patents its position in patent matters is more favorable than that of any or all of its competitors.

Street Railways Operated by Underground Electric Circuits.—Your company has secured the controlling interest in the stock of the Electro-Magnetic Traction Co. of West Virginia, and through it the control of valuable inventions relating to the operation of street railway cars in large cities by means of underground circuits. This system has been in continuous operation in Washington during the past year, and is now in successful operation on the tracks of your company in and about the buildings at East Pittsburg, where it is to be used for moving freight cars and for general work. This arrangement appears to be a complete solution of the problem of street car propulsion in all large cities. A model of this system is now in operation at our office at No. 120 Broadway, New York City, and will be exhibited to stockholders between the hours of 10 A. M. and 4 P. M. during July.

Tesla Power Distributing Inventions.—Your company owns the exclusive right to manufacture and sell apparatus under the patents of Nikola Tesla, covering the use of multiphase alternating currents for power distribution. The rights under these patents are of great value, for developments indicate that it is only by means of Tesla's inventions that elevated and long lines of railways can be successfully operated, and that power can be most economically distributed over wide areas, and throughout workshops. The 5,000 H. P. generators contracted for by the Niagara Cataract

Construction Company have been put in successful operation, and other important installations for power transmission under the Tesla patents have been made in various parts of the country. Recently your company has fitted a short branch of the Pennsylvania Railroad with ordinary electrical apparatus for the propulsion of standard cars, and the tests have been entirely satisfactory. Your company is, however, pushing forward the manufacture of multiphase motors under the Tesla patents for practical tests in running standard cars on elevated roads and long lines, the success of which will be of especial importance, for it will insure to your company a large amount of trade for which your rivals will have no right to compete.

Suits under the Tesla patents are pending against the Stanley Electric Manufacturing Company of Pittsfield, Mass., and the Thomson-Houston Company. In the latter case, on application made by attorneys of your Company, the defendants have been limited to the 7th of October within which to close their testimony, it being the intention of counsel to push all cases of infringement. It is estimated by experts that in the near future the bulk of the business will be done by means of alternating current multiphase apparatus, involving the use of Tesla's important inventions.

The New York Times July 9, 1895

NICOLA TESLA'S INVENTIONS

As time passes, Mr. Tesla's discoveries in electrical matters assume greater and greater importance. Cassier's Magazine, special Niagara number, just issued, describes at length and in detail the work that has been done at Niagara Falls for the commercial utilization of the great power that has so long gone to waste, and in connection with this work Mr. Tesla is quoted as saying that Niagara Falls power can be transmitted to New-York and Chicago and there sold in competition with steam power generated from coal.

Much has been written concerning the discoveries of Mr. Tesla in connection with the development of light in a manner that seems startling and mysterious; but it is fair to predict that his greatest inventions will prove to be those in connection with the transmission of power by alternating currents over long lines; for, without such discoveries, the cost for transmission would be so great that capitalists would be unwilling to undertake the development of great water powers.

At the present time much attention is given to the discussion of the replacing of the steam locomotive by the electric motor on standard railways. It is already apparent that such results are possible only by reason of Tesla's discoveries, for, with the continuous current apparatus, such as is used commonly by street railway companies, it would be most difficult to make such undertakings profitable.

To carry out Tesla's inventions requires generators of special construction—that is, generators capable of producing two alternating currents of electricity at the same time, in such relation to each other that one current is at its highest voltage while the other is at its lowest voltage. These currents can be produced by the generators at any required voltage, or they can be raised from a couple of thousand volts at the generator to ten, twenty, or thirty thousand volts by means of transformers, and then led out on lines of very small diameter, and consequently low cost, and can be carried any required distance. At the point of use these currents can be again transformed to the low voltage required for the safe operation of motors. Tesla's great discovery was in the form of motor for the utilization of these double, or, as they are called, two-phased currents. Prior to his time all motors required a revolving part, or armature, having a complicated device called a commutator, upon which were pressed the brushes or collectors. This armature revolved within a frame having inward projections wound with wires, which was termed the field of the generator, or motor. Tesla found that, by winding a portion of the field with wires taking currents from one of the circuits of the two-phase generator, and the other portion from the other circuit, he could cause the armature within these fields to rotate without using commutators or brushes, the armature of the motor being so wound that the appropriate currents were induced as a result of those acting through the two sets of wires in the field.

In the operation of a railway it will often happen that fully 1,000 horse power of electricity will be required to be transferred from the trolley line to the locomotive, and to transmit this 1,000 horse power a considerable distance, at 1,000 volts, which is the utmost limit for the continuous current, would take 100 times as much copper wire for the transmission lines as would be required in the Tesla system with a voltage of 10,000; and 400 times as much as would be required if Tesla carried the current on his transmission lines at 20,000 volts, which has already been proved practicable. It will be noted in reading the accounts of the work at Niagara Falls that a commission of eminent scientists was created to determine the proper method for the carrying of Niagara's power, and this commission, after two years of investigation, finally determined upon the use of the two-phase generators, which was an acknowledgment that Tesla's method was the only practicable way of distributing the electric current for commercial purposes; and, in the technical description given by the several writers in Cassier's Magazine, the induction, or Tesla motor is always referred to as the device for the utilization of the power generated at the Falls.

That much is to be heard of the Tesla inventions in the future is a foregone conclusion, because Tesla was the pioneer discoverer of the most practicable method for the transmission of electricity for power purposes. He has patented his inventions, and has sold his rights to the Westinghouse Company of Pittsburg, which concern has taken steps to enforce its exclusive rights under the Tesla patents. At the same time, the General Electric Company and the Stanley Company, in a minor way, are making Tesla motors and installing them. Litigation is already far advanced, and is bound to keep Tesla's name prominently before the public, for an unusual patent struggle must result over the exclusive right to manufacture and sell electrical apparatus which will within a short time exceed in value all other kinds of electrical machinery manufactured by the great electrical corporations of the country. If a prominent Director and official of the General Electric Company is reported correctly, he expects some arrangement to be effected which will enable his company also to manufacture legally apparatus under the Tesla inventions.

When Tesla's discoveries were first announced, the electricians of the country and the world at large conceded their novelty and pioneer character, and for several years confined themselves to the forms of apparatus operated by continuous currents, and it was only after the Cataract Construction Company had finally determined that it was by means of Tesla's inventions alone that its operations could be carried out that the actual copying of his work was begun in various quarters. There could be no better evidence of the practical quality of his inventive genius.

LEGAL NOTES.

TESLA PATENT LITIGATION.

The Suburban Electric Company of Philadelphia has filed an answer in the United States Circuit Court to the suit brought against it by the Westinghouse Electric and Manufacturing Co. and Tesla Electric Co. for alleged infringement on various patents. The Suburban Co. denies having made infringement as alleged, and claims that the patents of the complainants for electro-magnetic motors are void because the alleged inventions and improvements and all the substantial and material parts thereof were disclosed and well-known in the art long prior to any alleged inventions held by the complainants.

The New York Times July 16, 1895

TESLA'S WORK AT NIAGARA

In 1877 Sir William Siemens, who had lately been to America, in an address before the Iron and Steel Institute, says Clemens Herschel in Cassier's Magazine for July, thus outlined briefly his views as to the possible utilization of the world's great water powers:

The advantage of utilizing water power applies, however, chiefly to continental countries, with large elevated plateaux, such as Sweden and the United States of America, and it is interesting to contemplate the magnitude of power which is now for the most part lost, but which may be, sooner or later, called into requisition. Take the Falls of Niagara as a familiar example. The amount of water passing over this fall has been estimated at 100,000,000 tons per hour, and its perpendicular descent may be taken at 150 feet, without counting the rapids, which represent a further fall of 150 feet, making a total of 300 feet between lake and lake. But the force represented by the principal fall alone amounts to 6,800,000 horse power, an amount which, if it had to be produced by steam, would necessitate an expenditure of not less than millions of tons of coal per annum.

It would not be very difficult, indeed, to realize a large portion of the power so wasted by means of turbines and water wheels erected on the shores of the deep river below the falls, supplying them from races cut along the edges. But it would be impossible to utilize the power on the spot, the district being devoid of mineral wealth or other natural inducements for the establishment of factories. In order to render available the force of falling water at this and hundreds of other places similarly situated, we must devise a practicable means of transporting the power.

As regards electrical transmission, suppose water power be employed to give motion to a dynamo-electrical machine, a very powerful electrical current will be the result, which may be carried to a great distance, through a large metallic conductor, and then be made to impart motion to electro-magnetic engines, to ignite the carbon points of electric lamps, or to effect the separation of metals from their combinations. A copper rod, 3 inches in diameter, would be capable of transmitting 1,000 horse power a distance of, say, thirty miles, an amount sufficient to supply 250,000 candle power, which would suffice to illuminate a moderately sized town.

The audience smiled incredulously, and it is unlikely that a single man present, except the orator himself, gave any serious thought to the question. It was looked upon as a dream, as a permissable vagary of an accomplished scientist. But the visitor to Niagara to-day would speedily be impressed with the fact that the dream of the great German of 1877 is the accomplished reality of this year 1895.

Attracting little attention except in the scientific papers, there has been going on there for several years a work which stands completed to-day in its details, and which is the unrivaled engineering triumph of the nineteenth century.

Perhaps the most romantic part of the story of this great enterprise would be the history of the career of the man above all men who made it possible—not an American, not a Britisher, neither a Frenchman nor a German, but a Montenegrin, a man of humble birth, who has risen almost before he reached the fullness of manhood to a place in the first rank of the world's great scientists and discoverers—Nikola Tesla.

Extremely modest and retiring in disposition, he has kept himself so far in the background during his few years of brilliant and fruitful research, that it has only been within a few months that the world has come to know him at all. Even now the world is more apt to think of him as a producer of weird experimental effects than as a practical and useful inventor. Not so the scientific public, or the business men. By the latter classes Tesla is properly appreciated, honored, perhaps even envied. For he has given to the world a complete solution of the problem which has taxed the brains and occupied the time of the greatest electro-scientists of the last two decades—namely, the successful adaptation of electrical power transmitted over long distances to the varied uses demanded in commercial work.

The earliest electric lighting was by the arc system, the peculiarities of the current rendering the system totally unfit for anything else. Next came the low-tension incandescent system, which was gradually and successfully adopted for both arc lighting and motor service. But the limitations of this system were within such narrow lines that it was proved at once to be far short of perfection in a commercial sense. The distance from the station to which this low tension direct current can be profitably transmitted is not over a mile and a half. Clearly, something else was needed.

In 1887 the single-phase alternating system was first introduced in this country by the Westinghouse Company. It was a step in advance, yet not the ideal, in that only lighting could be done by the system, there being no fit motor invented for this current.

A short time after his in 1888—patents were first issued to Nikola Tesla on a complete polyphase alternating system. He labored diligently, taking out in all twenty-nine uncontested patents, all acquired by the Westinghouse Company, covering every part of the system, and it was not long before the scientific world knew that the long-hidden result was achieved—an electrical system, perfectly well adapted for use in small villages, but still so flexible that both arc and incandescent lights and power for factories or mills can be profitably furnished twenty miles or more from the dynamo. Indeed, the limit of distance over which it may practically be transmitted is not yet fully determined, and such engineers as Mr. E. H. Kennelly and Prof. Houston assert with confidence that Albany, 300 miles away, can easily be lighted and supplied with power from the great plant at Niagara Falls.

To Tesla belongs the undisputed honor of being the man whose work made this Niagara enterprise possible, for without the possibility of long-distance transmission with practical motor service no way could have been found for utilizing profitably the almost boundless power of the great waterfall. Within a few years Tesla motors will be driving tools in every manufactory in the civilized world.

PERSONAL.

DR. NIKOLA TESLA has had the Order of the Eagle conferred upon him by the Prince of Montenegro. He has already received the Order of St. Sava from the King of Servia.

NOTES.

Critical Condition of Tesla.—Our readers will be grieved to learn, on the authority of Mrs. Bloomfield Moore, in the *New Science Review*, that Mr. Tesla is in a very awkward position. It is a number of days, says this gifted woman, since Tesla crossed the border line of the circle in which other electricians are working, but he still remains in the interatomic field of research, unmindful of the triple conditions that govern electricity in the relation which it sustains to the first order of the "luminous." This is sad enough, but we have yet to tell the worst. It appears that by reason of Tesla's wicked neglect of Keely's system of resonance he has missed the chance of hobnobbing with electrical phenomena in the sympathetic field, and is standing on a bridge which connects the primary two-thirds of the electric stream—the subdominant current with the dominant. What a fearsome post is his! But the consequences of his folly will still pursue him, and even though he may hook on to the dominant, he will still be subserved to the terrestrial neutral far in the rear of sympathetic union to radiating celestial outreach, the connecting link of which exists in the interluminous. Mrs. Moore says, further, that even in the event of Tesla's salvation, he will not have reached the compound interetheric. If such be the case, we should advise Mr. Tesla to climb down at once from his supradominant hypoluminous outreachment, and no longer seek to attain the interatomic realm, but to content himself with hard pan. The sting of Mrs. Moore is, however, in her—well, our readers will understand. Given a prompt cash settlement, and Keely will plank down all his secrets, and tell us how we may make a ten thousand ton ship float like a gossamer in the summer breeze. (Our readers will kindly take notice that this last poetic vein is our own, not Mrs. Moore's.) Failing this settlement they will die with Keely. The cosmical law of sympathetic association will then be lost to an ungrateful world, and Keely will rise on his vibratory mediums into the far outreach after a life spent in over-reaching, amongst others, Mrs. Moore.

THE RESEARCHES OF TESLA.

Inventions, Researches, and Writings of Nikola Tesla. By Thomas Commerford Martin. (New York: *The Electrical Engineer*, 1894.)

WE have here an account of Nikola Tesla, his scientific inventions and work, by a devoted admirer. Mr. Martin is not a Boswell, and from the nature of the case his book could hardly have about it all that human interest which pervades the life and achievements of a veteran discoverer in science. Mr. Tesla is a young man whose career has been somewhat romantic, and whose ingenuity is such as to rank him very high indeed among the electrical workers and discoverers of the day. Born in Austro-Hungary, educated at the Realschule at Carstatt and the Polytechnic at Gratz, and professionally first in the Government Telegraph Department, and afterwards in Paris, his career as an engineer really began when he arrived in America little more than ten years ago.

In two or three years from the day on which he took off his coat in the Edison Works, Tesla motors had attracted attention, and he leaped at once to a position as a successful experimenter and inventor, which his subsequent work has only secured and made more important. His researches on the effects of alternating currents of high potential and frequency, in particular, though they had the misfortune to be made the subject of the speculations of the ordinary journalist, are of great scientific interest, and continued by Mr. Tesla himself and the army of enthusiastic workers we now have, cannot fail to yield theoretical results and practical applications which will more than fulfil the anticipations of those who took a sober and rational view of their possibilities. None of those who listened to Mr. Tesla at the Royal Institution will soon forget the almost marvellous experiments performed, their clear exposition in what was to the lecturer manifestly a foreign language, and the enthusiasm which the results displayed excited in those present who were best able to judge of their scientific interest and importance.

Mr. Martin's account of Mr. Tesla's work is interesting, and yet perhaps it might have been in some respects better than it is. He has had excellent materials, such as the various lectures delivered by Mr. Tesla on his researches generally, the papers read from time to time to scientific societies on particular inventions and points of interest, and apparently the specifications of Mr. Tesla's patents. Our complaint, if we have one, is that this material has hardly been sufficiently worked up. Many of the lectures and papers were, as was inevitable, hurriedly composed, and the expression of Mr. Tesla's theoretical views contained in them is not always so clear and complete as it might have been made by one not so rapidly carried forward by the stream of discovery. A great inventor can hardly be expected to spend time weighing words and phrases, at any rate he has a title to be excused from doing so, which others who expound him do not possess. As it is, Mr. Martin's book is on the whole a reproduction of articles which appeared from time to time in the *Electrical Engineer* (of New York), and all we wish is that he could have spared the time and trouble necessary to cast the matter into a more homogeneous and symmetrical form.

For the lectures which are reproduced we are very grateful. They give Mr. Tesla's own description of his inventions, and his views on points of theory—views, which if not always orthodox, and sometimes expressed in language which appears strange, are always fresh and suggestive. The unavoidable repetitions of the same ideas, and recurring descriptions of the same apparatus, are not without some advantage, though they interfere with the unity of Mr. Martin's book, as they enable the lecturer's meaning to be made out more completely than would otherwise be possible.

The book is divided into four parts: Polyphase currents; Tesla effects with high frequency and high potential currents; miscellaneous inventions and writings; early phase motors and the Tesla oscillators. The two first parts are of course much more interesting than the remaining two, which have to do with such things as oil condensers, anti-sparking dynamo brushes, unipolar generators, the Tesla exhibit at the World's Fair, and the Tesla mechanical and electrical oscillators.

The discussion of polyphase currents, which occupies the first 115 pages of the book, has more unity of treatment about it than the second part, which consists mainly of the lectures Mr. Tesla delivered in this country and America. After a short introductory and biographical chapter, Mr. Martin proceeds to expound the principle of the rotating magnetic field and the construction of synchronising motors. A paper by Tesla, on a "New System of Alternate Current Motors and Transformers," is reproduced in this connection, and contains the foundation on which is based the remaining twenty-one chapters which make up Part i. These contain numerous modifications of the original idea, many of them exceedingly ingenious. A motor "depending on 'magnetic lag' or hysteresis" is described in Chapter xii. The peculiarity of this is stated in an introductory paragraph to be "that in it the attractive effects or phases, while lagging behind the phases of current which produce them, are manifested simultaneously and not successively." This statement itself seems to want some little exposition, though the arrangement is really very simple. An iron disc is pivoted within a fixed coil, wound just

large enough to admit the diameter of the disc one way, and a little more than its thickness the other. The coil carries two pole-pieces, one at each end, which project from opposite sides a little way round the disc. Thus opposite poles are stretched out as it were from the coil round the disc in the same direction. An alternating current passed round the coil magnetises both these pole-pieces and the disc, and the repulsion between the adjacent similar polarities of the disc and pole-pieces produces the rotation, the polarities of both being of course reversed with the current. The disc is wound with closed coils, so that the induced currents augment the turning couple developed. This arrangement is further developed into a "multipolar motor"; but in neither case is there any clear statement of how the action depends on hysteresis.

In connection with these and similar devices it would have been interesting to have had some estimate of efficiency, but generally speaking, in no part of the book is there any discussion of this most important question. Indeed, when the word energy is used it seems to bear a somewhat peculiar sense. For example, at p. 81 we have a statement as to the "energies" of the field and the armature, and the importance of these being equal if for a given sum the motor is to have the greatest efficiency. This passage is a little difficult of interpretation, if the word energy is to be taken as it ought to be in its technical sense throughout, though it is not very hard to make out the idea intended.

By far the most interesting portion of the book to a student of electricity generally is Part ii. The alternator of high frequency which Mr. Tesla used is fully described, and the arrangements for using it explained in the first of the lectures already referred to. The phenomena produced are set forth in the remaining chapters with numerous illustrations which render the descriptions very easy to follow. The whole subject of high frequency phenomena is very intimately connected with the researches of Hertz on the one hand, and the work of Mr. Crookes on the other, and forms a most inviting field of research for experimentalists who possess the necessary equipment. Whether always the theoretical view taken by Mr. Tesla is correct, is matter for legitimate difference of opinion. For one thing, we do not think that there is any difference at all between electric force produced by what is properly called electrostatic action and that produced by electro-magnetic action. The distinction is only mathematical—the former force can be derived from a potential function, the latter cannot—and in a sense only expresses our ignorance of the mode of production of the force. But perhaps we are mistaken in supposing that Mr. Tesla regards the electric forces in these two cases as different in nature.

To every physical inquirer the perusal of these lectures cannot but be of the greatest benefit. It will again remind him that the field of research is unlimited, and quicken his scientific enthusiasm, if not to taking part in the work of this particular part of it, to at least prosecuting with renewed vigour the inquiry, whatever it is, which lies ready to his hand.

It was reported a few weeks ago that all the apparatus and machinery belonging to Mr. Tesla had been destroyed by fire. Every reader of his researches must sincerely sympathise with Mr. Tesla in his loss of valuable appliances and still more valuable time. That he at once set himself to repair the loss is only what was to be expected from his character; let us hope that it may result in such improvements of his means of experimenting as may, in some measure at least, make up for his disappointment, if it is not, what is perhaps too much to suppose, turned into a blessing.

A. GRAY.

Critical Condition of Mr. Tesla.

[*From the London Electrical Review.*]

Our readers will be grieved to learn, on the authority of Mrs. Bloomfield Moore, in the *New Science Review*, that Mr. Tesla is in a very awkward position. It is a number of days, says this gifted woman, since Tesla crossed the border line of the circle in which other electricians are working, but he still remains in the interatomic field of research, unmindful of the triple conditions that govern electricity in the relation which it sustains to the first order of the "liminous." This is sad enough, but we have yet to tell the worst. It appears that by reason of Tesla's wicked neglect of Keely's system of resonance he has missed the chance of hobnobbing with electrical phenomena in the sympathetic field, and is standing on a bridge which connects the primary two-thirds of the electric stream—the subdominant current with the dominant. What a fearsome post is his! But the consequences of his folly will still pursue him, and even though he may hook on to the dominant, he will still be subserved to the terrestrial neutral far in the rear of sympathetic union to radiating celestial outreach, the connecting link of which exists in the interluminous. Mrs. Moore says, further, that even in the event of Tesla's salvation, he will not have reached the compound interetheric. If such be the case, we should advise Mr. Tesla to climb down at once from his supradominant hypoluminous outreachment, and no longer seek to attain the interatomic realm, but to content himself with hard pan. The sting of Mrs. Moore is, however, in her—well, our readers will understand. Given a prompt cash settlement, and Keely will plank down all his secrets, and tell us how we may make a 10,000-ton ship float like a gossamer in the Summer breeze. (Our readers will kindly take notice that this last poetic vein is our own, not Mrs. Moore's.) Failing this settlement they will die with Keely. The cosmical law of sympathetic association will then be lost to an ungrateful world, and Keely will rise on his vibratory mediums into the far outreach after a life spent in overreaching, amongst others, Mrs. Moore.

TESLA'S MOTOR.

WHILE the Westinghouse Electric Company and the Baldwin Locomotive Works are combining the resources of their tremendous plants and are exerting all the energy that lies in millions upon millions of dollars to develop the possibilities of the Tesla motor, which some day will draw cars at a speed of 150 miles an hour, the inventor, Nikola Tesla, plods along in his workshop, planning and scheming and experimenting and maintaining a profound silence.

This workshop—a long, bare room at 46 East Houston Street—is fitted up with only a few electrical appliances. There Mr. Tesla is to be found every day, sitting at his desk, tinkering with figures and drawings. A Recorder reporter called upon him recently to learn something about this fabulous motor, which is going to send heavy trains rushing through space at such a terrific speed. As far as gaining any information from Mr. Tesla was concerned, the visit was fruitless.

Gently, yet very firmly—the manner was born of long experience—Mr. Tesla declined to be interviewed. The reporter, however, was allowed to see the marvelous motor, and later in the day, through the kindness of a gentleman who had devoted much time to studying the principle upon which it is constructed, was told exactly how the motor works. Truly, it is a marvelous invention The secret lies in turning the inert and seemingly lifeless force of magne ism into an active force more powerful than steam or a current from a dynamo.

If you take an ordinary magnet or a piece of iron, through which a magnetic current is passing, and hold it close to little pieces of iron or steel it will attract them and hold them motionless. This is practically all that the world has ever known of magnetic force. Now it seemed to Nikola Tesla—this was years ago, when he was a student in the Polytechnique—that this invisible force, pent up within the confines of the magnet, might, perhaps, be developed or transmitted or changed or utilized in such a manner that it would become active and quick where it had always lain passive. Upon this theory he worked for years, and its triumphant development led to the Tesla motor. The principle of the Tesla motor is this:

An electric current is passed through a circular magnet, in appearance resembling a life preserver. It consists simply of a ring of iron with copper wire bound around it. The electric current generates a strong magnetic current, which flashes around and around the circular magnet at terrific speed. Now if one holds a nail close to an ordinary electric magnet, it will be passive in the hand until it is brought close enough for the magnetic force to seize it, when it will fly out of the hand straight to the magnet. But—and here lies the wonder of it all—if one holds a nail close to this circular magnet of Tesla's, it will begin to revolve in the hand. That is, if the nail is held by the head and the point allowed to hang over the hollow center of the magnet, the point will move around in a circle, slowly at first, then faster and faster, until if it is dropped upon the table in the center of the hollow, it will spin around so rapidly that the eye cannot follow its motions.

One hears the explanation of the phenomenon—there are several magnetic currents in the iron ring, and they are chasing one another around in a furious race—and is as much mystified as ever. If one balances an iron wheel upon the nail or lets the wheel revolve upon a finger, using the finger as the axle, and holds it close to the magnet, it will fly around at a speed that will take one's breath away. It is not necessary to touch the magnet at all. All one needs do is to hold a piece of iron or steel in his hand and bring it within a foot of the magnet, and then he will feel a queer sensation as of some invisible force trying to draw the piece of metal out of his hand, and, failing in this, striving to twist it around in a circle.

If one places a wide board over the whole magnet, the force will make itself felt through the wood, for if a piece of iron shaped like an egg is dropped upon the board it will wobble around for a moment and then, as soon as it gains a little momentum, it will spin around on its narrower end like a top.

Such is the principle of the Tesla motor. In its application as a motive power on a railroad, the construction, of course, differs from that of the experimental magnet, but the idea is the same.

Here the circular magnet is attached to the bottom of the engine and the axle upon which the wheels revolve passes through the center of the magnet without touching it. When the current is turned on, the magnetic force whirling around in the hollow of the magnet catches the axle and turns it. The power for generating this magnetic current can be transmitted by underground wires for almost any distance, and there is practically no waste of power or energy.

The Westinghouse Company controls the American patents of this motor. Its application to railroads is merely one of its uses. Dozens of skilled mechanics are at work constructing machines which embody Mr. Tesla's idea in various forms and for various purposes, and electricians believe that before long it will have revolutionized electrical science.

As far as its ability to propel cars at a speed of 150 miles or more an hour is concerned, no expert whom the reporter saw has the slightest doubt of it. One electrician said:

"As far as speed is concerned, Mr. Tesla's invention contributes all that electricity can do as a motive power. There is not the faintest doubt in the world that the Tesla motor will propel a car at the rate of 150, 200—I hardly hesitate to say 300—miles an hour. Now, however, they must build engines and cars and roadbeds and tracks to stand the strain, and when they have done that rapid transit will be attained."—N. Y. Recorder.

HARNESSING NIAGARA.

THERE is no class of professional men who travel so much as engineers. Their experiences are often full of interest, and at times not devoid of excitement. Yet how seldom it is that any account of these travels is found in print. This is partly due to the fact that it all seems to the principal actor to be all in the day's work, and hardly worth committing to paper. But there is also a certain pleasure in having a store of experiences to relate to one's more intimate friends, which the vulgar crowd cannot read in a book.

At the present moment I am tempted to curb this natural reticence with the object of narrating my experiences of the last few years, which I believe are unique in our profession. Our engineers are often called upon to travel in difficult countries, and to accomplish what look like impossibilities. But it is by no means an everyday occurrence for the financial men in a great country like the United States, who are not in the habit of minimising the capabilities of their fellow-countrymen, to invite a foreigner to carry out one of the greatest works of modern times in that country. Some people say that the Americans are perhaps too much inclined to look upon their countrymen as the inventors of Electricity. It is, then, all the more surprising that the work about which the English engineer was asked to advise them was the electrical utilisation of Niagara Falls. It must, however, be remembered that this work involved entirely new problems and designs, while the American electrician has less capability of evolving entirely new plans, or designing entirely new machinery, than of adapting his past experience, exactly as it stands, to new conditions. It was for this reason that one of the ablest of American engineers said in public three years ago that it was impossible to transmit the power of the Falls to Buffalo, some twenty miles, so as to make it pay; whereas we have now established the fact that the limit of distance is to be counted by hundreds of miles.

There are two great mistakes commonly made as to Americans. One is, that they are original inventors; the other is, that they are humorous. Neither of these propositions is true. It is true that if asked to create a knitting-machine, or a type-writer, or a reaper, they will put together well-known mechanical devices to accomplish the result. But this is designing, not inventing; and the cause of so much work of this kind being done in America is the high price of labour, which must be replaced by steam and machinery. So with humour, with of course some brilliant exceptions, their periodical literature is filled with so-called wit, but it smells strongly of the midnight oil. I remember an incident related to me by an editor of a weekly journal. He said, "Yesterday a poor miserable man came into my office and laid before me some manuscript and said, 'O Mr ——, I wish you would look through these jokes and pick out any you can use. I was working at them all last night, and I need money badly to bury my poor wife.'"

Invention and humour require a gift of imagination, the same gift that shows itself in poetry and letters, in music, painting, and sculpture; and in no one of these directions has this gift of imagination been found to predominate amongst Americans.

I have given these reasons why it was perhaps natural to have recourse to a European to take hold of this great and entirely novel problem. Another reason is that all their electricians who may have had a wide practical experience are tied to manufacturing companies, and cannot be looked upon as independent either in thought or action; and since it was pretty certain that any plans that might be adopted would have much of novelty in them, and would be opposed in the first place both by scientific men and by the manufacturers, it required that the man selected should have nothing to gain or lose by the friendship or hostility of these two classes of men.

When I had finished my work at Niagara Falls the chairman (or president, as he is there called) of the company wrote me a letter, in the course of which he incidentally mentioned some of the reasons why I had been invited to carry out this work. These are given later on in this article.

Passing now from these digressions, let us come to the Falls themselves. I have no talent for pictorial description, and they are well known to a large number of my readers. I will only say that the river Niagara leaves Lake Erie at the City of Buffalo and meanders, innocently enough, through level plains for sixteen or eighteen miles, passing on the two sides of the Grand Island and then opening out into a wide lake-like expanse a mile wide, where, a mile above the Falls, the current becomes more swift. It then is parted in two by Goat Island, the narrow part dashing down by furious rapids to the American Fall, which is a straight curtain of water shooting down a perpendicular height of 160 feet. The wider branch makes a turn round Goat Island and is very wide, and the breakers dance merrily in the sunshine, until the waters concentrate themselves at the Horse-shoe, or Canadian, Fall — the greatest volume of water being at the V-shaped apex in the centre, where the depth of water at the lip is sufficient to impart a brilliant emerald colour to the water. From the Falls downwards for many miles the river runs through a precipitous gorge. For the first mile it is sluggish, but with gurgling upheavals of the water from below. Then come the terrible whirlpool rapids where Captain Webb was drowned. After that a sulky repentant river creeps to Lake Ontario.

There are three things at the Falls themselves which rivet the attention. 1. The water takes four or five seconds to fall, and in doing so it assumes the most fantastic forms of drapery. 2. The mist and spray rising from the base of either Fall is drifted by the wind, or in a calm rises in a cloud 1000 feet in height. 3. The third feature is the noise. You have not only the rushing noise of the Rapids, but also a booming, at times resembling a thunderclap, when the somewhat intermittent flow tumbles upon the water beneath, and shakes the foundations of houses half a mile away. The village or town of Niagara Falls on the American side of the river is built of wood. It is dirty, and the streets are bad. Its industry is the catering to excursionists. Cheap restaurants, merry-go-rounds, itinerant photographers, and museums of Indian and other

curiosities are the chief features. The last are mostly impostures, always excepting the world-famed "Katie & Libby's Stores," where genuine curios are to be found, and many pleasing souvenirs. This village is remarkably conducive to the concoction of lies, and the Falls lend themselves to the art. The prophets of this cult are the hackmen (cab-drivers), who earn the gratitude of the excursionist by the thrill of their narratives. I believe, however, I have reliable evidence for some remarkable statements. 1. On the 1st of April 1848 the Falls ran nearly dry owing to a stoppage by ice and a strong east wind on the lakes. 2. A drifting ship, drawing sixteen feet of water, went over the deepest part of the lip of the Horse-shoe Fall. 3. A steamer called the Maid of the Mist, built at the Falls, traversed the Whirlpool Rapids in order to escape creditors, and reached Lake Ontario in safety. I cannot, however, vouch for the generally-accepted statement that in doing so she turned a complete somersault. 4. At the Whirlpool there is a path descending to the water to a spot where they catch the bodies that float there. There is an average of one suicide a month, and they are invariably trapped by the Whirlpool. 5. There is another true story which is rather startling. A hundred yards above the brink of the American Fall a rock ten feet square projects for a foot above the water in mid-stream. One morning the inhabitants awoke and saw a man sitting on it. The noise of the Rapids prevented verbal communication. They did not, do not, and never will know how he got there. He stayed there thirty-six hours. The people telegraphed to Buffalo, and the railway company sent one excursion train after another for thirty-six hours to see the man on the rock. They painted signs and stuck them up for the man to read, saying, "We will save you." Two hundred yards above there is a bridge. From this, by ropes, they floated rafts with provisions to him. At the end of his stay a big one came for him to get on. What they were going to do with him if they got him in this seething rapid I know not. He tried and failed, and went over the Fall, and that is all!

People are differently affected by their first sight of the Falls. Some say, "How disappointing!" others, "How magnificent!" Some (Colonel Bob Ingersol was the first to say this to me, but I have heard the same from others), "How horrible!" and others say, "How seductive! I want to go over with the water."

The Falls in winter are totally different from what they are in summer. Every bush and tree is a work in silver filigree. The precipices are concealed behind icicles 60 feet long. Every rock in the river is the nucleus for a dome of frozen spray rising 150 feet it may be.

When you know the river you will love it; but to know it you must see it at every season and at every hour—at sunrise, noon, and by moonlight; in sunshine and storm; with the mist rising as a tower, or drifting away to unveil new points of beauty. You must know every corner, peaceful or violent; you must see it from above and from below, and from every point of view, and always you will hear that thundering boom that shakes the ground. It is best to live on the Canadian side at the Clifton House, open only in summer. The most impressive points of view are those that make you feel the smallest. Mr Bayard, the United States Ambassador in London, tells me that the only true way to appreciate the grandeur is in the early morning to swim across from the Canadian to the American side, just below the Falls. He has often done it, so he ought to know.

To me the great charm of the Falls is their immutability and change. The drifting spray and varying light give the changes of a kaleidoscope, but the volume of water pouring over never varies. They remind me of the face of a dear friend, always the same but never two moments alike. I suppose there is nothing to compare with them in size or grandeur except the Victoria Falls of the Zambesi; and Livingstone, who never exaggerated, said that these were the finer.

The "utilisation of Niagara" is a hateful phrase to the lover of nature. But it must be stated at the outset that what is being done does not in the least degree affect its beauty. Only a small fraction of the water is to be used, and all the works are more than a mile above the Falls.

It is time now to leave the digressions about the beauties of Niagara to explain how it is possible to make use of this power without affecting the scenery. Now, "gentle reader," do not for a moment imagine that I am going to burden you with engineering details in any part of this article. I hope to allude to them only in such a manner as to excite your interest rather than to bore you. Any one who has visited the Falls of late years knows that the land on the two sides has been appropriated by the United States and Canada respectively for national parks. The old mills which used to be in the stream above the American Fall have been removed for æsthetic purposes, and the land laid out with some attempt at good taste. On the Canadian side the same thing was done, but I regret to say that the rapacity of the Legislature of Ontario has not proved equal to withstanding the blandishments of the greedy capitalist. Two lines of rails traverse the whole of the National Park at the edge of the gorge. After the land had been confiscated by the Government, and the owners had been paid only a fraction of its true value, it is now turned into a source of revenue by the Government, and a gold mine to the capitalists, at the expense of the visitors, who can no longer enjoy the peaceful quiet which Lord Dufferin tried so hard to give them.

In spite of all that the Americans have done for preserving the beauty of the Falls, there is one terrible eyesore—a large number of mills have been erected at the edge of the precipice over the gorge. To these the water of the upper river has been led by a canal passing through the town. This water drives water-wheels or turbines in the mills, and is then shot over as waste water down the precipice. Not only is this hideous in itself, but it is repulsive to the engineer, because of the great waste. They use only a few feet of the fall, and waste over 100 feet.

Thirty years ago an American engineer of the name of Evershed proposed a plan by which the mills should not be in view of the Falls, and by which the power might be utilised without detracting from their appearance, and the fundamental idea of this plan has now been actually executed. Mr Evershed's idea was to take in the

water from the river by a long canal a mile or two above the Falls. Along the banks of the canal mills were to be placed requiring power. At each mill a hole or shaft was to be dug in the ground to a depth of about 150 feet. The bottoms of these shafts were to be all connected by a long tunnel passing from them under the town at a gradual slope, and emerging at a tunnel mouth below the Falls, on a level with the lower river. At each mill-site a water-wheel or turbine was to be placed at the bottom of the pit, which would rotate a vertical steel shaft coming to the surface. At the top this shaft would, by means of cog-wheels or belts, turn the machinery of the mill. In this way the canal was to bring water to the pit, and, having given up its power to the water-wheels, was to flow away by the tunnel into the lower river. Such a tunnel has been built, though the details of Mr Evershed's plan have been altered. The result is that the factories and mills are far distant from the Falls, and do not interfere with the views. The tunnel has been built so as to be capable of using 100,000 horse-power or more. There are not many manufacturing towns in the world whose steam-engines all combined would give so enormous an amount of power as this. As Dominie Sampson would say, "It is prodigious!" The tunnel-mouth can be seen from the Canadian side of the river, and looks like a mere speck compared with the volume of water which is pouring over the Falls. A single glance is sufficient to convince anybody that even when 100,000 horse-power, or many times that, has been used, the effect will be imperceptible. But even now the water which is being used issues from the mouth with great velocity, and sets up quite a strong current across the surface of the stream.

Probably every engineer who ever visited this spot has been struck with the vast amount of power going to waste. But I am very doubtful whether its use could have been a commercial success before the electrical art had been so much developed that it was possible to distribute power by its means for all kinds of purposes.

Nevertheless, before this question had been entered upon, some New York capitalists were found who were prepared to take the matter in hand. At that date such an action was a bold stroke; but fortune in this case favoured the bold, and the electrical work which I have carried out has been done at a cost which even now seems incredible to many.

In 1889 the Niagara Falls Power Company was formed to carry out this work, and their first act was to buy up all the land in the neighbourhood. The capital subscribed was wholly American, and amounted to £2,000,000, about one-half of which has been spent. The acting committee consisted of railway men and lawyers. The chairman, as usual, is called a president. They like giving big names to things in America. A pond is a lake, and a hill is a mountain; they never speak of the sea, it must be called the ocean; a meeting is a convention, a dictionary is a "speller and a definer," a town is a city, a chairman is a president, and so on. The only exception I know of is that the wealthy people who own those charming country residences at Tuxedo and Lennox call them cottages. But these are not average Americans, and in that country

the manners and customs, as seen by the ordinary traveller, are governed by the average man, who is not a good specimen. He is apt to be a most awful "bounder," has no taste, and does not know the meaning of the word "repose"; but you need never meet this type except in railway trains and hotels. His ideal, as one of them told me, is to spend his nights "on the cars" and his days in getting the better of his fellow-men. But the refined American is quite different. These are mostly met in Washington and the south, and, of course, Boston is a thing apart; and as you approach this town you are told that the humming you hear is the noise of people reading Browning. Tuxedo also is a great exception, where you can have congenial society. It is a large estate with woods and lakes and forty miles of well-laid roads. Country houses or cottages have been built all over it, and there is an excellent residential club—into which, however, the female element has progressed so far as to have introduced even babies into the bedrooms!

I must really ask to be excused for such digressions, but I must tell my story in my own way or leave it alone. The chairman of the company which has utilised the Falls is Mr E. D. Adams, well known as a banker and a reorganiser of railways. The first vice-president is Mr F. L. Stetson, a lawyer who has also had much experience in the finance of railway companies. Mr Cleveland, the U.S.A. President, is a partner in his law business. The second vice-president is Mr E. A. Wickes, also a railway-man. The secretary and treasurer, Mr W. B. Rankin, is one of the most able and energetic and charming men I met in the States. I only hope he will not utterly ruin his health by overwork. All these are very able business men, though not engineers, and the affairs of the company could hardly be in better hands.

In October 1889 the Niagara Falls Power Company was formed to carry out the great work of utilising the Niagara Falls on so gigantic a scale that all previous attempts to use water-power at once sank into insignificance. The Cataract Construction Company was at the same time formed by the same people to carry out the work. All that they had then settled was that they would make the tunnel proposed by Evershed for carrying away the used water. They had not settled whether the mills should be brought to the power, or the power to the mills. They had no estimates of the cost. If power were to be distributed to mills and factories, they had no notion whether it would be by means of air or water under pressure in pipes, or by wire ropes, or by electricity. None of the acting committee were engineers, but they had faith in the evolution of ideas which would culminate in success.

In order to obtain more definite ideas they invited certain engineers to prepare plans of any methods they might think best. These were to be laid before a Commission of engineers and physicists from England, France, Switzerland, and America, with Lord Kelvin as chairman.

At first I declined this invitation on the grounds that the method of competition is contrary to my professional practice, and also that with so novel a problem I would not accept any man, or combination of men, to adjudicate upon the project which I might decide upon.

Having learnt, however, accidentally, that any electrical plans to be submitted would not be of a satisfactory nature, I withdrew my refusal in order that a plan, as I conceived on proper lines, might be at least in evidence.

Up to this date there had been only one example of electric-power distribution, and that was in a small village called Oyonnaz, on the frontiers of France and Switzerland. But the problem now before me was entirely new in many ways, besides being of gigantic proportions. The object was to send *power* rather than *light* over the wires. But I found that every different user of the power would want his electricity delivered at a different pressure (it is not here necessary to understand the meaning of the words "electric pressure"). House-lighting, street-lighting, electric tramways, flour-mills, metallurgical processes, all required different "pressures." Also, if we were to carry any of this power through wires to a distance, the "pressure" must (for sake of economy) be very high during transit, and be reduced at the place where it is used.

Now let me say, without explanations, that there are two kinds of electric current—a "continuous current," always flowing in the same direction, and an "alternating current," in which the direction of flow is reversed, it may be hundreds of times in a second.

I soon realised the fact that not only could the latter current be more easily obtained at high pressures, but that it could easily, and without moving machinery, be transformed to any required pressure at any spot when it was wanted.

Up to that date, 1890, both kinds of electric current had been used for electric lighting, but the alternating current had never been used for giving mechanical power except in an experimental way. For this reason it seemed to most people absurd to suggest its use for Niagara Falls. I would have shared this view were it not that for several years I had visited the United States and the continent of Europe to study the progress that others were making in electric work. I had thus become well acquainted with the system which Nicola Tesla, a young Montenegran, was experimenting on at Pittsburg, U.S.A., called a "two-phase" system. He distributes two alternating currents, one of which attains its maximum when the other is at its zero value. With these two currents a simple form of motor could be worked to supply power to shops, factories, or mills. I also had seen many things in various parts of Europe not generally known in England. Owing to these varied experiences, I had an opportunity above all others at that date of foreseeing that the alternating current would soon be very generally applied not only to light, but also to motive power.

Acting upon this knowledge, I worked out complete plans, using only machinery which could then be got in the open market, and was able to furnish complete working plans, drawings, specifications, and estimates of cost. This laborious work when concluded left no doubt in my mind that the alternating current must be adopted.

The Commission sat upon these plans, and, as I expected, denounced the alternating current, for none of them had had the experience which I possessed of

the latest developments. How well I remember walking along Piccadilly with a member of the Commission. He told me of this decision with an air of sympathy with my supposed misfortune. He was somewhat surprised when I replied that nothing could have given me greater satisfaction than this decided expression of opinion, "for," I said, "the alternating current will certainly be adopted at Niagara."

I heard no more from the promoters of this enterprise for over a year. It took them all this time to realise that the Commission had made a mistake. Lord Kelvin was the most violent opponent of the alternating current; and for long afterwards (although he is my most esteemed and oldest scientific friend), even when I was appointed as the consulting engineer, he continued to write and cable to the company, though his opinion on this point was not asked for, telling them that they were making a "fatal mistake" if they followed my advice. His latest expression of opinion in this sense was in November 1894, when my work was practically completed. Such a line of action has hitherto been unknown among professional men. I need hardly say that this opposition on the part of so eminent a man was a stumbling-block which might well have wrecked the whole scheme; but in this and other points where my plans were at variance with the opinions of others, I was most loyally supported by the directors, and through this support alone they and I have been enabled to put the works into their present satisfactory condition.

To add to the difficulty, the highest scientific authority in the States had taken up the same position as Lord Kelvin. Fortunately, however, the year 1891 saw some great developments in the use of alternating currents for motive power in Europe over a distance of 112 miles, and our American opponent frankly confessed to a change of opinion owing to the results then attained.

Early in the year 1892 it became evident to the acting committee that the views of engineers had been undergoing a change, and that the use of alternating currents for Niagara was a necessity, thus indorsing the prophecy I had made long before. They then asked me to act as their electrical consulting engineer, and during that year and the next and the next I was almost constantly in the States. The only real rest I ever got was in my voyages across the Atlantic. I soon came to feel at home on all the large liners. The Campania, Lucania, Umbria, Etruria, Majestic, Teutonic, and many others were havens of rest; and one always feels glad to meet old friends in Captains M'Micken (now, alas! dead), Haines, Parcell, Walker, M'Kay, Murray, and many others. The misfortune is that at most seasons the only class who travel much are American bagmen, or drummers, and they are not a favourable class to judge Americans by.

Sometimes I lived in New York, where the offices were; sometimes at Niagara, to be near the works. I did not care to go much into society, but I made some very firm friends, specially the Hewitts, and our amiable Consul-General Sir William Booker and his charming American wife. My greatest friend of former days had been S. L. M. Barlow, a well-known and remarkable man. Roscoe, Conklin, and I used to dine with him

every Sunday. These two lawyers, both able men, on opposite sides in politics, and also in the great Stewart will case, amused and instructed me much by the exposition of their views on men and things. Both were dead now, and I had two friends the less to help me to pass these three years. Part of the time I lived at Tuxedo, an hour from New York, where you could have fishing, shooting, boating, bathing, and golf; and I shall never forget the cordial welcome I there received from the Potters, Bruzes, Lorillards, Delafields, Fishes, Kents, Rushmores, Prestons, Van Courtlandts, Van Nests, and from Allen Lathrop and many others. The lovely scenery and genial society of this place helped me greatly to retain health during a period of anxious and arduous work.

Now I must go on to describe what has been accomplished. The tunnel of which I spoke is 21 feet high and 19 feet broad, and is horse-shoe-shaped. It was expected that no lining would be necessary, but at the outset the roof began to fall in, and it had to be lined with four courses of bricks, increasing the cost largely and diminishing the capacity from 120,000 to 100,000 horse-power. The tunnel is 7000 feet long, mostly on a slope of 7 feet in 1000 feet. At the mouth there is a curved surface of iron for the water to flow over smoothly. The level of the water below the Falls varies a good deal. Sometimes it is far below the tunnel-mouth, at other times it is several feet above.

The plan of having a separate shaft for a mill has been adopted in only one case, the largest paper-mill in the country, where at present 3300 horse-power is being used. The paper is made out of wood-pulp, and trunks of trees have to be ground down for this purpose. This accounts for the large amount of power used.

It is intended to supply all the rest of the power from a great power-house where electricity is generated. Within this building a slot in the ground, communicating with the tunnel, has been excavated to a depth of 150 feet. It is 20 feet wide and some 150 feet long. Parallel with this slot there is a canal of great width taking in water from the river. From the canal to the slot there are water-passages from which iron pipes $7\frac{1}{2}$ feet diameter descend to the bottom of the slot. At the bottom of these the water passes into the casing of the turbines, and in passing through these develops power to the extent of 5000 horse-power for each unit. Three of these are in place. The power is given to a vertical shaft $2\frac{1}{2}$ feet in diameter except at the three bearings, where it is less. This steel shaft extends right up to the surface of the ground, and is attached at the top to the revolving part of the dynamo, which generates the electric current. Two designs of these turbines or water-wheels had been received from Swiss makers, and the selection of the best was intrusted to another English engineer, Professor W. C. Unwin. The company has, besides its powers on the American side, acquired a control of the rights on the Canadian side, rendering the undertaking international in its character, and also in the benefits to be conferred. In the autumn of 1892 Professor Unwin accompanied me to the Falls, and he then made a study for the company of the hydraulic work to be done on the Canadian side. So

that English engineering has been represented in more than one part of this great work.

In 1892, when I came to examine the plans put in by various manufacturers, I found that some of the crudest work conceivable had been submitted by the Americans. The Europeans sent some excellent designs, especially the Oerlikon Fabrik, near Zurich. But these makers were handicapped by the duty imposed on machinery imported into America. There was, however, one fatal defect in all the plans then or subsequently submitted by the manufacturers. I must explain that all the revolving parts of turbine, shaft, and dynamo have their weight supported by a hydraulic piston in the turbine—being balanced, in fact, by the water-pressure. The total weight which could be supported was thus strictly limited. Also, the designers of the turbines (Messrs Faesch & Picard of Geneva) required that there should be a certain momentum or fly-wheel effect to assist the regulation of speed. In none of the designs submitted had the revolving part of the dynamo sufficient fly-wheel effect. In every case it was necessary to add a large heavy fly-wheel; and in every case this increased the weight beyond what was permissible. The American manufacturers were entreated to alter their dynamo designs to meet this difficulty. They tried, but they were unable to do so. We were then in a most awkward dilemma, and it looked as if a serious departure from the original design of turbines must be made. Meanwhile I had been constantly working at various new designs, and at this stage I saw that, for the credit of the company, it was imperative that I should, if possible, get out a design on new lines which should have the required fly-wheel effect without too great a weight. A dynamo always consists of two main parts, a fixed and a revolving part. In every one of the many designs sent in the revolving part was central—*i.e.*, inside of the fixed part. It occurred to me that if I could make the external part revolve I should get a maximum of fly-wheel effect with a minimum of weight. By making the external part bell-shaped, I was able to attach the centre or top of the bell to the top of the vertical shaft, and the central fixed part resting on the floor could be reached from below. I proceeded to get out rough designs, and found, with the utmost satisfaction, that I could meet all the requirements of the turbine-makers. I also found that this design gave far greater mechanical strength to the revolving part of the dynamo—an important matter, with this forty tons revolving more than four times a second. Further, the magnetic attractions which in all the other designs increased the dangers from centrifugal force, in my design actually diminished them. It soon became evident that this happy idea of revolving the external parts completely extricated the company from the very awkward dilemma in which they had been placed. I then proceeded with a large staff of draughtsmen to get out the working drawings, and I secured an American patent as a protection to myself and my company. It was a matter of considerable satisfaction to all concerned that I had thus so simply got over the serious difficulty which at one time threatened us with starting afresh on all the machinery, turbines and

all. We were now able to feel quite easy about the hydraulic and electric generating plant. The only weak part in the scheme seemed to me to be the vertical steel shaft. The officials, however, were satisfied, as it had been passed by the Swiss firm who designed the turbines (though made in Philadelphia). I had always wished to put the dynamos at the bottom of the pit close to the turbines, and I still believe that this arrangement would have served us better.

The designing of a suitable dynamo was, however, only one of a number of difficulties that had to be overcome. Some of these were of an engineering character, but others savoured of "politics" in the sense in which that word is used in the States. There *politics* means intriguing, underhand dealing, and jobbery, and is always used in conversation to express that meaning. Until I went to America the manufacturers of electrical machinery never had a consulting engineer to reckon with, but dealt directly with the financiers, who knew nothing about cost or efficiency of machinery. When they knew that I was to advise the Niagara Company, they tried by every means in their power to revert to the old plan. Every game of bluff, bounce, and threats was used, but without the least effect. One of our engineers, in another department to mine, who knew nothing of electricity, was completely taken in by one of these firms. This and other intrigues hindered me a good deal in carrying out my plans. Then, again, I had at times great difficulty in keeping the president and vice-presidents in hand. One of the latter, after he had learnt a little about ohms and volts, believed himself capable of instructing me as to which tenders I ought to recommend for acceptance, and did his best to try to influence my judgment. Most of them began to think they knew something about the subject, and that they were quite capable of settling what tests the machines should be put to. All this was generally amusing enough, but became almost tragic at times when I found them endangering the whole work. On such occasions I would write to my millionaires and tell them that if they did not do what I told them they would be personally answerable to the directors and shareholders for any disaster that might occur. This always had the desired effect, and my point was carried. I fear that at times they wished me at Jericho, but after any one of these tiffs was over I think they were glad that I had taken that line.

I have said that there were many new electrical problems to attack. One of these was a new departure on my part, which involved a very heavy piece of calculating and designing before I could be perfectly certain that my conclusions were correct. It occurred to me that with the large machinery we were using (the dynamos which I designed were three or four times as powerful as any that had then been made) it would be best to make the alternating current reverse its direction as slowly as was consistent with making a good dynamo. This would not do so well for *lighting*, but for a *power* station like ours the advantages were powerful and numerous. The one objection that struck me was that the machines used for changing the electric pressure would be more expensive. This compelled me to design all these machines (they are called

transformers), and to calculate the cost of construction. I was then agreeably surprised to find that the cost was enormously less than any one had dreamt of. At the same time, out of every 100 horse-power put into such a transformer we could get out 98½ horse-power, a result which had never been approached in smaller machines. Then, again, some of the manufacturers threatened us with patent-litigation if we used certain types of machinery, so I had to get out designs of another kind of motor to drive the mills, so that in any eventuality we should be prepared and able to go on in spite of these threats. Then our first customers wanted continuous current, and I had to select a method of making the conversion. In fact, I found myself obliged, before we advanced a step, to have all the designs ready for manufacturing all kinds of machinery, even if they were not all to be used. This work, carried out under all kinds of difficulties put in my way, was chiefly done in the summer of 1893 at the Falls. I had a lovely house in parklike grounds (as the agents say) on the banks of the placid river above the upper rapids. I went to bed early and rose at five or six in the morning, and I shall never forget the delights of these glorious summer mornings at one of the most beautiful sites in the whole neighbourhood. In the afternoons I generally took a drive in a buggy on the Canadian side, where the roads were passable, and sometimes I rode. I had a nigger servant to look after the house, who differed from all his race I ever saw in his desire for work. If I did not want the gravel rolled or the grass cut, he grumbled. He always got up at five o'clock, and prepared my bath. I used to ask Jim about his previous life, and found he had been "porter" on a railway, and latterly servant in a gambling-hell in Buffalo! He was a good servant. This house belonged to one of the Porter family, who have long owned most of the property here. A Miss Porter was once travelling in Europe, and at the *table d'hôte* her neighbour said, "Oh, if you are an American I suppose you have seen Niagara Falls?" She turned to her inquirer, and fixing him with her eyes, she said, "I own them!"

An Englishman in America should always try to retain his Englishness,—otherwise in a year or two he will be reduced to the level of an average American. Where all men think themselves equal, individuality is at a premium. An American once tried to find fault with me for pitching into my servant, because, forsooth, all men were equal. I never saw the man before, and would never see him again. So I told him that if he wished to be placed on a par with my valet I would willingly acquiesce, but he must not attempt to define my place on so short an acquaintance.

I acquired quite a reputation on the New York Central Railway from a little Englishman. I had forgotten all about it when a friend at the Falls, arriving home from New York, said he had heard of me. "How is that?" I asked in the vernacular. "Well," he said, "you seem to be able to get the better of the conductors on our railways" (the most insolent class of men in the country). "I was talking to one on the cars, and when he heard I belonged to Niagara Falls he said, 'Oh then, you know Professor Forbes.' I said I did, and he said, 'Well,

there's no flies on him.' I asked him why, and he said, 'One night we were coming from New York, and in the early morning six of us conductors were in the smoking-room yarning when in comes Professor Forbes: he takes a look round and then says, "I want to smoke, but pray don't disturb yourselves, I am only a passenger;" and we all put our tails between our legs and slunk out, and then we roared with laughing to think how he had got the better of us in his quiet way.'"

These were very happy days, though I lived quite a solitary life. Of course I had anxieties and worries, but I felt quite certain of loyal support in any case where the safety of the work was threatened.

The dynamos were at last made and tested, after most annoying delays and disingenuousness on the part of the manufacturer. The makers of the transformers and machinery for getting a continuous current, on the other hand, were prompt and obliging, and the tests came out well. Then I got bids for the appliances for transmitting power to Buffalo. All the conclusions I had arrived at from my own designs were now confirmed. Their cost per horse-power, even with my low frequency, was a fifth part of those that had been used for lighting, and the efficiency guaranteed was as I had stated. I decided on all this transmission plant, and it is not now put in only because the Buffalo people want to get the power for next to nothing. There is too much "politics" in this business at Buffalo. Another triumph I have had is, that engineers all over the world have learned to appreciate my low frequency of alternations, while we ourselves have found new merits in it at every step.

I had also arranged for special apparatus for people who had set up a factory within a mile of the power-house, and who wanted 1000 horse-power, and wished to be able to vary the electric pressure during the heating of their electric furnace. Arrangements for arc-lighting, for tramways and house-lighting, had also to be arranged. When this was all completed and the first plant in place, the period of construction and design gave way to a period of dividend-earning, and my continuing to take charge would have swallowed up too much of the annual income, so I concluded my engagement with the company. In writing my farewell letter, I felt how much I had been assisted by the acting directors, and I told them so while summarising the results which we had been enabled to attain to. In this letter I said that we now had completed a work which for successful working, security against break-downs, high efficiency, and low cost, was ahead of anything that had hitherto been even dreamt of, and that I was confident of a great success from a commercial point of view.

The company, through their president, replied in cordial terms as to the satisfactory results of our co-operation, from which it may be interesting to make the following extract:—

"In our desire to secure the best theoretical results under your eminent and valuable advice, it has been most gratifying to have had your cordial co-operation up to this point, where the commercial manufacturers are ready to give us satisfactory guarantees of performance.

"When you were selected as the electrical consulting engineer of this company, we recognised that the novelty in the proposed size of units to be used in the Niagara installation, and in the character of the station proposed for the generation and distribution of power, was such that we must have the benefit of the very highest scientific advice. We further recognised that in the advocacy of the use of the alternating current and of low frequencies you were a pioneer, and we join you in the feeling of just satisfaction in the conclusion which has now been reached in respect of those features. In this, too, your independence of thought and action has been of peculiar service, while, through your original design of the stationary armature and revolving [external] field of the generators, adopted by us, you have relieved us of one most embarrassing question in connection with the relation of the generator to the turbine. Nor can we fail to recognise the value of the vast fund of information which you have brought to us concerning electrical installations in different parts of the world, and well described in your various and exhaustive reports.

"In making you this partial expression of our appreciation of your assistance during your professional connection with this company, we beg to assure you that we now part from you with the best wishes for your professional and personal success."

The letter from which I have made this extract attributes the splendid results which we attained mainly to engineering skill. I am inclined to believe that they were fully as much the result of an exercise of tact, judgment, and forbearance, combined with firmness—qualities which I do not hesitate to say that both the officers of the company and myself recognised in each other, and without which we should have found it difficult to obtain satisfaction from the manufacturers. We had the utmost difficulty in enforcing proper tests for balance of the dynamos, and the strict rule that no circuit should be suddenly opened or closed while carrying a large current. I mention these as being two matters of prime importance, the neglect of which would have been a crime. Owing to the support I obtained from the acting directors, the whole work for which I was responsible has been put in place and set agoing without a single hitch. This is not usual in a novel work of so great magnitude. I feel confidence in asserting that so long as the instructions I insisted upon are acted on, there will be no trouble with the electrical machinery.

In jotting down these personal experiences, I may have failed to give a *coup d'œil* of the whole scheme. Now there is at the Falls a small tower of observation, like Eiffel's, 300 feet high. The last time I was there I penned a letter to the 'Times,' which was published at the end of the year 1894, from which I may make an extract:—

"I am perched on the top of a small Eiffel tower, lately erected, and casting my eyes up the river, over the house-tops and beyond the town, I see a new world created. There is a wide canal leading water from the river into that gigantic tower-house where three turbines are set up to drive three dynamos of 5000 horse-power each. There is the bridge to carry cables across to the transformer house. Inside the tower-house the water is carried down pipes $7\frac{1}{2}$ feet diameter into the turbines, and thence it passes through a 7000-feet tunnel under the town, emerging below the Falls, the tunnel being capable of developing 100,000 horse-power. Far as the eye can reach extend the company's lands, with here and there a huge factory either now using the water-power, or waiting for the electric

supply. One of them uses 3300 horse-power, another 300, a third one 1500, and that unfinished one requires 1000. You can see, far away, the model village for working men, and improved sewage-works with drainage, pumps for water-supply, electric light, and well-paved streets. There again is the dock where ships from all parts of the Great Lakes can unload, and there a huge expanse of reclaimed land; while the whole is swept by the company's railway, seven miles long, connecting every factory with the great trunk lines."

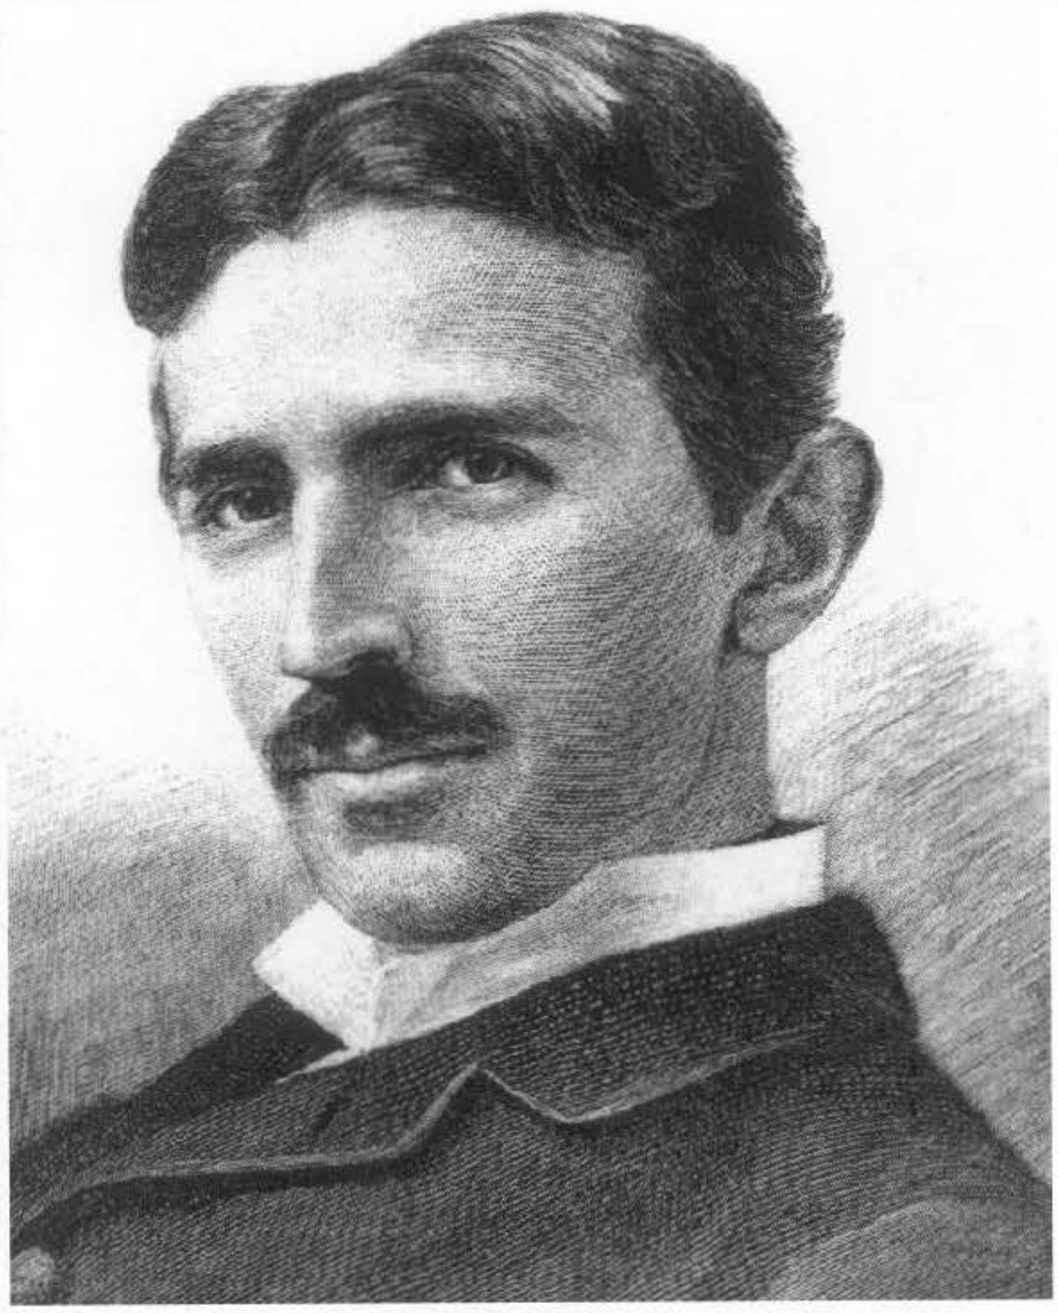
Since these words were written the machinery has been set to work on its commercial task of supplying power and earning money.

The directors have no present desire to send the current to great distances. It will pay better to create a smokeless manufacturing town in the neighbourhood. If required, the power could be sent much more than a hundred miles, and still be more economical than steam, even though coal is cheap there. In countries where power is much wanted, but very costly, the electrical transmission will be successful at distances of many hundreds of miles. Such cases occur in many places where there are valuable mines but no fuel.

In conclusion, I may say that the work done at Niagara is the forerunner of much more, and already I have in hand the preparation of plans of schemes nearly as important.

I also wish to bear tribute to the kindly friendship which I almost universally experienced at the hands of American engineers. Hardly a single case occurred where any jealousy was shown at an Englishman (or rather Scotchman) being selected to carry out the work.

GEORGE FORBES.



NIKOLA TESLA AND THE ELECTRICAL OUTLOOK.

THE NEW DEVELOPMENT IN POWER TRANSMISSION.

WHEN Nikola Tesla last gave to the world the results of his explorations into the field of electricity, the predictions which he ventured as to the possibilities of his discoveries were skeptically received. That was two years ago, in a lecture which he delivered before the Electrical Congress in session at the World's Fair. "His work is brilliant, but of what use is it?" said one of Europe's leading savants when Mr. Tesla had finished; and in this exclamatory interrogation the learned scientist voiced the general opinion of the whole Congress. Mr. Tesla was regarded as a theorist and his inventions as impracticable.

A few weeks ago we witnessed one of the triumphs of this industrial age, the yoking into service of old Niagara herself. While this event is yet news, there comes the announcement that one of our great electrical companies has formed a business alliance with the largest locomotive works in the country, with the view of substituting electricity for steam on our railroads. These two projects are themselves an answer to the question asked by the incredulous savant: Of what use is Mr. Tesla's brilliant work? for neither of them would at this time have been practically possible but for his discovery known as the "rotating magnetic field," which opened the way to the conversion (by means of the alternating, as against the direct current) of electrical into mechanical energy and the economical transmission of power through long distances. This discovery forms the basis of the Niagara Company's attempt to utilize on a large scale that enormous power which for centuries has been running to waste and thus to turn machinery in towns and cities so far away as Buffalo, 20 miles distant, and perhaps New York and Chicago. And it underlies the hardly less bold venture of the Westinghouse and Baldwin companies to drive a through railway express by electricity. It is not too much to say that the Tesla motor is behind all the large attempts at power transmission by electricity which are being made throughout the country, not only in the fields of manufacture and transportation, but also in mining, irrigation and farming.

The "rotating magnetic field" was discovered by Mr. Tesla over ten years ago, when the problems engaging the attention of the electrical world were the furnishing of light and the transmission of sound. The advantages of the alternating current as applied to lighting were already recognized, but no attempt had been made to adapt it to motor work if, indeed, it had been seriously thought of. The direct current then in use was difficult to transform and not practicable for long distances. Mr. Tesla was at least the first to conceive an effective method of utilizing the undulating current. As every one knows, a small piece of soft iron, when placed close to an ordinary magnet (or bar of iron around which is passing an electric current), will be drawn to the magnet and adhere motionless to it. It occurred to Mr. Tesla that if instead of a bar of iron he should take an iron ring and use two alternating currents, so regulated that one would be positive in value when the other was negative, he could, by means of wires wrapped alternately about the ring,

NIKOLA TESLA.

produce a magnetic current which would travel around the ring in accordance with the frequency of the alternations in the electric currents. His theory worked in practice and he thus had a magnet the north and south poles of which revolved while the magnet itself remained stationary. A piece of iron pivoted at its centre and placed within the magnetic field of the ring, and concentric to it, would, therefore, be revolved by the changing poles of the magnetized ring. In this way Mr. Tesla was able to convert electrical into mechanical energy much more simply, economically and effectively than it had been possible to do it by the direct current. It was now only necessary to pass alternating currents around the axle of a wheel in order to set in motion the machinery of a mill or drive a railway engine.

For transmission purposes, as well as in transforming electrical into mechanical energy, Mr. Tesla was soon able to demonstrate the superiority of the

undulating over the direct current. It will be sufficient here to say that by means of his motor, which is only a development of his ring magnet, power may be sent long distances with but small loss. The magnitude of the field opened up by the Tesla motor will be apparent when it is considered that ten years ago it was not economically possible to transmit power more than a few hundred feet away from the source of production, while to-day its transmission is no longer a question of state of the art, but one of capital only. As early as 1891, Mr. Tesla's method was successfully employed in the experiment of sending 100 horse-power 109 miles from Lauffen to the Frankfort exposition grounds. In Southern California there has been in operation for two or three years a plant which transmits power equivalent to 10,000 volts from a waterfall to a sub-station at Pomona, 13¾ miles distant, and San Bernardino, 28 miles away; and there is now being projected, also in California, an enterprise which will involve an outlay of from $2,000,000 to $3,000,000 for supplying motors in San Francisco and adjacent cities with 20,000 horse-power from the outlet of Clear Lake, 75 miles to the north. Mr. Tesla believes that it is easily possible at the present time to place 100,000 horse-power on a line at Niagara and deliver it to New York or Chicago, with a loss in energy of less than 25 per cent.; and it would seem that the Cataract Construction Company is also persuaded that this is within the limits of practical achievement.

The alliance of the Westinghouse and Baldwin companies is in line with the policy recommended by Dr. Lewis Duncan in his address on the substitution of electricity for steam in railway practice, delivered last June at the Niagara meeting of the American Institute of Electrical Engineers—that of making electricity an ally instead of an enemy of steam. This union of large railway and electric interests would seem to mark the beginning of a new era in traction, coming as it does along with the substitution of electricity for steam by the Old Colony road on its Nantucket Division out of Boston; the adoption of an electric instead of a steam engine by the Baltimore & Ohio Railroad, for use in hauling heavy express and freight trains through the long tunnel underneath the city of Baltimore, and the installation of an electric line by the Pennsylvania Road from Mt. Holly to Burlington. The purpose of the Westinghouse Baldwin combination, as officially announced, is to develop the possibilities of the Tesla motor as applied to railroad service. It is declared that with this motor, power is assured sufficient to draw cars at the rate of 150 miles an hour. This is perhaps the possible speed under favorable conditions of road and equipment rather than the rate likely to be attained in every day travel.

The method of electric traction in use on the three roads named is the trolley, the power being supplied to the motor or motor cars from the central station by means of wires. It is the same system that is in general use upon our electric street railways, except that the alternating instead of the direct current is employed, the direct, as has already been noted, not being practicable in long distance transmission. The trolley, either the overhead or the underground, is the only method that has so far been demonstrated as suitable to general railroad practice. By means of the Tesla motor it is now regarded by conservative railway men and electricians entirely possible to run trains under this system, say from New York to Philadelphia, or through multiplication of the power stations from, Boston to Washington, or even across the continent from New York to San Francisco. But whether or not it would be feasible at the present time for our large companies to change from steam to electricity, in part or throughout, is another question. These are transition days for electric traction and it is not probable that any of them is at present willing to go to the expense of equipping electrically a considerable part of its line with a system which may soon be rendered obsolete by some new method.

Perhaps we already have this new and superior method of traction in the combination steam and electrical engine upon which Mr. Tesla has been at work for many months. The invention has been taken over by the Westinghouse Company and it is probable that it is this application of the Tesla motor that the new alliance is to develop. This engine is designed to do away with the use of the unpopular and well-abused trolley. Instead of drawing its power by wire from a central station, the engine generates its own power by converting steam into electric energy and then into mechanical. By this transformation a large per cent. of the power that is now wasted in steam locomotion is conserved. From the same amount of fuel Mr. Tesla has demonstrated, experimentally, that he can easily obtain twice as much effective energy, and under favorable conditions three times as much. He effects this saving by means of a "mechanical and electrical oscillator,"—an engine which is in itself a dynamo, and which operates with small frictional losses. The principle of this mechanism rests on the law of vibrations. With the machine electrical currents may be transmitted of a perfectly constant period and at an absolutely certain rate, and so regulated as to drive with precision an engine or a watch; thus, in railroad practice, overcoming the wear and tear to which cars are now subject by the continual change in steam pressure. The Tesla "oscillator" is really a power station on wheels, instead of a locomotive designed to draw a train of cars. The power which it generates is communicated to the wheels of the cars as well as to its own. This is accomplished by applying the principle of the "rotating magnetic field" in simply passing alternating currents around each axle. Thus an even, steady motion is attained and favorable conditions afforded for a high rate of speed.

Nikola Tesla, who is thus helping so effectively to solve one of the great industrial problems of our day, the economical transmission of power, is still a young man in the very vigor of life. His work has only begun.

The Tesla Patents in France.—*L'Industrie Electrique* states that MM. Schneider et Cie, sole concessionnaires for France of the Tesla rotary-field patents, has issued writs against MM. Weyher et Richémond, who build Brown motors, MM. Guitton et Bertolus, who own the Oerlikon patents in France, and M. Joly, Lyons representative of the firm of Alioth, of Basle and of the Société Grenobloise, which makes a rotary-field motor.

LEGAL NOTES.

THE TESLA PATENTS.

THE Westinghouse Electric and Manufacturing Co. has issued a circular directing attention to its Tesla patents, under which it is suing the General Electric and Stanley Cos., and asserting that these patents control all the developments of polyphase and multiphase working, both for lighting and for power.

The Tesla Patents.

The Westinghouse Electric and Manufacturing Company have issued the following circular letter to central station men:

DEAR SIRS: In view of the great prominence given to the multiphase motors covered by the patents of Mr. Nikola Tesla, we think it right to direct your attention to the fact that this company claims the exclusive right to manufacture and sell all forms of motors operated by currents of two, three or more phases, and all forms of single phase motors where a second phase is induced so as to make the same a two phase induction motor—notably the form used for the operation of fans. Suits are now pending against the Thomson-Houston Electric Company (the General Electric Company), the Stanley Manufacturing Company of Pittsfield, Mass.; and numerous suits have been entered against the users of apparatus purchased from the above companies; it being the intention of this company to enforce its exclusive right to manufacture and sell multiphase generators and motors, the two being used in combination as a system, and such system being covered by the patents of Nikola Tesla above referred to. In the first-named suits, the General Electric Company has put in its defence, and the Court has limited it to October 7, 1895, in which to complete its testimony, so that a hearing may be had in the latter part of this year or the beginning of 1896. We are advised that the defence has been unable to produce a single working device that can in any way take from Mr. Tesla the pioneer character of his inventions.

We have been informed that the two companies named have offered to guarantee the purchaser of infringing apparatus against damage or loss, but you can well appreciate that it will be impossible for such companies to make good their guarantees to cover all losses if the courts enjoin the use of apparatus made in imitation of that covered by Tesla's patents.

We are prepared to furnish multiphase generators and motors for all classes of work, and being the owners of the patents, no contingency can arise by which the purchasers of such apparatus made by us can in any way be interfered with in its continued commercial use.

It is the opinion of those who have given the subject most careful attention that in the near future a very large proportion of electric work will be done by the multiphase system, and this together with the fact that in the main we believe men would prefer to purchase property from its rightful owners, has led us to write to you and give you an opportunity to place your orders with this company for such multiphase apparatus as you may desire to use, and thus avoid the risks incident to the purchase of apparatus from unlawful manufacturers.

The adoption by the General Electric Company of the term "Monocyclic" in connection with their use of multiphase apparatus does not free them from the charge of infringement, but on the contrary makes the case against them stronger, because of the sale of apparatus under misleading terms.

In conclusion, we wish to call your attention to the fact that with our system incandescent lights, arc lamps and alternating motors can be operated from the same circuits, and that it will be of especial advantage to companies desiring to remodel or to increase their plants to make a full and careful investigation of the Tesla apparatus as installed in our works at East Pittsburg, and you are invited to come or send a representative, to whom every facility will be given for careful inspection. Yours truly,

WESTINGHOUSE ELECTRIC AND MFG. CO.

The Tesla Multiphase System.

Mr. Lemuel Bannister, vice-president and general manager of the Westinghouse Electric and Manufacturing Company, of Pittsburgh, is sending the following letter to central stations throughout the country:

In view of the great prominence given to the multiphase motors covered by the patents of Mr. Nikola Tesla, we think it right to direct your attention to the fact that this company claims the exclusive right to manufacture and sell all forms of motors operated by currents of two, three or more phases, and all forms of single-phase motors where a second phase is induced so as to make the same a two-phase induction motor, notably the form used for the operation of fans. Suits are now pending against the Thomson Houston Electric Company (the General Electric Company), the Stanley Manufacturing Company, of Pittsfield, Mass., and numerous suits have been entered against the users of apparatus purchased from the above companies; it being the intention of this company to enforce its exclusive right to manufacture and sell multiphase generators and motors, the two being used in combination as a system, and such system being covered by the patents of Nikola Tesla above referred to. In the first named suits, the General Electric Company has put in its defense, and the court has limited it to October 7, 1895, in which to complete its testimony, so that a hearing may be had in the latter part of this year or the beginning of 1896. We are advised that the defense has been unable to produce a single working device that can in any way take from Mr. Tesla the pioneer character of his inventions.

We have been informed that the two companies named have offered to guarantee the purchaser of infringing apparatus against damage or loss, but you can well appreciate that it will be impossible for such companies to make good their guarantees to cover *all* losses if the courts enjoin the use of apparatus made in imitation of that covered by Tesla's patents.

We are prepared to furnish multiphase generators and motors for all classes of work, and being the owners of the patents, no contingency can arise by which the purchasers of such apparatus made by us can in any way be interfered with in its continued commercial use.

It is the opinion of those who have given the subject most careful attention, that in the near future a very large proportion of the electric work will be done by the multiphase system, and this, together with the fact that in the main, we believe, men would prefer to purchase property from its rightful owners, has led us to write to you and give you an opportunity to place your orders with this company for such multiphase apparatus as you may desire to use, and thus avoid the risks incident to the purchase of apparatus from unlawful manufacturers.

The adoption by the General Electric Company of the term "Monocyclic" in connection with their use of multiphase apparatus, does not free them from the charge of infringement, but on the contrary makes the case against them stronger, because of the sale of apparatus under misleading terms.

In conclusion we wish to call your attention to the fact that with our system incandescent lights, arc lamps and alternating motors can be operated from the same circuits, and that it will be of especial advantage to companies desiring to remodel or to increase their plants to make a full and careful investigation of the Tesla apparatus as installed in our works at East Pittsburgh, and you are invited to come or send a representative, to whom every facility will be given for careful inspection.

ELECTRICITY.

attention to the fact that this company claims the exclusive right to manufacture and sell all forms of single-phase motors where a second phase is induced so as to make the same a two-phase induction motor, notably the form used for the operation of fans." The advice is also given to those who are using motors of the kind named to avoid permanent injunction by arranging with the company betimes, as a decision in important suits now pending is expected early in 1896, and all indications point to a decision in favor of the owners of the Tesla patents.

Progressive Age (Oct. 11), which gives these facts with editorial comments, while regarding much of the circular as "pure advertising," to be "taken with the large modicum of salt needed by the statement of a corporation with millions at stake and whose fate is still in the hands of the courts, undecided," yet feels it a duty to present the facts on the side of the company.

"It is undoubtedly true that electrical apparatus depending upon alternating currents of two or more phases will play an important part in the electrical industry of the near future. It is still more certain that a decision of the suits in question will throw a tremendous amount of existing apparatus out of legitimate use, and a corresponding amount of new business into the hands of the victor; while rumor has it that all the points of equity, if not of law, are on the side of the aggressive corporation. So that, whichever way the proceeding turns,—and we do not presume to undertake prophecy, or legal analysis of the question,—there will be a large volume of property affected, outside of that owned by the two principal combatants."

The guarantees to purchasers under which a large number of this class of motors have been sold our contemporary regards as worthless, in case the favorable decision expected by the company shall be obtained. "The intentions of the insuring party may have been of the best, but it is now clear that the liabilities which he has thus gradually accumulated are such as will fall, if at all, in a lump, and, when they fall, are certain not only to swamp,

---

The Tesla Patents.

THE company which controls the patents granted to Mr. Nikola Tesla evidently is planning to make it warm for infringers. In a circular recently sent out to persons and corporations deemed to need the warning, they say: "In view of the great prominence given to the multiphase motors covered by the patents of Mr. Nikola Tesla, we think it right to direct your

but to leave by far the greater portion of the insured without protection or protector. The questions therefore arise: Are these parties, so plainly damaged in equity, to have no recourse in law? And if so, to whom?"

It appears to us that there is no recourse. In such cases one would wish that purchasers could be protected, if possible; but we can see no way whereby a person, having accepted an insufficient security and relied upon it as a sole remedy, can be resecured; and the editorial reviewed admits the extreme difficulty of the case. "Clearly the purchasers should be protected. But by whom? It is plainly not the duty of the successful litigant, who has been merely defending his rights. It is as plainly beyond the powers of the vanquished party. So the question is not a simple one. But it would certainly seem that, if the State cannot guarantee the validity of its patents, before it issues them, or is so slow settling that validity by other means that large numbers of its citizens become involved in losses as a consequence, it cannot be regarded as clear of blame, or at least of indebtedness."

Emanations from an Egoist.

PROF. FORBES SURVEYS HIMSELF AND IS FULLY SATISFIED.

How He "Harnessed Niagara."

The pest of society is egotists. . . . In the distemper known to physicians as chorea the patient sometimes turns round and continues to spin slowly on one spot. Is egotism a metaphysical varioloid of this malady?—*Emerson.*

Prof. George Forbes, C. E., has contributed an article to the current number of *Blackwood's Magazine*, in which he settles forever a great many disputed points in regard to the Niagara transmission scheme and the work of those connected with it. There is no longer any doubt as to who did it at all. The master mind was that of Forbes. Forbes has confessed it in 9,000 words, of which 200 are personal pronouns. Kelvin, Turrettini, Mascart, Sellers, Unwin, the Westinghouse Company, and the rest were never in it from start to finish except as disturbing elements to annoy the Master Mind.

Yet the creation of the great Niagara plant is not the Professor's crowning achievement. His glory of glories must forever be the *Blackwood's* article. We print such of it as is of especial interest to Americans, with a few brief comments, which are offered in a spirit of abject humility, as becomes an editor who at one time in his life was an American bagman:

There is no class of professional men who travel so much as engineers. Their experiences are often full of interest, and at times not devoid of excitement. Yet how seldom it is that any account of these travels is found in print. This is partly due to the fact that it all seems to the principal actor to be all in the day's work, and hardly worth committing to paper. But there is also a certain pleasure in having a store of experiences to relate to one's more intimate friends, which the vulgar crowd cannot read in a book.

At the present moment I am tempted to curb this natural reticence with the object of narrating my experiences of the last few years, which I believe are unique in our profession.

How can any one curb a natural reticence?

Our engineers are often called upon to travel in difficult countries, and to accomplish what look like impossibilities. But it is by no means an everyday occurrence for the financial men in a great country like the United States, who are not in the habit of minimizing the capabilities of their fellow-countrymen, to invite a foreigner to carry out one of the greatest works of modern times in that country. Some people say that the Americans are perhaps too much inclined to look upon their countrymen as the inventors of Electricity. It is, then, all the more surprising that the work about which the English engineer was asked to advise them was the electrical utilization of Niagara Falls. It must, however, be remembered that this work involved entirely new problems and designs, while the American electrician has less capability of evolving entirely new plans, or designing entirely new machinery, than of adapting his past experience, exactly as it stands, to new conditions. It was for this reason that one of the ablest of American engineers said in public three years ago that it was impossible to transmit the power of the Falls to Buffalo, some twenty miles, so as to make it pay; whereas we have now established the fact that the limit of distance is to be counted by hundreds of miles.

The remark of the American engineer must stand as truth until the contrary is proved. Power has not yet been sent to Buffalo. The statement that "the limit of distance is to be counted by hundreds of miles" is contrary to experience.

There are two great mistakes commonly made as to Americans. One is, that they are original inventors; the other is, that they are humorous. Neither of these propositions is true.

We yield both points to Forbes; he is the greatest inventor and the most humorous humorist of the age; and thank God he is not an American.

. . . Invention and humor require a gift of imagination, the same gift that shows itself in poetry and letters, in music, painting, and sculpture; and in no one of these directions has this gift of imagination been found to predominate amongst Americans.

In no one of these directions, save perhaps in poetry, does the Anglo-Saxon race lead; and in poetry America has no cause to be ashamed of her productions. In fact, more copies of Longfellow have been sold in England than of Tennyson.

I have given these reasons why it was perhaps natural to have recourse to a European to take hold of this great and entirely novel problem. Another reason is that all their electricians who may have had a wide practical experience are tied to manufacturing companies, and cannot be looked upon as independent either in thought or action; and since it was pretty certain that any plans that might be adopted would have much of novelty in them, and would be opposed in the first place both by scientific men and by the manufacturers, it required that the man selected should have nothing to gain or lose by the friendship or hostility of these two classes of men.

When I had finished my work at Niagara Falls the chairman (or president, as he is there called) of the company wrote me a letter, in the course of which he incidentally mentioned some of the reasons why I had been invited to carry out this work. . . .

Passing now from these digressions, let us come to the Falls themselves. I have no talent for pictorial description. . . .

Forbes is too modest. His whole article is a word-picture, a living picture, and when one finishes it the image of Forbes is fixed on his mind never to be effaced.

The village or town of Niagara Falls on the American side of the river is built of wood. It is dirty, and the streets are bad. Its industry is the catering to excursionists. Cheap restaurants, merry-go-rounds, itinerant photographers, and museums of Indian and other curiosities are the chief features. The last are mostly impostures, always excepting the world-famed "Katie & Libby's Stores," where genuine curios are to be found, and many pleasing souvenirs.

Who would dream that Forbes could have been taken in by our old friends Katie and Libby?

This village is remarkably conducive to the concoction of lies, and the Falls lend themselves to the art. . . .

We fear the Professor stayed there too long.

To me the great charm of the Falls is their immutability and change.

The drifting spray and varying light give the changes of a kaleidoscope, but the volume of water pouring over never varies. They remind me of the face of a dear friend, always the same but never two moments alike. I suppose there is nothing to compare with them in size or grandeur except the Victoria Falls of the Zambesi; and Livingstone, who never exaggerated, said that these were the finer.

. . . The old mills which used to be in the stream above the American Fall have been removed for æsthetic purposes and the land laid out with some attempt at good taste.

To what æsthetic purposes have they been devoted?

On the Canadian side the same thing was done, but I regret to say that the rapacity of the Legislature of Ontario has not proved equal to withstanding the blandishments of the greedy capitalist. Two lines of rails traverse the whole of the National Park at the edge of the gorge. After the land had been confiscated by the Government, and the owners had been paid only a fraction of its true value, it is now turned into a source of revenue by the Government, and a gold mine to the capitalists, at the expense of the visitors, who can no longer enjoy the peaceful quiet which Lord Dufferin tried so hard to give them. . . .

In 1889 the Niagara Falls Power Company was formed to carry out this work, and their first act was to buy up all the land in the neighborhood. The capital subscribed was wholly American, and amounted to £2,000,000, about one-half of which has been spent. The acting committee consisted of railway men and lawyers. The chairman, as usual, is called a president. They like giving big names to things in America. A pond is a lake, and a hill is a mountain; they never speak of the sea, it must be called the ocean; a meeting is a convention, a dictionary is a "speller and a definer."

How many Americans knew this before Prof. Forbes told them?

A town is a city, a chairman is a president, and so on. The only exception I know of is that the wealthy people who own those charming country residences at Tuxedo and Lenox call them cottages. But these are not average Americans, and in that country the manners and customs, as seen by the ordinary traveller, are governed by the average man, who is not a good specimen. He is apt to be a most awful "bounder," has no taste, and does not know the meaning of the word "repose"; but you need never meet this type except in railway trains and hotels. His ideal, as one of them told me, is to spend his nights "on the cars" and his days in getting the better of his fellowmen. But the refined American is quite different. These are mostly met in Washington and the South, and, of course, Boston is a thing apart; and as you approach this town you are told that the humming you hear is the noise of the people reading Browning. Tuxedo also is a great exception, where you can have congenial society. It is a large estate with woods and lakes and forty miles of well-laid roads. Country houses or cottages have been built all over it, and there is an excellent residential club—into which, however, the female element has progressed so far as to have introduced even babies into the bedrooms!

I must really ask to be excused for such digressions, but I must tell my story in my own way or leave it alone.

And not even the "average American" would stop you, Professor. You are a peach.

The chairman of the company which has utilized the Falls is Mr. E. D. Adams, well known as a banker and a reorganizer of railways. The first vice-president is Mr. F. L. Stetson, a lawyer who has also had much experience in the finance of railway companies. Mr. Cleveland, the U. S. A. President, is a partner in his law business. The second vice-president is Mr. E. A. Wickes, also a railway-man. The secretary and treasurer, Mr. W. B. Rankine, is one of the most able and energetic and charming men I met in the States. I only hope he will not utterly ruin his health by overwork. All these are very able business men, though not engineers, and the affairs of the company could hardly be in better hands——

Unless Forbes took charge again.

In October, 1889, the Niagara Falls Power Company was formed to carry out the great work of utilizing the Niagara Falls on so gigantic a scale that all previous attempts to use water-power at once sank into insignificance. The Cataract Construction Company was at the same time formed by the same people to carry out the work. . . .

In order to obtain more definite ideas they invited certain engineers to prepare plans of any methods they might think best. These were to be laid before a Commission of engineers and physicists from England, France, Switzerland, and America, with Lord Kelvin as chairman.

At first I declined this invitation on the grounds that the method of competition is contrary to my professional practice, and also that with so novel a problem I would not accept any man, or combination of men, to adjudicate upon the project which I might decide upon.

Having learnt, however, accidentally, that any electrical plans to be submitted would not be of a satisfactory nature, I withdrew my refusal in order that a plan, as I conceived on proper lines, might be at least in evidence. . . .

Now let me say, without explanations, that there are two kinds of electric current—a "continuous current," always flowing in the same direction, and an "alternating current," in which the direction of flow is reversed, it may be hundreds of times in a second.

I soon realized the fact that not only could the latter current be more easily obtained at high pressures, but that it could easily, and without moving machinery, be transformed to any required pressure at any spot when it was wanted.

Up to that date, **1890,** both kinds of electric current had been used for electric lighting, but the alternating current had never been used for giving mechanical power except in an experimental way. For this reason it seemed to most people absurd to suggest its use for Niagara Falls. I would have shared this view were it not that for several years I had visited the United States and the continent of Europe to study the progress that others were making in electric work. I had thus become well acquainted with the system which Nicola Tesla, a young Montenegron, was experimenting on at Pittsburg, U. S. A., called a "two-phase" system. I also had seen many things in various parts of Europe not generally known in England. Owing to these varied experiences, I HAD AN OPPORTUNITY ABOVE ALL OTHERS AT THAT DATE of foreseeing that the alternating current would soon be very generally applied not only to light, but also to motive power.

Here we must digress long enough to introduce a little correspondence between Prof. Forbes and the Westinghouse Company, in **1891,** which needs no comment.*

Acting upon this knowledge, I worked out complete plans, using only machinery which could then be got in the open market, and was able to furnish complete working plans, drawings, specifications and estimates of cost. This laborious work when concluded left no doubt in my mind that the alternating current must be adopted.

The Commission sat upon these plans, and, as I expected,

---

* (*Prof. Forbes to Mr. George Westinghouse, Jr.*)

34 Great George Street, London, S. W.,
September 19, 1891.

Dear Mr. Westinghouse: I am going to read a paper on alternate current motors. I want to emphasize the importance of your work on the Tesla motors. May I ask you kindly to allow me to have as full information as possible by instructing one of your staff to forward some details? I daresay you cannot give me all the facts I want, but if I indicate them generally perhaps you will give me some of the points. First, and most essential, I want a drawing to show the winding of the armatures, especially the unsymmetrical winding, which I saw last year. I should also like to have drawings of the complete machines, generator and motor, the dimensions, weight, speed of revolution, output and efficiency of any particular machine that you have made. What are the largest and smallest machines you have had giving good results? What is the period of alternations and e.m.f. you have used? What examples may I quote of their successful use in practice? I know that the development of the motor has been retarded by other than engineering difficulties. I am glad to learn that the financial difficulties of the company have been surmounted.

With kind regards I am, yours most truly,

GEORGE FORBES.

P. S.—I also want facts about the power when starting the motor.

(*Mr. George Westinghouse, Jr., to Prof. Forbes.*)

Pittsburgh, Pa., October 30, 1891.

Prof. George Forbes, 34 Great George Street,
London, S. W., England.

My Dear Sir: I desire to apologize for not having written earlier in answer to yours of September 19th. I have given the matter very full and careful attention,

denounced the alternating current, for none of them had had the experience which I possessed of the latest developments. . . .

I heard no more from the promoters of this enterprise for over a year. It took them all this time to realize that the Commission had made a mistake. Lord Kelvin was the most violent opponent of the alternating current; and for long afterwards (although he is my most esteemed and oldest scientific friend), even when I was appointed as the consulting engineer, he continued to write and cable to the company, though his opinion on this point was not asked for, telling them that they were making a "fatal mistake" if they followed my advice. . . . But in this and other points where my plans were at variance with the opinions of others, I was most loyally supported by the directors, and through this support alone they and I have been enabled to put the works into their present satisfactory condition. . . .

Early in the year 1892 it became evident to the acting committee that the views of engineers had been undergoing a change, and that the use of alternating currents for Niagara was a necessity, thus indorsing the prophecy I had made long before. They then asked me to act as their electrical consulting engineer, and during that year and the next and the next I was constantly in the States. The only real rest I ever got was in my voyages across the Atlantic. I soon came to feel at home on all the large liners. . . . The misfortune is that at most seasons the only class to travel much are the American bagmen or drummers, and they are not a favorable class to judge Americans by.

Sometimes I lived in New York where the offices were; sometimes at Niagara to be near the works. I did not care to go much into society, but I made some very firm friends, specially the Hewitts, and our amiable Consul-General Sir William Booker and his charming American wife. My greatest friend of former days had been S. L. M. Barlow, a well-known and remarkable man. Roscoe Conkling and I used to dine with him every Sunday. These two lawyers, both able men, on opposite sides in politics and also in the great Stewart will case, amused and instructed me much by the exposition of their views on men and things. Both were dead now and I had two friends the less to help me pass these three years. Part of the time I lived in Tuxedo, an hour from New York, where you could have fishing, shooting, boating, bathing and golf; and I shall never forget the cordial welcome I there received from the Potters Bruzes, Lorillards, Delafields, Fishes, Kents, Rushmores, Prestons, Van Courtlandts, Van Nests and from Allen Lathrop and many others. The lovely scenery and genial society of this place helped me greatly to retain health during a period of anxious and arduous work.

This is all of intense interest, and the Professor should not have cut it off so short. We crave for more.

In 1892 when I came to examine the plans put in by various manufacturers, I found that some of the crudest work conceivable had been submitted by the Americans. The Europeans sent some excellent designs, especially the Oerlikon Fabrik, near Zurich. But these makers were handicapped by the duty imposed on machinery imported into America. There was, however, one fatal defect in all the plans then or subsequently submitted by the manufacturers. . . . The American manufacturers were entreated to alter their dynamo designs to meet this difficulty. They tried, but they were unable to do so. . . . Meanwhile I had been constantly working at various new designs, and at this stage I saw that, for the credit of the company, it was imperative that I should, if possible, get out a design on new lines which should have the required fly-wheel effect without too great a weight. . . . It occurred to me that if I could make the external part revolve I should get a maximum of fly-wheel effect with a minimum of weight. . . . I proceeded to get out rough designs and found, with the utmost satisfaction, that I could meet all the requirements of the turbine-makers. I also found that this design gave far greater mechanical strength to the revolving part of the dynamo—an important matter, with this forty tons revolving more than four times a second. Furthermore, the magnetic attractions which in all the other designs increase the dangers from centrifugal force, in my design actually diminish them. It soon became evident that this happy idea of revolving the external parts completely extricated the company from the very awkward dilemma in which they had been placed. I then proceeded with a large staff of draughtsmen to get out the working drawings, and I secured an American patent as a protection to myself and my company. It was a matter of considerable satisfaction to all concerned that I had thus so simply got over the serious difficulty which at one time threatened us with starting afresh on all the machinery, turbines and all. . . .

The designing of a suitable dynamo was, however, only one of a number of difficulties that had to be overcome. Some of these were of an engineering character, but others savored of "politics" in the sense in which that word is used in the States. There *politics* means intriguing, underhand dealing and jobbery, and is always used in conversation to express that meaning. *Until I went to America the manufacturers of electrical machinery never had a consulting engineer to reckon with*, but dealt directly with the financiers who knew nothing about cost or efficiency of machinery. When they knew that I was to advise the Niagara Company, they tried by every means in their power to revert to the old plan. Every game of bluff, bounce and threats was used but without the least effect. One of our engineers in another department to mine, who knew nothing of electricity, was completely taken in by one of these firms. This and other intrigues hindered me a good deal in carrying out my plans. Then, again, I had at times great difficulty in keeping the president and vice-presidents in hand. One of the latter, after he had learnt a little about ohms and volts, believed himself capable of instructing me as to which tenders I ought to recommend for acceptance, and did his best to try to influence my judgment. Most of them began to think they knew something about the subject, and that they were quite capable of settling what tests the machines should be put to. All this was generally amusing enough, but became almost tragic at times when I found them endangering the whole work. On such occasions I would write to my millionaires and tell them that if they did not do what I told them they would be personally answerable to the directors and shareholders for any disaster that might occur. This always had the desired effect and my point was carried. I fear that at times they wished me at Jericho, but after any one of these tiffs was over I think they were glad that I had taken that line.

I have said that there were many new electrical problems to attack. One of these was a new departure on my part, which involved a very heavy piece of calculating and designing before I could be perfectly certain that my conclusions were correct. It occurred to me that with the large machinery we were using (the dynamos which I designed * were three or four times as powerful as any that had then been made) it would be best to make the alternating current reverse its direction as slowly as was consistent with making a good dynamo. This would not do so well for *lighting*, but for a *power* station like ours the advantages were powerful and numerous.

Then again, some of the manufacturers, threatened us with patent-litigation if we used certain types of machinery, so I had to get out designs of *another kind of motor* to drive the mills, so that in any eventuality we should be prepared and able to go on in spite of these threats. Then our first customers wanted continuous current, and I *had to select* a method of making the conversion. . . . In the afternoons I generally took a drive in a buggy on the Canadian side, where the roads were passable, and sometimes I rode. I had a *nigger* servant to look after the house, who differed from all his race. . . .

In this difference the nigger was similar to Prof. Forbes

An Englishman in America should always try to retain his Englishness—otherwise in a year or two he will be reduced to the level of an average American. Where all men think themselves equal, individuality is at a premium. An American once tried to find fault with me for pitching into my servant, because, forsooth, all men were equal. I never saw the man before, and would never see him again. So I told him that if he wished to be placed on a par with my valet I would willingly acquiesce, but he must not attempt to define my place on so short an acquaintance. . . .

It is unfortunate that Prof. Forbes never had any "Englishness" to retain. If Englishness means anything, it means refinement and good breeding. The process by which Forbes would reach the level of "the average American" is outlined in the Darwinian theory. It is not a process of reduction.

The dynamos were at last made and tested, after most annoying delays and disingenuousness on the part of the manufacturer. The makers of the transformers and machinery for getting a continuous current, on the other hand, were prompt and obliging, and the tests came out well. Then I got bids for the appliances for transmitting power to Buffalo. All the conclusions I had arrived at from my own designs were now confirmed. Their cost per horse power, even with my low frequency,* was a fifth part of those that had been used for lighting, and the efficiency guaranteed was as I had stated. I decided on all this transmission plant, and it is not now put in only because the Buffalo people want to get the power for next to nothing. There is too much "politics" in this business at Buffalo. Another triumph I have had is, that engineers all over the world have learned to appreciate *my low frequency of alternations*, while we ourselves have found new merits in it at every step. . . .

When this was all completed and the first plant in place, the period of construction and design gave way to a period of dividend-earning, and my continuing to take charge would have swallowed up too much of the annual income, so I concluded my engagement with the company.

Prof. Forbes's salary was $400 a month, including expenses, about one-half of what a good American bagman receives.

This letter from which I have made this extract attributes the splendid results which we attained mainly to engineering skill. I am inclined to believe that they were fully as much the result of an exercise of tact, judgment and forbearance, combined with firmness—qualities which I do not hesitate to say that both the officers of the company and myself recognized in each other, and without which we should have found it difficult to obtain satisfaction from the manufacturers. . . .

Of course he does not hesitate—not Forbes. Why should any man who has so plainly shown his tact, judgment and forbearance, combined with firmness, hesitate.

. . . Owing to the support I obtained from the acting directors, the whole work for which I was responsible has been put in place and set agoing without a single hitch. This is not usual in a novel work of so great magnitude. I

---

and I have come to the conclusion that our company cannot afford at this time to make public the information it has acquired in its work on the Tesla motor. The Tesla patents and discoveries include many very important matters, and his patents particularly cover the multiphase forms of motors and generators now attracting so much attention.

You must have become aware that patent rights are no longer respected in this country; that whatever is brought out and fully explained is immediately availed of by unscrupulous competitors; and we now feel it is a matter of great importance to maintain for the present, and until we are well established, what are properly secrets of the trade. To no one would I sooner give the information asked for than to yourself, and I hope the day is not far distant when we will be able, with safety to ourselves, to meet your wishes in this respect.

Trusting that you will appreciate the reason given for not promptly complying with your request,

I am, very truly yours,

GEO. WESTINGHOUSE, JR.

(*Mr. George Westinghouse, Jr., to the London Times, Aug. 29, 1895.*)

. . . Business relations were established between Prof. Forbes and this company in 1888 by the purchase of his patent for a meter operated by hot air currents, and he was afterwards employed by us as an expert in a patent case and in making tests on transformers. He thus had every opportunity to become acquainted with our practice and ideas in connection with the use of alternating currents for light and power purposes, and also had an opportunity to see considerable of the early work on the Tesla motors. That such opportunities were valuable to him is shown by the fact that the first plan submitted by him for the transmission of power from Niagara Falls was almost identically on the lines that we had laid out for such work and freely discussed with him.

In consequence of Prof. Forbes having written the foregoing letter without stating that he was a competitor for the honor that would accrue to the successful designer of a complete plan, our company, for that and other good business reasons. refused to permit Prof. Forbes under any circumstances to visit its works or to have anything to do with the designing, constructing, or testing of the generators, and we are not aware that he has ever seen the apparatus which is now in operation at Niagara and for which he seeks to claim the entire credit.

. . . In our [World's Fair] exhibit generators, motors, and rotary transformers were operated at 3,600 alternations per minute, being practically identical with the frequency actually adopted at the Falls, and very different from Prof. Forbes's recommendation of about 1,000 alternations per minute.

Prof. Forbes made a suggestion for a device for commutating currents, in place of a rotary transformer, which device was built, and upon test the fact was disclosed that it was not anything like as good as the rotary transformer which we had designed and which form was afterwards adopted by a rival company, as Mr. Forbes says, on his recommendation.

WESTINGHOUSE ELECTRIC & MANUFACTURING CO.,
(GEO. WESTINGHOUSE, JR., President).

* (*Mr. George Westinghouse, Jr., to the London Times, Aug. 29, 1895.*)

After a lapse of two years, and prior to the design of the dynamo referred to by Prof. Forbes, this company submitted to the Cataract Construction Company plans and specifications for a dynamo, with a system of distribution for the operation of arc lights, incandescent lights, street cars, and for electrolytic purposes, including rotary transformers. Full information and particulars were communicated to the engineers and officers of the Cataract Construction Company. Owing to the purloining of our plans by a rival company and for other reasons all tenders for generators were rejected by the Cataract Construction Company, who afterwards, in September, 1893, submitted to us plans for a 5,000 H. P. generator, saying that such plans had been prepared by their engineers, and asking us to make a tender for its construction and erection. A careful consideration of the plans submitted disclosed the fact that if constructed according to such plans the generator would be a failure, and this company thereupon refused to tender on the drawings and specifications presented. We, however, offered to accept the general form of generator, and to re-design it so that it would be a perfect machine mechanically and electrically, and to submit new plans and specifications upon which the company would tender. This was agreed to by the Cataract Construction Company, and the generators now in use at Niagara Falls were built by us according to plans and specifications prepared by our own engineers. There is about the same difference between the machine designed by Prof. Forbes and that designed by us as there is between the picture of a man and the man himself—the appearance externally being very similar, but internally there is no resemblance whatever.

---

* See letter of George Westinghouse, Jr., to "London Times."

feel confidence in asserting that so long as the instructions I insisted upon are acted on, there will be no trouble with the electrical machinery.

I penned a letter to the *Times*, which was published at the end of the year 1894, and from which I may make an extract:

"I am perched on the top of a small Eiffel tower, lately erected. . . ."

Nonsense, Forbes. You are farther from the earth than the top of the Eiffel tower. You are flying through limitless space, and if you get too near the sun, as did Icarus of old, and melt your wings, you will still fall to earth unbruised—if you can light on your cheek.

. . . The directors have no present desire to send the current to great distances. It will pay better to create a smokeless manufacturing town in the neighborhood. If required, the power could be sent much more than a hundred miles, and still be more economical than steam, even though coal is cheap there. In countries where power is much wanted, but very costly, the electrical transmission will be successful at distances of many hundreds of miles, Such cases occur in many places where there are valuable mines but no fuel.

In conclusion, I may say that the work done at Niagara is the forerunner of much more, and already I have in hand the preparation of plans of schemes nearly as important.

I also wish to bear tribute to the kindly friendship which I almost universally experienced at the hands of American engineers. Hardly a single case occurred where any jealousy was shown at an Englishman (or rather Scotchman) being selected to carry out the work.

GEORGE FORBES.

American engineers jealous of Forbes! Perish the thought!

ELECTRICITY has a warm love for Englishmen and for England, and this feeling is the rule rather than the exception in America. But we rejoice that Forbes belongs to England and not to us.

Polyphase Litigation.—We hear on good authority that the Helios Company, of Cologne, who are the owners in Germany of the Tesla patents, have brought actions at law for infringement against all the firms in Germany who are using the three-phase system of motors. In the United States, as we have already stated, the Westinghouse Company has brought suits against the General Electric Company in connection with the "monocyclic" system. And they have gone so far as to prosecute also the Stanley-Kelly Company for using the Stanley two-phase system, although in the motors of that Company the two circuits are kept separate, and not combined to make a rotatory field. Our British manufacturers will doubtless look on with feelings of gratification at the circumstance that, whoever gains or loses, the battle is being fought at the expense of their rivals.

The Tesla Patents in France.—It was recently stated in *L'Industrie Electrique* that Messrs. Schneider et Cie, of Creusot, who, in 1893, purchased exclusive rights to the Tesla rotary field patents for France, have entered suit against the French manufacturers of Brown and of Oerlikon motors in France, and against the Lyons representative of the Swiss firm of Alioath, which makes rotary field motors.

LEGAL NOTES.

THE TESLA POLYPHASE PATENTS.

The General Electric Co. has been granted more time, viz., until Nov. 16, to file evidence in the suit of the Westinghouse Co. against it for infringement of the Tesla patents; and the plaintiffs have twenty davs thereafter for cross-examination. The original limit was Oct. 7.

ETHERIC LIGHTING.

Stimulated and encouraged by the results produced by Mr. Tesla in obtaining phosphorescent vacuum tube lighting by means of currents of high frequency and high potential, inventors have taken up this work and results are already beginning to manifest themselves. In the path marked out for himself, Mr. D. McFarlan Moore has confined his efforts to the production of effects by the employment of comparatively low potentials intensified, however, by the abruptness of the impulses. The method of securing the desired abruptness of breaking of the current by placing the interruptor in a vacuum is an exceedingly simple expedient, which gives Mr. Moore's system one of its principal claims to recognition. The effects already obtained with the Moore apparatus, some of which we have witnessed, give promise of success in the creation of a practical illuminant for general purposes; but even in its present condition the system already possesses unquestioned commercial value.

Tesla Discharge.—The Lond. "Elec.," Oct. 4, notices a paper by Mr. Overbeck in the "Wied. Ann." No. 8, which shows that the Tesla discharge invariably consists of two oscillatory discharges of different frequencies, which latter are not the same as those of the primary and secondary circuits by themselves; in one case where the latter were both 10,000,000 per second those of the two discharge currents were 8,000,000 and 15,000,000 respectively.

INVENTIVE INDEPENDENCE.

History has, it is said, and a new instance proves it, an intolerable tendency to repeat itself. Some fifteen or twenty years ago, we were all—that is, those of us then in the field—we were all watching with intense interest, the endeavors of Edison, Sawyer, Weston, Maxim, Swan, Brush and others to create a practical commercial incandescent lamp. The struggle was intense. A golden goal lay ahead, and it was nip and tuck all the way. Jealous as each man was of the others, there can be no question that the successes of any one encouraged and stimulated all the rest in turn, and led on to further effort. At last the prize was reached, and the incandescent lighting art lifted itself suddenly out of the realm of visionary experiment and wild speculation, into that of tangible and concrete engineering and manufacture.

Vacuum tube lighting has now, in the same fashion, it seems to us, reached the point where the solid ground of practicality looms immediately in front. The earnest workers in the field are not few. Some have published their results, others keep silent; but between them all is the subtle interdependence which leads to simultaneous inventions, parallel discoveries, duplicate experiments, needless repetitions, and finally to differing types of apparatus and the choice of separate paths. We publish a letter this week, on page 478, which to those who have been through it all once before, will be a curious reminder of the earlier assertions of independent work and a not less curious augury of the nearness of the new goal. Although sharply challenged, we do not intend to recall what we said, any more than we intended when it was written to imply that the one inventor borrowed from the other. We simply repeat, that the knowledge of other work being done in the same field, must encourage and stimulate all along the line. It is not for us, or anybody else, yet to pronounce which method of giving light without heat is most preferable, most economical, or most original. All one can ask is that these various workers shall be speedy and industrious, for, heaven knows, the art they are seeking to establish is large enough to employ a hundred geniuses; and in the long run each will get his deserts. That Mr. Moore is pursuing his aim with courage, vigor, tenacity of purpose, and remarkable results is apparent to all who know him.

LETTERS TO THE EDITOR.

MOORE'S ETHERIC LIGHTING.

ON reading your editorial of the 23d inst., on "Etheric Lighting," we were greatly surprised to read,

"Stimulated and encouraged by the results produced by Mr. Tesla in obtaining phosphorescent vacuum tube lighting by means of high potentials and high frequencies, inventors have taken up this work and results are already beginning to manifest themselves."

We feel that this is hardly just to Mr. D. MacFarlan Moore. While we disclaim any intention of disparaging Mr. Tesla's work, we call your attention to the fact that you have unconsciously fallen into error in coupling Mr. Moore's name and Mr. Tesla's.

The public has gotten the impression that Mr. Moore's discoveries and inventions were due primarily to his being "*stimulated by Mr. Tesla.*"

Such is *not* the case. Mr. Moore's interest in phosphorescent lighting dates back a number of years and was never affected by Mr. Tesla's references to the subject.

Some of your readers are aware that there is nothing whatever in common between the widely differing methods employed by each inventor, except that the light is produced by electricity.

Moreover, Mr. Moore was the originator of the term "Etheric" in connection with his lighting system, and long before he had his present laboratory, had written and published a number of articles, intimating in a general way the theory he proposed to employ in producing light with a minimum of heat.

Facts have since demonstrated the correctness of his theory, though originally some of the best electrical authorities pronounced his ideas "impracticable."

The very issue containing your editorial records the fact that nine patents were granted to Mr. Moore on the day named and that many more would follow.

Some of these patents were granted after the Examiner had pronounced the claims non-operative by any known electrical law.

Mr. Moore proved his claims by laboratory demonstration and the patents issued. He was victor at all points.

You have seen Mr. Moore's confidential exhibitions in his laboratory, and in due time we expect you will reproduce the photographs taken at that time, and since, by their own, etheric light, and that you will impart information to your readers which meantime we prefer to keep in abeyance.

We would not trespass on your columns to correct the impression your editorial created, were it not that Mr. Moore's name has been repeatedly coupled with Mr. Tesla's. This was most noticeable at the time Mr. Moore's article on "The Light of the Future" appeared in Cassier's Magazine, July, 1894. The leading journals of the day, although they described only Mr. Moore's work, headed the articles in a way which gave readers the impression that the system referred to was worked out by Mr. Tesla, when in reality he had nothing whatever to do with it. "Honor to whom honor is due."

Moore Electrical Company,
E. J. WESSELS,
Vice-President.

NEWARK, N. J. Oct. 31, 1895.

Electricity Without Wires.

TO THE EDITOR OF THE HERALD:—

In reply to your question as to what discovery would do most to better our condition, in my opinion the demonstration that the earth's electrical charge can be distributed, and thereby electrical waves efficiently transmitted to any distance without the use of cables or wires, would be the most beneficial.

The conveying of motive power from sources such as Niagara in this manner to any place, however remote, would increase many times the productive capacity of mankind. It would bring millions of miserable creatures from the darkness of the coal pits to the light of day. It would cause a kinder feeling to spring up between the weak and the strong, which would lead to a generous adjustment of the evermore difficult questions of labor and capital.

Even if power could not be distributed, the mere transmission of intelligible signals would be of incalculable benefit. Such a realization would do away with the instability of the financial markets, which is the cause of much suffering and misery. It would greatly facilitate the evolution of noevl ideas, as well as the prevention of evils. It would increase the safety of travel and give a new impetus to the press and spread of knowledge. The first message transmitted would be the signal to general disarmament and a closer union of nations, and the words of the great German poet, "Seid umschlungen Millionen, diesen Kuss der ganzen Welt," would be deeply felt everywhere.

Our present knowledge is sufficient to fill us with the conviction that the solution of these important problems is not far off. May the new year witness these triumphs.

NIKOLA TESLA.

NEW YORK, Dec. 31, 1895.

POWER TRANSMISSION.

TESLA ON ELECTRICITY WITHOUT WIRES.

Mr. Tesla thus writes the New York *Herald* under date Dec. 31:—

In reply to your question as to what discovery would do most to better our condition, in my opinion the demonstration that the earth's electrical charge can be distributed, and thereby electrical waves efficiently transmitted to any distance without the use of cables or wires, would be the most beneficial.

The conveying of motive power from sources such as Niagara in this manner to any place, however remote, would increase many times the productive capacity of mankind. It would bring millions of miserable creatures from the darkness of the coal pits to the light of day. It would cause a kinder feeling to spring up between the weak and the strong, which would lead to a generous adjustment of the evermore difficult questions of labor and capital.

Even if power could not be distributed, the mere transmission of intelligible signals would be of incalculable benefit. Such a realization would do away with the instability of the financial markets, which is the cause of much suffering and misery. It would greatly facilitate the evolution of novel ideas, as well as the prevention of evils. It would increase the safety of travel and give a new impetus to the press and spread of knowledge. The first message transmitted would be the signal to general disarmament and a closer union of nations, and the words of the great German poet, "Seid umschlungen Millionen, diesen Kuss der ganzen Welt," would be deeply felt everywhere.

Our present knowledge is sufficient to fill us with the conviction that the solution of these important problems is not far off. May the new year witness these triumphs.

THE NEW TESLA RAILWAY MOTOR.

A gentleman, described by the St. Louis *Globe-Democrat* as "one of the shrewdest electrical engineers in the employ of the Westinghouse Electric and Manufacturing Company," was recently interviewed by a reporter of that paper, to whom the following statements were made in reference to the Westinghouse-Baldwin combination, and the new railway motor now being perfected by Nikola Tesla :

The Westinghouse and Baldwin companies have become convinced that the demand for electric locomotives will grow rapidly in the near future. The steam locomotive which the Baldwin company has been making for sixty years is not to be laid on the shelf right away, but that company has come to believe, I think, that it will gradually, but surely, be displaced by its electric successor, and has grasped the opportunity to take advantage of the coming change by joining forces with one of the two great electric manufacturing companies which control the supply of such motors in the United States.

The allied companies propose to perfect and to offer to the steam railroads electric locomotives which they will buy and use. The resources of both concerns; the electric inventions, devices and experts of the one ; the methods, the expert locomotive and running gear machinists of the other, are being taxed in the effort to produce a motor which the steam companies can use to advantage for any kind of service, but especially for the rapid and safe transportation of passenger trains running more frequently than the steam trains at the present time.

The demand first to be satisfied is for electric locomotives to draw passenger trains on the suburban roads of the trunk lines. The demand already exists —in fact, all the Eastern steam companies have placed large orders.

Tesla is working on an idea in the shape of a motor that I believe will about successfully equip a locomotive with the power desired. This motor is entirely original and truly marvelous. The secret lies in turning the inert and seemingly lifeless force of magnetism into an active force more powerful than steam or a current from a dynamo.

The principles of the motor, concisely put, are these : An electric current is passed through a circular magnet, in appearance resembling a life-preserver. It consists simply of a ring of iron with copper wire bound around it. The electric current generates a strong magnetic current which flashes around and around the circular magnet at terrific speed. Now, if one holds a nail close to an ordinary electric magnet it will be passive in the hand until it is brought close enough for the magnetic force to seize it, when it will fly out of the hand straight to the magnet. But if one holds a nail close to the circular magnet of Tesla it will begin to revolve in the hand ; that is, if the nail is held by the head and the point allowed to hang over the hollow center of the magnet, the point will move around in a circle, slowly at first, then faster and faster, until, if it is dropped upon the table in the center of the hollow it will spin around so rapidly that the eye can not follow its motions.

Several explanations are given of the phenomenon one that there are several magnetic currents in the iron ring and they are chasing one another around in a furious race, but the mystery is as profound as ever.

Another interesting experiment is the balancing of an iron wheel on a nail, or let the wheel revolve upon the finger, using the finger as the axle, and holding it close to the magnet. It will fly around at a rate that will take one's breath away. It is not necessary to touch the magnet at all. All one needs to do is to hold a piece of iron or steel in the hand and bring it within a foot of the magnet, and then he will feel a queer sensation, as of some invisible force trying to draw the piece of metal out of his hand, and, failing in this, trying to twist it around in a circle.

Such is the principle of the coming Tesla motor. In its application as a motive power on the railroad, the construction, of course, differs from that of the experimental magnet, but the idea is the same.

In equipping the new locomotives the circular magnet is attached to the bottom of the engine, and the axle upon which the wheels revolve passes through the center of the magnet without touching it. When the current is turned on, the magnetic force whirling around in the hollow of the magnet catches the axle and turns it. The power for generating this magnetic current can be transmitted by underground wires for almost any distance, and there is practically no waste of power or energy.

We think the time has arrived when we may, with perfect justice and propriety, clearly indicate the policy of this paper in relation to press notices of a character similar to that printed above.

We should like to know—

1st. Is the Westinghouse Company responsible for the statements in that article, or does it encourage its press agent to give public currency to such statements?

2d. If it does, what is the object of such statements?

3d. Who is the person referred to as "one of the shrewdest electrical engineers in the employ of the Westinghouse Company?"

We ask these questions because we should like to definitely fix the responsibility for the many obviously untruthful statements made in the article.

Can it be truthfully stated that either or both of the two great electrical manufacturing companies in this country control the supply of electric locomotives employing either direct or alternating currents? We think not. Indeed we know that this field of work is fully open to any one who wishes to enter it, or any who are already engaged in it.

We know that Mr. Tesla is not engaged on electric locomotive work, and the description of the motor given in the article and its principles of operation differ in no way from the well-known rotary field motor used for years past in this country and Europe.

Is it not about time that the large electrical manufacturing companies of this country stopped this kind of puffery and misstatement of facts? Such notices certainly do not materially strengthen the position of the company responsible for them in the eyes of the general public, nor increase the confidence of capitalists in electrical enterprises.

Any sensible business man knows if any company engaged in any line of business has a startlingly novel and useful invention, of such a revolutionary character as is supposed to be described in the above article, that it is most unwise to publicly announce the fact before the invention is ready for the market, such a course of action being invariably followed by its competitors exerting unusual diligence to find out what the new thing is, and stimulating them to make the utmost exertions not to be left behind in the race. An article of the kind referred to may indeed be looked upon as public notice to its competitors of the direction in which the company making the announcement is working—a thing which everyone possessing a modicum of common sense desires to avoid and carefully endeavors to conceal.

The public have already had enough of promises of what is going to be done and too little fulfilment of such promises.

REVIEWS

*Fisica Tecnologica: Elettricitá e Magnetismo Nozioni fondamentali della Elettrotecnica illustrate da una compendiosa Esposizione delle principali Applicazioni nell, attrale loro Svilluppo.** By RINALDO FERRINI, Professor at the Higher Institution of Milan. Second edition, entirely re-written and illustrated with 169 figures. Milan: Ulrico Hoepli, 1896. 8vo., pp. 534.

Among the numerous important treatises on electricity, for which we are indebted to Italian authors, the volume before us may justly claim an honourable place.

In his preface, Prof. Ferrini objects to some of the names for electrotechnical units which have found their way into Italian, as well as into other European languages. He objects to the abridgments "volt" and "farad," and would write these names in full. For "impedance" he would substitute "impediment"; for "voltage," "electric pressure," and for "shunt," "derivation." It may, however, be asked, whether it is not advantageous to have a set of identical terms used and understood by electricians in all countries, analogous to the names of weights and measures which have been introduced everywhere along with the metric system, and which are more cumbrous than the electrotechnical terms in question?

The first chapter of the work treats of electrostatics, and gives an exposition of the subject, which will not encounter any objections.

The second chapter takes up continuous currents and electrolysis. Among the practical applications of electrolysis there are some of unquestionable value, and others of doubtful utility. It has latterly been observed that aluminium obtained by the electrolytic process is liable to contain an impurity of sodium which, though small in amount, renders the metal very unstable, and open to destructive action (*Comptes Rendus*, cxxi., p. 794).

Goppelsroedor's electric production of coal-tar colours has not yet come into use on a commercial scale. Hermite's treatment of sewage, which is certainly practicable in maritime localities, is open to one grave objection, the organic nitrogen, or "allumenoid ammonia," and the other nitrogen compounds, are either decomposed, or allowed to remain in a soluble state, and consequently unutilised. Now, the great desideratum in the treatment of sewage, is to obtain all the nitrogenous compounds in such a form that they may be applicable to the land. Whether the effluent water from Hermite's process can be advantageously used in irrigation is yet undecided.

That copper can be refined electrically in a satisfactory manner is unquestionable. To the value of the Elmore process (which is here mentioned) we need not refer.

In the same chapter we have an account of the primary couples and batteries of Clamond, Gülcher, Smee, Grove, Bunsen and Daniell. In the table of electro-chemical equivalents (p. 91) we find no mention of platinum, but on p. 116 is a more complete table of the specific resistances of metals and alloys.

In tabulating the electric units with their definitions, the author proposes a set of symbols, such as C for the coulomb, A for the ampere, O for the ohm, V for the volt, F for the farad, J for the joule, and W for the watt.

* Technological Physics: Electricity and Magnetism. The fundamental notions of electrotechnics illustrated in a compendious exposition of their principal applications.

The third chapter discusses magnetic induction. We find here an account of aperiodic and ballistic galvanometers, of the galvanometer of Arsonval, the solenoid amperemeter or ammeter, the electro-dynamometer, the thermic ammeter, the Carpentier electrometer, the Siemens and Cardew voltmeters, and the wattmeter.

The fourth chapter treats of induction currents, and the fifth is devoted to dynamos, motors, and what may be in great part called the mechanical applications of electricity. There is an account of electric motors, continuous and alternating, of polyphase motors, of the monophase motors of Brown, of Benisohke's asynchronous motor, and of transformers.

Electric lighting is duly considered, as is natural in a work written in a country so rich in water-power as is Italy. The experiments of Tesla are not overlooked; but it is remarked that the conditions for such illumination are as yet much less advantageous than is the case with ordinary electric lamps.

The question of protection against lightning the author rightly regards as requiring further study. The disaster to the Town Hall of Brussels, though fitted with conductors according to the Franklin principle, all in perfect order, is unpleasantly significant.

The New York Herald January 17, 1896

TESLA'S NEW CURE BY SHAKING.

The Electrician Has a New Device for Giving Exercise Without Exertion.

Nicola Tesla, the electrician, has directed his inventive genius in a new direction. He has produced a machine which he calls an oscillator, and its object, briefly stated, is to produce a shaking up of the human system, thereby causing certain physical conditions which will result in the healing of some ailments.

He has also produced an artificial light which, under certain conditions, is powerful enough to penetrate the human body. The last named was taken up some months ago by a physician in Vienna, who, it is said, has discovered that by its use the bacilli of tuberculosis may be destroyed. By its means the most remarkable medical cures may become possible.

The oscillator is a platform, which produces a number of more or less violent mechanical vibrations. For persons whose systems are in need of exercise this is said to be particularly useful. Force of movement can be given to the oscillator equal to the exercise or shaking up of the system which could be obtained by walking or riding for half an hour or even an entire day. These results are obtained without the fatigue which would result were the exercise taken in customary ways. These conditions are brought about through the use of electricity, powerful but minute electric shocks being rapidly distributed through the system.

Former Mayor Abram S. Hewitt recently visited the laboratory of Mr. Tesla and submitted to an application of electricity in the region of his liver. While in Europe last year he submitted to electrical treatment for liver trouble and received much benefit.

Mr. Tesla intends making several oscillating machines and placing them in the hands of certain doctors or medical institutions for the purpose of having their usefulness positively determined.

[87665.]—**Tesla Coil.**—In No. 97, April, 1892, of the *Journal* of the Institution of Electrical Engineers, "Max" will find the report of Count Tesla's lecture at the Royal Institution on "Experiments with Alternate Currents of High Potential and High Frequency." The article is illustrated, and the coil used by Tesla is figured and dimensions given, with instructions for making. If "Max" finds any difficulty in getting the number, the Society's library is open to members of other scientific bodies, or, on application to the secretary, to the public generally. F. J. R.

FROM NICOLA TESLA.

He Writes About His Experiments in Electrical Healing.

Some weeks ago this journal published an interesting article concerning electrical oscillations as observed by the eminent scientist, Nicola Tesla. So much interest was shown in the subject that Mr. Tesla was appealed to directly and in response to that appeal he sends to The Detroit Free Press this open letter:

Nos. 46 and 48 E. Houston street,
New York, February, 10, 1896.

During the past few weeks I have received so many letters concerning the same subject that it was entirely beyond my power to answer all of them individually. In view of this I hope that I shall be excused for the delay, which I much regret, in acknowledging the receipt, and also for addressing this general communication in answer to all inquiries.

The many pressing demands which have been made upon me in consequence of exaggerated statements of the journals have painfully impressed me with the fact that there are a great many sufferers, and furthermore that nothing finds a more powerful echo than a promise held out to improve the condition of the unfortunate ones.

The members of the medical fraternity are naturally more deeply interested in the task of relieving the suffering from their pain, and, as might be expected, a great many communications have been addressed to me by physicians. To these chiefly this brief statement of the actual facts is addressed.

Some journals have confounded the physiological effects of electrical oscillations with those of mechanical vibrations, this being probably due to the circumstance that a few years ago I brought to the attention of scientific men some novel methods and apparatus for the production of electrical oscillations which, I learn, are now largely used in some modification or other in electro-therapeutic treatment and otherwise. To dispel this erroneous idea I wish to state that the effects of purely mechanical vibrations which I have more recently observed, have nothing to do with the former.

Mechanical vibrations have often been employed locally with pronounced results in the treatment of diseases, but it seems that the effects I refer to have either not been noted at all, or if so, only in a small degree, evidently because of the insufficiency of the means which have eventually been employed in the investigations.

While experimenting with a novel contrivance, constituting in its simplest form a vibrating mechanical system, in which from the nature of the construction the applied force is always in resonance with the natural period, I frequently exposed my body to coptinued mechanical vibrations. As the elastic force can be made as large as desired and the applied force need be very small, great weights, half a dozen persons, for instance, may be vibrated with great rapidity by a comparatively small apparatus.

I observed that such intense mechanical vibrations produce remarkable physiological effects. They affect powerfully the condition of the stomach, undoubtedly promoting the process of digestion and relieving the feeling of distress, often experienced in consequence of the imperfect function of the organs concerned in the process. They have a strong influence upon the liver, causing it to discharge freely, similarly to an application of a cathartic. They also seem to affect the glandular system, notably in the limbs; also the kidneys and bladder and more or less influence the whole body. When applied for a longer period they produce a feeling of immense fatigue, so that a profound sleep is induced.

The excessive tiring of the body is generally accompanied by nervous relaxation, but there seems to be, besides, a specific action on the nerves.

These observations, though incomplete, are, in my own limited judgment, nevertheless positive and unmistakable, and in view of this and of the importance of further investigation of the subject by competent men I prepared about a year ago a machine with suitable adjustments for varying the frequency and amplitude of the vibrations, intending to give it to some medical faculty for investigation. This machine, together with other apparatus, was unfortunately destroyed by fire a year ago, but will be reconstructed as soon as possible.

In making the above statements I wish to disconnect myself with the extraordinary opinions expressed in some journals, which I have never authorized and which, though they may have been made with good intent, cannot fail to be hurtful by giving rise to visionary expectations. Yours very truly,

N. TESLA.

The New York Herald February 23, 1896

TESLA AND THE ROENTGEN RAYS.

The Famous Electrician Has Succeeded in Making a Photograph of the Human Brain.

HIS FORMER INVENTION.

He Once Took Fairly Successful Cathode Pictures of Mark Twain, Joe Jefferson and Others.

HIS APPEARANCE DESCRIBED.

R. TESLA took a photograph of the human brain last week. I surprised the fact out of him in a conversation in which he was telling me for my own information something about the X ray, or "Roentgen ray" as it is known popularly. The photograph was not satisfactory, except as an evidence that it was possible to photograph through the skull. It remains to be seen whether the nature of the X ray limits its field to such demonstrations as have been made in the past, or whether, as Nikola Tesla says, you can take photographs through a brick wall twelve feet thick. The whole situation is summed up in his statement that if the Roentgen ray is etheric, as Roentgen believes it to be, its scope is limited to the penetration of comparatively thin substances. You can photograph through a book with it, but you cannot photograph through an inch of glass. But if the waves which produce the effects in what is called "cathode photography" are produced by waves propagated in straight lines like sound waves, their possibilities are almost boundless. Mr. Tesla has been at work in his shop on Houston street ever since the Roentgen experiments were made public, and he hopes to be able to determine in the near future the character of the agents which are at work in the Roentgen and other experiments.

TESLA'S DISCOVERY.

It is a remarkable fact that not to Roentgen nor to any of the recent experimenters is the credit of discovering the penetrative power of the X ray due. Its development, like that of most great discoveries, has been gradual and has proceeded by a regular process of evolution, in which many men of science have taken part. Mr. Tesla himself made public several years ago the fact that when there were sudden discharges of electricity through a wire, certain waves, which he designated "sound waves of electrified air," were propagated; or, as he himself explained it, "certain kinds of waves which I called 'sound waves of electrified air' are propagated from conductors when a strong rapidly vibrating current passes through them, such as sudden discharges from condensers. These propagate in straight lines like sound. They are longitudinal waves, penetrating bodies, and they cannot be stopped by interposing metal plates."

Whether his "sound waves of electrified air" are similar to the cathode ray or different from it Mr. Tesla does not yet know. But the real discovery of the Roentgen ray dates back even beyond Mr. Tesla's experiments and the use of the ray for photographing is not new. Lenard more than two years ago took photographs through metal plates and published results of experiments in the scientific papers. These experiments, like those of Mr. Tesla, were not of a popular character, and they attracted no attention outside scientific circles. It remained for Professor Roentgen to photograph money in a purse and to take pictures of the bones of the human hand. That appealed immediately to the popular imagination. When excitement has calmed down a little and the situation is reviewed credit will be given to all those who contributed to the development of the wonderful X ray and its application. Then another fact will be remembered and accorded to the credit of Mr. Tesla—that all the discoveries made through the popularization of the Roentgen experiments were made possible by a remarkable invention of Mr. Tesla—his converter. For, whether credit is given to Mr. Tesla in the reports of experiments or whether he is ignored or slighted by the mention of "a converter" used in the process, the Tesla converter is used universally to obtain the sudden discharges of electricity through which the X ray is produced.

Five or six years ago Mr. Tesla started out to find a way to produce an alternating current of high frequency of conversion from any kind of electricity. He found that he could discharge a condenser charged from a static machine (such as Roentgen is using in his experiments) or from any other source into a wire coil and get oscillations at a terrific rate. To get the secondary current which he wanted he put a second coil around the first. But the necessity of using miles of fine wire in the secondary coil made it expensive and limited its practical use. Then Mr. Tesla found a way to produce the same result with a few thick wires that was produced with a great many miles of thin wires. How he achieved this result is for scientists to know and understand. It is enough for the average intelligence to comprehend the fact that he produced a revolution in the electric world.

"If every one who uses my machine in electro-therapy alone would give me a quarter I would be a very wealthy man," he said with an ingenuous smile when I asked him what return beyond the fame of his achievement he had received. "It is used now by millions of persons, but I have never received a dollar from it, and there is no way in which I could."

I asked if there was any invention from which Mr. Tesla received an income—for ideas, however valuable, will not conduct costly experiments.

"I receive a small income from my invention of the rotating field," said Mr. Tesla, "and I have a small income from my home. And all of that I blow in here."

THE INVENTOR'S WORK.

It was said with an accent which robbed the words of the character of slang. The gesture which accompanied them took in comprehensively the dark spaces beyond the trim little office on the second floor of the Houston street building, which has been the headquarters of the inventor since he was burned out, a year ago. Here he has been conducting experiments with which he hopes to revolutionize the production of electric power. He believes he will be able to produce electricity before long at an infinitely smaller cost than at present is possible, and with an apparatus which will be comparatively simple and cheap. But the details of his experiments in this direction are known only to himself. He took me into his workshop one day recently, but his description of it was so brief and his whole manner so indicative of horror at the thought of publicity that we were not in the room more than a minute, and the amount of information I obtained about it could be summed up in one of the shortest paragraphs ever written.

Mr. Tesla is tall and slender, with very black, thick hair. He wears a very small mustache over a small mouth. All of his features are delicate. His cheeks are rather hollow but they have the flush of health. His cheek bones are conspicuous. His manner is cordial, and as attractive in its way as his appearance for he is not the careless, begrimed machinist as he issues from his shop, but a "well groomed" man, whose clothing is stylish and well fitting, and whose hands and face are as pink and clean as a baby's. Like most inventors, he is a late worker. The forces of both mind and body, he thinks, operate better at night than in the daytime. So he is often in his shop until two or three o'clock in the morning. He seldom comes down before noon. Occasionally he is attracted by "society" and he was one of the star features at a recent "function," at which Sarah Bernhardt also shone. But his work absorbs most of his time, and he has little taste for anything else.

HIS EARLY PICTURES.

A curious fact about Mr. Tesla, which is recalled by the recent experiments with the cathode rays, is the fact that he demonstrated first the possibility of taking photographs with those rays. He took photographs of Joe Jefferson, Mark Twain and others by their light, and these photographs were reproduced to illustrate a story about his workshop. But the experiments made then did not possess the quality of popularity as did the Roentgen experiments, or, in fact, the earlier experiments of Mr. Tesla himself. Probably the only parallel to the interest displayed by the public in the Roentgen experiments is to be found in the excitement which prevailed when it was announced that Mr. Tesla had produced an illuminating glow in the centre of a room without the use of wires or other electrical connections. The popular mind conjured up at once the picture of great halls illuminated by an artificial light diffused like the daylight, and the changes were rung for many days on the possibilities to be developed under the new discovery. All of the speculation about the practical application of the discovery ceased when the workshop of Mr. Tesla was destroyed by fire, and in its destruction was lost the apparatus which it may take the greater part of a lifetime to reproduce. But during the excitement which prevailed it was said the story of the demonstrations made by Mr. Tesla in London reached the eyes of the reading public through the medium of 30,000 American newspapers.

Electrical Progress.

NIKOLA TESLA thinks that "the discovery which would do most to better our condition would be the demonstration that the earth's electrical charge can be disturbed, and thereby electrical waves efficiently transmitted to any distance without the use of cables or wires." Edison says that "the discovery or invention which would do most to better the conditions of life" would be "the production of electricity direct from coal."

Engineering Magazine March 1896

PROFESSOR RÖNTGEN'S DISCOVERY OF A NEW RADIANCE.

By Michael I. Pupin.

RÖNTGEN'S discovery of what appears to be a new form of radiant energy has justly atracted universal attention. The interest attached to it is a twofold one: first, its purely scientific significance; second, its practical importance. The discovery may be stated broadly as follows: if an electric current be sent through a vacuum tube—the so-called Crookes tube,—then, in addition to the heat and fluorescent light generated in the glass of the tube, there is, according to Röntgen's discovery, another form of radiant energy generated, which we may call the Röntgen rays. The following characteristic elements describe this energy: it produces fluorescence in fluorescent substances, just as ultra-violet light; it affects the photographic plate, just as the actinic part of the solar spectrum; it penetrates all bodies, even the metals, in a greater or smaller degree, and it is neither reflected or refracted appreciably. No other known form of radiant energy resembles the Röntgen rays in this last respect.

Much has been written lately about this discovery, but little has been said which would serve as trusty and intelligible guidance to those who are not familiar with modern electric appliances. It seems desirable, therefore, to give here a brief and simple description of the apparatus, and of the method of operation.

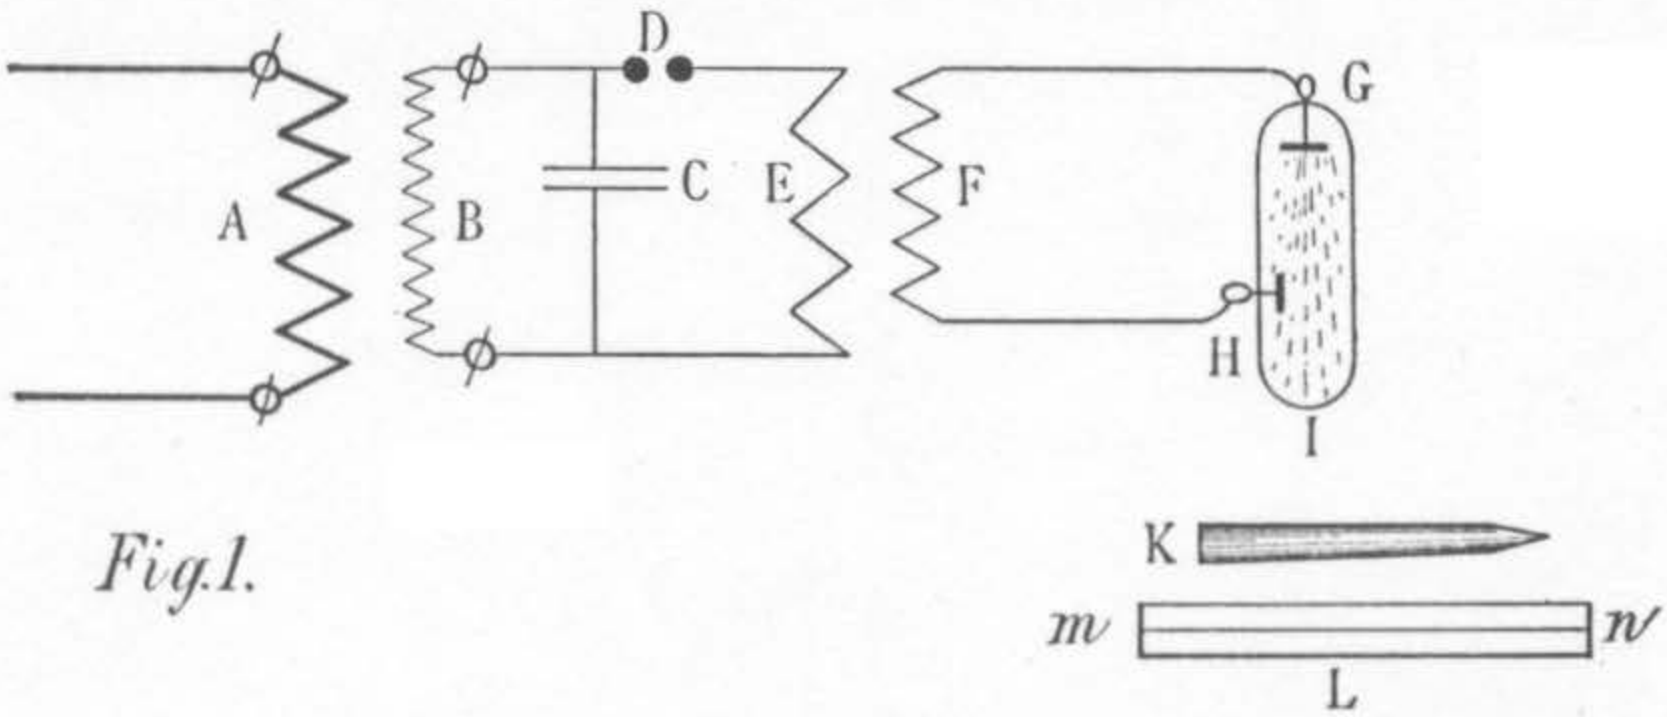


Fig. 1.

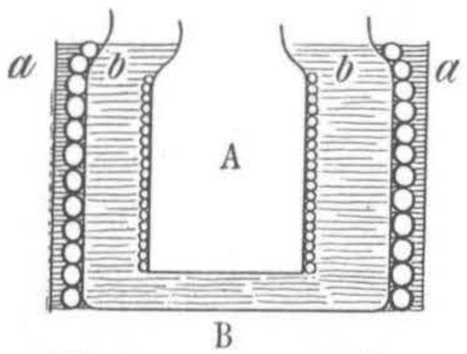
In Fig. 1 we have an ordinary induction coil, AB. Its primary coil, A, is connected to the mains of an alternating current circuit, and the supply of current is regulated by an auxiliary resistance-box. The secondary winding, B, is connected to a Leyden jar, C. A gal-

lon jar with a medium-sized coil gives a sufficiently strong effect. The jar is connected to an oscillatory transformer, EF, which needs a more detailed description. It can be constructed as follows. Take two large glass jars, A and B (Fig. 2); wind about eighteen turns of very coarse, well-insulated wire, aa, on the outside jar, B, and about two hundred turns of fine wire, bb, on the inside jar. Place the jar, A, into B, and fill the space between them with very hot paraffin. Pour very hot beeswax over the outside winding, aa, until a thick crust is formed. This is then an oscillatory transformer. The coarse wire winding, aa, is the primary, and the fine wire winding is the secondary, of this transformer. In Fig. 1 the primary, indicated by E, is connected to the Leyden jar, C, and the secondary to the vacuum tube, GH. The plateholder, L, containing the sensitive photographic plate, mm, is in line with the electrode, G, so that it is in the line of discharge from this electrode. The object, K, to be photographed, is placed between the tube and the plate.

Fig.2.



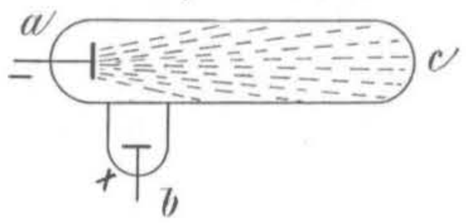


Fig.3.

We can pass now to the operation. Observe first that the circuit, CDE, contains an air-gap, D, between two small brass spheres. As soon as the current is admitted into A, there is induced a very high tension current in B, which charges the jar until the tension between the small spheres of the air-gap is high enough to break through. The jar discharges then, and the discharge current will oscillate back and forth in the circuit, CDE, at a rate of several hundred thousand vibrations per second. These vibrations die out rapidly, but the alternating current in B makes a break through the gap, D, at every alternation, and sets up, after each disruptive break, a series of oscillations. In fact, the circuit, CDE, may be compared to a church bell, and the disruptive action at the gap, D, performs the function of the swinging tongue of the bell. After each stroke, a series of waves spreads out into space,—melodious sound waves in one case, silent electric waves in the other. These rapidly-vibrating waves induce in the secondary circuit, F, a series of waves of the same rapidity, but of much

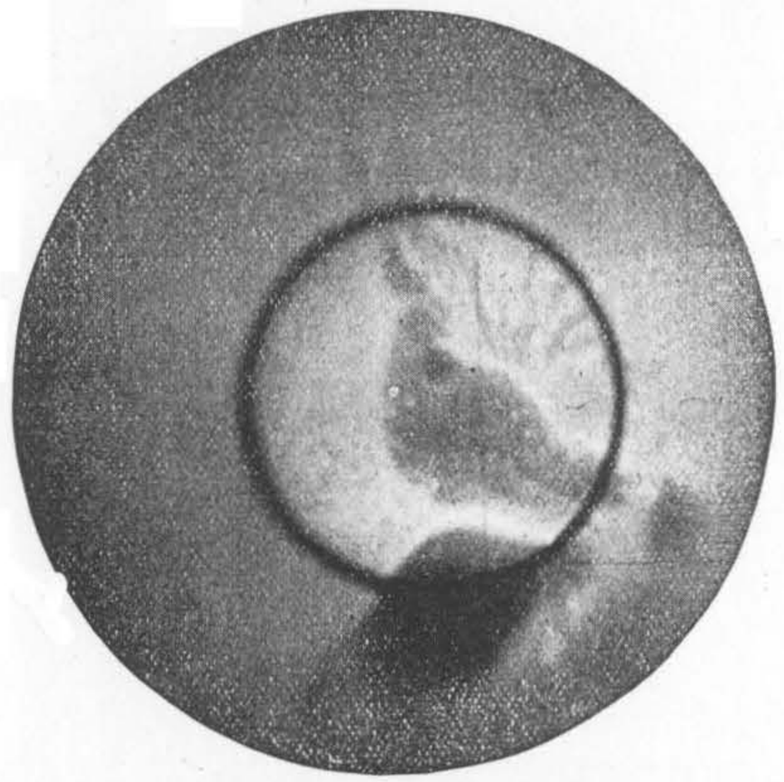
Employing a Holtz Machine and a Crookes Tube. Time of Exposure, 50 Minutes.

higher tension. The oscillatory current in the tube, GH, produces a luminescence in the attenuated gas in the vacuum tube. If the vacuum is not very high, the luminescence is almost entirely within the gas itself; this is not the case in very high vacua. For the purpose of pointing out clearly how these Röntgen rays are produced, it is well



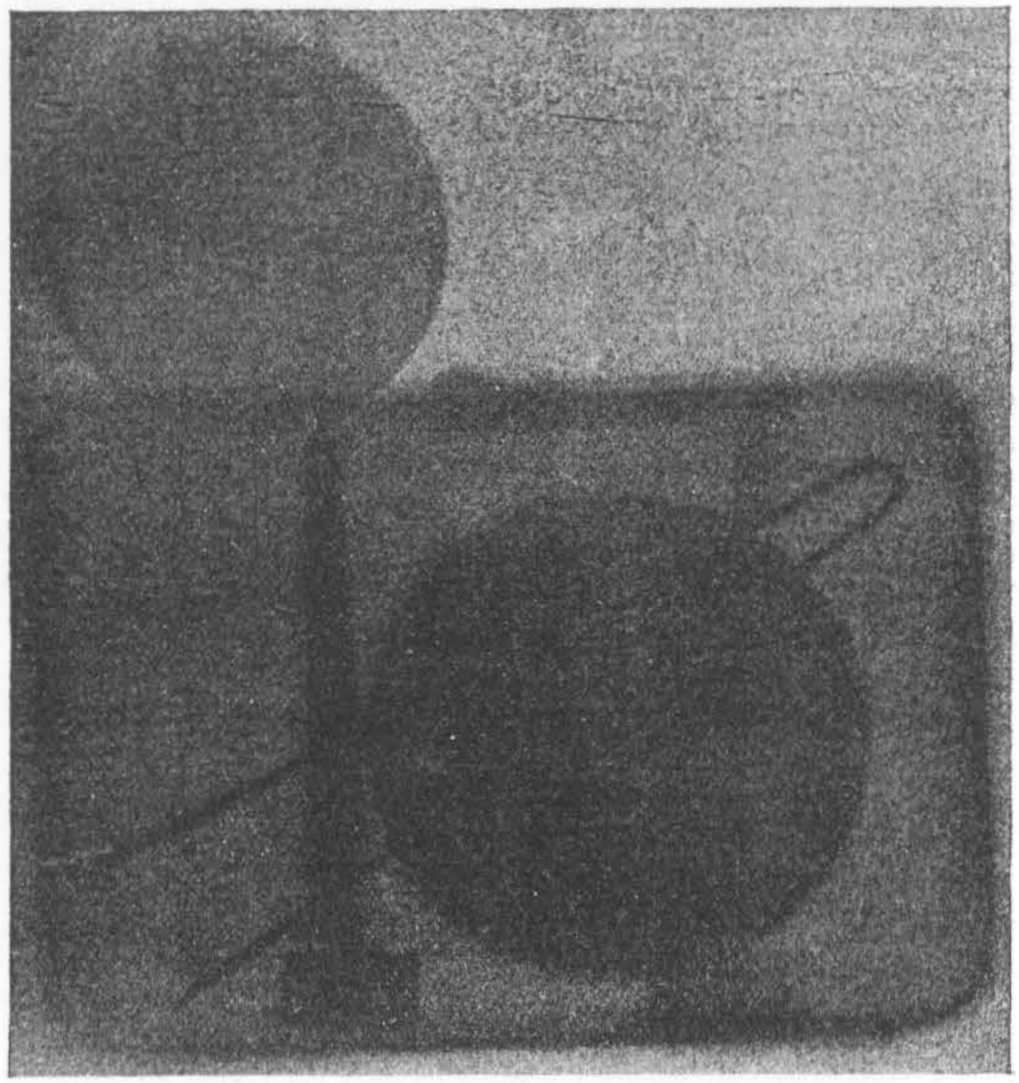
to consider briefly the electrical discharge in the tube when the vacuum is very high.

Fig. 3. represents a typical form of a vacuum tube, capable of giving a strong Röntgen effect. Two platinum wires, a and b, carrying aluminum discs, are sealed in a glass tube. They are the electrodes which are connected to the high tension coil. The electrode which at any moment is connected to the negative pole is called the cathode, and that connected to the positive pole is the anode. When the current is oscillatory, as in the arrangement described in Fig. 1, each electrode alternates periodically between being anode and cathode. Thus, in an alternating current reversing one hundred times per second, each electrode will be anode fifty times and cathode fifty times per second. Fix, now, any moment when a is the cathode and b is the anode. Suppose that the air pressure in the tube has been gradually reduced by the action of a mercury pump to something like one millionth of an atmosphere. The electrical discharge, which, as long as the vacuum is not high, appears as a bright luminescence of the gas, is hardly visible at this excessively low pressure.

In place of this luminescence of the gas, there appears in very high vacua a vivid fluorescence of the glass,—blue in American glass, green in German glass. This fluorescence is produced by faint streamers which proceed in straight lines from the cathode, as indicated by the dotted lines in Fig. 3. Where these streamers meet the tube, there the fluorescence and the heating of the glass take place. Professor Röntgen finds that this brightly-fluorescing surface in the walls of the tube is the seat of a radiant energy, which possesses the characteristic features described above. These rays, which Röntgen calls the X-rays, can be observed in a dark room by means of a paper screen saturated with an emulsion of a fluorescing substance. The discoverer employed barium platino-cyanid. Wherever the rays strike this screen, they cause it to fluoresce, and the intensity of the fluorescence measures the intensity of the Röntgen rays. By interposing a substance between the tube and the screen, the relative opacity of the substance for these rays can be determined. It is found that even metals are transparent to it, but in various degrees. Thus, if a given thickness of platinum will absorb a certain amount of these rays, it is found that the same amount of absorption will be produced by a lead plate of three times the thickness, by a zinc plate of six times the thickness, and by an aluminum plate of two hundred times the thickness. Wood, ebonite, rubber, water, and organic compounds, are more transparent than metals, but none of them are perfectly transparent, nor is any substance perfectly opaque. A fact deserving an especial mention is that glass, especially that containing lead, is nearly opaque. Bone is much more

opaque than flesh; the shadow of a human hand on a fluorescent screen will, therefore, show the skeleton darker than the flesh.

Another method of studying this new form of radiant energy is by means of photography. Röntgen found that a photographic film is affected by the X-rays, but, since these rays are neither reflected or refracted, it is useless to employ lenses. The plate remains shut up in the plate-holder, and the object to be photographed is placed upon it, so as to be between the tube and the plate, as indicated in Fig. 1. The time of exposure varies with the quality of the vacuum and the



AN ALUMINUM DISC WITH FIGURES IN RELIEF.

The negative shows much detail and also want of homogeneity in the metal of the upper plate above the crest of of the bird, the plate being less transparent in this part than in the lower part. Taken by M. I. Pupin with a Holtz machine and an electrodeless tube. Time of exposure, 25 minutes.

electric tension employed. It may be as short as four minutes, or it may be as long as two hours. The nearer the tube is to the plate, the shorter is the time of exposure, but evidently the less defined will be the shadow picture. There is good prospect of perfecting both the means of producing the vacua and also the construction of the tubes, so as to produce the X-rays in a larger quantity. This would shorten the time of exposure, and also improve the definition of the photographs.

Röntgen's experiments have been repeated in this country in several laboratories,—at Harvard, Yale, Johns Hopkins, Princeton, and

ALUMINUM BOX CONTAINING AN ALUMINUM MEDAL AND HAIRPIN.
Under-exposed. Taken by M. I. Pupin.

in the writer's laboratory at Columbia. At the McGill University in Montreal a bullet was located in a man's leg by means of this photography. Similar reports have reached us from Europe. Several hospitals in this city intend to put in an outfit suitable for the production of the X-rays. The surgeons expect much help from this remarkable discovery, and the experimental results obtained in this country so far seem to hold out a very bright prospect.

But surgery is not the only profession which is going to reap the immediate benefits from the practical application of this discovery. Metallurgy and mineralogy expect to overcome some of their old difficulties with the aid of the X rays. Various minerals have a various degree of opacity for these rays, and it is not at all difficult to distinguish a real gem from an imitation. The occlusion of metals is

particularly easy to detect, since metals seem to be more opaque than other substances. But even the metals themselves have a various degree of opacity, as has been already pointed out. Hence, if two metals are mixed to make an alloy, and the mixture is not perfectly homogeneous, it would be an easy matter to detect the want of uniformity, provided, of course, that a sufficiently thin plate is cut from the sample to be examined; thick plates are too opaque to permit an appreciable part of the X-rays to pass through. It is, therefore, not quite clear to the writer how this new method of photography can be employed in its present stage of development to detect flaws in steel guns and armor-plates, unless these rays are made much more powerful than we have been able to make them so far, and unless also we discover photographic plates which are much more sensitive to these rays than the plates now in the market. The author confesses his belief, however, that we shall, in all probability, soon reach both these improvements. A sufficiently long exposure will, even now, as the writer knows from his own experiments, reproduce the various details in the structure of a body. So, for instance, the photograph of a pair of spectacles in a leather case and separated from the plate by a thin sheet of ebonite will, with sufficiently long exposure, show the curvature of the lenses. The photograph of an aluminum medal will sometimes come out so neat and well-defined as to show the lettering and the figures,—that is, in the negative. In the printing this fine detail is not always clearly shown. But it must be remembered that we are only at the beginning of a new art. We hope, and with reason, that this new photography will reveal the interior structure, not only of dead matter, but also of living organisms.

The photographs accompanying this article explain themselves.

Since writing the above I have been able to collect additional facts which seem of sufficient interest to merit mention.

The apparatus described above was discarded as too complicated and too severe on the tube. A six-plate Holtz machine made by the Galvano Faradic Company of New York was tried and gave complete satisfaction. The Röntgen effect with such a machine is sufficiently powerful, and the wear on the tubes is small. In fact, they seem to improve with use, instead of deteriorating. The tube should be connected in series with the outside coatings of the two jars, and the capacity of the jars should not be too large for the size of the tube. With a pear-shaped Crookes tube of 5 inches diameter half-pint jars give excellent results. A cylindrical vacuum tube without internal electrodes, but with external tinfoil coatings at the extremity of the tube, will do very well as a substitute for a Crookes tube. The

vacuum should be as high as anybody can possibly obtain. This is one of the good things of which we cannot have too much,—at least with the methods of exhausting now employed in this country. It should be observed that these methods are perfectly wretched.

Regarding the detail of the things photographed, it is important to observe that Röntgen photography acts differently from ordinary photography. We cannot speak here of over-exposure, unless we specify that it is over-exposure with regard to certain parts which are exposed. Take, for instance, the shadowgraph of a number of objects enclosed in an aluminum cigar box. With a short exposure the details of the structure of the box appear, but those of the enclosed objects do not. With a long exposure the box itself is almost invisible, but the details of the enclosed objects appear. A still longer exposure will make the things enclosed in the box disappear one by one. The most opaque will remain longest. Again, consider the photograph of the human hand. A short exposure gives nothing but the flesh. A little longer exposure brings out the nails. Still longer, and the skeleton begins to appear, whereas the flesh begins to disappear. Still longer, and nothing but the bones appear the various parts being accurately represented in their relative opacity. A still longer exposure will make the various parts of the skeleton disappear one by one, according to their relative opacity. A sufficiently-prolonged exposure would reveal opaque objects concealed in the bone itself. There is no doubt that by a sufficiently long exposure the homogeneity of not excessively thick metal plates can be examined with considerable accuracy.

Tesla's Marvellous Achievement.

COMMUNICATING FOUR MILES THROUGH PIKE'S PEAK WITHOUT WIRES.

EARTH ELECTRICITY TO KILL MONOPOLY

A Way to Harness Free Electric Currents Discovered by Nikola Tesla.

THE world is on the eve of an astounding revelation. The conditions under which we exist will be changed. The end has come to telegraph and telephone monopolies with a crash. Incidentally, all the other monopolies that depend on power of any kind will come to a sudden stop. The earth currents of electricity are to be harnessed. Nature supplies them free of charge. The cost of power and light and heat will be practically nothing.

The scientist-electricians who have for years been trying to master the mystery of electrical earth currents with which the ground beneath your feet is filled, are on the threshold of success. The success of the experiments they have under way means much to them, but vastly more to the people. It means that if Nikola Tesla succeeds in harnessing the electrical earth currents and putting them to work for man there will be an end to oppressive, extortionate monopolies in steam, telephones, telegraphs and the other commercial uses of electricity, and that the grasping millionaires who have for two decades milked the people's purse with electrical fingers will have to relinquish their monopoly.

Nikola Tesla has discovered the secret of the electric earth currents of nature, and they will be adapted to the uses of man. He has succeeded in transmitting sound by the currents that make an electric rot of the earth. The transmission of power will follow. His experiments reduced to commercially practicable uses will mean that men will be able to tap the electric currents of the earth and make them serve the purposes of industry and of trade just as a well-digger over on Long Island taps water or a Pennsylvania miner opens a vein of coal. The mighty electrical energy that has been stored up in the earth for ages will be harnessed and made to move the machinery of men.

Electricity will be as free as the air. For the privilege of its use legislatures will not have to be bribed or men corrupted at the polls, and public boards will not have to be "seen" to bestow exclusive franchises upon corporations organized to use public property for purposes of private gain, and make the people pay the original cost of their investment and excessive charges for service in order to squeeze dividends out of copiously watered shares.

Monopolies for purveying steam power too will be forced to capitulate to free electricity, for with the latter manufacturers will only have to connect their dynamos with the earth current to set their machinery in motion. The successful adaptation of Tesla's discovery will administer a death-blow to the most galling slavery that has ever yoked the activities of men to the treadmill of monopoly. Tesla is the wizard who is going to emancipate modern industries from the shackles of corrupting, dividend-grabbing, monopolistic corporations.

Sound travels with amazing speed, but electrical vibrations travel so swiftly that it is difficult to conjure up a figure which will graphically illustrate their speed. Here is one that will, perhaps, convey a vivid and lucid impression. In fancy place yourself at a table with a revolver in one hand and a finger of the other hand on the key of a telegraph instrument connected with a wire that girdles the globe seven times and laps over on the eighth turn a distance. the pistol and simultaneously press the telegraph key. While the sound of the report of the revolver is travelling 1,120 feet the electrical impulse imparted by the pressure on the key will pass seven times [illegible] around the world through the wire with which the key is connected.

Sound travels 1,250 feet a second, an electrical impulse 186,000 miles a second. If the electrical currents with which the earth is filled can be harnessed and put to work a new era in electricity will have dawned. It is to the mastering of the mystery of these earth currents and their adaptation that scientists like Tesla have been striving.

In the course of Tesla's experiments it is reported he found that in the vicinity of large cities there were so many conflicting earth currents that satisfactory results could not be obtained. So he went out to Denver and near there found a better field for experimenting. There he met a friend interested in electrical research. They went to Pike's Peak. Conspicuous among their baggage were two autoharps.

Tesla and his friend scaled the rugged sides of the peak. At an elevation agreed upon they separated. Tesla skirted the peak and, on reaching a point precisely opposite the place at which he left his friend he stopped. The two experimenters, on a line drawn straight through the peak, were thus separated by four miles of stratified rock. The two autoharps had been very delicately attuned before the scientists parted, and a time fixed for Mr. Tesla's comrade to play an air (also agreed upon) on the autoharp.

Tesla waited patiently the arrival of the appointed time. Then he connected his harp with the ground in such a way as to secure harmonic resonance with the earth current. The manner and medium of this connection are secrets. The receiving autoharp was equipped with a microphone. As the time approached for his friend on the other side of the peak to strum the appointed tune Tesla listened with rapt attention.

At last, as a tuning-fork responds to its harmonic note sounded on the strings of a piano, the autoharp in Mr. Tesla's hands gave out the harmonic tones of "Ben Bolt," which his companion at his station four miles away straight through the peak was plucking from the tense wires of his instrument. The experiment was a success. After many tunes had been played Tesla and his companion descended the peak. A statement of the facts and results of the experiments was written and attested before a notary public as a matter of scientific record.

The electric currents are in the earth. Their strength is great enough to furnish all the power and light man needs. Mr. Tesla has overcome the initial difficulty, and has located and tapped the earth currents. The rest will follow, as followed the telephone, Prof. Bell's discovery of how to transmit speech over a wire.

TESLA'S STARTLING RESULTS IN RADIOGRAPHY AT GREAT DISTANCES THROUGH CONSIDERABLE THICKNESSES OF SUBSTANCE.

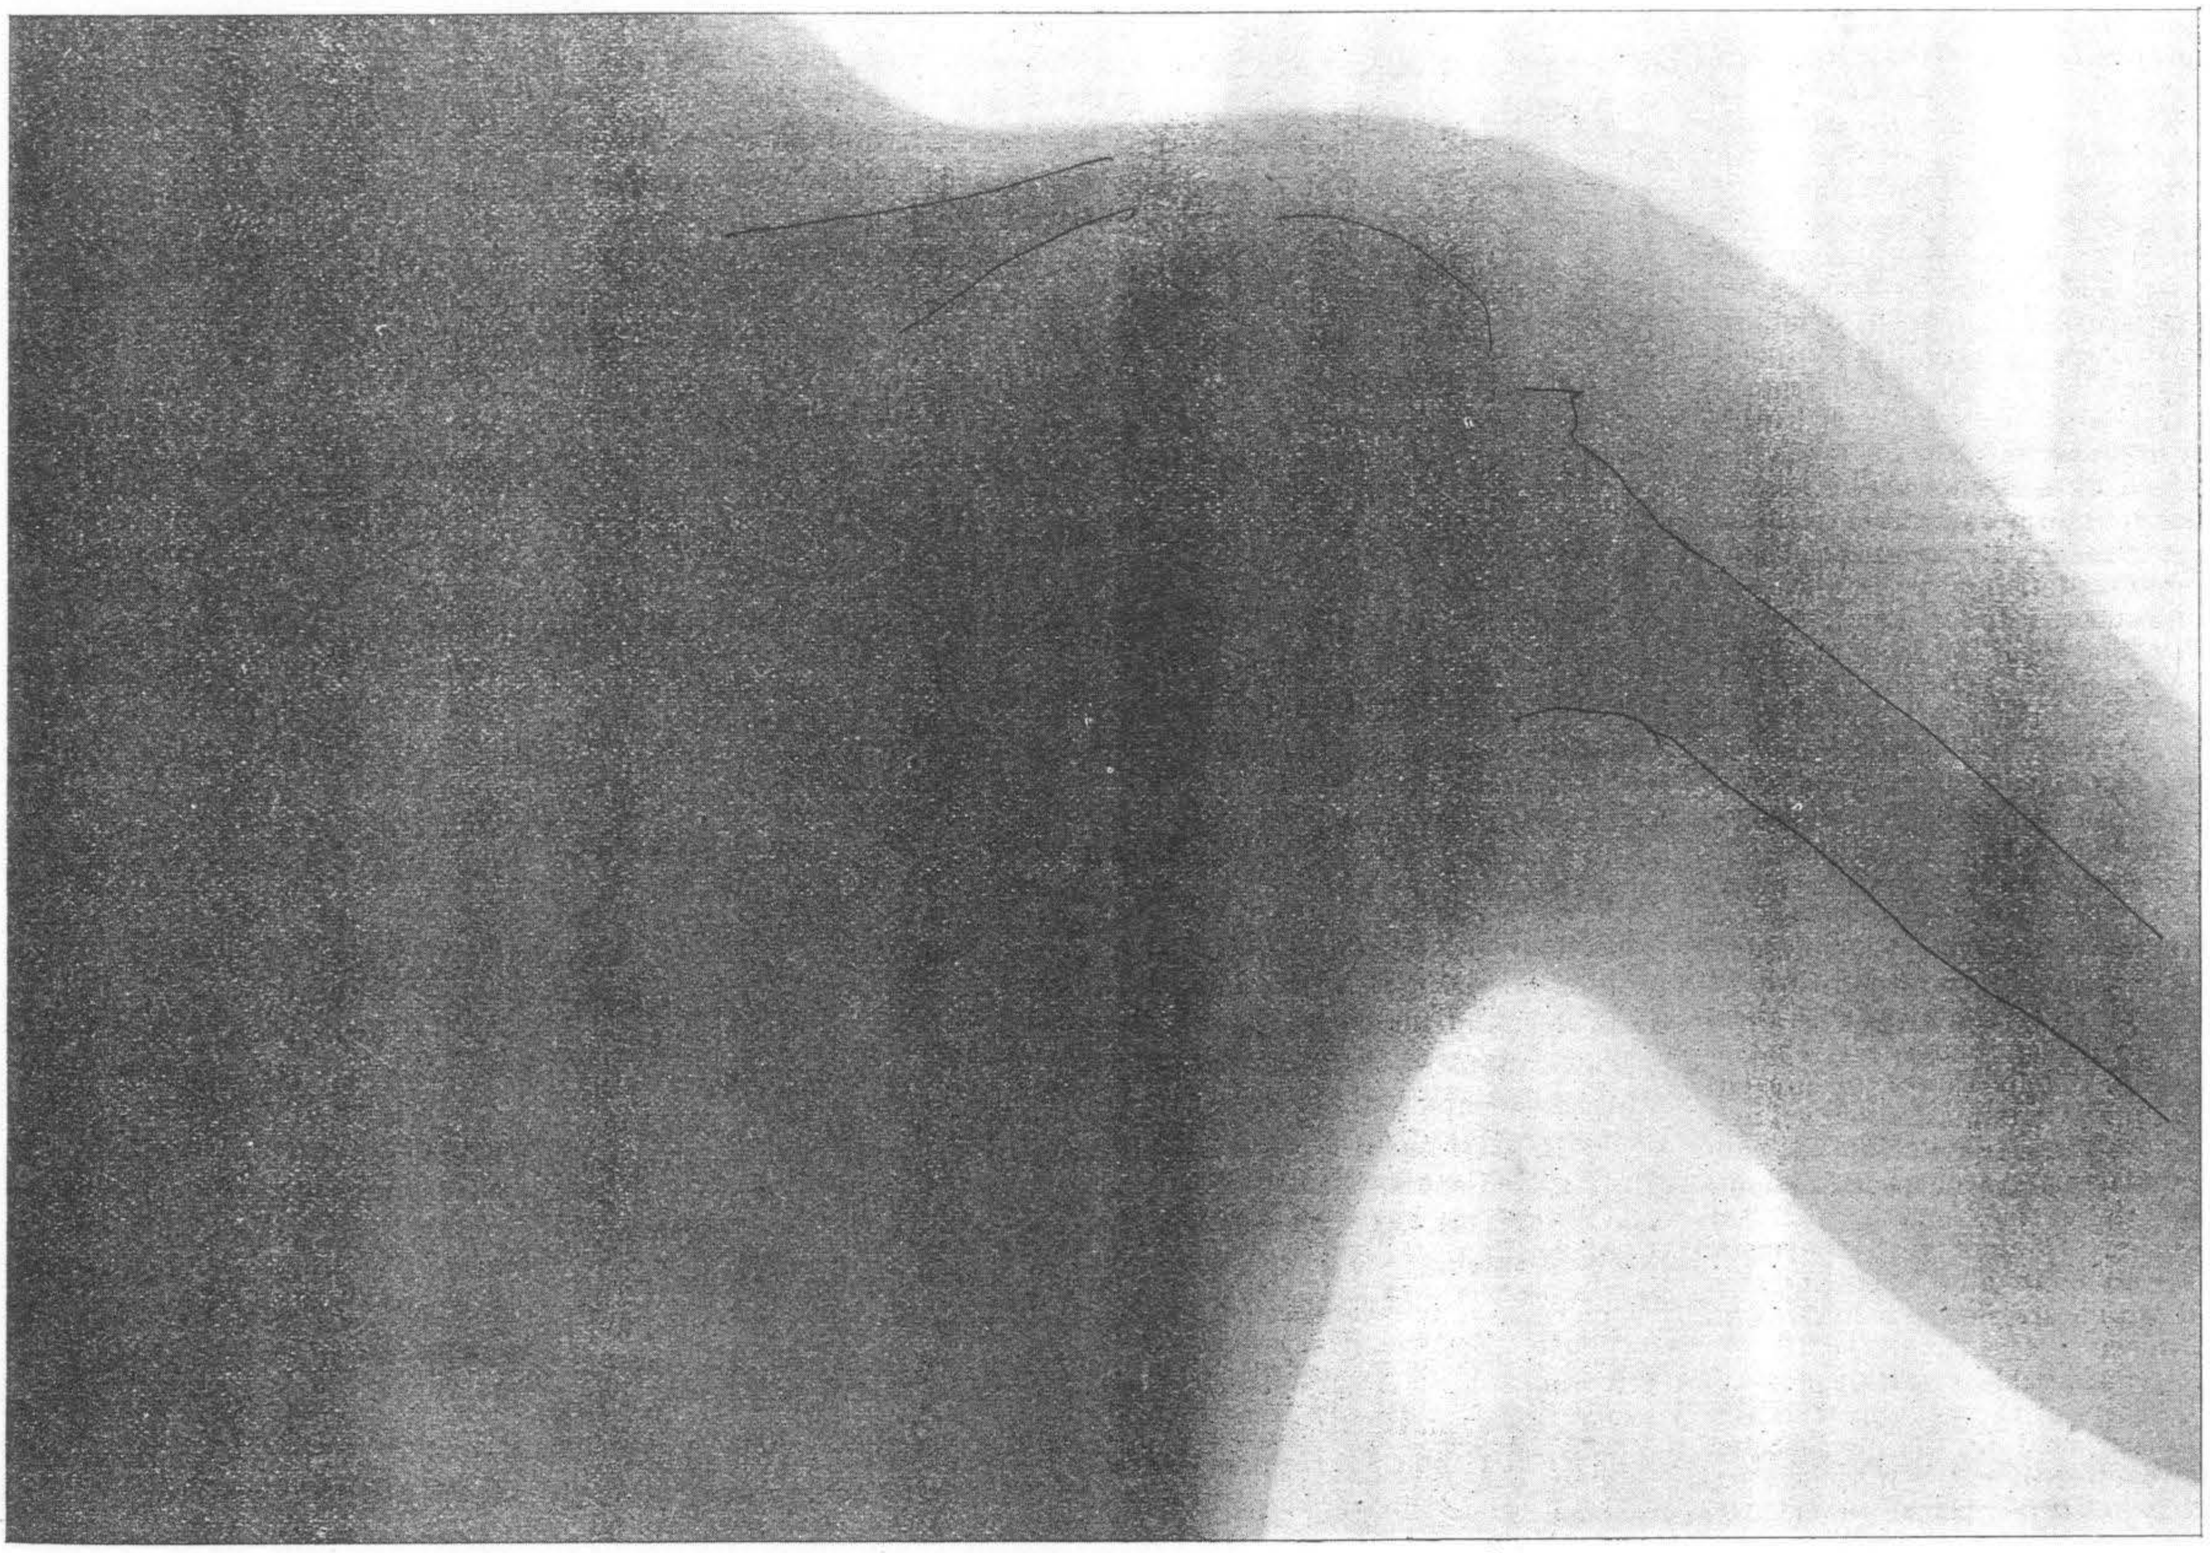

FIG. 1.—PHOTO-ENGRAVING OF TESLA RADIOGRAPH OF RIGHT SHOULDER OF A MAN, SHOWING RIBS AND SHOULDER AND UPPER ARM BONES—TAKEN THROUGH CLOTHING, BOARD, ETC., AT A DISTANCE OF FOUR FEET.

TESLA ON ROENTGEN RAYS.

A HIGHLY INTERESTING AND VALUABLE COMMUNICATION FROM THE TALENTED YOUNG INVENTOR.

TO THE EDITOR OF ELECTRICAL REVIEW:

One can not help looking at that little bulb of Crookes' with a feeling akin to awe, when he considers all that it has done for scientific progress—first, the magnificent results obtained by its originator; next, the brilliant work of Lenard, and finally the wonderful achievements of Roentgen. Possibly it may still contain a grateful Asmodeus, who will be let out of his narrow prison cell by a lucky student. At times it has seemed to me as though I myself heard a whispering voice, and I have searched eagerly among my dusty bulbs and bottles. I fear my imagination has deceived me, but there they are still, my dusty bulbs, and I am still listening hopefully.

After repeating Professor Roentgen's beautiful experiments, I have devoted my energies to the investigation of the nature of the radiations and to the perfecting of the means for their production. The following is a brief statement which, I hope, will be useful, of the methods employed and of the most notable results arrived at in these two directions.

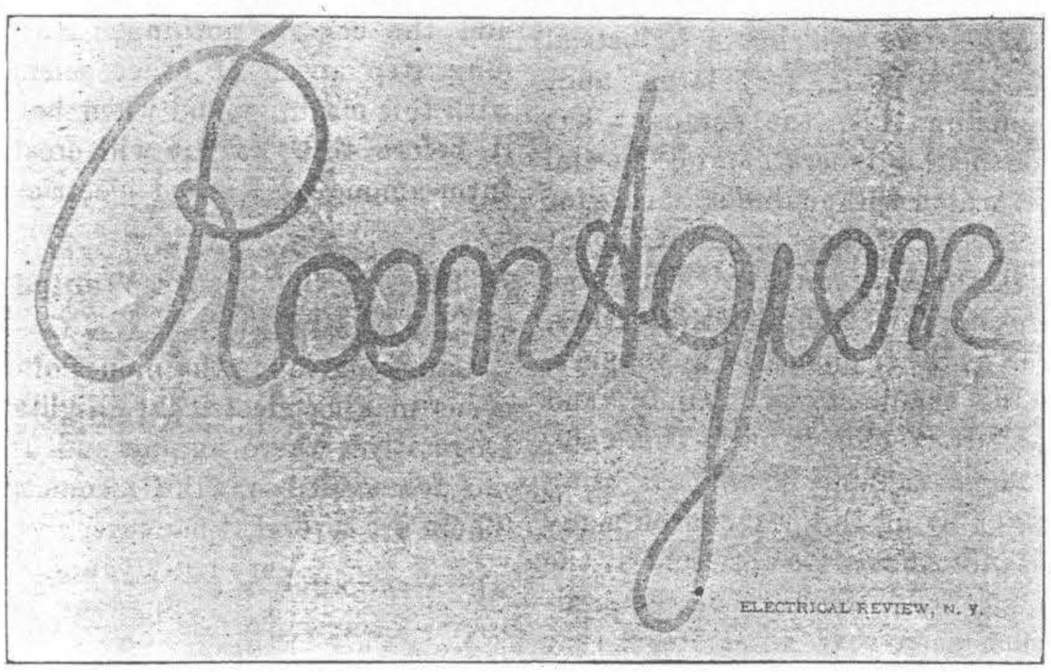

FIG. 2.—TESLA'S RESPECTS TO PROF. ROENTGEN—A RADIOGRAPH OF A WIRE SIGN TAKEN THROUGH A WOODEN COVER AT THE REMARKABLE DISTANCE OF ELEVEN FEET, WITH ONE-HALF HOUR'S EXPOSURE.

In order to produce the most intense effects we have first to consider that, whatever their nature, they depend necessarily on the intensity of the cathode streams. These again being dependent on the magnitude of the potential, it follows that the highest attainable electrical pressure is desirable.

To obtain high potentials we may avail ourselves of an ordinary induction coil, or of a static machine, or of a disruptive discharge coil. I have the impression that most of the results in Europe have been arrived at through the employment of a static machine or Ruhmkorff coil. But since these appliances can produce only a comparatively small potential, we are naturally thrown on the use of the disruptive discharge coil as the most effective apparatus. With this there is practically no limit to the spark length, and the only requirement is that the experimenter should possess a certain knowledge and skill in the adjustments of the circuits, particularly as to resonance, as I have pointed out in my earlier writings on this subject.

After constructing a disruptive coil suitable for any kind of current supply, direct or alternating, the experimenter comes to the consideration as to what kind of bulb to employ. Clearly, if we put two electrodes in a bulb, or use one inside and another outside electrode, we limit the potential, for the presence not only of the anode but of any conducting object has the effect of reducing the practicable potential on the cathode. Thus, to secure the result aimed at, one is driven to the acceptance of a single electrode bulb, the other terminal being as far remote as possible.

Obviously, an inside electrode should be employed to get the highest velocity of the cathode streams, for the bulbs without inside terminals

(Continued on page 134.)

TESLA ON ROENTGEN RAYS.

(*Concluded from page 131.*)

are much less efficient for this special object in consequence of the loss through the glass. A popular error seems to exist in regard to the concentration of the rays by concave electrodes. This, if anything, is a disadvantage. There are certain specific arrangements of the disruptive coil and circuits, condensers and static screens for the bulb, on which I have given full particulars on previous occasions.

Having selected the induction apparatus and type of bulb, the next important consideration is the vacuum. On this subject I am able to make known a fact with which I have long been acquainted, and of which I have taken advantage in the production of vacuum jackets and all sorts of incandescent bulbs, and which I subsequently found to be of the utmost importance, not to say essential, for the production of intense Roentgen shadows. I refer to a method of rarefaction by electrical means to any degree desirable, far beyond that obtainable by mechanical appliances.

Though this result can be reached by the use of a static machine as well as of an ordinary induction coil giving a sufficiently high potential, I have found that by far the most suitable apparatus, and one which secures the quickest action, is a disruptive coil. It is best to proceed in this way: The bulb is first exhausted by means of an ordinary vacuum pump to a rather high degree, though my experiences have shown that this is not absolutely necessary, as I have also found it possible to rarefy, beginning from low pressure. After being taken down from the pump, the bulb is attached to the terminal of the disruptive coil, preferably of high frequency of vibration, and usually the following phenomena are noted. First, there is a milky light spreading through the bulb, or possibly for a moment the glass becomes phosphorescent, if the bulb has been exhausted to a high degree. At any rate, the phosphorescence generally subsides quickly and the white light settles around the electrode, whereupon a dark space forms at some distance from the latter. Shortly afterward the light assumes a reddish color and the terminal grows very hot. This heating, however, is observed only with powerful apparatus. It is well to watch the bulb carefully and regulate the potential at this stage, as the electrode might be quickly consumed.

After some time the reddish light subsides, the streams becoming again white, whereupon they get weaker and weaker, wavering around the electrode until they finally disappear. Meanwhile, the phosphorescence of the glass grows more and more intense, and the spot where the stream strikes the wall becomes very hot, while the phosphorescence around the electrode ceases and the latter cools down to such an extent that the glass near it may be actually ice-cold to the touch. The gas in the bulb has then reached the required degree of rarefaction. The process may be hastened by repeated heating and cooling and by the employment of a small electrode. It should be added that bulbs with external electrodes may be treated in the same way. It may be also of interest to state that under certain conditions, which I am investigating more closely, the pressure of the gas in a vessel may be augmented by electrical means.

I believe that the disintegration of the electrode, which invariably takes place, is connected with a notable diminution of the temperature. From the point on, when the electrode gets cool, the bulb is in a very good condition for producing the Roentgen shadows. Whenever the electrode is equally, if not hotter than the glass, it is a sure indication that the vacuum is not high enough, or else that the electrode is too small. For very effective working, the inside surface of the wall, where the cathode stream strikes, should appear as if the glass were in a fluid state.

As a cooling medium I have found best to employ jets of cold air. By this means it is possible to operate successfully a bulb with a very thin wall, while the passage of the rays is not materially impeded.

I may state here that the experimenter need not be deterred from using a glass bulb, as I believe the opacity of glass as well as the transparency of aluminum are somewhat exaggerated, inasmuch as I have found that a very thin aluminum sheet throws a marked shadow, while, on the other hand, I have obtained impressions through a thick glass plate.

The above method is valuable not only as a means of obtaining the high vacua desired, but it is still more important, because the phenomena observed throw a light on the results obtained by Lenard and Roentgen.

Though the phenomenon of rarefaction under above conditions admits of different interpretations, the chief interest centers on one of them, to which I adhere—that is, on the actual expulsion of the particles through the walls of the bulb. I have lately observed that the latter commences to act properly upon the sensitive plate only from the point when the exhaustion begins to be noticeable, and the effects produced are the strongest when the process of exhaustion is most rapid, even though the phosphorescence might not appear particularly bright. Evidently, then, the two effects are closely connected, and I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocities. Taking as a basis the estimate of Lord Kelvin on the speed of projected particles in a Crookes' bulb, we arrive easily by the employment of very high potentials to speeds of as much as a hundred kilometres a second. Now, again, the old question arises: Are the particles from the electrode or from the charged surface generally, including the case of an external electrode, projected through the glass or aluminum walls, or do they merely hit the inner surface and cause particles from the outside of the wall to fly off, acting in a purely mechanical way, as when a row of ivory balls is struck? So far, most of the phenomena indicate that they are projected through the wall of the bulb, of whatever material it may be, and I am seeking for still more conclusive evidence in this direction.

It may not be known that even an ordinary streamer, breaking out suddenly and under great pressure from the terminal of a disruptive coil, passes through a thick glass plate as though the latter were not present. Unquestionably, with such coils pressures are practicable which will project the particles in straight lines even under atmospheric pressure. I have obtained distinct impressions in free air, not by streamers, as some experimenters have done, using static machines or induction coils, but by actual projection, the formation of streamers being absolutely prevented by careful static screening.

A peculiar thing about the Roentgen rays is that from low frequency to the highest obtainable there seems to be no difference in the quality of the effects produced, except that they are more intense when the frequency is higher, which is very likely due to the fact that in such case the maximum pressures on the cathode are likewise higher. This is only possible on the assumption that the effects on the sensitive plate are due to projected particles, or else to vibrations far beyond any frequency which we are able to obtain by means of condenser discharges. A powerfully excited bulb is enveloped in a cloud of violet light, extending for more than a foot around it, but outside of this visible phenomenon there is no positive evidence of the existence of waves similar to those of light. On the other hand, the fact that the opacity bears some proportion to the density of the substance speaks strongly for material streams, and the same may be said of the effect discovered by Prof. J. J. Thomson. It is to be hoped that all doubts will shortly be dispelled.

A valuable evidence of the nature of the radiations and progress in the direction of obtaining strong impressions on the plate might be arrived at by perfecting plates especially sensitive to mechanical shock or impact. There are chemicals suitable for this, and the development in this direction may lead to the abandonment of the present plate. Furthermore, if we have to deal with streams of material particles, it seems not impossible to project upon the plate a suitable substance to insure the best chemical action.

With apparatus as I have described, remarkable impressions on the plate are produced. An idea of the intensity of the effects may be gained when I mention that it is easy to obtain shadows with comparatively short exposures at distances of many feet, while at small distances and with thin objects, exposures of a few seconds are practicable. The annexed print is a shadow of a copper wire projected at a distance of 11 feet through a wooden cover over the sensitive plate. This was the first shadow taken with my improved apparatus in my laboratory. A similar impression was obtained through the body of the experimenter, a plate of glass, nearly three-sixteenths of an inch thick, a thickness of wood of fully two inches and through a distance of about four feet. I may remark, however, that when these impressions were taken, my apparatus was working under extremely unfavorable conditions, which admitted of so great improvements that I am hopeful to magnify the effects many times.

The bony structure of birds, rabbits and the like is shown within the least detail, and even the hollow of the bones is clearly visible. In a plate of a rabbit under exposure of an hour, not only every detail of the skeleton is visible, but likewise a clear outline of the abdominal cavity and the location of the lungs, the fur and many other features. Prints of even large birds show the feathers quite distinctly.

Clear shadows of the bones of human limbs are obtained by exposures ranging from a quarter of an hour to an hour, and some plates have shown such an amount of detail that it is almost impossible to believe that we have to deal with shadows only. For instance, a picture of a foot with a shoe on it was taken, and every fold of the leather, trousers, stocking, etc., is visible, while the flesh and bones stand out sharply. Through the body of the experimenter the shadows of small buttons and like objects are quickly obtained, while with an exposure of from one to one and a half hour the ribs, shoulder-bones and the bones of the upper arm appear clearly, as is shown in the annexed print. It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body.

An outline of the skull is easily obtained with an exposure of 20 to 40 minutes. In one instance an exposure of 40 minutes gave clearly not only the outline, but the cavity of the eye, the chin and cheek and nasal bones, the lower jaw and connections to the upper one, the vertebral column and connections to the skull, the flesh and even the hair. By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body.

Roentgen advanced modestly his results, warning against too much hope. Fortunately his apprehensions were groundless, for, although we have to all appearance to deal with mere shadow projections, the possibilities of the application of his discovery are vast. I am happy to have contributed to the development of the great art he has created.

TESLA'S RADIOGRAPHS.

We publish a welcome addition to the Roentgen ray literature. It is from the always interesting pen of Nikola Tesla, and is the first authorized description of the experiments of this thorough and conscientious inventor. Mr. Tesla gives full credit to the discovery by Roentgen, and is personally much elated over discoveries of his own as his careful experiments are developed. The Tesla radiographs we present show wonderful results under severe conditions. While Tesla has heretofore been silent since the announcement by Roentgen, he has not been idle, but has evidently been striving for valuable and tangible results. Further information from his laboratory will be awaited with interest.

MAY MEDICATE RAYS.

Nikola Tesla Hints That Streams of Chemicals May Be Projected Into the Body.

WILL PRODUCE SLEEPINESS.

Odd Effects Noticed While Making Radiographs of a Human Head.

BOMBARDMENT BY PARTICLES.

New Problems Presented by the Scientific Investigator of Roentgen's Discoveries.

Nikola Tesla, the electrician, since Professor Roentgen made known his discovery of X rays has been experimenting with them. He has been pursuing his researches on his own lines with tubes of his own make. His results and conclusions Mr. Tesla has made known in the current number of the Electrical Review. In connection with his communication the Electrical Review prints two remarkable radiographs.

One shows the right shoulder of a man taken under very severe conditions, as he wore his clothing and between him and the sensitized plate there was a plate of glass three-sixteenths of an inch thick and two inches of wood. This radiograph, which was made at a distance of four feet from the source of the X rays, shows the ribs, shoulder bones and bones of the upper arm.

The other radiograph shows a copper wire bent to form the word "Roentgen," and was made at a distance of eleven feet from the wooden slide covering the sensitized plate.

Mr. Tesla states that the rarefaction of Crooke's tubes, used in these experiments, may be increased by electrical means to any degree desirable—to a degree far beyond that obtainable by mechanical appliances.

VELOCITY OF THE RAYS.

In regard to the nature of X rays, he says:—"I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocities. Taking as a basis the estimates of Lord Kelvin on the speed of projected particles in a Crooke's bulb, we arrive easily, by the employment of very high potentials, to speeds of as much as a hundred kilometres a second. Now, again, the old question arises:—Are the particles from the electrode or from the charged surface generally, including the case of an external electrode, projected through the glass or aluminum walls, or do they merely hit the inner surface and cause particles from the outside of the wall to fly off, acting in a purely mechanical way, as when a row of ivory balls is struck? So far, most of the phenomena indicate that they are projected through the wall of the bulb, of whatever material it may be, and I am seeking for still more conclusive evidence in this direction."

"It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body."

HOLLOWS IN BONES PICTURED.

Tesla has secured radiographs showing the bony structure of birds and rabbits, even to the hollow of the bones. He has secured a radiograph of a rabbit after an hour's exposure, in which not only every detail of the skeleton is visible, but also a clear outline of the abdominal cavity. The location of the lungs and the fur are also shown.

Radiographs of large birds show the feathers distinctly. In another instance an exposure of forty minutes gave a radiograph of the human skull, showing clearly not only the outline, but the cavities of the eyes, chin, cheek, nasal bones, the lower jaw and connections to the skull, the flesh and even the hair.

"By exposing the head to a powerful radiation," Mr. Tesla says, "strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these remarkable effects be verified by men with a keener sense of observation I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body.

"Roentgen advanced modestly his results, warning against too much hope. Fortunately, his apprehensions were groundless, for, although we have to all apperances to deal with mere shadow projections, the possibilities of the application of his discovery are vast."

PROFESSOR MORTON'S SHADOWGRAPHS.

At his laboratory, in East Twenty-eighth street, yesterday Dr. William J. Morton made a picture of the bones of the hand, in which the hollows in the bones of the thumb were distinctly visible, and thus, then, was obtained a confirmation, though not so intended, of the results of Mr. Tesla's experiments mentioned. But, it was explained, the shadowgraphs delineating the hollows in bones show that the central portions of bones are less dense than the outer hard or ivorylike structure. The Roentgen process, it is therefore argued, by properly timed exposure will delineate the interior of the bone as well as the exterior and thus indicate the presence of any disease there. In this way the X rays will be of incalculable value to medicine and surgery.

The New York Sun March 11, 1896

TESLA AND THE X RAYS.

THEIR ALMOST MAGIC POWERS SHOWN BY HIS EXPERIMENTS.

The Young Electrician Obtains Results that Suggest New Fields of Usefulness for Prof. Roentgen's Marvellous Discovery—Possibilities, He Says, Are Vast.

An article by Nicola Tesla is published in the *Electrical Review* to-day describing his experiments in radiography. The scientific world has been eagerly awaiting an expression of opinion from Mr. Tesla, who is known to have begun his experiments within half an hour after the news of Prof. Roentgen's discovery was cabled to this country. Two remarkable radiographs are printed with the article. One of these shows the right shoulder of a man taken through his clothing and through a plate of glass three-sixteenths of an inch thick and two inches of wood. This radiograph, which was made at the distance of four feet from the source of the X rays, shows the ribs, shoulder bones, and bones of the upper arm. The other radiograph shows a copper wire bent to form the word "Roentgen," and was made at a distance of eleven feet from the wooden slide covering the sensitized plate.

Mr. Tesla also states that the rarefaction of Crookes tubes used in these experiments may be increased by electrical means to any degree desirable, far beyond that obtainable by mechanical appliances. In regard to the nature of X rays he says:

"I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocities. Taking, as a basis, the estimate of Lord Kelvin on the speed of projected particles in a Crookes bulb, we arrive easily, by the employment of very high potentials, to speeds of as much as a hundred kilometres a second. Now, again, the old question arises: Are the particles from the electrode or from the charged surface generally, including the case of an external electrode projected through the glass or aluminum walls, or do they merely hit the inner surface and cause particles from the outside of the wall to fly off, acting in a purely mechanical way, as when a row of ivory balls is struck? So far most of the phenomena indicate that they are projected through the wall of the bulb, or whatever material it may be, and I am seeking for still more conclusive evidence in this direction. It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body."

Tesla has also secured radiographs showing the bony structure of birds and rabbits, even to the hollow of the bones. He has secured a radiograph of a rabbit after an hour's exposure in which not only every detail of the skeleton is visible, but also a clear outline of the abdominal cavity, the lungs, and the fur. Radiographs of large birds show the feathers distinctly. In another instance an exposure of forty minutes gave a radiograph of the human skull, showing clearly not only the outline, but the cavities of the eye, chin, cheek, nasal bones, the lower jaw and connections to the skull, the flesh, and even the hair. Mr. Tesla concludes his communication as follows:

"By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and the quick lapse of time. Should these remarkable effects be verified by men with keener senses of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body.

"Roentgen advanced modestly his results, warning against too much hope. Fortunately his apprehensions were groundless, for, although we have to all appearance to deal with mere shadow projections, the possibilities of the application of this discovery are vast."

NIKOLA TESLA DISCUSSES X RAYS.

Important Results of Experiments with Roentgen's Discovery

The Electrical Review will publish to-day a communication from Nikola Tesla, describing, for the first time, his interesting experiments in radiography. The scientific world has been awaiting an expression of opinion from Mr. Tesla, who began his experiments within half an hour after the news of Prof. Röntgen's discovery was cabled to this country.

In connection with Mr. Tesla's communication, The Electrical Review will print two remarkable radiographs. One shows the slight shoulder of a man taken through his clothing, a plate of glass three-sixteenths of an inch thick, and two inches of wood. This radiograph, which was made at a distance of four feet from the source of the X rays, shows the ribs, shoulder bones, and bones of the upper arm.

The other radiograph shows a copper wire bent to form the word "Röntgen," and was made at a distance of eleven feet from the wooden slide covering the sensitized plate.

Mr. Tesla says the rarefaction of Crookes tubes used in these experiments may be increased by electrical means to any degree desirable—far beyond that obtainable by mechanical appliances. In regard to the nature of X rays, he says:

"I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocities. Taking as a basis the estimates of Lord Kelvin on the speed of projected particles in a Crookes bulb, we arrive easily by the employment of very high potentials, to speeds of as much as a hundred kilometers a second.

"Now, again, the old question arises: Are the particles from the electrode or from the charged surface generally, including the case of an external electrode, projected through the glass or aluminum walls, or do they merely hit the inner surface and cause particles from the outside of the wall to fly off, acting in a purely mechanical way, as when a row of ivory balls is struck? So far, most of the phenomena indicate that they are projected through the wall of the bulb, of whatever material it may be, and I am seeking for still more conclusive evidence in this direction.

"It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body."

Mr. Tesla has also secured radiographs showing the bony structure of birds and rabbits, even to the hollow of the bones. He has secured a radiograph of a rabbit after an hour's exposure in which not only every detail of the skeleton is visible, but also a clear outline of the abdominal cavity, location of the lungs, and the fur are shown. Radiographs of large birds show the feathers distinctly.

In another instance, an exposure of forty minutes gave a radiograph of the human skull, showing clearly not only the outline, but the cavities of the eye, chin, cheek, nasal bones, the lower jaw, and connections to the skull, the flesh, and even the hair. Mr. Tesla concludes his communication as follows:

"By exposing the head to a powerful radiation, strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time.

"Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body.

"Röntgen advanced modestly his results, warning against too much hope. Fortunately, his apprehensions were groundless, for although we have to all appearances to deal with mere shadow projections, the possibilities of the application of his discovery are vast. I am happy to have contributed to the development of the great art he has created."

The New York Tribune March 11, 1896

NIKOLA TESLA ON RADIOGRAPHY.

HIS INTERESTING EXPERIMENTS—AN ACCOUNT OF THEM BY HIMSELF.

"The Electrical Review" publishes to-day a communication from Nikola Tesla, describing for the first time his interesting experiments in radiography. The scientific world has been eagerly awaiting an expression of opinion from Mr. Tesla, who is known to have begun his experiments within half an hour after the news of Professor Röntgen's discovery was cabled to this country. In connection with Mr. Tesla's communication, "The Electrical Review" prints two remarkable radiographs. One of these shows the right shoulder of a man taken through his clothing, a plate of glass three-sixteenths of an inch thick and two inches of wood. This radiograph, which was made at the distance of four feet from the source of the X rays, shows the ribs, shoulder bones and bones of the upper arm. The other radiograph shows a copper wire bent to form the word "Röntgen," and was made at a distance of eleven feet from the wooden slide covering the sensitized plate.

A STREAM OF MATERIAL PARTICLES.

Mr. Tesla says that the rarefaction of the Crookes tubes used in these experiments may be increased by electrical means to any degree desirable, far beyond that obtainable by mechanical appliances. This method he describes. In regard to the nature of X rays, he says: "I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocity. Taking as a basis the estimates of Lord Kelvin on the speed of projected particles in a Crookes bulb, we arrive easily by the employment of very high potentials to speeds of as much as 100 kilometres a second. Now, again, the old question arises: 'Are the particles from the electrode or from the charged surface generally, including the case of an external electrode, projected through the glass or aluminum walls, or do they merely hit the inner surface and cause particles from the outside of the wall to fly off, acting in a purely mechanical way, as when a row of ivory balls is struck?' So far, most of the phenomena indicate that they are projected through the wall of the bulb, of whatever material it may be, and I am seeking for still more conclusive evidence in this direction. . . . . It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body."

RADIOGRAPHS OF BIRDS AND RABBITS.

The writer has also secured radiographs showing the bony structure of birds and rabbits, even to the hollow of the bones. He has obtained a radiograph of a rabbit after an hour's exposure, in which not only every detail of the skeleton is visible, but a clear outline of the abdominal cavity, the location of the lungs and the fur are shown. Radiographs of large birds show the feathers distinctly. In another instance an exposure of forty minutes gave a radiograph of the human skull, showing clearly not only the outline, but the cavities of the eye, chin, cheek, nasal bones, the lower jaw and connections to the skull, the flesh and even the hair.

EFFECTS OF RADIATION ON THE HEAD.

Mr. Tesla closes his communication in the following words: "By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep, and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep, and a quick lapse of time. Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus, it may be possible by these strange appliances to project a suitable chemical into any part of the body.

"Röntgen advanced modestly his results, warning against too much hope. Fortunately, his apprehensions were groundless, for, although we have to all appearance to deal with mere shadow projections, the possibilities of the application of his discovery are vast. I am happy to have contributed to the development of the great art he has created."

The New York Times March 12, 1896

VIEWS ON TESLA'S IDEAS

Doctors Are Much Interested in His Theory of X Rays.

POSSIBLE VALUE IN TREATING DISEASE

What Cyrus Edson and J. Mount Bleyer Say of the Deductions and Experiments of the Electrician.

The publication in THE NEW-YORK TIMES yesterday of the results of the experiments of Nikola Tesla in radiography has excited a great deal of interest in the medical profession. His conclusions were to the effect that the X rays were of the nature of a stream of material particles which strike the sensitive plate with great velocities.

It has been demonstrated by Mr. Tesla to his satisfaction that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the human body. He also gives it as his opinion that it might be possible by the use of the X rays to project a suitable chemical into any part of the body, which would make it a valuable therapeutic agent.

Dr. Cyrus Edson, formerly Health Commissioner, when asked by a reporter for THE NEW-YORK TIMES about Tesla's deductions, said that he had been much interested in the subject and had given it considerable attention.

"It is an undoubted fact," said the doctor, "that you can decompose certain chemicals by means of light. The principle of photography rests upon this fact. These X rays decompose the chemicals with which the film is sensitized and effects this decomposition through what have hitherto been regarded as opaque bodies, such as the hand, for instance. Light is vibration, and it has been demonstrated that these X rays will pass through an opaque body. That these vibrations in passing through the skull should affect the delicate nerve tissues of the brain and stimulate them is a perfectly natural result.

"This accounts for the sensations experienced by Tesla when he exposed his head to a powerful radiation. But there is no more reason to believe that the X rays will carry a medicinal agent through the body and into the distant spot, the seat of disease, than that a ray of light will be able to project such a chemical on to the surface of the body. When we have succeeded in projecting medicine on to the exterior surface by means of light we may be able to penetrate into the interior by means of ultra-viole rays.

"The theory of the vibrations of light is not a new one. It originated with Sir Isaac Newton, who believed that luminous bodies shot out infinitely small particles in straight lines, which, by penetrating the transparent parts of the eye and falling on the nervous tissue, produced vision. Other philosophers drew a parallel between the properties of light and those of sound, and considered that as sound was certainly the effect of vibrations, or little waves projected through elastic bodies, so light might be nothing more than the consequence of similar vibrations transmitted with inconceivable velocity through a highly elastic medium. The wave hypothesis of light is at present generally adopted simply because it is in harmony with all the known phenomena discovered since the time of Newton.

"The deductions of Tesla as the result of his experiments are absolutely in harmony with the Newtonian theory. We can certainly expect some marvelous results from the X rays, things not even dreamed of yet. I believe that they will prove a valuable adjunct to medical science, and I think that the ultra violet rays will be sooner or later obtained by passing ordinary sunlight through certain media, without the agency of electricity."

Dr. J. Mount Bleyer, who has taken great interest in determining the effects of all light rays on animal and vegetable life, said yesterday:

"I am not at all surprised at the results of Tesla's experiments. I have been experimenting for some time with the associated light rays—the sunlight and the different colors, such as blue, red, and orange—in connection with the treatment of infectious diseases and vegetations. The results obtained by Tesla are simply marvelous, but are just what I expected. I have contended from the beginning, and it has now been proved beyond a doubt by Tesla, that this bombardment of particles does pass through glass and other materials at an enormous velocity. As far as the therapeutic effects of the rays are concerned, they may be likened in some way to a massage effect, if they do not form a high class of bacteracidal agent. As these experiments have been proved by Tesla, acting in a purely mechanical way, this would be a new and perhaps more beneficial way of using massage.

"As far as the photographing of certain deposits in the human system, such as the lung substance in phthisis and other pulmonary diseases, I have not yet reached the exact depth of radiography that Tesla has, but a short time ago, by means of the Röntgen rays, I made a fine photograph of the interior of the larynx of a patient where a tumor was situated, showing its exact location and condition, and which could not have been obtained with such exactitude in any other way that I know of.

"As to the sensations described by Tesla as having been experienced by him in his experiments, I have experienced exactly similar sensations in exposing my head to powerful radiation. It does not seem to me at all improbable that the suggestion made by Tesla of projecting a suitable chemical or medicament into any part of the body by means of the X rays may be found practical, for it is impossible to determine the results to be achieved by further experimentation. The present difficulty is that the Crookes tubes now in use for the making of radiographs are not powerful enough to be used for therapeutic purposes, which require very high potentials to secure good results, and nothing below that is of value.

"Solariums for the treatment of infectious diseases, with associated light rays, will no doubt be the next advance in hospital architecture. I have made a number of experiments with the associated light rays in hospital and among my private patients in cases of phthisis and tuberculosis. I have resorted to the treatment wherever it was possible, and never failed to obtain the best results. Ordinary light is one of the main factors in the growth of animal life. We know that sunlight is essential for the growth and development of both animal and vegetable tissue. We have in light a therapeutic agent that has been underestimated and neglected, and which should be taken up and thoroughly studied."

The New York Times March 13, 1896

CHARACTER OF THE X RAYS

Prof. Rood Inclined to Believe They Are Like Light Waves.

SHORTNESS, THOUGH, UNPRECEDENTED

His View Excludes All Idea of a Molecular Bombardment Outside of the Crookes Tube.

Ogden N. Rood, Professor of Physics in Columbia College, was asked yesterday by a reporter for THE NEW-YORK TIMES whether recent experiments with the Röntgen rays had altered his views as to the nature of the phenomena.

It will be remembered that before full details of Röntgen's discovery reached here Prof. Rood tentatively expressed his view that the rays were of the same nature as light waves, only much shorter than any previously known.

Since that time numerous theories have been suggested by experimenters on both sides of the Atlantic. One of these, adapted from Crookes, is that the rays represent a bombardment of the molecules in a highly rarefied atmosphere, and that this bombardment is communicated to other particles of matter outside the inclosing envelope. Prof. Rood thinks this theory in its entirety is not necessary to account for the Röntgen phenomena, and is extremely improbable in any case.

After glancing through the article by Nikola Tesla in The Electrical Review, also printed in part in THE NEW-YORK TIMES Wednesday last, Prof. Rood dictated the following statement of his views:

"It is never proper to frame a new hypothesis in order to account for discoveries when an old and well-established theory is capable of giving them an explanation. Our knowledge of the waves of light, of radiant heat, and of the ultra violet rays is confined within narrow limits.

"Thus far, according to our previous experience, the shorter the length of the wave the more it will be bent, or refracted, by substances in general. It, however, does not at all follow that this will hold good if the length of the wave is shortened to a degree beyond our experience.

"On the other hand, it is highly probable that if this shortening process goes on till the length of the wave has become of the same order of magnitude with the molecules of matter that the effect in the matter of refraction will diminish. This would account for the fact that no one has succeeded thus far in refracting or reflecting the Röntgen rays. In my own experiments I have so far found them to act in the same general way with waves of ordinary light, and I am inclined to believe that they are simply waves of light of unprecedented shortness.

"This view necessarily excludes all idea of a molecular bombardment outside of the Crookes tube. I believe that it will be eventually demonstrated that the Röntgen rays are capable of reflection and refraction, although it will require more delicate work than has thus far been extended in this direction."

General Electric—Westinghouse Electric & Manufacturing—*Agreement as to Patents.*—Late Thursday afternoon the directors of these companies reached an agreement for pooling their patents. This agreement will stop the costly litigation so long in progress and ensure the joint use of the patents during their life. Certain patents are excluded, but Charles A. Coffin, President of the General Electric, is quoted as stating that in a general way it can be said that all the patents held by the two companies for lighting and power will be included except those pertaining to cables and underground trolley material.

A statement given out by the two companies describes the agreement as follows: "The General Electric Co. has contributed 62½ per cent and the Westinghouse Electric & Manufacturing Co. 37½ per cent in value of the combined patents, and each company is licensed to use the patents of the other company, except as to the matters excluded, each paying a royalty for any use of the combined patents in excess of the value of its contribution to the patents. The patents are to be managed by a board of control consisting of five members, two appointed by each company and a fifth elected by the four so appointed."

The statement adds that it is expected the economies to be effected by this arrangement will be very considerable. The especial incentives leading to it were the recent decisions in favor of patents of the General Electric Company controlling the overhead system of electric railways, the approaching trials on a number of other important General Electric patents and the equally strong position of the Westinghouse Company in respect to power transmission covered by the patents of Nikola Tesla, etc.

An interesting account of the patents of the Westinghouse Company, including that on the underground trolley, was in the CHRONICLE of July 6, p. 25.—V. 61, p. 871; V. 62, p. 320.

ELECTRICITY IN RELATION TO DENTISTRY.[1]

BY GEORGE HELI GUY.

I SHALL confine myself to a brief reference to some of the departments of electrical work in which the members of the dental profession are likely to work out their own salvation. In considering this question, it is a most hopeful sign that, although until recently, electricity has been but little employed in dental surgery, except for the driving of mechanisms, cauterization, the translumination of soft tissue, or the illumination of cavities, yet the profession are taking kindly to it. A large section of your medical brethren are still regarding its progress and increasing popularity with distrust and blind unbelief. Not long since, I asked a leading fashionable physician in New York his opinion as to the likelihood of electricity being eventually taken up in earnest by the profession. He replied: "It never will be. I have tried it myself, and have come to the conclusion that there is nothing in it." The whole electrical apparatus of this physician turned out to be a small faradic battery, and he had been treating all ailments with the same kind of current. There are thousands of practitioners who still think as he did. But there are many signs which go to show that the progressive and intelligent section of the dental profession are going with the times, and I was struck, and very much gratified, when attending the Dental Convention last year, at Asbury Park, to see the intense interest and appreciation with which the papers discussing electrical problems were received. I read not long ago of some electrical experiments upon floating organisms. If a galvanic current be passed through a bath containing paramecia in sufficient abundance, a curious sight is observed. When contact is made, the whole crowd of paramecia fall into order with their noses toward the cathode, and begin to swim toward it in converging curves; while, if the current be reversed, the crowd breaks up, all its units turn around and begin to swim away, as if of one mind, from the new anode to the new cathode. The creatures are evidently more "comfortable" when swimming with the electric current than the reverse way. In another experiment, a number of tadpoles were put into a lantern bath. They began to move about very leisurely, and to jostle

1. Abstract of response to toast of "The Coming Dentist Electrically Considered," at the annual dinner of the Central Dental Association, of Northern New Jersey, at Newark, N. J., Feb. 17, 1896.

each other in all directions. On sending a current of electricity through the bath there was prodigious excitement. As Dr. Waller, who conducted the experiment, described it, "The tadpole community seems to have gone mad; a writhing mass is all that can be distinguished; but the disturbance does not take long to subside, and now all the tadpoles are fixed as if at attention, heads to anode, viz., traversed by a current from head to tail, stroked down the right way." It appears to me that the dentists, like the tadpoles, have begun to find that it is wise to yield themseves to the current of electrical progress that has set in; it points their heads the right way, and means, in the long run, less trouble, better work, and last, but not least, relatively better pay.

One of the great drawbacks to the adoption of electricity in general dental practice is the cheap outfit and the poor installation work. Any man who can put up an electric bell now calls himself an electrician. If it were not for the inspection department of the Board of Underwriters, there would be, from bad wiring, such a crop of fires in large cities as would render the lighting of the streets entirely unnecessary. But there are no such adequate official restrictions and precautionary measures for the protection of the dentist. Beware of cheap outfits. Don't try to save a dollar or two in your battery plant; get the best that is in the market. Go, for your motors, and your dental equipment, to the best houses, that spend money on experimentation instead of letting you pay for it directly, and that insure careful inspection, and sound installation, and don't subject you to the curses of defective wires, poor plugs, and inferior tackle of every description. I know of an instance in New York, where the dentist had the hard luck to be taken in hand by a cheap, so-called electrician. Before he got through, he spent $500 in his electrical outfit, and then he threw it out and vowed he wouldn't have anything more to do with electricity, as it was a rank fraud. Therefore, I say dental electric outfits are like bicycles; if you want one to wear well, run smoothly, and save lurid language, get the best you can lay your hands on; you will get gratifying results, and you won't have any hard things to say about electricity.

Now, as to the electrical possibilities of the future in dentistry. Although we can't gauge them, we have been lately getting some glimmering as to the trend they are likely to take. I wish I could help saying something about cataphoresis; but I can't. The coming work in cataphoresis will not only be vast in extent, but marvelous in its general bearing on dental practice. Many occasions constantly arise where anaesthetic drugs may be introduced into tissue and into dentine, and also other drugs, such as iodine, etc., may be used in the same way, and their familiar topical effects be vastly enhanced by the aid of electricity. Few can comprehend the limitations of this great aid to the local application of drugs within the cavity of the mouth. Broadly, it may be said that any drug that has been previously used without electricity within the mouth to produce specific effect, may now be electrically used with tenfold its former power for good. The subject of cataphoresis is already very wide, and I am not going to enter further upon it. I would, however, say, as it leads up to another point, that the question of the resistance of the liquid used has a most important bearing in the therapeutical applications of cataphoresis. If the resistance is too high, as with chloroform, sulphuric ether, alcohol, glycerine, etc., little or no current is conveyed, and no cataphoresis takes place, while on the other hand, if the electric resistance is too low, as with strong saline and acid solutions, much current passes, but little or no cataphoric action takes place. Now, you are all familiar with the points of the late discussion on guaia-cocaine. It may be, and undoubtedly is, an excellent anaesthetic, but it is ill-smelling and escharotic, and none of you like it. It has been proposed to add almond oil to it, but if the resistance is thus increased, more current will have to be used. Dr. Morton, however, has found a way out of the difficulty. He says that guaiacol alone, and other similar substances and derivatives, in themselves non-conductors of electricity, by the addition of a very minute quantity of some innocent substance of an electrolytic nature, like, say, salts of caffeine or quinine, or any salts of the alkaloids, may be caused to penetrate tissue by the aid of electricity, and thus exhibit anaesthetic effects unobtainable without the aid of the added electrolyte. But this is one of the points that you gentlemen will have to straighten out before the best results from cataphoresis can be reached.

Further developments in the uses of the different kinds of currents is another subject which is too comprehensive to be discussed here. I may, however, promise that the sinusoidal current will sooner or later find its way into dental laboratories. As you know, a dynamo current is uneven, but the sinusoidal, with its very high vibrations, has soft, wave-like impulses; the current is agreeable and soothing to the patient, and more horse-power of electricity can be administered than if the frequency were lower and the wave less symmetrical. For example, the present sinusoidal machines run up to 2,000 alternations per second, whereas the alternations per second of an induction coil would be, probably, at their highest limit, 500 per second. Added to that, the graphic curve from the induction coil would be comparatively unsymmetrical, i. e., irregular. It is these two elements, the frequency and the graphic curve, or, as D'Arsonval calls it, "the characteristic of excitation," which determines whether the current is painful or not, and it is pain only, which limits the extent to which the induced currents from ordinary medical apparatus may be administered. On this head, I may mention, that guesswork in electrical dosage will soon be a thing of the past. The time is approaching when electricity will be prescribed and administered not only in measured units of intensity, density, and time, but with definite ideas of the electromotive force curve, and of the therapeutic indications that a given curve may be expected to fulfill.

There are many other branches of electrodental work in which we are on the verge of epoch-making improvements, and among them are the important ones of translumination, implantation, and sterilization. For the purpose of translumination, it is probable that more attention will be paid to the intensifying of the light. For instance, instead of confining the lamps for that purpose to small candle-powers, they might be run up to, say, 20-candle-power. Until lately, the difficulty has been that candle-power produced heat. This has been practically overcome by enclosing the first bulb in a second bulb through which water is made to flow. But here comes the fascinating question of the part which the phosphorescent, or "etheric" light, the "Tesla glow," or, as it is also called, "the light of the future," will play in translumination. I had the pleasure about two years ago, of seeing, in Mr. Tesla's laboratory, a demonstration of the then newly developed phosphorescent light. The room was darkened, and electrostatic currents played into it at the rate of possibly a million vibrations a second. Vacuum tubes, in fancy shapes, lay all around, and as these were taken up and lifted into the "field" they burst forth into beautiful luminescence, and the room was illuminated. Tesla then prophesied that it would not be long before our houses were lighted without wires, and even without lamps, and that the night would be made as day by means of phosphorescent light caused by the play of current through air-exhausted tubes. Last year a photograph of Mr. Tesla was taken by this light. As a photograph it was not much to boast of, but as a piece of history, it was most interesting. It was the first time that a photograph had been taken by that light. That line of work was taken up by a man in your own city, Mr. D. McFarlan Moore, who in the short time that has since elapsed, has so developed it that he published a week or two ago, a bold and striking picture, possessing the clearness and strength of a daylight photograph, which was secured by a three-minute exposure under the new light in his laboratory. If such strides can be made in twelve months, and we are coming at such a rapid rate nearer to the electrician's—and, for the matter of that, the dentist's—ideal, of light without heat, I think it may pay the dentists to let their spirit of investigation drift in the direction of translumination by phosphorescent light.

Electricity as an agent in implantation, etc., of teeth is a very attractive subject, and we are on the eve of great developments in this field, but I must not detain you longer.

There is, however, an incident which I should like to tell you of, which bears on another important branch of work, sterilization. Some time ago, a German physician wrote to Mr. Tesla and said that he had been experimenting with the play of etheric light on the bacilli of tuberculosis, and not only had he killed the microbes while experimenting, but he had by the same means cured tubercular developments in the human subject. This letter, sad to say, was burnt up in the fire at the laboratory, and Mr. Tesla has never been able to find where it came from. Now, gentlemen, you will see how beautifully this bears on the question of sterilization: pyorrhoea alveolaris should have no further terrors when it can be swept out of the human jaw with a brush of glowing phosphorescence, and a new charm will be given to dental work when light will not only illume, but purify and sterilize, and even kill the deadliest germs that work havoc within the soft tissue of the mouth.

And now, gentlemen, the Röntgen rays—no speech to-day is complete without something about them. I don't think any of us yet realize what they may mean to dentistry. If it can be established that the cathodic rays will, like light, kill microbes, you see at once where it carries you. There is one thing, however, that cathodic rays have done, that you gentlemen, I am sure, will take careful note of. They have passed through ivory, and photographed pieces of metal on the other side. Where fangs and other parts of the teeth are being treated, it is often necessary to know which teeth already con-

tain filling. There is now no further difficulty about this. As metallic substances intercept light to a greater degree than bone does, a cathodograph will show the location of all the filling in the teeth which have already been operated upon. Dr. W. J. Morton has proposed to put the Röntgen rays within the cavity of the mouth, and a sensitive plate within the plate holder outside on the cheek, and thus reproduce the teeth, in situ, fangs, filling, etc. In this connection, it would also be possible to determine the existence of ostitis, deformations, diseases of the bone, pus deposits, etc., in fact, the whole concealed pathology of the teeth in their relation to the jaw and gums would be thus revealed.

GENERAL ELECTRIC-WESTINGHOUSE COMBINATION.

A Mutual Working Agreement Made.

THE NEW ARRANGEMENT WILL SAVE HUNDREDS OF THOUSANDS OF DOLLARS IN LITIGATION AND EXPERT EVIDENCE TO BOTH COMPANIES — APPARENTLY AN EQUITABLE DIVISION OF PATENTS —A BOARD OF CONTROL WILL MANAGE THE PATENTS.

As predicted in the ELECTRICAL REVIEW some time ago, a working arrangement based on the patents owned by both companies has been entered into by the General Electric Company, of Schenectady, N. Y., and the Westinghouse Electric and Manufacturing Company, of Pittsburgh, Pa. This arrangement is in no sense a consolidation of the companies. Its object is to do away with the expensive patent litigation which has been indulged in for years by both these great concerns. The legal expenses and fees for expert testimony have been something enormous and out of all proportion to the commercial value of the patents involved. These expenses will be saved under the new mutual arrangement.

The news that such a deal had been made became public on the evening of March 12, when the following official statement, representing the views of both companies, was given out by Mr. Charles A. Terry, one of the counsel of the Westinghouse company:

Negotiations between the General Electric Company and the Westinghouse Electric and Manufacturing Company have resulted in an arrangement with respect to a joint use of the patents of the two companies, subject to existing licenses on terms

which are considered mutually advantageous.

It has been agreed that after certain exclusions the General Electric Company has contributed 62½ per cent and the Westinghouse Electric and Manufacturing Company 37½ per cent in value of the combined patents, and each company is licensed to use the patents of the other company, except as to the matters excluded, each paying a royalty for any use of the combined patents in excess of the value of its contribution to the patents.

The patents are to be managed by a board of control, consisting of five members, two appointed by each company and a fifth selected by the four so appointed. Both companies have acquired during their existence a large number of valuable patents, and numerous suits have been instituted in consequence of the infringement of these patents by one party or the other or by their customers. In the prosecution of these suits large sums of money have been expended and the general expenses of the companies have in this manner been greatly increased. It is expected that the economies to be effected will be very considerable and that the two companies and their customers will be mutually protected.

The especial incentives which led to the arrangement at this time were the recent decisions in favor of patents of the General Electric Company controlling the overhead system of electric railways, the approaching trials on a number of other important General Electric patents on controllers and details of electric railway apparatus and systems and other electrical devices, and the equally strong position of the Westinghouse company in respect to power transmission, covered by the patents of Nikola Tesla, and in view of its other patents in active litigation, some of which are of controlling importance.

President Charles A. Coffin, of the General Electric Company, stated on Saturday to the ELECTRICAL REVIEW that "the arrangement between the two companies had been formally approved by the directors of both companies. The agreement is as yet in skeleton form. It may take a few weeks to complete it. I should say it might perhaps be perfected and put into effect by June 1. It is the intention that it shall continue during the life of the patents of the companies. The patents which are excluded are foreign patents, which can not be embraced, patents on cable and underground railway materials, which are covered by licenses, and a few patents excluded for special reasons."

Continuing, Mr. Coffin said: The companies will stop fighting each other in the courts, and will join in prosecuting infringements of their patents. How much will be saved by the termination of litigation I can not say, as all legal expenses are included in one account. It would be necessary to separate the items to furnish actual figures. The saving, however, will be large.

No monopoly of the electrical business will be created by the agreement. There are other important concerns in the business. The General Electric and Westinghouse companies do not consolidate. They retain their entire independence and will, in fact, as heretofore, be competitors in business. Prices will doubtless be agreed upon which will benefit customers of the companies and the companies themselves, but and supplies. It has not yet been figured out how much the revenues of the companies will be increased by the arrangement, nor can it be until the arrangement has been put in more perfect form.

The first proposition for an agreement between the companies was made several years ago, but the negotiations which resulted in the agreement were opened recently.

Mr. Geo. Westinghouse, Jr., could not be seen, as he had left the city. Vice-President Geo. W. Hebard stated to the ELECTRICAL REVIEW that the announcement given out by Mr. Terry embodied what his company wished to say to the public.

The New York *Recorder* of March 13 referred to the deal as follows:

The annual meeting of the General Electric Company will be held in May, and efforts will be made to oust President Coffin. Yesterday Duer, Strong & Jarvis, lawyers, of 50 Wall street, advertised for the names and addresses of stockholders opposed to the management of Mr. Coffin. A. Pennington Whitehead of the firm said he represented clients whom he could not name. However, Mr. Coffin's master stroke in forming a combination with the Westinghouse company may temper the opposition materially. He is not at all worried, apparently, as to the security of his place as executive.

The authorized capital stock of the General Electric Company is $50,000,000, of which $10,000,000 may be preferred. The amount of common stock outstanding is $30,460,000 and of the preferred stock $4,252,000. Prior to August, 1893, dividends at the rate of eight per cent a year were paid on the common stock, but no dividends have been paid since that date. The preferred is entitled to dividends at the rate of seven per cent a year, and these are cumulative, so that when unpaid they become a lien on earnings. The dividends on the preferred stopped with the one due January, 1894. The company has issued $8,750,000 of five per cent debenture bonds, which are convertible into stock on the basis of $100 in stock for $120 in bonds.

The surplus reported by the company for the year ended January 31, 1895, after charging off $932,521 for old losses, depreciation, etc., was $414,643. The annual meeting takes place May 12. The company's principal works are at Schenectady, N.Y. It has other works at Harrison, N.J., and at Lynn, Mass. The company was organized on April 15, 1892, and acquired all of the capital stocks of the Edison Electric Light, Edison General Electric, Thomson-Houston Electric and Thomson-Houston International Electric companies. It controlled all the Edison patents for electric lighting.

The Westinghouse company has outstanding $179,150 old common stock, $5,333,940 assenting stock and $4,000,000 preferred seven per cent cumulative stock, $500,000 United States Electric Light Company six per cent bonds, $250,000 collateral trust five per cent notes and $194,560 old scrip for dividends. The company holds in its treasury $6,735 preferred stock and $663,349 assenting stock. The total net income of the company for the year ended March 31, 1895, was $802,409. The new works of the company are at East Pittsburgh, Pa.

A Boston man, acquainted with both companies, says that the agreement means that 12 per cent will be easily earned on both of the Westinghouse stocks and at least seven per cent will be earned on General Electric common. He claims that there has not been in five years so important a deal as this one.

Matthew Marshall, the well known financial writer for the New York *Sun*, referred to the deal on Monday last as "The Electric Treaty." He says: "As usual, the speculators for a rise in General Electric stock, who had early information of the negotiations which have resulted in the peace just announced, overestimated its beneficial effect upon the market. The stock, which, since last January, had been gradually going up from 22 to 35, jumped, upon the news of the making of the treaty, nearly to 40, but immediately receded and closed finally on Saturday at 37. This shows that the uninformed public is not convinced that the cessation of the war between the two companies guarantees anything more than a cessation of the losses resulting from the previous hostilities. Whether, eventually, positive profits will be reaped, is not yet certain."

TESLA'S WORK IN RADIOGRAPHY.

Radiography leads all discoveries of modern times in the intelligent and spontaneous attention it has received from scientists and experimenters all over the civilized world. The announcement of Nikola Tesla's achievements in the new art, first published in the ELECTRICAL REVIEW of March 11, in the author's own modest language, has added fresh impetus to the work in this direction. His disruptive discharge coil has been universally used where the best results in radiography have been obtained, and his two marked improvements, namely, the single electrode tube and his method of rarefaction, promise great results. Other important points about Tesla's work are the fine details he has obtained in his radiographs, the great distance at which the radiographs have been made, and brief time of exposure.

We feel sure that the second communication from Mr. Tesla, which we publish in this issue, will be appreciated by our readers. He now produces shadows at 40 feet distance and promises still more. He, furthermore, brings out the important fact of reflection of the rays, demonstrating this property beyond any doubt, besides other interesting details bearing on the nature of the radiation. To most men the facts presented will appear as a revelation.

The pleasant criticism of our halftone reproduction of the radiograph of the shoulder of a man is, we admit, justified, but any one who knows the difficulties of the procedure involved will be convinced that as much was done as could be done under the circumstances.

Mr. Tesla is pursuing quietly his work and giving all credit to Roentgen; and it is significant, we think, that the first radiograph he produced in his laboratory was the name of the discoverer. We wish that such courtesies among scientists would always be practiced.

TESLA'S LATEST RESULTS.

HE NOW PRODUCES RADIOGRAPHS AT A DISTANCE OF MORE THAN FORTY FEET.

To the Editor of Electrical Review:

Permit me to say that I was slightly disappointed to note in your issue of March 11 the prominence you have deemed to accord to my youth and talent, while the ribs and other particulars of Fig. 1, which, with reference to the print accompanying my communication, I described as clearly visible, were kept modestly in the background. I also regretted to observe an error in one of the captions; the more so, as I must ascribe it to my own text. I namely stated on page 135, third column, seventh line: "A similar impression was obtained through the body of the experimenter, etc., through a distance of four feet." The impression here referred to was a similar one to that shown in Fig. 2, whereas the shadow in Fig. 1 was taken through a distance of 18 inches. I state this merely for the sake of correctness of my communication, but, as far as the general truth of the fact of taking such a shadow at the distance given is concerned, your caption might as well stand, for I am producing strong shadows at distances of 40 *feet*. I repeat, 40 feet and even more. Nor is this all. So strong are the actions on the film that provision must be made to guard the plates in my photographic department, located on the floor above, a distance of fully 60 feet, from being spoiled by long exposure to the stray rays. Though during my investigations I have performed many experiments which seemed extraordinary, I am deeply astonished observing these unexpected manifestations, and still more so, as even now I see before me the possibility, not to say certitude, of augmenting the effects with my apparatus at least tenfold! What may we then expect? We have to deal here, evidently, with a radiation of astonishing power, and the inquiry into its nature becomes more and more interesting and important. Here is an unlooked-for result of an action which, though wonderful in itself, seemed feeble and entirely incapable of such expansion, and affords a good example of the fruitfulness of original discovery. These effects upon the sensitive plate at so great a distance I attribute to the employment of a bulb with a single terminal, which permits the use of practically any desired potential and the attainment of extraordinary speeds of the projected particles. With such a bulb it is also evident that the action upon a fluorescent screen is proportionately greater than when the usual kind of tube is employed, and I have already observed enough to feel sure that great developments are to be looked for in this direction. I consider Roentgen's discovery, of enabling us to see, by the use of a fluorescent screen, through an opaque substance, even a more beautiful one than the recording upon the plate.

Since my previous communication to you I have made considerable progress, and can presently announce one more result of importance. I have lately obtained shadows by *reflected rays only*, thus demonstrating beyond doubt that the Roentgen rays possess this property. One of the experiments may be cited here. A thick copper tube, about a foot long, was taken and one of its ends tightly closed by the plate-holder containing a sensitive plate, protected by a fiber cover as usual. Near the open end of the copper tube was placed a thick plate of glass at an angle of 45 degrees to the axis of the tube. A single-terminal bulb was then suspended above the glass plate at a distance of about eight inches, so that the bundle of rays fell upon the latter at an angle of 45 degrees, and the supposedly reflected rays passed along the axis of the copper tube. An exposure of 45 minutes gave a clear and sharp shadow of a metallic object. This shadow was produced by the reflected rays, as the direct action was absolutely excluded, it having been demonstrated that even under the severest tests with much stronger actions no impression whatever could be produced upon the film through a thickness of copper equal to that of the tube. Concluding from the intensity of the action by comparison with an equivalent effect due to the direct rays, I find that approximately two per cent of the latter were reflected from the glass plate in this experiment. I hope to be able to report shortly and more fully on this and other subjects.

In my attempts to contribute my humble share to the knowledge of the Roentgen phenomena, I am finding more and more evidence in support of the theory of moving material particles. It is not my intention, however, to advance at present any view as to the bearing of such a fact upon the present theory of light, but I merely seek to establish the fact of the existence of such material streams in so far as these isolated effects are concerned. I have already a great many indications of a bombardment occurring outside of the bulb, and I am arranging some crucial tests which, I hope, will be successful. The calculated velocities fully account for actions at distances of as much as 100 feet from the bulb, and that the projection through the glass takes place seems evident from the process of exhaustion, which I have described in my previous communication. An experiment which is illustrative in this respect, and which I intended to mention, is the following: If we attach a fairly exhausted bulb containing an electrode to the terminal of a disruptive coil, we observe small streamers breaking through the sides of the glass. Usually such a streamer will break through the seal and crack the bulb, whereupon the vacuum is impaired; but, if the seal is placed above the terminal, or if some other provision is made to prevent the streamer from passing through the glass at that point, it often occurs that the stream breaks out through the side of the bulb, producing a fine hole. Now, the extraordinary thing is that, in spite of the connection to the outer atmosphere, the air can not rush into the bulb as long as the hole is very small. The glass at the place where the rupture has occurred may grow very hot—to such a degree as to soften; but it will not collapse, but rather bulge out, showing that a pressure from the inside greater than that of the atmosphere exists. On frequent occasions I have observed that the glass bulges out and the hole, through which the streamer rushes out, becomes so large as to be perfectly discernible to the eye. As the matter is expelled from the bulb the rarefaction increases and the streamer becomes less and less intense, whereupon the glass closes again, hermetically sealing the opening. The process of rarefaction, nevertheless, continues, streamers being still visible on the heated place until the highest degree of exhaustion is reached, whereupon they may disappear. Here, then, we have a positive evidence that matter is being expelled through the walls of the glass.

When working with highly strained bulbs I frequently experience a sudden, and sometimes even painful, shock in the eye. Such shocks may occur so often that the eye gets inflamed, and one can not be considered over-cautious if he abstains from watching the bulb too closely. I see in these shocks a further evidence of larger particles being thrown off from the bulb. Nikola Tesla.

New York, March 14 1896

THE RÖNTGEN X-RAYS

Nikola Tesla's Results and Theories

In the *Electrical Review* for March 11 appears the first authorized communication from Nikola Tesla regarding his work with the X-rays. The following is condensed from his full statement:

In order to produce the most intense effects we have first to consider that, whatever their nature, they depend necessarily on the intensity of the cathode streams. These again being dependent on the magnitude of the potential, it follows that the highest attainable electrical pressure is desirable. We are naturally thrown on the use of the disruptive discharge coil as the most effective apparatus. With this there is practically no limit to the spark length. If we put two electrodes in a bulb, or use one inside and another outside electrode, we limit the potential, for the presence not only of the anode but of any conducting object has the effect of reducing the practicable potential on the cathode. Thus, to secure the result aimed at, one is driven to the acceptance of a single electrode bulb, the other terminal being as far remote as possible.

Mr. Tesla then describes at length a process of his own for obtaining, by an electrical discharge of high potential from a disruptive coil through the bulb, a degree of rarefaction far beyond that obtainable by mechanical appliances, and goes on to say:

Though the phenomenon of rarefaction under above conditions admits of different interpretations, the chief interest centers on one of them, to which I adhere—that is, on the actual expulsion of the particles through the walls of the bulb. I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocities. A peculiar thing about the Röntgen rays is that from low frequency to the highest obtainable there seems to be no difference in the quality of the effects produced, except that they are more intense when the frequency is higher, which is very likely due to the fact that in such case the maximum pressures on the cathode are likewise higher. This is only possible on the assumption that the effects on the sensitive plate are due to projected particles, or else to vibrations far beyond any frequency which we are able to obtain by means of condenser discharges.

With apparatus as I have described, remarkable impressions on the plate are produced. The bony structure of birds, rabbits, and the like is shown within the least detail, and even the hollow of the bones is clearly visible. In a plate of a rabbit under exposure of an hour, not only every detail of the skeleton is visible, but likewise a clear outline of the abdominal cavity and the location of the lungs, the fur and many other features. Prints of even large birds show the feathers quite distinctly. Clear shadows of the bones of human limbs are obtained by exposures ranging from a quarter of an hour to an hour. A picture of a foot with a shoe on it was taken, and every fold of the leather, trousers, stocking, etc., is visible, while the flesh and bones stand out sharply. Through the body of the experimenter the shadows of small buttons and like objects are quickly obtained, while with an exposure of from one to one and a half hour the ribs, shoulder-bones, and the bones of the upper arm appear clearly.

An outline of the skull is easily obtained with an exposure of 20 to 40 minutes. In one instance an exposure of 40 minutes gave clearly not only the outline, but the cavity of the eye, the chin and cheek and nasal bones, the lower jaw and connections to the upper one, the vertebral column and connections to the skull, the flesh, and even the hair. By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body.

Criticism of Tesla's Statements

Dr. Cyrus Edson, formerly health commissioner, when asked by a reporter for the New York *Times* about Tesla's deductions, said that he had been much interested in the subject and had given it considerable attention. Said he:

It is an undoubted fact that you can decompose certain chemicals by means of light. The principle of photography rests upon this fact. These X-rays decompose the chemicals with which the film is sensitized and effects this decomposition through what have hitherto been regarded as opaque bodies, such as the hand, for instance. Light in vibration, and it has been demonstrated that these X-rays will pass through an opaque body. That these vibrations in passing through the skull should affect the delicate nerve tissues of the brain and stimulate them is a perfectly natural result. This accounts for the sensations experienced by Tesla when he exposed his head to a powerful radiation. But there is no more reason to believe that the X-rays will carry a medicinal agent through the body and into the distant spot, the seat of disease, than that a ray of light will be able to project such a chemical onto the surface of the body.

The theory of the vibrations of light is not a new one. It originated with Sir Isaac Newton, who believed that luminous bodies shot out infinitely small particles in straight lines, which, by penetrating the transparent parts of the eye and falling on the nervous tissue, produced vision. Other philosophers drew a parallel between the properties of light and those of sound, and considered that as sound was certainly the effect of vibrations, or little waves projected through elastic bodies, so light might be nothing more than the consequence of similar vibrations transmitted with inconceivable velocity through a highly elastic medium. The wave hypothesis of light is at present generally adopted simply because it is in harmony with all the known phenomena discovered since the time of Newton. The deductions of Tesla as the result of his experiments are absolutely in harmony with the Newtonian theory. We can certainly expect some marvelous results from the X-rays, things not even dreamed of yet. I believe that they will prove a valuable adjunct to medical science, and I think that the ultra violet rays will be sooner or later obtained by passing ordinary sunlight through certain media, without the agency of electricity.

Dr. J. Mount Bleyer, who has taken great interest in determining the effects of all light rays on animal and vegetable life, said:

I am not at all surprised at the results of Tesla's experiments. I have been experimenting for some time with the associated light rays—the sunlight and the different colors, such as blue, red, and orange—in connection with the treatment of infectious diseases and vegetations. The results obtained by Tesla are simply marvelous, but are just what I expected. I have contended from the beginning, and it has now been proven beyond a doubt by Tesla, that this bombardment of particles does pass through glass and other materials at an enormous velocity. As far as the therapeutic effects of the rays are concerned, they may be likened in some way to a massage effect, if they do not form a high class of bactericidal agent. Solariums for the treatment of infectious diseases, with associated light rays, will no doubt be the next advance in hospital architecture. I have made a number of experiments with the associated light rays in hospitals and among my private patients in cases of phthisis and tuberculosis. I have resorted to the treatment wherever it was possible, and never failed to obtain the best results. Ordinary light is one of the main factors in the growth of animal life. We know that sunlight is essential for the growth and development of both animal and vegetable tissue. We have in light a therapeutic agent that has been underestimated and neglected, and which should be taken up and thoroughly studied.

Ogden N. Rood, professor of physics in Columbia College, after glancing through the article by Nikola Tesla, dictated to a New York *Times* reporter the following statement of his views:

It is never proper to frame a new hypothesis in order to account for discoveries when an old and well-established theory is capable of giving them an explanation. Our knowledge of the waves of light, of radiant heat, and of the ultra violet rays is confined within narrow limits. Thus far, according to our previous experience, the shorter the length of the wave the more it will be bent, or refracted, by substances in general. It, however, does not at all follow that this will hold good if the length of the wave is shortened to a degree beyond our experience. On the other hand, it is highly probable that if this shortening process goes on till the length of the wave has become of the same order of magnitude with the molecules of matter that the effect in the matter of refraction will diminish. This would account for the fact that no one has succeeded thus far in refracting or reflecting the Röntgen rays. In my own experiments I have so far found them to act in the same general way with waves of ordinary light, and I am inclined to believe that they are simply waves of light of unprecedented shortness. This view necessarily excludes all idea of a molecular bombardment outside of the Crookes tube. I believe that it will be eventually demonstrated that the Röntgen rays are capable of reflection and refraction, although it will require more delicate work than has thus far been extended in this direction.

The New York Tribune March 20, 1896

TESLA'S X-RAY RESEARCHES.

IMPORTANT ADVANCES MADE—PICTURES AT FORTY FEET—RAYS REFLECTED—EVIDENCE OF PROJECTED PARTICLES.

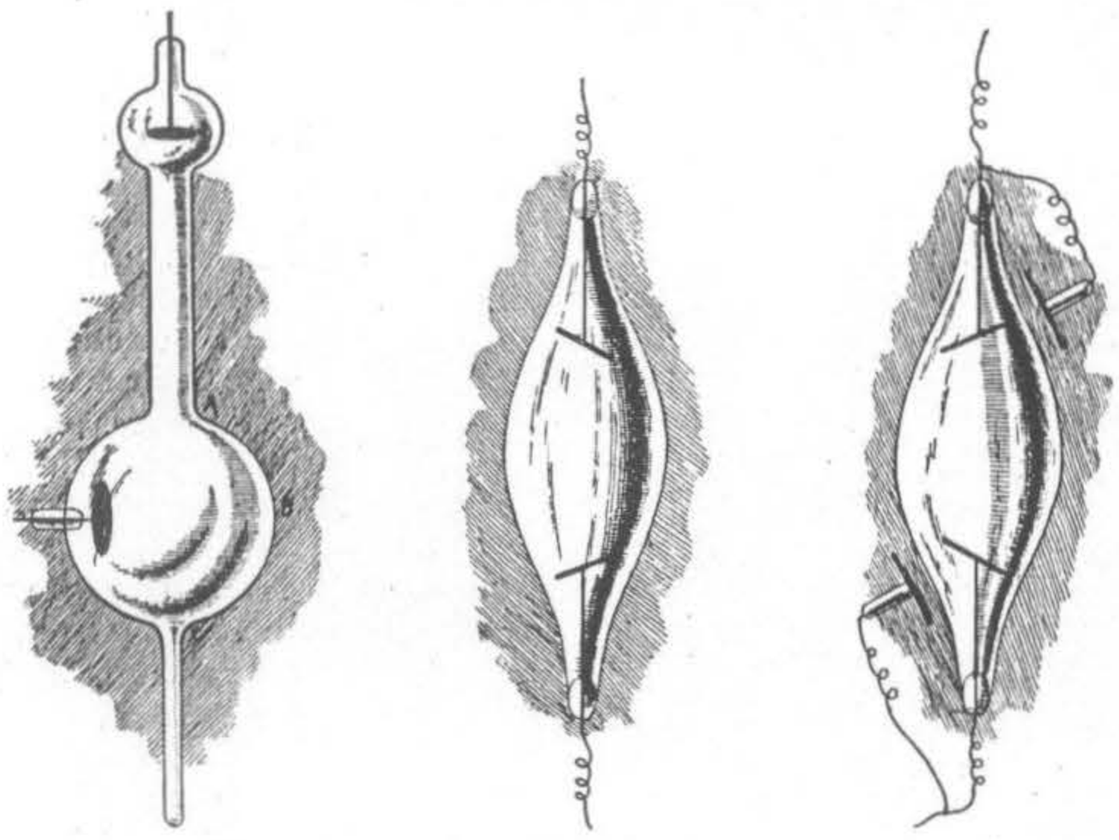
Nikola Tesla in The Electrical Review.

I am producing strong shadows at distances of forty feet. I repeat, forty feet and even more. Nor is this all. So strong are the actions on the film that provision must be made to guard the plates in my photographic department, located on the floor above, a distance of fully sixty feet, from being spoiled by long exposure to the stray rays. . . . Even now I see before me the possibility, not to say certitude, of augmenting the effects with my apparatus at least tenfold! What may we then expect? We have to deal here, evidently, with a radiation of astonishing power, and the inquiry into its nature becomes more and more interesting and important. Here is an unlooked-for result of an action which, though wonderful in itself, seemed feeble and entirely incapable of such expansion, and affords a good example of the fruitfulness of original discovery.

The effects upon the sensitive plate at so great a distance I attribute to the employment of a bulb with a single terminal, which permits the use of practically any desired potential and the attainment of extraordinary speeds of the projected particles. With such a bulb it is also evident that the action upon a fluorescent screen is proportionately greater than when the usual kind of tube is employed, and I have already observed enough to feel sure that great developments are to be looked for in this direction. I consider Röntgen's discovery of enabling us to see, by the use of a fluorescent screen, through an opaque substance even a more beautiful one than the recording upon the plate.

Since my previous communication to you I have made considerable progress, and can presently announce one more result of importance. I have lately obtained shadows by reflected rays only, thus demonstrating beyond doubt that the Röntgen rays possess this property. One of the experiments may be cited here. A thick copper tube, about a foot long, was taken and one of its ends tightly closed by the plate-holder containing a sensitive plate, protected by a fibre cover as usual. Near the open end of the copper tube was placed a thick plate of glass at an angle of 45 degrees to the axis of the tube. A single-terminal bulb was then suspended above the glass plate at a distance of about eight inches, so that the bundle of rays fell upon the latter at an angle of 45 degrees, and the supposedly reflected rays passed along the axis of the copper tube. An exposure of 45 minutes gave a clear and sharp shadow of a metallic object. This shadow was produced by the reflected rays, as the direct action was absolutely excluded, it having been demonstrated that even under the severest tests with much stronger actions no impression whatever could be produced upon the film through a thickness of copper equal to that of the tube. Concluding from the intensity of the action by comparison with an equivalent effect due to the direct rays, I find that approximately 2 per cent of the latter were reflected from the glass plate in this experiment. I hope to be able to report shortly and more fully on this and other subjects. . . .

I am finding more and more evidence in support of the theory of moving material particles. . . . I have already a great many indications of a bombardment occurring outside of the bulb, and I am arranging some crucial tests which, I hope, will be successful. The calculated velocities fully account for actions at distances of as much as 100 feet from the bulb, and that the projection through the glass takes place seems evident from the process of exhaustion, which I have described in my previous communication. An experiment which is illustrative in this respect, and which I intended to mention, is the following: If we attach a fairly exhausted bulb containing an electrode to the terminal of a disruptive coil, we observe small streamers breaking through the sides of the glass. Usually such a streamer will break through the seal and crack the bulb, whereupon the vacuum is impaired; but, if the seal is placed above the terminal, or if some other provision is made to prevent the streamer from passing through the glass at that point, it often occurs that the stream breaks out through the side of the bulb, producing a fine hole. Now, the extraordinary thing is that, in spite of the connection to the outer atmosphere, the air cannot rush into the bulb as long as the hole is very small. The glass at the place where the rupture has occurred may grow very hot—to such a degree as to soften; but it will not collapse, but rather bulge out, showing that a pressure from the inside greater than that of the atmosphere exists. On frequent occasions I have observed that the glass bulges out and the hole through which the streamer rushes out becomes so large as to be perfectly discernible to the eye. As the matter is expelled from the bulb the rarefaction increases and the streamer becomes less and less intense, whereupon the glass closes again, hermetically sealing the opening. The process of rarefaction, nevertheless, continues, streamers being still visible on the heated place until the highest degree of exhaustion is reached, whereupon they may disappear. Here, then, we have a positive evidence that matter is being expelled through the walls of the glass.



Edison's Röntgen Rays Experiments.

BY EDWIN J. HOUSTON AND A. E. KENNELLY.

Mr. Thomas A. Edison, after numerous experiments on the Röntgen rays with about 150 different glass vacuum tubes, has communicated the following information to us for publication :

First. There is no apparent advantage in obtaining a very high vacuum in the Crookes tubes employed for obtaining shadowgraphs of metal gratings. The effect of a very high vacuum is to require a greater voltage to produce fluorescence. The best degree of vacuum seems to be that at which the internal luminescence or striæ in the tube just disappear and fluorescence of the walls remains. The Röntgen rays are still produced even when internal striæ are observed, but are then much enfeebled.

Second. Thin walls are preferable to thick walls in the glass vacuum tubes. A thick wall will fluoresce more noticeably and become very hot. A thin wall will emit rays upon the photographic plate, but may scarcely fluoresce visibly and will remain very cool. This is proved by a number of experiments, of which the following is one : The tube of a shape roughly indicated in Fig 1 has its

FIGS. 1, 2 AND 3.—FORMS OF RAY LAMPS.

walls blown thick in the zone of *A C*, but thin at *B*. When this tube is exhausted and excited, the thin part, *B*, which is in the most active area, remains cool and the radiographic power is active, while the glass becomes hot in the ring *A C*. If B be made thick and *A C* thin, the glass at *B* may become melted by the heat, but its effect on a photographic plate is reduced, although its visible fluorescence is greater. Walls one eighth of an inch thick become unmanageable by excessive heating and rapid melting.

Third. For any given tube in a given condition of exhaustion, the radiographic power of the tube, *i. e.*, the swiftness with which is produced a developable image, is roughly proportional to the square of the fluorescent candle-power or total visible fluorescent light given out by the tube.

Fourth. The duration of exposure has been found to be as follows: With the most sensitive plates in an ordinary plate-holder having a vulcanized fibre light-tight cover of about $\frac{1}{32}$ of an inch in thickness, the time necessary for obtaining a good radiograph of a metal grating or grid is less than one second, when the tube is within ¼ of an inch of the grating and about ⅜″ from the sensitive plate. At two feet distance, the time for an equally good radiograph is approximately 150 seconds, and at three feet, 450 seconds. For rough purposes the duration of exposure may be reckoned as proportional to the square of the distance.

Fifth: Of the photographic plates as ordinarily employed for photographic purposes, the medium rapid plates appear to be the most suitable for Röntgen rays; *i. e.*, to require less duration of exposure. Rapid plates and slow plates appear to be equally unfavorable in regard to sensitiveness for Röntgen rays as compared with medium plates. To test this, a composite sensitive plate was made from five strips cut from plates of different photographic sensitiveness, and a radiograph of a series of metal bars was taken, with the bars at right angles to the strips of the composite plate. For the same exposure and same development, the definition of the radiograph produced did not bear any apparent relation to the photographic sensibilities of the strips according to their sensitometer numbers. The medium rapid plate gave, however, much the densest image in every such experiment.

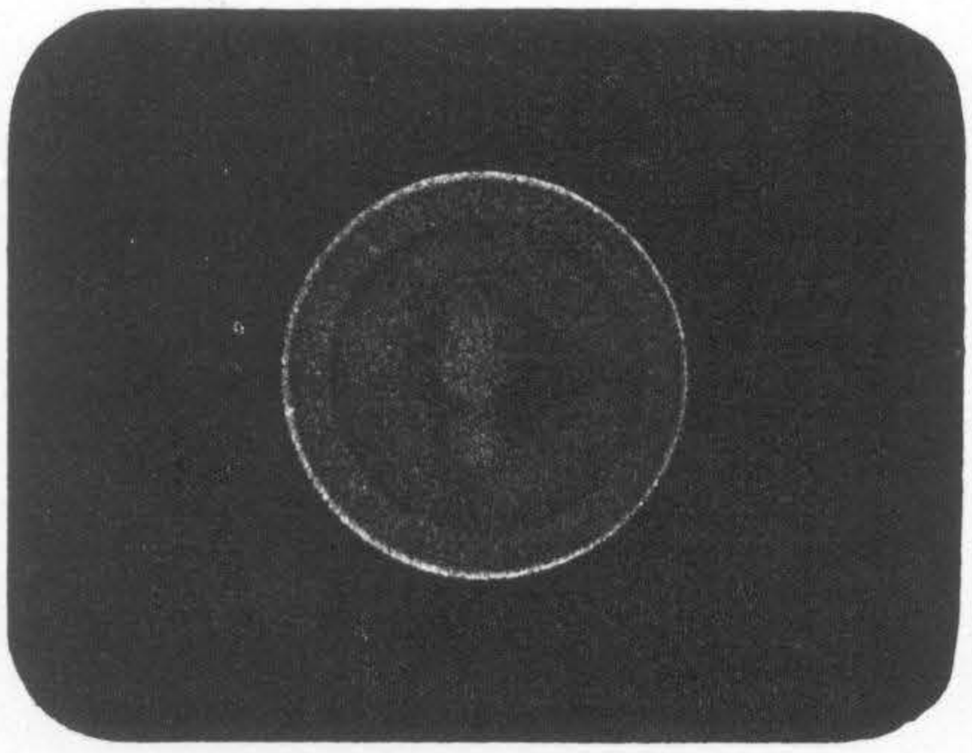
Sixth: The power of a tube having a given degree of exhaustion and disposition of electrodes increases with the surface area of its fluorescent walls; thus, a large vacuum tube exposing a large total fluorescent surface has a more rapid action on the sensitive plate; *i. e.*, requires less exposure, but will require more voltage and more electric power to excite. On the other hand, for a given distance of the tube from the plate, the image is sharper and less distorted as the tube diminishes in size. Consequently, for a given tube used without a diaphragm, long distance and long exposure produce the sharpest radiograph. A small tube will produce a sharp image at a lesser distance, and for rapid exposures a very small tube at a very short distance is the best. The smallest tubes experimented with have been about one inch in diameter, with about two inches between electrodes, and with thin glass walls. A small tube requires a small E. M. F., so that tubes can be made to suit almost any induction coil.

Seventh. For a given thickness of glass wall, German glass appears to give better results than lead glass. The German glass employed gives a yellowish fluorescence, while lead glass gives a greenish fluorescence. These glasses phosphoresce visibly for at least ten minutes after the cessation of the discharge through the tube. A particular quality of Scotch boiler water-gauge glass used gives apparently equally good radiographic results, but does not appreciably phosphoresce after the cessation of the current. The residual phosphorescence has not yet been found to produce a visible photographic image. All phosphorescence yet observed is pale white, whatever the color of the preceding fluorescence under excitation.

Eighth. The form of the tube arrived at by a gradual process of selection is shown in Fig. 2. The length is about three times the diameter. This tube is made in various sizes. When the glass walls are thin for producing the best radiographic effect, a spark is apt to pierce the wall and destroy the vacuum. Partly on this account, tinfoil caps are placed over the extremities of the tube, as indicated by the shaded areas in the sketch. These tinfoil caps are in connection with the electrodes, and are cemented to the external surface of the tube by shellac.

Ninth. It was found in numerous trials with many tubes that the fluorescent and radiographic power of all the tubes without caps was greatly increased, roughly doubled, in fact, by bringing two metallic discs, connected with the respective electrodes, to the opposite points, represented in Fig. 3. The supposition is that the tube thus becomes at once an ordinary and electrodeless tube combined. The metal caps above mentioned were the outcome of these experiments, and not only have all these capped tubes remained unperforated, but their fluorescent and radiographic powers have been enhanced by the caps. The caps serve three purposes : (a) To stop piercing by permitting excessive sparking to escape over the external surface. (b) To increase the radiographic and fluorescent power. (c) To prevent undue heating of the internal electrodes, and a consequent charge of vacuum.

Tenth. The exciting apparatus consists of a large Ruhmkorff coil capable of giving a 12-inch spark, although such a length of spark is rarely required. The coil is excited either from a storage battery through an interrupter, or preferably from a 120-volt continuous-current circuit, through a bank of from 8 to 20 16-cp incandescent lamps arranged in parallel, with a rapidly rotating wheel-interrupter driven by a small motor. About 400 interruptions are made per second, and the duration of closure in the circuit is twice that of opening. An air-blast is directed upon the spark over the periphery of the interrupting wheel through a fine nozzle. This tends to produce a sudden breaking of the circuit. It has been found that greatly improved results have followed the removal of the usual condenser and the substitution of the air-blast. The resulting secondary E. M. F. is almost symmetrical, like an alternating E. M. F., and the two electrodes are apparently equally active. The secondary terminals of the induction coil are led directly to the vacuum tube. If the air-blast is removed and the condenser substituted, the fluorescent and radiographic power of the tube is greatly diminished.



We believe that these observations of Mr. Edison cannot fail to be valuable to many practical workers with Röntgen rays. We hope to communicate further experimental results at some future time,

Röntgen Rays Experiments.

BY DAYTON C. MILLER.

Experiments with Röntgen rays have been carried on very persistently at the Case School of Applied Science for several weeks, and some very interesting results have been obtained. The main object has been to secure good photographs of the human skeleton in a living subject, and to increase the practical efficiency of the apparatus. The accompanying photograph of an aluminum medal will indicate the degree of success obtained.

A hand and forearm was photographed with an exposure of 20 minutes, while the medal required but five minutes. The Crookes tube used is of the well-known spherical form, having four elec-

RADIOGRAPH OF ALUMINUM MEDAL.

trodes, designed to show that the discharge in a high vacuum is independent of the anode, and is one of a set which was exhibited at the World's Fair. It was excited by an induction coil giving about a six-inch spark in air, when using a current of three amperes and 20 volts obtained from 11 cells of storage battery. The arm was held by bandages to the plate-holder, which was supported in an inclined position upon a special stand. The usual plate-holder slide of hard pasteboard was between the hand and plate. The tube was placed at a distance of 12 inches above the wrist. Rapid plates were used and developed in the usual way with eikonogen and hydrochinon developer. A photograph showing the bones of the fingers has been made with 10 seconds' exposure, the tube being at a distance of two inches. Of course, the outlines are not as well defined as when the tube is farther away.

Bullets have been clearly located in the hands of two men with exposures of eight minutes. The first one found had been carried for over fourteen years, and was thought to lie between the bones of the forearm. A single negative disproved this, while two photographs of the hand plainly located the ball at the base of the little finger. In the second case the bullet was received in the back of the hand last August, and five negatives, taken with the hand in various positions, all plainly located the ball at the base of the thumb.

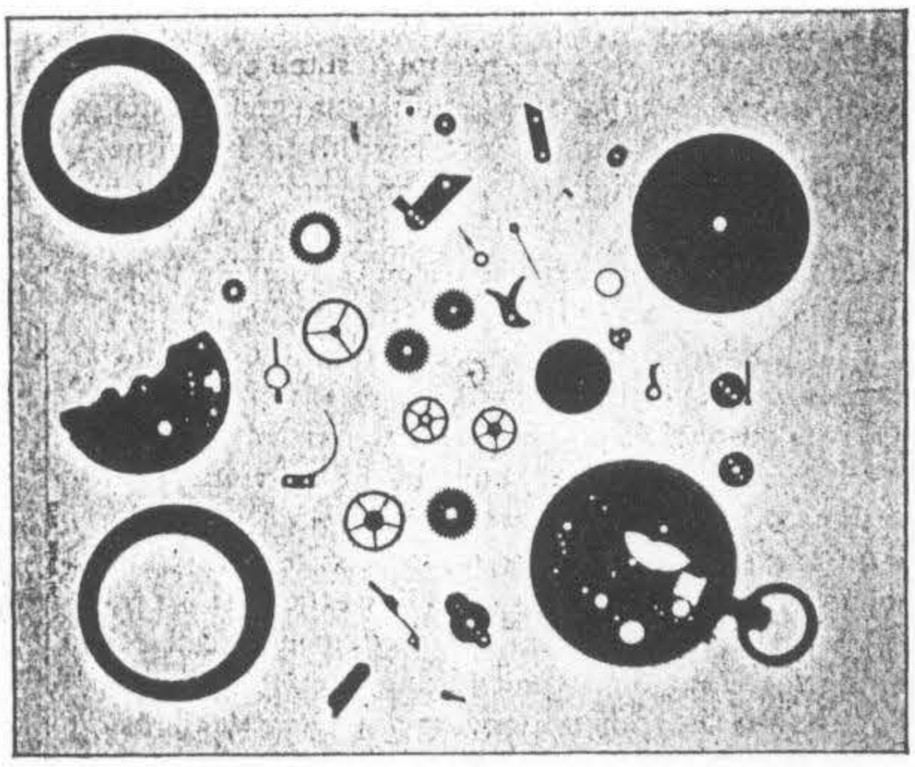
The bones of the elbow joint and upper part of the arm, and of the foot, have been photographed with exposures varying from five to thirty minutes. Longer exposures do not give better results. Some of the negatives made clearly show the ligaments connecting the bones at the joints, while none have so far shown any blood vessels or nerves.

Besides the above, a number of other surgical cases have been satisfactorily examined. Among these were the determination of injuries done to the fingers by a planing machine, the extent of diseases of the bones of the hand, and the examination of a number of fractures of the bones of the forearm to ascertain the nature of the fracture, and whether the bones were properly set.

A most interesting study has been the position of the various small bones of the wrist in different positions of the hand.

Many interesting points are noted in the work, which are suggestive in a theoretical way, details of which are not ready for publication. As already announced by Prof. Rowland, it appears that the anode is as important in the matter as the cathode. We have a number of tubes which give results, but none better than the one mentioned, while a tube just received, of American manufacture, promises to equal the imported ones.

The success so far obtained with the arm and foot encourage us to think that still thicker portions of the human body may be studied advantageously, and experiments will be immediately undertaken in this direction.



[The radiograph of the hand and forearm above referred to, which is very distinct in its outlines, has not been engraved owing to the unsatisfactory reproduction by the half-tone process of the delicate shadings of radiographs.—ED.]

Röntgen Rays.

The possibility of direct-vision radiography has for the past week been exploited in a sensational manner by the newspaper press. The invention of the apparatus for this purpose, the so-called "cryptoscope," is claimed by Prof. Salvione, of Rome, but, as pointed out by the London *Electrical Review*, this method was really used by Röntgen in his earliest experiments. Mr. Swinton, of England has been making some successful experiments in this direction, which are reported in the English electrical journals of March 6. He soaks a piece of blotting paper in a solution of barium platino-cyanide and places it inside a tube at the back of a sheet of opaque paper covering the end. The eye placed at the aperture at the other end of the tube can see a shadow of the object on the fluorescent paper.

Prof. Pupin has had no difficulty in seeing through solid bodies with the aid of such a screen. In an interview with the New York *Journal*, he states that it is easy to look through the bones of the hands, and when the light is just right even some of the muscles may be seen on the screen and traced throughout their length.

Mr. Edison used a disposition somewhat different from the above. He encloses very small crystals of platino-cyanide of barium between two plates of mica and secures this fluorescent screen at the bottom of a pasteboard box about 6 inches square and 7 inches deep. In extremely sensational accounts of his experiments in this line which have appeared in the daily press, it appears that a shadow may be seen on the screen when an object is passed between it and the source of Röntgen rays, though opaque substances are interposed between the object and the screen, but the outlines of the shadow are not well defined.

RADIOGRAPH OF PARTS OF WATCH.

Mr. Albert Sauver has taken some extremely sharp radiographs in the laboratory of the Illinois Steel Company. One of these we reproduce, showing the different parts of a watch. The sensitive plate was covered with a sheet of black paper placed in a cardboard box and the latter enclosed in another similar box. Quick plates were used, the exposure being about one and one half hours. The current was derived from a three-cell storage battery and an induction coil giving a three-inch spark was employed. The distance of the tube from the plate was five inches.

Among some recent radiographs taken in the Shallenberger laboratory is one of a human embryo, which illustrates in a striking manner the extent of the service which Röntgen rays will render to science. In this instance the stage of bone development is clearly indicated; some parts of the skeleton structure are shown to have neared their final shape, while others are as yet only partly developed. The growth of bone would appear to commence near the middle of the final length, the ends being formed last. Another radiograph taken by Mr. Herbert W. Shallenberger is of the head and neck of a fowl, in which the gullet is sharply outlined, showing that its substance is more opaque to rays than the surrounding flesh.

VIEWS, NEWS AND INTERVIEWS.

In 1883 three men who have since become world famous, were at the University of Strasburg, although they were then unknown to one another or to fame. They were Paderewski, Roentgen and Tesla. Paderewski was at that time an instructor in music in the University; Roentgen was a professor of physics, and Tesla was installing the electric light plant in the University. Of the three men Roentgen was the last to achieve fame. When his X-ray discovery was announced, the recognition of his work was prompt and now he is Baron Roentgen. Tesla has declined several offers of titles and decorations made to him by rulers of foreign countries, but takes a proper pride in the honors conferred upon him by scientific bodies in different parts of the world.

The New York Sun March 25, 1896

WE MAY SIGNAL TO MARS

OR, GIRD THE EARTH WITH NEWS WITHOUT A WIRE.

Nicola Tesla Convinced that to the Latter Extent at Least His Plan Is Practicable, and Why Not Between Planets, as Between the Sun and the Earth?

Nicola Tesla, the electrician and scientist, has had in course of development for some time a project for instantaneous and simultaneous communication to all parts of the earth, and perhaps to some of the nearer planets. Mr. Tesla's plan does not deal with fireworks, or the illumination of a large part of the earth's surface in hope of attracting the attention of the dwellers on Mars, but deals wholly with the electric waves. In regard to it, Mr. Tesla said yesterday to a SUN reporter:

"I have had this scheme under consideration for five or six years, and I am becoming more convinced every day that it is based upon scientific principles and is thoroughly practicable. We know that electric disturbances on the sun are productive of similar disturbances on the earth in the form of thunder showers. Now, why is it not equally conceivable that a disturbance on the earth's surface should produce some tangible effect on other planets. The transmission of disturbances on the sun shows beyond doubt that waves of electricity are propagated through all space.

"The objection may be put forward that sufficient electrical disturbance cannot be made on the earth's surface, and that we should be wholly dependent upon thunder storms and other phenomena of nature for the success of our experiment. But, on the contrary, we can make all the artificial thunder and lightning we want. There is no difficulty in making electric apparatus with a spark gap of a mile, and if that did not prove effective it could be increased.

"Do not get the impression," continued Mr. Tesla, "that the success of the experiment is in any way dependent upon the light, noise, or vibration accompanying such an electric discharge. It is wholly through the electricity waves, which are propagated through the atmosphere and the ether beyond, that we may hope to obtain any results. But if there are intelligent inhabitants of Mars or any other planet, it seems to me that we can do something to attract their attention.

"This, of course, is the extreme application of this principle of the propagation of electric waves. The same principle may be employed with good effect for the transmission of news to all parts of the earth. It was formerly thought that in order to get any power out of electricity a conducting circuit must exist, but it has been shown that the same results may be accomplished with a single wire. It is perfectly possible to operate a motor or an electric light with just a single line of wire leading to the apparatus. It naturally occurred to me that, as the earth is a conductor, an electrical disturbance at one point, causing a change in the equilibrium of the earth's electricity, should be felt at all points on the earth's surface, and might be recorded by properly constructed instruments.

"The possibilities of such a transmission of intelligence cannot be exaggerated. Every city on the globe could be on an immense ticker circuit, and a message sent from New York would be in England, Africa, and Australia in an instant. What a grand thing it would be in times of war, epidemic, or panic in the money market!"

Mr. Tesla is at present engaged in finishing his calculations and perfecting the apparatus necessary for experiment in his new field of investigation, and he hopes soon to be able to show the practicability of his plan.

THE DEVELOPMENT OF THE NEW RADIOGRAPHY.

WE might expect from Nikola Tesla the most intelligent discussion of the new Röntgen rays, but we were not prepared for his announcement in the last week's *Electrical Review*. He says he is now producing strong shadow pictures at a distance of forty feet, and he finds it necessary to guard the plates in his photographic department on the floor above, and sixty feet away, from being spoiled by long exposure to strong rays. He confesses himself amazed by the astonishing power of this radiation, especially as he sees the certitude of augmenting the effects at least tenfold. These effects on a sensitive plate at so great distance he obtains by the use of a bulb with a single terminal, which permits the use of practically any desired potential, and the attainment of extraordinary speeds of the projected particles; for he adopts the theory, not yet generally accepted, that the action is not that of waves of a certain sort of light, but that of actual atoms or *ions* projected at enormous speed right through glass, wood or metals.

We owe to Mr. Tesla also the proof that the Röntgen rays can be partially reflected, and he has succeeded in obtaining radiographs with reflected rays. He was able to reflect about two per cent. of the rays from a thick glass, these reflected rays being made to pass through a copper tube, and then give a clear and sharp shadow.

But most surprising of all his statements is that which he offers in proof that the Röntgen phenomena are caused by moving material particles, like those supposed in Newton's corpuscular theory of light. He gives the following experiment:

"If we attach a fairly exhausted bulb containing an electrode to the terminal of a disruptive coil, we observe small streamers breaking through the sides of the glass. Usually such a streamer will break through the seal and crack the bulb, whereupon the vacuum is impaired. But, if the seal is placed above the terminal, or if some other provision is made to prevent the streamer from passing through the glass at that point, it ofter occurs that the stream breaks out through the side of the bulb, producing a fine hole. Now, the extraordinary thing is that, in spite of the connection to the outer atmosphere, the air cannot rush into the bulb as long as the hole is very small. The glass at the place where the rupture is may grow very hot, to such a degree as to soften; but it will not collapse, but rather *bulge out*, showing that a pressure from the inside greater than that of the atmosphere exists. On frequent occasions I have observed that the glass bulges out, and the hole, through which the streamer rushes out, becomes so large as to be perfectly distinguishable to the eye. As the matter is expelled from the bulb, the rarefaction increases, and the streamer becomes less and less intense, whereupon the glass closes again, hermetically sealing the opening. . . . Here we have positive evidence that matter is being expelled through the walls of the glass."

In the rapid development, by the concurrent labors of hundreds of students, of the discovery of Professor Röntgen, we see the advantage which comes, in science, from that fine and generous ambition which leads scholars to hasten to give to the world the results of their discoveries, that others may make applications and improvements. Professor Ramsay, who was associated with Lord Rayleigh in the discovery of argon last year, has suggested that a certain deference be paid to those who first announce a new discovery, by consulting them and getting their permission before others publish on the subject. This would be as foolish as it is impracticable. The analogy of patents, which he adduces, does not tell in favor of his claim. Every improvement on a patent is itself patentable. The honor which the discoveries of argon and the x rays have earned will not be diminished but rather enhanced by every new development of knowledge to which it gives occasion.

MAY SIGNAL STARS.

Electrical Envelope of the Earth, Nicola Tesla Says, Will So Be Used.

DETACHED ELECTRIC LIGHTS.

These as Well as the Problem of Heating Will Be Solved by His Electric Oscillator.

IT IS NEARING COMPLETION.

Great Inventor Speaks Modestly but Hopefully of Nea Possibilities of Electrical Science.

Nicola Tesla stood in the outer room of his laboratory, at No. 48 East Houston street, yesterday afternoon, and smiled as he said:—"My electric oscillator is nearing completion. I have spent years in experiments, and have been alternately encouraged and discouraged by the results. But now there is everything to promise success. It seems to be close ahead."

Mr. Tesla's remarks were occasioned by inquiries concerning the truth of a rumor that he was perfecting an instrument for communicating with the planets by means of electrical waves. The inventor nodded his handsome head and remarked:—

"Perhaps, in time. But not yet. We have to begin with little things before we can accomplish great ones. I am confident that the principles upon which I have been working are correct. How soon they will be demonstrated of course I cannot say. The perfection may come in ten minutes and perhaps not for years. But that it will be possible to signal all parts of the earth instantaneously, and that from the logical development of this it will be possible to signal the stars by electrical disturbances here I have no doubt whatever.'

HIS RECENT EXPERIMENTS.

"Years ago, in St. Louis, I delivered an address before the National Academy of Sciences. I then declared it would be possible to use economically the electricity in the atmosphere for lighting and heating, and, of course, for communication between different parts of the earth's surface. The problem was the conservation of electrical energy at the least possible cost to the other elements. That problem, I was confident then, I could solve by my oscillator. At present I am sure it can be done. From my most recent experiments I am convinced that within a very short time we shall be independent of the clumsy methods of generating electricity now in vogue. The electrical fluid in the atmosphere will give energy enough. The same electric envelope of the earth will enable us to send messages from one part of the globe to all other parts in an instant of time. The same element, which, I believe, finite and is not confined to this atmosphere, may be used to communicate with the other planets."

"Can you give any description of this apparatus?" I asked.

"I regret very much to say that I cannot at present. It is rather a tool than an apparatus. My experiments are made scientifically, on a small scale, for I have neither the money nor the space at my disposal to do more. But it is readily admitted that if I prove my principle in this minor way, and I am able to do what I am sure can be done with electricity in a limited fashion, it will only need an extension of method to accomplish the greatest results. Simultaneous announcements may then be made in all parts of the world. In case of disaster, of pestilence, of atmospheric disturbances, in all events which are international in their character, the word may be sent from any place to all other places. The principle is the same as that which was so generally discussed some time ago in regard to the possibility of signalling at sea, telephonically or otherwise, between ships or with the shore and without wire."

APPLIED TO LIGHT.

"Will the work accomplished by the oscillator be suited to the sending of messages of this kind?" I inquired.

"No, not at all," Mr. Tesla replied. "It will realize the possibility of generating light so that the means we now use will at once appear old fashioned. Electric light will be exceedingly cheap, and so will electric heat. The principle will be applied to all lines of necessity in which the use of the force is now important. In photography I have already achieved results from the experiments with the oscillator on the Roentgen principle at a distance of forty feet, and have secured photographs that are much more elaborate in detail than any others I have seen or that I have heard described."

The principle of lighting to which Mr. Tesla referred ,and which is a part of the discoveries which he declares he has made, will enable one to use electric lights unattached to any dynamo by wire or other medium. They may rest upon your drawing room table unilluminated, and by merely grasping them you may generate conditions which will make them glow and shed light.

The New York Tribune March 27, 1896

NIKOLA TESLA'S EXPERIMENTS.

BRIEF EXPOSURE TO X RAYS—MESSAGES BY ELECTRICAL WAVES.

The great length of time required for the exposure of objects to the X rays before satisfactory impressions could be obtained on the sensitized plates has hitherto proved a source of considerable trouble to scientists who have experimented with the new radiance. When operations were first begun in this country with the rays, an exposure of from two to three hours was often found necessary. To a large extent this fact was due to a paucity in the supply of good tubes. Gradually the experimenters improved their apparatus, by the importation, principally, of Crookes tubes, but even with the best vacuum tube that could be got in this way, exposures of from twenty to forty minutes were essential. Consequently, it is obvious, the discovery of a method for the perfection of the apparatus, whereby results could be obtained with more rapidity, would be of especial value and importance, particularly in the treatment of surgical cases.

It is interesting, therefore, to know that Nikola Tesla, the New-York scientist and electrician, has succeeded in taking photographs of various objects, including the bones of the hand, in the actual time of one second. To a Tribune reporter, who saw him yesterday at his laboratory, No. 46 East Houston-st., Mr. Tesla said that this result was due primarily to exceedingly high vacuum tubes, considerably higher in fact than the best Crookes tubes. Mr Tesla said he had exhausted the bulbs himself by electricity. He was also able, he said, with these tubes, to photograph articles at a distance of forty feet. Mr. Tesla was not inclined to make public the details of his method for making the tubes, although, he said, he had communicated his principles to several scientists, who had written testifying to the value of the bulbs in experiments with the X rays.

Speaking of the report that he was engaged in the development of an instrument for communicating with the nearer planets, and for conveying messages from one centre to another without wires, by means of electrical waves, Mr. Tesla said: "To say that I am developing an instrument to communicate with the planets is, to say the least, somewhat premature. But by electrical disturbances which will act upon my instrument I am confident that I shall be able to signal all parts of the earth instantaneously. In an address which I gave some few years ago to a scientific audience, I demonstrated that it would be possible to use the electricity in the atmosphere and the earth for lighting and heating and for communication with distant parts of the earth. The problem of conserving this electrical energy I am now at work upon, and by the aid of the apparatus I have made I am confident that we shall be able to get all the electrical energy we want from the atmosphere. The present methods of generating electricity would in that event become a thing of the past. This electric envelope of the earth will enable us to send messages to all parts of the world instantly, and, in the belief that this electrical fluid is not confined to this atmosphere, I think it is possible that we may be able to use it to communicate with other planets."

ELECTRO-PHYSICS AND MAGNETISM.

Röntgen Rays. Shettle. Lond. *Elec. Rev.* and *Elec. Eng.* March 6. —He claims that the cause of the phenomena discovered by Röntgen (referring to the photographic effect of the rays) is the direct result of electric stress and not, as was supposed, of invisible light. He describes an experiment in which a cotton-covered wire "was bent five times upon itself in parallel lines" and then fastened to a cardboard and placed directly on the sensitive surface of a photographic plate; a very thin magnetic strip was fastened to the back of the plate by strips of paper, the whole being wrapped in ruby and in black paper; an alternating current of eight amperes at a frequency of 40 was passed through the wire for about 45 minutes; a complete and distinct image of the magnetic strip and the paper fastening it was formed on the plate.—He claims that the "effects were the product of stress in the wire exercised through the glass plate upon the magnet and the paper." He endeavors to explain the process by which he thinks all photographs are taken; all forms of matter are polar, that is, assume a definite direction, and they are free to move in a magnetic field; owing to the terrestrial magnetism all matter exists in a magnetic atmosphere; when light, which is one of the distributing elements, falls on the sensitive surface, the molecules are thrown into motion and the general effects on the surface are the same; when it is reflected from an image the counterpart of that image would be produced on the plate; he claims that the same principle holds good in images obtained by the stress of magnetism, as the sensitive matter on the plate registers the various directions in which impressions have been conveyed to it directly or indirectly, through intermediate bodies; any body which intercepts the lines of stress modifies their effects on the plate; bodies of greater density interfere more with the lines of stress. Editorially it is thought that the image obtained by Dr. Shettle is due to electromagnetic induction and has nothing to do with the magnetic field produced by the magnet, a bar of soft iron it is thought would act equally well (from the photograph there appears to be no difference whatsoever between the poles and the middle of the magnet; also that where the paper overlaps the magnet the image is darker; the image of the magnet and the paper are about equally dark); the alternating current through the gridiron conductor would induce currents in the gelatine filament and this would cause decomposition of the salts in proportion to their intensity; the presence of the metallic bar on the back of the plate would modify the intensity of the currents in the film immediately above it (but the paper, which is a non-conductor, appears to act like the magnet, as far as causing the image is concerned).

Another article in the Lond. *Elec. Rev.* gives a brief summary of recent developments. The doubt which was expressed as to Blythswood's experiment being a genuine photographic effect has been removed by further experiment; at the suggestion of Lord Kelvin the sensitive plate was placed in a tight zinc box with an aluminum window in the lid, the box being carefully earthed and placed between the two poles of the large influence machine, which latter were two feet apart and produced a silent brush discharge; the object was placed either inside the box or outside on the aluminum window; photographs were obtained in half an hour. It is thought that the long-known electric shadows produced by influence machines may be due to the same cause; Holtz produced these shadows by using a point and a disc on his machine, the disc being hollow and covered with silk; conducting bodies between the point and the disc threw distant shadows on the silk of the disc, while insulating bodies were apparently transparent; he therefore concluded that the nature of the surface was important in determining the transparency; Lehmann found by using a disc on each electrode that a shadow of the interposed body was projected on the faces of both discs. Gossart and Chevallier made a curious discovery (see *Comptes Rendus*, 122, p. 316) which appears to add to the mystery concerning the nature of the radiations in the Crookes tube; they found that the Röntgen rays exercise a mechanical directive action on the vanes of the wheel in the Crookes radiometer; they created a field of force inside the radiometer, which is opposed to that due to the heat; the direction and intensity of the field of force around the Crookes tube was explored by means of the radiometer; it was found by experimenting with 20 substances that this force was transmitted and arrested by the same media as the Röntgen rays are; only when the radiometer was placed in the Crookes field was the field "modified by currents, especially by those of the exciting coil of the Crookes tube, modified by the presence of statically charged electrified bodies; and finally energetically distributed by a magnet"; by moving a magnet circularly about a radiometer the vanes in some way are set free and become again obedient to a source of heat; when placed in the path of cathode radiations the motion of the vanes is dampened, sometimes one pair and sometimes another taking up the axial position of equilibrium; when the current in the Crookes tube ceases the directive

action of the vanes persists for about five minutes afterward in spite of the constant action during that time of the Locatelli lamp; the vanes may be started again by directing on them the radiation from the anode, when they will at first undergo an impulsion opposite to the normal direction, which they afterward resume; the inertia effect, which lasts for five minutes, was obtained with a Ruhmkorff coil, but a Wimshurst machine failed to produce it; paraffin was found to be more transparent than air.

Henry thinks that his experiments verify the hypothesis of Poincaré that all fluorescing bodies emit Röntgen rays; a faint white image of a wire placed between a fluorescing body which had been exposed to light and a sensitive plate was produced on a dark rectangular background. Meslans made experiments to determine the influence of chemical constitution in the transparency of bodies to the Röntgen rays (see *Comptes Rendus*, 122, p. 309); he found that carbon and its compounds with hydrogen, oxygen and nitrogen is extremely transparent, but when combined with chlorine, sulphur, phosphorus or iodine, its opacity is considerably increased; he believes that the difference in the chemical constitution of the materials forming the nerves and the blood will without doubt enable photographs of these constituents of the body to be obtained by virtue of their unequal transparency. Prof. J. J. Thomson, in *Nature*, gives an account of some very interesting investigations; he tried to determine the leakage in air at different pressures; in following up his discovery that all bodies become conductors when traversed by these rays, he found that the rate of leakage is greater at a high pressure than at a low one, and for a wide range is approximately proportional to the square root of the pressure; he believes the leakage of electricity through non-conductors is considered to be due to a kind of electrolysis, "the molecule of the non-conductor being split up by Röntgen rays, which act the part played by the solvent in ordinary electrolytic solutions"; he obtained indications that the rate of leakage through air is proportional to the number of ions; he concludes that the Röntgen rays are not all of the same kind, and that their penetrative power varies greatly with the efficiency of the tube which produces them; he found that most tubes improve for a time after they are sealed off, and after attaining a maximum efficiency they then deteriorate.

According to the *Jour. des Inventeurs*, March 1, Mr. DE HEEN wrote to the French Academy of Sciences that according to his experiments the Röntgen rays of Lenard and Röntgen did not emanate from the cathode, but from the anode; to demonstrate this, one has only to place between the Crookes tube and the sensitive plate a screen of lead perforated with several holes allowing the rays to pass through; the direction of these on the photographic plate indicate that they emanate from the positive and not from the negative pole and that they are therefore anode rays.

According to the *Elek. Zeit.*, March 5, SATORI in Vienna stated that he obtained very intense Röntgen rays with a comparatively small influence machine by connecting the Crookes tube in series with a spark gap and in parallel with two condensers "whose outer coatings were short circuited," the machine gave a spark of about 12 cm; the result was not successful when the spark gap, which is in series with the tube, was omitted, probably because the voltage was then too low; that this method is much cheaper and simpler than the one usually used is self-evident, besides requiring no source of current, as the machine is turned by hand.

The paper by Mr. Perrin, noticed in the *Digest*, March 14, is published in full in the *Bul. Soc. Int. des Elec.* for February.

Present Ideas Concerning Cathode Rays. GUILLAUME. *La Nature*, Feb. 29.—He considers that the phenomena discovered by Röntgen is already becoming less mysterious and there appears a possibility of explaining it without having recourse to any new ideas; he believes that Raveau has come nearest to a satisfactory theory based on a remark of Prof. Schuster. In a previous article in that journal (July 28, 1894) Guillaume reproduced two photographs obtained by Lenard showing two spots produced by the cathode rays which are deflected and which are not deflected by a magnet; they show that the original rays consist of two distinct kinds, one of which is nearly independent of the effect of the magnet, while the other was deflected by a magnetic field into a band like a spectrum. He thinks it an established fact that the Röntgen rays are derived from the cathode rays, but are not cathode rays themselves; there is a great probability that the Lenard photographs were produced by two kinds of rays, one the true cathode rays and the others which are not deflected. There are at present two hypotheses, that of bombardment and that of radiation; that they are contradictory is not surprising if it is true that heretofore two absolutely different phenomena have been observed together. There is no doubt that Röntgen rays are essentially different from the cathode, and that they are produced at the point of impact of the original ones on a body; they diminish as the square of the distance measured from the point of impact. If the rays proceed in straight lines from the point where they are produced, it is none the less true that they do not come in a straight line from the cathode to objects exterior to the tube. He considers that the tests of the theory of longitudinal vibrations of the ether have not met with success, and he thinks this theory ought to be rejected, adding that it might be kept in reserve for the future "to be given in a still more embarrassing case." Lenard thought his phenomena might be explained by the hypothesis of very short wave-lengths; the difficulties in the way appear great, but he thinks Raveau has overcome most of them; it is known that ultra-violet radiation, which in general is very refrangible, is capable of traversing a body without being deflected or strongly absorbed; the abnormal refraction discovered by Lerous was considered an exceptional phenomenon; it consists in a reversing in the order of refrangibilities. Kundt found that many metals have an index less than unity in the visible spectrum and it is therefore natural that they possess a strong absorption and that when the band has once been passed they become more transparent; the coefficient becomes less than unity at the extremity of the band and increases again asymptotically toward unity; if it has been thought that most bodies are completely absorbent for low wave-lengths, it was perhaps due to the fact that it was not possible to produce sufficiently short waves; Chardonnet long ago showed the transparency of silver to ultra-violet rays.

Longitudinal Light. JAUMANN. Lond. *Elec.*, March 6; the first part of a translation of a paper from the *Wied. Ann.*, 51, p. 147.—The style is somewhat brief and not very clear. He gives results of experiments concerning the nature of light in a vacuum and of cathode rays, accompanied by a theory of electric phenomena in rarefied air, which he considers makes cathode rays and kindred phenomena perfectly intelligible. The first part refers to the determination of the direction of vibration of electric rays, which direction he states may be determined by discharge experiments; he gives what he calls a discharge law and shows how it can be used for determining the direction of vibration of cathode rays and of light in rarefied air; he claims to have given an experimental proof of the longitudinal character of cathode rays founded on the discharge effect of these rays; as they have a strong discharge effect he claims they are electric waves of great amplitude; they also have a strong discharge effect when their direction is perpendicular to the electrode surface and hence the direction of their electric oscillation coincides with their direction of propagation; "they are rays with a great longitudinal component, and, therefore, from symmetry, essentially pure longitudinal electric rays."

Movable Light Phenomena in Rarefied Gases Caused by Electric Oscillations. ELSTER and GEITEL; *Elek. Zeit.*, March 5; abstracted from the *Wied. Ann.*, 56, p. 733.—They describe experiments from which they conclude that cathode rays are not due to a bombardment of particles detached from the electrode, but are movements of the ether analogous to light, that is, to what Jaumann calls longitudinal light.

Resistance to Alternating Currents. BRYLINSKI. *Bul. Soc. Int. des Elec.*, February.—A communication referring to the recent paper of Mascart (*Digest*, Feb. 8 and Jan. 18). He gives a formula for finding the increase in the (apparent) resistance (due to the frequency) of copper wires of any given diameter for a frequency of 80; after reducing the formula of Mascart to the same form, he compares numerical results obtained from both of them for various diameters, with the results in the table of Lord Kelvin, showing that his (Brylinski's) formula gives closer results, although the other is sufficient for practical purposes. He then discusses the subject of iron wires, coming to conclusions which are quite opposite to those arrived at by Mascart; he finds that the increase of resistance produced by high-frequency currents in iron wire appears to be the only reason why it is impossible to use iron for long-distance telephone lines, while Mascart concluded that iron wire was better, all other conditions being the same; he takes a numerical example assuming the permeability to be about 100, according to Massin, and finds that the increase of resistance is much greater than for copper; in a table he gives the effective resistances of various iron wires for the frequencies corresponding to certain sounds of the human voices.

Experiment with an Incandescent Lamp and Magnet. SALOMONS. Lond. *Elec.* and *Elec. Eng.*, March 6; a brief abstract of a Physical Society paper.—When an incandescent lamp through which an alternating current passed, was brought near a continuous-current magnet the filament was found to be set into vibration; if brought sufficiently near, the vibrations were sufficiently intense to break the filament; the number and position of the nodes formed were found to be independent of the natural period of the filament, but depend on the frequency of the alternating current. Prof. Ayrton suggested that the magnetic leakage was very large in that experiment and wanted to know whether this method was more sensitive for mapping out the field than those ordinarily employed; he thought that the natural period of the filament would to a certain extent influence the results; he called attention to some measuring instruments in which a similar principle was made use of. Salomons replied that the arrangement was not intended for making measurements; the character of the vibrations remained unaltered for many hours; he found the vibrating filament useful for microscopic work, where a surface rather than a line of light was required.

Röntgen Rays.—The *Elec. Rev.*, March 11, contains an interesting article by Mr. TESLA, giving his views and results obtained by him, including a large reproduction of a photograph of the shoulder of a man, showing the ribs and upper arm bones taken at a distance of 4 feet, and another showing a clear image of wire taken at a distance of 11 feet. His experiments were directed toward investigating the nature of the radiations and to perfecting means for their production; their intensity depends on the intensity of the cathode streams, and he concludes that the

highest obtainable electric pressure is therefore desirable; the best results would therefore be obtained by using the disruptive discharge with which there is practically no limit to the spark-length, the only requirement being a certain knowledge and skill in the adjustment of the circuits, particularly as to resonance. By having two electrodes in the same bulb the potential is limited and one is therefore lead to the use of a single electrode bulb, the other terminal being as far away as possible; an inside terminal should be used as tubes without such terminals are much less efficient on account of loss through the glass; it is an error to suppose that concave electrodes will concentrate the rays; they are if anything a disadvantage. Regarding the vacuum, he calls special attention to an electrical method of rarefaction which may be used to any degree desirable, and gives a vacuum far beyond that obtainable by any mechanical appliances; although this can be done by means of a static machine, a disruptive coil is far better; after exhaustion with an ordinary vacuum pump, the bulb is attached to the disruptive coil, and there will then be at first a milky light throughout the bulb, and the phosphorescence of the glass, which subsides quickly, and a white light then settles around the electrode, a dark space forming at some distance from it; the light then becomes reddish and the terminal grows very hot, requiring careful regulation to prevent it from being consumed; after this the light again becomes white and gets weaker and weaker until the streams finally disappear, the phosphorescence growing more intense and the spot where the stream strikes the wall becomes very hot, the phosphorescence around the electrode ceases and it becomes quite cool; the gas in the tube has then reached the required degree of rarefaction; the process may be hastened by repeated heating and cooling and by the use of a small electrode; bulbs with external electrode may be treated in the same way; whenever the electrode is as hot if not hotter than the glass, it is a sure indication that the vacuum is not high enough or that the electrode is too small; as a cooling medium he found it best to use jets of cold air, thus enabling one to use very thin tubes. He thinks the opacity of the glass and transparency of aluminum have both been somewhat exaggerated. He believes that there is an actual expulsion of the particles through the walls of the bulb; he is becoming more and more convinced that the phenomena is due to a stream of material particles which strike the sensitive plate with a great velocity; based on an estimate of Lord Kelvin, he believes that with very high potentials the speeds are as great as 100 kilometers a second. Even an ordinary stream under a great pressure passes through a thick glass plate as though it were not there; from a low to the highest frequency obtainable there seems to be no difference in the quality of the effects produced except that they are more intense when the frequency is higher, which he thinks is due to the fact that the maximum pressures of the cathode are then also higher; this is on the assumption that the effects on the sensitive plate are due to projected particles or else vibrations far beyond any frequency which can be obtained by means of the condenser discharges; the fact that the opacity of a body bears some relation to the density speaks strongly for the material streams; strong impressions on the plate might be arrived at by perfecting plates especially sensitive to mechanical shock or impact; this may lead to the abandonment of the present plate. He has obtained remarkable impressions with the apparatus described; shadows may be obtained at distances of many feet while at small distances and with thin objects an exposure of a few seconds is sufficient; he hopes to be able to magnify the effects many times; with a rabbit exposed for one hour, not only the skeleton was visible, but there was also a clear outline of the abdominal cavity, the location of the lungs, the fur and other features being also shown; images of human limbs are obtained in a quarter of an hour to an hour; metallic objects and bony or chalky deposits can now be invariably detected in any part of the body; an outline of the skull is obtained in 20 to 40 minutes, the latter showing the cavities of the eye, and the chin, cheek and nasal bones, etc., as also the flesh and even the hair; the action of the rays on the head appears to cause a feeling of drowsiness, a sensation of warmth and a general soothing effect. It may be possible, he thinks, by these strange appliances to project a suitable chemical into any part of the body. The issue of March 18 contains a further contribution from the same author. After making a few corrections in his former article, he states that he is now producing strong shadows at a distance of 40 feet and even more, with "the possibility not to say certitude of augmenting the effects with my apparatus at least ten-fold"; he attributes the effects of this great distance to the use of a bulb with a single terminal which permits the use of practically any desired potential and the attainment of extraordinary speeds of the projected particles. He also obtained shadows by reflected rays only, thus demonstrating that the rays possessed this property; a thick copper tube was used at the one end of which the plate holder was placed, while at the other, open end, there was a thick plate of glass at an angle of 45 degrees above which was the bulb; a clear, sharp shadow was produced with an exposure of 45 minutes; he satisfied himself that no action would be produced through the copper tube; he also found that approximately 2 per cent. of the rays were reflected. He is finding more evidence in support of the theory of moving material particles and is arranging some crucial tests; a fairly exhausted bulb containing the electrode connected to the disruptive coil produced small streamers breaking through the sides of the glass, producing a fine hole through which, however, the air does not rush into the tube; the glass in the neighborhood of the rupture may grow hot enough to soften but it will not collapse but rather bulge out, showing that the pressure from the inside is greater than that of the atmosphere; as the matter is expelled from the bulb the rarefaction increases and the streamers become less intense, whereupon the glass closes again, hermetically sealing the opening; he thinks this a positive evidence that matter is being expelled through the walls of the glass.

The same journal contains brief extracts from articles published in daily papers, among which is one stating that Edison found that he could see with the naked eye all the bones of the hand, also moving objects through eight inches of wood; he states that it makes a great difference who does the glass blowing for the bulbs, as the nature of the breath of the glass blower is said to make a difference.

The *West. Elec.*, March 21, contains an article by Mr. Jones in which he expresses the belief that there is an analogy between ordinary light and this new radiation; the latter seems to be made up of many different rays which differ widely in penetrating power, just as white light is the sum of rays of various wave-lengths; the time of exposure decreases with the rise in voltage, but lower voltages will also produce radiations; a sheet of aluminum is fairly opaque to low potential radiation but quite transparent to those produced by higher voltages; he thinks his experiments justify the theory that Röntgen rays vary greatly in penetrating power and that the voltage at the tubes plays a similar part to temperature in producing light rays, new waves being excited as the temperature rises; he is carrying out further experiments. His results also indicate that each ray requires a definite time to produce its maximum effect; an experiment is described showing that particular rays produced their maximum effect in 5 to 15 minutes and that a longer exposure was useless.

E. P. Thompson, in the *Elec. Eng.* and *West. Elec.*, March 7, describes an application of the X-rays for seeing objects in motion; with the apparatus referred to in the *Digest*, Feb. 29, he saw the motion of the bones of the fingers when bent backward and forward; he believes that with this apparatus the skeleton of a fish could be seen in the act of swimming; he thinks a fracture in a limb could thus be made visible by bending or stretching the limb; another experiment showed the effect of a solid passing through a solid, which suggests a possibility in surgery where it is desirable to follow the point of the instrument through the flesh. He finds that certain precautions are necessary in preparing the fluorescent screens; when the barium platino-cyanide is crystallized on a sheet of paper, or if the crystals are pressed on the surface, the screens are of little use; excellent results were obtained when the cyanide was powdered as finely as possible and applied with the clearest colorless varnish on a piece of tracing cloth, to the depth of about one eighth of an inch, care being taken not to make it too thin; either side of the screen may be directed toward the tube; it is important to perform the experiments in a dark room.

The *Elec. Eng.*, March 11, contains an article by Prof. Stine in which he covers partly the same ground as in the article abstracted above. He considers that his experiments strongly confirm the theory of longitudinal vibrations; he has not been able to detect that the light speed of dry plates has an influence on the time of exposure to the X-rays, and he now prefers slow plates, as they give clearer shadows; an experiment seems to indicate that ultra-violet rays have nothing to do directly with the phenomena; he appears to think that fluorescence is not the cause of the photographing action; the anode and cathode streams seem to be identical; he tested many incandescent lamps as bulbs for producing these rays, and found only one that would answer, from which he concludes that the vacuum is too low; he obtained some negatives of tourmaline, which he thinks proves that the rays are not transverse in character, and that the ultra-violet wave theory can no longer be entertained. He calls attention to the difference between such photographs and the so-called "electrographs," which latter he thinks are the result of an electrolytic action on the silver salts; he considers that the cathode is the prime source, but that the fluorescent bulb is a secondary source; the yellowish-green fluorescence is thought to be due to the uranium in the glass; he made other experiments with uranium to find whether it was the cause of the rays, and did not obtain the slightest effect; the Crookes tubes should have an extremely high vacuum, so high that there is only a faint trace of purple light around the anode; a successful tube shows a green fluorescence, while in those that failed it is yellow; a tube improves with use; he thinks the photograph is not the result alone of molecular bombardment, but rather of the nature of electrolysis; the seat of the effect may be in the molecules containing a charge of static electricity and vibrating with a frequency of green fluorescence or ultra-violet light.

TESLA ON ROENTGEN'S RAYS.

THE leading article of the month on the Roentgen rays is Nikola Tesla's contribution on the subject appearing in the *Electrical Review*. At once on hearing of Roentgen's discovery, Mr. Tesla repeated the learned professor's experiment, and since then has been devoting his energies to the investigation of the nature of the radiations and to the perfecting of the means for their production. He describes in detail the methods he has employed and the arrangement of his apparatus. Suffice it here to say that he has been able to obtain shadows with comparatively short exposures at distances of many feet, while at small distances and with thin subjects, exposures of a few seconds are practicable. The first shadow taken with his improved apparatus was that of a copper wire bent so as to form the word "Roentgen," projected at a distance of eleven feet through a wooden cover over the sensitive plate. A similar impression was obtained through the body of the experimenter, a plate of glass, nearly three-sixteenths of an inch thick, a thickness of wood of fully two inches, and through a distance of about four feet. By improvements in his apparatus Mr. Tesla is confident that he can magnify the effects many times.

Continuing the account of his results, Mr. Tesla says: "The bony structure of birds, rabbits and the like is shown within the least detail, and even the hollow of the bones is clearly visible. In a plate of a rabbit under exposure of an hour, not only every detail of the skeleton is visible, but likewise a clear outline of the abdominal cavity and the location of the lungs, the fur and many other features. Prints of even large birds show the feathers quite distinctly.

"Clear shadows of the bones of human limbs are obtained by exposures ranging from a quarter of an hour to an hour, and some plates have shown such an amount of detail that it is almost impossible to believe that we have to deal with shadows only. For instance, a picture of a foot with a shoe on it was taken, and every fold of the leather, trousers, stocking, etc., is visible, while the flesh and bones stand out sharply. Through the body of the experimenter the shadows of small buttons and like objects are quickly obtained, while with an exposure of from one to one and a half hours the ribs, shoulder bones and the bones of the upper arm appear clearly on the sensitized plate. It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body.

"An outline of the skull is easily obtained with an exposure of twenty to forty minutes. In one instance an exposure of forty minutes gave clearly not only the outline, but the cavity of the eye, the chin and cheek and nasal bones, the lower jaw and connections to the upper one, the vertebral column and connections to the skull, the flesh and even the hair. By exposing the head to a powerful radiation

strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible by these strange appliances to project a suitable chemical into any part of the body.

"Roentgen advanced modestly his results, warning against too much hope. Fortunately his apprehensions were groundless, for, although we have to all appearance to deal with mere shadow projections, the possibilities of the application of his discovery are vast. I am happy to have contributed to the development of the great art he has created."

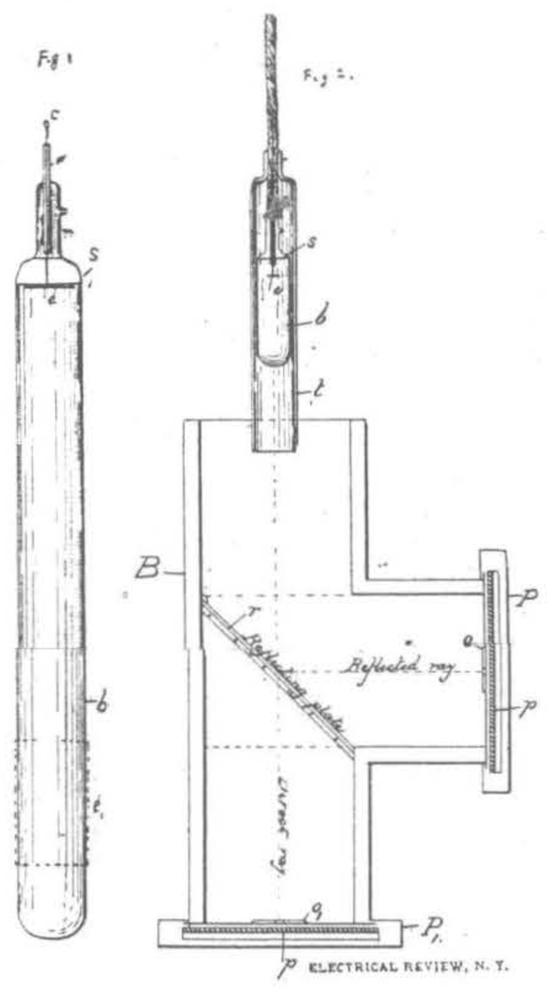
TESLA'S LATEST CONTRIBUTION TO SCIENCE.

We publish in this issue a communication from Mr. Tesla, which is even more interesting and important than his previous contributions presented in our columns. After announcing the extraordinary results obtained by means of his apparatus, which speak for the correctness of his conclusions regarding the character of the radiations, and after proving in crucial tests the long-sought-for property of reflection, he makes known a result which will probably lead to one of the most important realizations in science. His investigations of the reflective power of conductors disclose a singular relationship which seems capable of leading us to a deeper insight into the primary condition of matter than we have ever been able to obtain heretofore. Why is zinc, for instance, which is one of the first in Volta's electric contact series, one of the best reflectors? asks Tesla. Evidently such can only be the case if these mysterious rays emanating from the bulb convey matter in its primary state or condition. Let us hope that soon the full light of day will illuminate these obscure but immensely promising fields.

TESLA ON REFLECTED ROENTGEN RAYS.



To the Editor of Electrical Review:

In previous communications to your esteemed journal in regard to the effects discovered by Roentgen, I have confined myself to giving barely a brief outline of the most noteworthy results arrived at in the course of my investigations. To state truthfully, I have ventured to express myself, the first time, after some hesitation and consequent delay, and only when I had gained the conviction that the information I had to convey was a needful one; for, in common with others, I was not quite able to free myself of a certain feeling which one must experience when he is trespassing on ground not belonging to him. The discoverer would naturally himself arrive at most of the facts in due time, and a courteous restraint in the announcement of the results on the part of his co-workers would not be amiss. How many have sinned against me by proclaiming their achievements just as I was good and ready to do it myself! But these discoveries of Roentgen, exactly of the order of the telescope and microscope, his seeing through a great thickness of an opaque substance, his recording on a sensitive plate of objects otherwise invisible, were so beautiful and fascinating, so full of promise, that all restraint was put aside, and every one abandoned himself to the pleasures of speculation and experiment. Would but every new and worthy idea find such an echo! One single year would then equal a century of progress. A delight it would be to live in such age, but a discoverer I would not wish to be.

Amongst the facts, which I have had the honor to bring to notice, is one claiming a large share of scientific interest, as well as of practical importance. I refer to the demonstration of the property of reflection, on which I have dwelt briefly.

Having had opportunities to make many observations during my experience with vacuum bulbs and tubes, which could not be accounted for in any plausible way on any theory of vibration as far as I could judge, I began these investigations—disinclined, but expectant to find that the effects produced are due to a stream of material particles. I had many evidences of the existence of such streams. One of these I mentioned, describing the method of electrically exhausting a tube. Such exhaustion, I have found, takes place much quicker when the glass is very thin than when the walls are thick, I presume because of the easier passage of the ions. While a few minutes are sufficient when the glass is very thin, it often takes half an hour or more if the glass be thick or the electrode very large. In accordance with this idea I have, with a view of obtaining the most efficient action, selected the apparatus, and have found at each step my supposition confirmed and my conviction strengthened.

A stream of material particles, possessing a great velocity, must needs be reflected, and I was therefore quite prepared—assuming my original idea to be true—to demonstrate sooner or later this property. Considering that the reflection should be the more complete the smaller the angle of incidence, I adopted from the outset of my investigations a tube or bulb *b* of the form shown in Fig. 1. It was made of very thick glass, with a bottom blown as thin as possible, with the two obvious objects of restricting the radiation to the sides and facilitating the passage through the bottom. A single electrode *e*, in the form of a round disk of a diameter slightly less than that of the tube, was placed about an inch below the narrow neck *n* on the top. The leading-in conductor *c* was provided with a long wrapping *w*, so as to prevent cracking, by the formation of sparks at the point where the wire enters the bulb. It was found advantageous for a number of reasons to extend the wrapping a good distance beyond the neck, on the inside and outside as well, and to place the seal-off in the narrow neck. On other occasions I have dwelt on the employment of an electrostatic screen in connection with such single-terminal bulbs. In the present instance the screen was preferably formed by a bronze painting *s*, slightly above the aluminum electrode and extending to just a little below the wrapping of the wire, so as to allow seeing constantly the end of the wrapping. Or else a small aluminum plate *s*, Fig. 2, was supported in the inside of the bulb above the electrode. This static screen practically doubles the effect, as it prevented all action above it. Considering, further, that

Figs. 1 and 2.—Illustrating Tesla's Experiments on Reflected Roentgen Rays.

the radiation sideways was restricted by the use of a very thick glass and most of it was thrown to the bottom by reflection, as I then surmised, it became evident that such a tube should prove much more efficient than one of ordinary form. Indeed, I quickly found that its power upon the sensitive plate was very nearly four times as great as that of a spherical bulb with an equivalent area of impact. This kind of tube is also very well adapted for use with two terminals by placing an external electrode e_1 as indicated by the dotted lines in Fig. 1. When the glass is taken thick the stream is sensibly parallel and concentrated. Furthermore, by making the tube as long as one desired, it was possible to employ very high potentials, otherwise impracticable with short bulbs.

The use of high potentials is of great importance, as it allows shortening considerably the time of exposure, and affecting the plate at much greater distances. I am endeavoring to determine more exactly the relation of the potential to the effect produced upon the sensitive plate. I deem it necessary to remark that the electrode should be of aluminum, as a platinum electrode, which is still persistently employed, gives inferior results and the bulb is disabled in comparatively short time. Some experimenters might find trouble in maintaining a fairly constant vacuum, owing to a peculiar process of absorption in the bulb, which has been pointed out early by Crookes, in consequence of which, by continued use, the vacuum may increase. A convenient way to prevent this I have found to be the following: The screen or aluminum plate *s*, Fig. 2, is placed directly upon the wrapping of the leading-in conductor *c*, but some distance back from the end. The right distance can be only determined by experience. If it is properly chosen, then, during the action of the bulb, the wrapping gets warmer, and a small bright spark jumps from time to time from the wire *c* to the aluminum plate *s* through the wrapping *w*. The passage of this spark causes gases to be formed, which slightly impair the vacuum, and in this manner, by a little skillful manipulation, the proper vacuum may be constantly maintained. Another way of getting the same result in a tube shown in Fig. 1 is to extend the wrapping so far inside that, when the bulb is normally working, the wrapping is heated sufficiently to free gases to the required amount. It is for this purpose convenient to let the screen of bronze painting *s* extend just a little below the wrapping, so that the spark may be observed. There are, however, many other ways of overcoming this difficulty, which may cause some annoyance to those working with inadequate apparatus.

In order to insure the best action the experimenter should note the various stages which I have pointed out before, and through which the bulb has to pass during the process of exhaustion. He will first observe that when the Crookes phenomena show themselves most prominently there is a reddish streamer issuing from the electrode, which in the beginning covers the latter almost entirely. Up to this point the bulb practically does not affect the sensitive plate, although the glass is very hot at the point of impact. Gradually the reddish streamer disappears, and just before it ceases to be visible the bulb begins to show better action, but still the effect upon the plate is very weak. Presently a white or even bluish stream is observed, and after some time the glass on the bottom of the bulb gets a glossy appearance. The heat is still more intense and the phosphorescence through the entire bulb is extremely brilliant. One should think that such a bulb must be effective, but appearances are often deceitful, and the beautiful bulb still does not work. Even when the white or bluish stream ceases, and the glass on the bottom is so hot as to be nearly melting, the effect on the plate is very weak. But at this stage there appears suddenly at the bottom of the tube a star-shaped changing design, as if the electrode would throw off drops of liquid. From this moment on the power of the bulb is tenfold, and at this stage it must always be kept to give the best results.

I may remark, however, that while it may be generally stated the Crookes vacuum is not high enough for the production of the Roentgen phenomena, this is not literally true. Nor are the Crookes phenomena produced at a particular degree of exhaustion, but manifest themselves even with poor vacua, provided the potential is high enough. This is likewise true of the Roentgen effects. Naturally, to verify this, provision must be made not to overheat the bulb when the potential is raised.

(Concluded on page 174.)

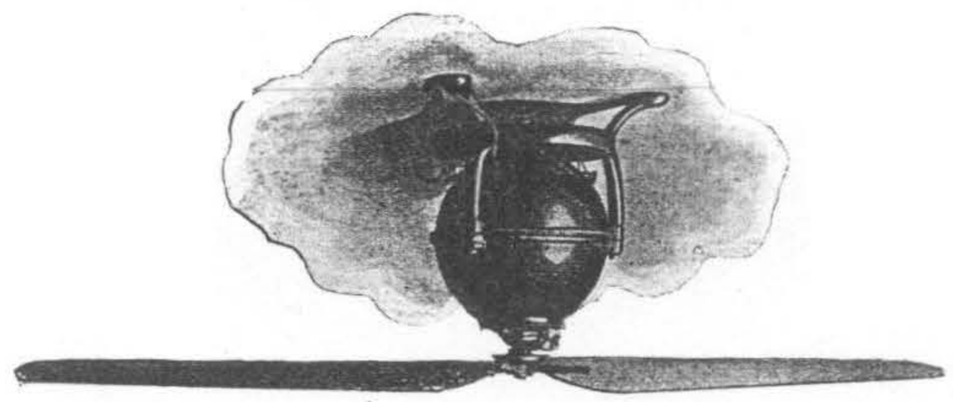
TESLA ON REFLECTED ROENTGEN RAYS.

(*Concluded from page 171.*)

This is easily done by reducing the number of impulses or their duration, when raising the potential. For such experiments, it will be found of advantage to use in connection with the ordinary induction coil a rotating commutator, instead of a vibrating brake. By changing the speed of the commutator, and also regulating the duration of contact, one is enabled to adjust the conditions to suit the degree of vacuum and potential employed.

In my experiments on reflection, presently considered, I have used the apparatus shown in Fig. 2. It consists of a T-shaped box throughout, of a square cross-section. The walls are made of lead over one-eighth of an inch thick, which, under the conditions of the experiments, was found to be entirely impervious, even by long exposures to the rays. On the top end was supported firmly the bulb *b*, inclosed in a glass tube *t* of thick Bohemian glass, which reached some distance into the lead box. The lower end of the box was tightly closed by a plate-holder P_1, containing the sensitive film p_1, protected as usual. Finally the side end was closed by a similar plate-holder P, with the sensitive protected film *p*. To obtain sharp images the objects *o* and o_1, exactly alike, were placed in the center of the fiber cover, protecting the sensitive plates. In the central portion of the box, provision was made for inserting a plate *r* of material, the reflective power of which was to be tested, and the dimensions of the box were such that the reflected ray and the direct one had to go through the same distance, the reflecting plate being at an angle of 45 degrees to the incident as well as reflected ray. Care was taken to exclude all possibility of action upon the plate *p*, except by reflected rays, and the reflecting plate *r* was made to fit tight all around in the lead box, so that no rays could reach the film p_1, except by passing through the plate to be tested. In my earliest experiments on reflection I observed only the effects of reflected rays, but in this instance, on the suggestion of Prof. Wm. A. Anthony, I provided the above means for simultaneously examining the action of the direct rays, which eventually passed through the reflecting plate. In this manner it was possible to compare the amount of the transmitted and reflected radiation. The glass tube *t* surrounding the bulb *b* served to render the stream parallel and more intense. By taking impressions at various distances I found that through a considerable distance there was but little spreading of the bundle of rays or stream of particles.

To reduce the error which is caused unavoidably by too long exposures and very small distances, I reduced the exposure to an hour, and the total distance through which the rays had to pass before reaching the sensitive plates was 20 inches, the distance from the bottom of the bulb to the reflecting plate being 13 inches.



It is needless to remark that all the precautions in regard to the sensitive plates—constancy of potential, uniform working of the bulbs, and maintenance of the same conditions in general during these tests have been taken, as far as it was practicable. The plates to be tested were made of uniform size, so as to fit the space provided in the lead box. Of the conductors the following were tested: Brass, toolsteel, zinc, aluminum, copper, lead, silver, tin, and nickel, and of the insulators, lead-glass, ebonite, and mica. The summary of the observations is given in the following table:

Reflecting body.	Impression by transmitted rays.	Impression by reflected rays.
Brass.	Strong.	Fairly strong.
Toolsteel.	Barely perceptible.	Very feeble.
Zinc.	None.	Very strong.
Aluminum.	Very strong.	None.
Copper.	None.	Fairly strong, but much less than zinc.
Lead.	None.	Very strong, but a little weaker than zinc.
Silver.	Strong, a thin plate being used.	Weaker than copper.
Tin.	None.	Very strong; about like lead.
Nickel.	None.	About like copper.
Lead-glass.	Very strong.	Feeble.
Mica.	Very strong.	Very strong; about like lead.
Ebonite.	Strong.	About like copper.

By comparing, as in previous experiments, the intensity of the impression by reflected rays with an equivalent impression due to a direct exposure of the same bulb and at the same distance—that is, by calculating from the times of exposure under assumption that the action upon the plate was proportionate to the time—the following approximate results were obtained:

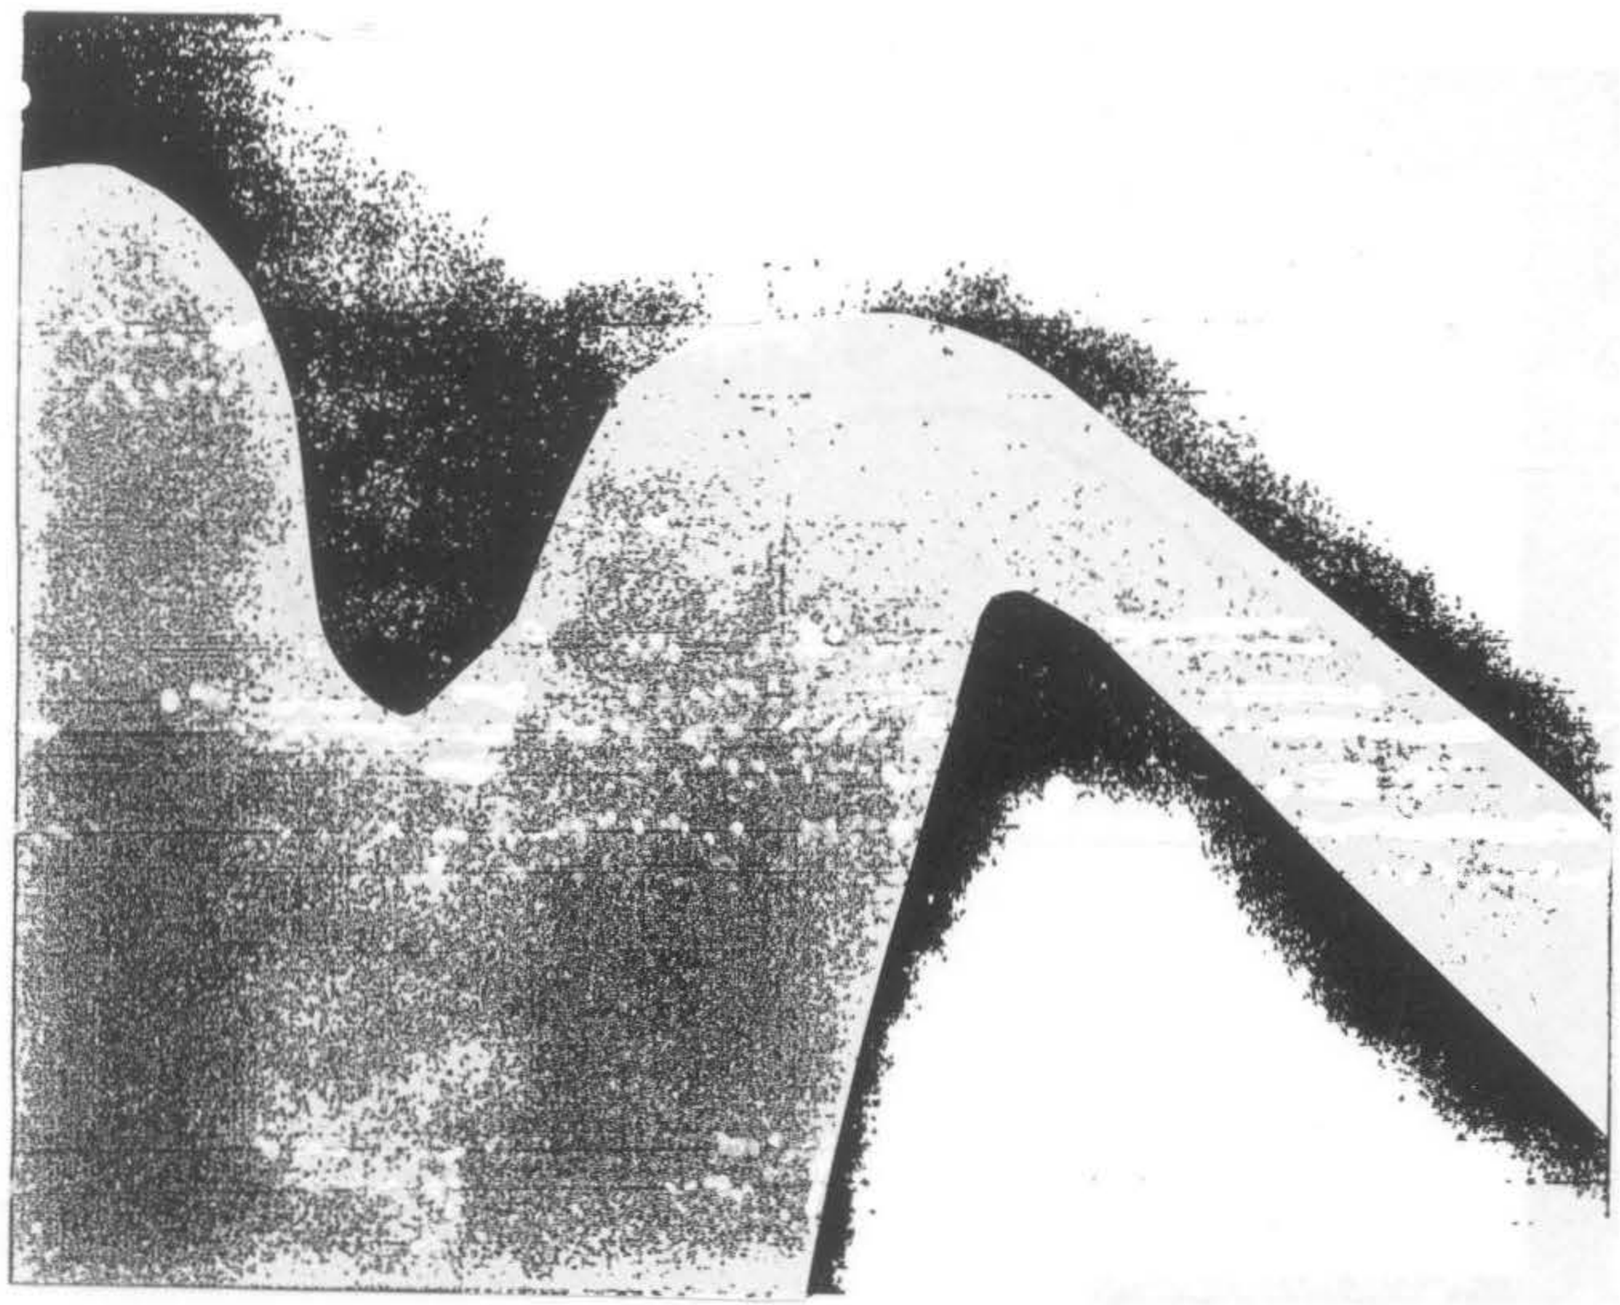
Reflecting body.	Impression by direct action.	Impression by reflected rays.
Brass	100	2
Toolsteel	100	0.5
Zinc	100	3
Aluminum	100	0
Copper	100	2
Lead	100	2.5
Silver	100	1.75
Tin	100	2.5
Nickel	100	2
Lead-glass	100	1
Mica	100	2.5
Ebonite	100	2

While these figures can be but rough approximations, there is, nevertheless, a fair probability that they are correct, in so far as the relative values of the impressions by reflected rays for the various bodies are concerned. Arranging the metals according to these values, and leaving for the moment the alloys or impure bodies out of question, we arrive at the following order: Zinc, lead, tin, copper, silver. The tin appears to reflect fully as well as lead, but, allowing for an error in the observation, we may assume that it reflects less, and in this case we find that this order is precisely the contact series of metals in air. If this proves true we shall be confronted with the most extraordinary fact. Why is zinc, for instance, the best reflector among the metals tested and why, at the same time, is it one of the foremost in the contact series? I have not as yet tried magnesium. The truth is that I was somewhat excited over these results. Magnesium should be even a better reflector than zinc, and sodium still better than magnesium. How can this singular relationship be explained? The only possible explanation seems to me at present that the bulb throws out streams of matter in some primary condition, and that the reflection of these streams is dependent upon some fundamental and electrical property of the metals. This would seem to lead to the inference that these streams must be of uniform electrification; that is, that they must be anodic or cathodic in character, but not both. Since the announcement, I believe in France for the first time, that the streams are anodic, I have investigated the subject and find that I can not agree with this contention. On the contrary, I find that anodic and cathodic streams both affect the plate, and, furthermore, I have been led to the conviction that the phosphorescence of the glass has nothing whatever to do with the photographic impressions. An obvious proof is that such impressions are produced with aluminum vessels when there is no phosphorescence, and, as regards the anodic or cathodic character, the simple fact that we can produce impressions by a luminous discharge excited by induction of a closed vessel, when there is neither anode nor cathode, would seem to dispose effectually of the assumption that the streams are issuing solely from one of the electrodes. It may, perhaps, be useful to point out here a simple fact in relation to the induction coils, which may lead an experimenter into an error. When a vacuum tube is attached to the terminals of an induction coil, both of the terminals are acted upon alike as long as the tube is not very highly exhausted. At a high degree of exhaustion both the electrodes act practically independently, and since they behave as bodies possessing considerable capacity, the consequence is that the coil is unbalanced. If the cathode, for instance, is very large, the pressure on the anode may rise considerably, and if the latter is made smaller, as is frequently the case, the electric density may be many times that on the cathode. It results from this that the anode gets very hot, while the cathode may be cool. Quite the opposite occurs if both of them are made exactly alike. But assuming the above conditions to exist, the hotter anode emits a more intense stream than the cool cathode, since the velocity of the particles is dependent on the electrical density, and likewise on the temperature.

THE LUNDELL "WHITE WINGS" ELECTRIC FAN.

From the previous tests an interesting observation can also be made in regard to the opacity. For instance, a brass plate one-sixteenth inch thick proved fairly transparent, while plates of zinc and copper of the same thickness showed themselves to be entirely opaque.

Since I have investigated reflection and arrived to results in this direction, I have been able to produce stronger effects by employing proper reflectors. By surrounding a bulb with a very thick glass tube the effect may be augmented very considerably. The employment of a zinc reflector in one instance showed an increase of about 40 per cent in the impression produced. I attach great practical value to the employment of proper reflectors, because by means of them we can employ any quantity of bulbs, and so produce any intensity of radiation required.



One disappointment in the course of these investigations has been the entire failure of my efforts to demonstrate refraction. I have employed lenses of all kinds and tried a great many experiments, but could not obtain any positive result.

NIKOLA TESLA.

New York, March 30.

Tesla on the X Rays.

None of the scientists who have made practical investigations as to the scope and value of the Röntgen ray discovery have reached more important or wonderful results than Nikola Tesla, the well-known inventor. A communication from him recently published in the *Electrical Review*, which is the organ of the best scientific thought and literature of the time, mentions some of the results of his experiments in radiography. He gives it as his opinion that the rarefaction of the Crookes tubes used in these experiments may be increased by electrical means to any degree desirable; far beyond that obtained by mechanical appliances. In the course of his experiments he secured radiographs showing the bony structure of birds and rabbits, even to the hollow of the bones. He has obtained a radiograph of a rabbit after an hour's exposure, in which not only every detail of the skeleton is visible but a clear outline of the abdominal cavity, the location of the lungs the fur, and many other features are shown. Radiographs of large birds show the feathers distinctly. In another instance an exposure of forty minutes gave a radiograph of the human skull, showing clearly not only the outline, but the cavities of the eye, chin, cheek, nasal bones, the lower jaw and connections to the skull, the flesh, and even the hair. In this connection he says: "By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep, and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull. Thus it may be possible, by these strange appliances to project a suitable chemical into any part of the body." He declares it to be already "demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the living human body."

A TESLA RADIOGRAPH OF THE RIGHT SHOULDER OF A MAN, SHOWING THE RIBS AND THE BONES OF THE SHOULDER AND UPPER-ARM.

The illustration given herewith depicts one of the most remarkable of the Tesla radiographs. It shows the right shoulder of a man, taken through his clothing, a plate of glass three-sixteenths of an inch thick, and a thickness of wood of fully two inches, at a distance of four feet from the source of the X rays. The bones of the shoulder and of the upper-arm are plainly visible, but Tesla states that with improvements of his apparatus he will be able to produce much clearer and more distinct effects.

THE WESTINGHOUSE ELECTRICAL WORKS.

(FROM OUR NEW YORK CORRESPONDENT.)

THE new works of the Westinghouse Electric and Manufacturing Company are situated at Brinton, not far from Pittsburg, and on the line of the Pennsylvania Railroad, so that admirable transport facilities are secured. They have been built to replace the old works of the same company, which were located in Pittsburg, and where nearly 3000 hands were employed. These new works, which are not yet complete—such works never are finished—were visited by the members of the American Institute of Mining Engineers during their recent meeting at Pittsburg, and the excursion was one of the most interesting of the series provided for the entertainment of members by their hospitable hosts. As these works are of exceptional size, at all events in the United States, and as they represent the most advanced practice in electrical engineering, your correspondent purposes to describe them in some detail, assisted by illustrations kindly placed at his disposal by the engineer of the company.

Fig. 1, page 430, is a general view of these works. The company has 40 acres in this tract in a rectangular form, the frontage on the railway being 2300 ft. At present eight buildings have been erected, as follows: A machine shop 754 ft. long by 231 ft. wide, the ground floor of which covers 4 acres, while the galleries cover 3; a warehouse 754 ft. long by 76 ft. wide. At one end are the offices of the administration, engineering and drafting departments, and at the opposite end meters, arc lamps, switchboards, and similar apparatus are constructed. The other buildings are the pattern shop, the blacksmiths' shop (241 ft. by 80 ft.), the power house (206 ft. by 76 ft.), the drying and dipping shop (187 ft. by 25 ft.), and the brass foundry, which measures 241 ft. by 40 ft. (see plan, Fig. 2).

In respect to the interior of the machine shop, shown in Fig. 3, it may be said it is carefully arranged to reduce the labour in handling the material to a minimum. The building is divided into three aisles of equal width, and railway tracks extend through each the entire length of the building. Two 30-ton cranes are used for moving material. The side aisles contain a second storey, and each is divided by a row of columns supporting it, which also serve to carry the runways for two 10-ton travelling cranes. Ten stairways and 10 elevators furnish communication between the two floors, the elevators being driven by a belt from a 10 horse-power motor. The side walls of the buildings are of brick, and inclose steel columns supporting the floors and roof. The girders and roof are of steel, wood being used only for the window sashes and floors. The shops are unusually well lighted, and in the machine shop are 12 toilet rooms with ample washing facilities. It is well known that cleanliness on the part of the employés is productive of care in their work, and this question has been amply considered. By means of the fan system of hot air, a temperature of 60 deg. is maintained, and the 9,171,000 cubic feet of air is changed and rewarmed in 20 minutes. The amount of heating surface in the six heaters is 20,000 square feet, and the fans are driven by a 30 horse-power (Fig. 4) motor, the heated air being distributed by overhead blast-pipes.

Nearly all the machinery used in these great shops, comprising upwards of 1250 machine tools, is operated by Tesla polyphase motors, supplied with two-phase alternating current at a frequency of 25 cycles per second. This is the identical system worked out by the Westinghouse Electric and Manufacturing Company for the use of the Cataract Construction Company in their great work at Niagara Falls. The alternating current generators are located in the power house, from which current is conveyed by insulated conductors to motors conveniently placed throughout the various shops. The potential used is 200 volts, and this is supplied directly to the motors without the interposition of transformers. The line shafting throughout the buildings is divided into comparatively short sections, and motors ranging from 10 to 50 horse-power are employed to drive the sections; in certain cases large tools will be separately driven by independent motors.

In the power house three 500 horse-power two-phase generators, direct driven by Westinghouse compound engines, are installed. They are driven at a speed of 215 revolutions, and deliver current to two separate circuits, these currents differing in their time relation or phase by 90 deg. They are separately excited, current being derived from a small direct current machine.

In Fig. 4 is shown a 40 horse-power Tesla motor used for driving some of the large tools in the machine shop. In respect to this motor it may be said that the object which Nikola Tesla sought to attain when he began the work which led up to the invention of these motors, which are now so celebrated, was the elimination of the commutator—the weak point and the most troublesome element in all direct current motors, which at the time Tesla began his work were the only motors available for practical purposes. Since that time much has been done to improve the construction of commutators, but they still remain the weakest element in direct current machinery, and when well made are very expensive. They are necessarily built up of a large number of segments of copper, and each segment must be insulated from adjacent segments by insulation of ample strength for the potentials employed, and without the slightest crack or pinhole. Any failure to realise these conditions will cause a breakdown and interruption of service. Moreover, the constant rubbing of the brushes against the commutator, causes rapid wear of the metal and a breaking-down of the insulation, involving trouble in maintenance and cost in repair; and this deterioration of brush and commutator is, in spite of the best construction, inevitably more rapid than in the case of the alternating current motor, where the brushes bear against the rings of a collector. The engraving Fig. 6 shows an extremely well-made modern commutator, and Fig. 5 illustrates a collector. The latter consists essentially of rings of metal, usually copper or brass, centred on the same shaft, and separated from each other by heavy rings of insulating material. The parts, as compared with the commutator, are relatively few, and the insulation can be as heavy as desired. In the larger Tesla motors collectors are used, but in the smaller ones even these are discarded.

The efficiency of a 10 horse-power motor, delivering half load (5 horse-power) is 79 per cent.; under full load (10 horse-power) it is 84 per cent.; and under an overload of 50 per cent. (*i.e.*, when delivering 15 horse-power) its efficiency is 75 per cent. A 20 horse-power motor delivering 5 horse-power works at an efficiency of 78 per cent.; delivering 10 horse-power its efficiency is 84 per cent.; and at full load (20 horse-power) its efficiency is 82 per cent. A 50 horse-power motor delivers 5 horse-power at an efficiency of 72 per cent.; 10 horse-power at 81 per cent.; 20 horse-power at 89 per cent.; 30 horse-power at 91 per cent; 40 horse-power at 91 per cent.; 50 horse-power at 89 per cent.; 60 horse-power at 88 per cent. A 1 horse-power motor delivers $\frac{1}{4}$ horse-power at 61 per cent.; $\frac{1}{2}$ horse power at 72 per cent.; $\frac{3}{4}$ horse-power at 75 per cent.; 1 horse-power at 73 per cent., and $1\frac{1}{4}$ horse-power at 69 per cent.

These motors are intentionally so designed that their maximum efficiency occurs at a load somewhat less than their rated output. This is thought desirable for the reason that motors in shop work are apt to run at somewhat less than their rated outputs, and the net efficiency of the plant is therefore improved by so constructing the motors that they work at their best efficiency at from 10 per cent. to 25 per cent. less than the full loads which they are capable of carrying.

In using the polyphase system it should be noted that if the frequency selected be suitable, the shops can be lighted from the same circuits that are used to supply motors. The frequency adopted in the Westinghouse shops is 25 cycles per second, or 3000 alternations per minute. This permits incandescent lighting that is entirely satisfactory for shop work, but it is too low for arc lighting. A similar system of motors manufactured by the Westinghouse Electric and Manufacturing Company is designed for frequency of 60 cycles per second, or 7200 alternations per minute, and this is adapted to incandescent and arc lighting.

In Fig. 7 may be seen a Westinghouse engine direct connected to 500 horse-power two-phase generators.

Conspicuous in these vast works, the following branches are of great interest: The converter department, on the second floor, the winding department, the lightning arrester department, and the insulating department. In two of these the "coming woman" is in decided evidence. The electrical field is evidently a congenial one, and, judging from the samples we saw the occupation is a most healthy one. We were also shown the new Baldwin-Westinghouse electric locomotive. It is mounted on two four-wheeled trucks with 42-in. wheels, and each of the four axles is driven by a 200 horse-power single-geared motor under the car. Its weight is 160,000 lb., which rests on the eight driving wheels, and the horse-power is 1000.

A gas engine designed to utilise 50 per cent. of the heat energy of coal was also shown. It consisted of a three-cylinder engine on the Otto cycle, compounded, having one high-pressure and two low-pressure cylinders. The initial pressure is as high as 375 lb. per square inch, and the compounding gives a high rate of expansion. There still remains a good deal to be said about the construction and arrangement of these important works.

(*To be continued*)

THE WESTINGHOUSE ELECTRICAL WORKS.

(FROM OUR NEW YORK CORRESPONDENT.)

(*Concluded from page* 429.)

IT will be seen by reference to the plan, Fig. 2 of our last article on the new works of the Westinghouse Electrical Company at Brinton (see page 430 *ante*), that the general arrangement is of a very simple character. A small stream secures a complete water frontage, and branches from more than one railroad provide ample railway communications. The various buildings are all rectangular in plan, and placed in two parallel rows; a railway runs in front of the whole range, and branches are taken from it into, through, or close beside all of the buildings. Apart from the carpenters' shop, which is 200 ft. long, and somewhat isolated, the plan is quite symmetrical. The main building is the machine shop, 231 ft. wide by 754 ft. long, and having three lines of rails traversing it from end to end. Behind it is the blacksmiths' shop, with one through track, and 83 ft. by 243 ft. Parallel to these are four buildings—the warehouse, 70 ft. by 754 ft.; the power house, 76 ft. by 206 ft.; the punch shop, 76 ft. by 258 ft.; and the foundry, 150 ft. wide by 706 ft. long. Between the machine shop and the warehouse, which are separated by a passage 64 ft. wide, is a small building, the drying and dipping shop. These are all the shops that constitute the works at present, though doubtless before long they will be considerably enlarged. Figs. 8 to 11 are details that give some idea of the machine shop. From Fig. 8 it will be seen that this building consists of a central and two side spans, the former being 69 ft. wide, and the latter each 81 ft. 3 in. The general character of construction—the type of roof trusses, the columns, transverse and longitudinal bracing, are indicated in the sections, and are also shown in the perspective view of the power house, Fig. 22, a very similar character of construction being followed throughout; the walls in all the buildings are of brickwork, inclosing the steel columns that carry the roofs, flooring, &c. The central gallery of the machine shop is open to the roof, which is higher than that of the two side galleries; this arrangement allows the introduction of a row of clerestory

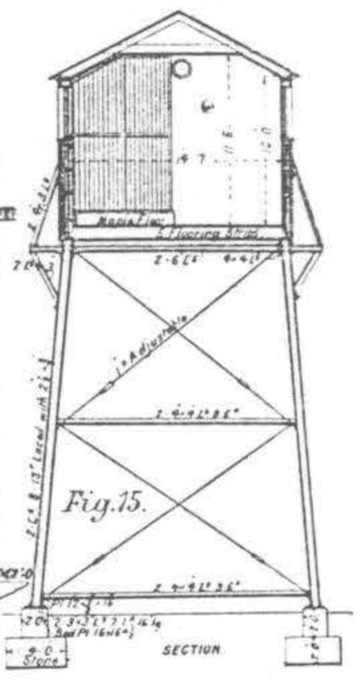

Fig. 15.

windows on each side beneath the roof springing (Figs. 10 and 11). A 30-ton travelling crane spans this central gallery, and runs on rails supported by the columns, from end to end of the building. The arrangement of the side galleries is symmetrical. Each is divided for its length, and nearly along the central axis, by a row of columns that carry the framing for an upper floor, which is also divided as shown in Fig. 8. Ten-ton travelling cranes are provided for the lower floors of this part of the shop. Communication between the different levels is provided by 10 stairways and 10 elevators. Heating this vast building, which contains nearly 10 million cubic feet, was a very serious undertaking, considering the extreme cold that usually prevails during the winter. Waste, as well as live, steam is used, and the air in the building is changed three times an hour. This is effected by means of a number of fans placed at some distance above the floor level, and each driven by a 30 horse-power Tesla motor. The warehouse is separated from the machine shop by a passage-way about 75 ft. in width. This building is of the same length as the machine shop, and is 76 ft. wide. Figs. 12 and 13 are respectively longitudinal and transverse sections; from the latter it will be seen that the building is divided into three galleries by the two rows of columns, running from end to end, and that there is an upper storey, the height of the ground floor being 25 ft. 10 in. Both floors are provided with 10-ton travelling cranes, the rail levels of which are shown in the section. Facility in handling and shipping goods is well arranged for in this building; it is connected with the machine shop by six bridges, of the type shown in Figs. 14 and 15; they are about 15 ft. wide and are provided with tracks, and, as shown on the plan, Fig. 2, there is a line of rails on the ground level on each side of the warehouse, so that goods may be loaded up along the whole length, there being ample door accommodation provided for this purpose. For loading into railway cars from the upper floor an elevated track is carried on a staging (Fig. 13). The dipping and drying shop between these two large buildings is about 30 ft. wide and

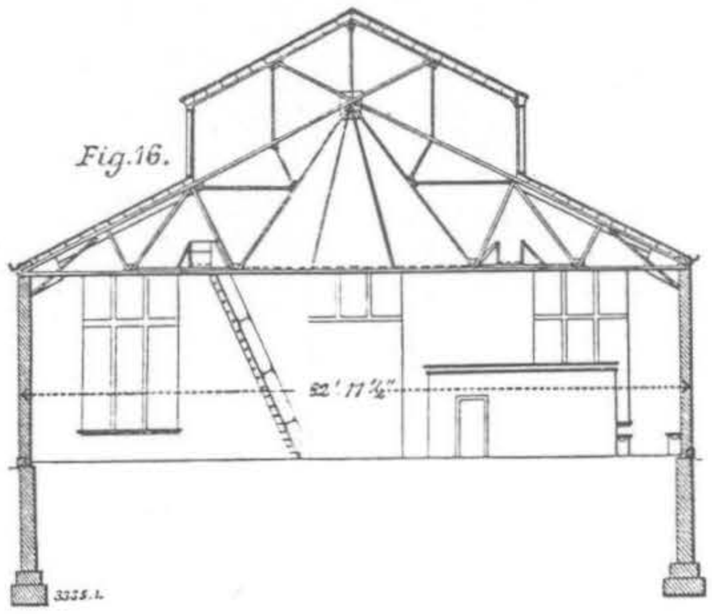
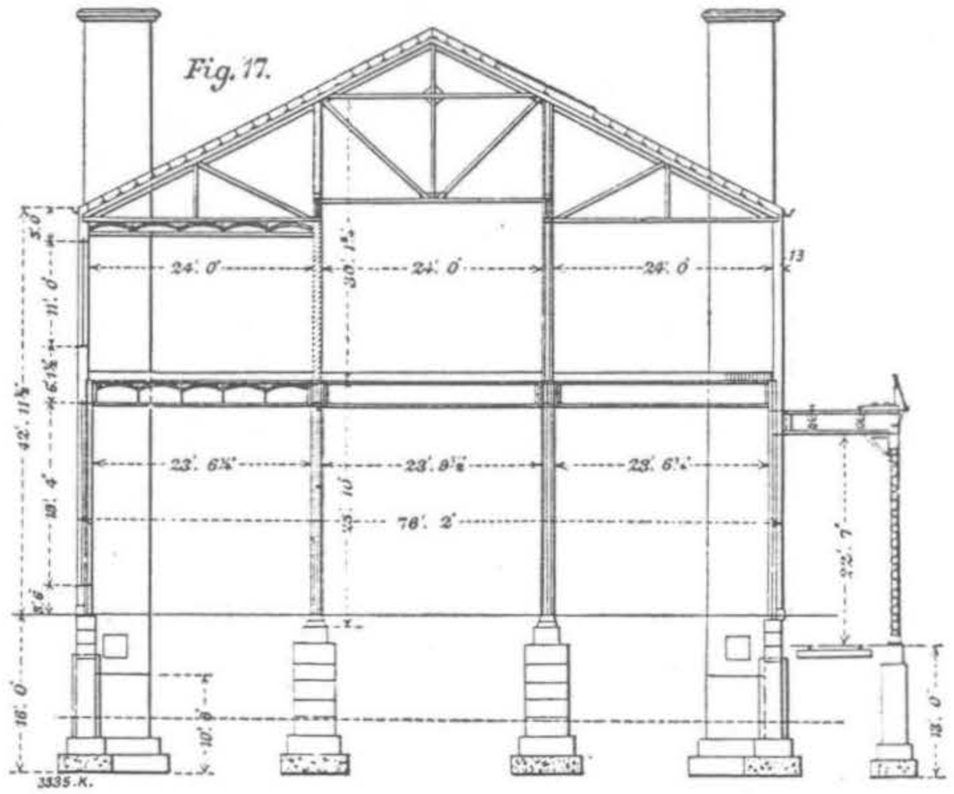
180 ft. long. In it all the nickel plating, japanning, varnishing, and general surfacing of finished parts is carried on.

The blacksmiths' shop is covered by single span trusses of 82 ft. 6 in. span; a cross-section of it is given in Fig. 16, page 502. Its construction is very similar to that of the other buildings, and calls for no special notice, except perhaps that the ventilating arrangements are excellent, and that all the power required is supplied by electrical motors mounted on the roof trusses to be out of the way. It contains 40 forges, and a large number of presses, hammers, &c.; one of the presses is driven by a 30 horse-power motor. Beyond comes the punch house (Fig. 17), a very important department, where so many pieces have to be stamped and cut into shape; it is 76 ft. 2 in. wide and 258 ft. long. As will be seen, it contains two storeys, besides a third floor near a part of the roof. The construction is somewhat heavier than that of the other buildings, and the first floor is formed with brick arches turned between the steel joists, while the small top storey, which is used as a store, is supposed to be fireproof. The heavier machinery is arranged on the ground floor, and is driven off shafting by a 40 horse-power motor. The appliances here comprise annealing ovens, hydraulic presses, and the heavier punching and shearing machines. Above, and also driven by shafting coupled to three motors of 20 horse-power each, are a large number

THE WESTINGHOUSE ELECTRICAL WORKS, BRINTON, NEAR PITTSBURG.

Fig. 16.





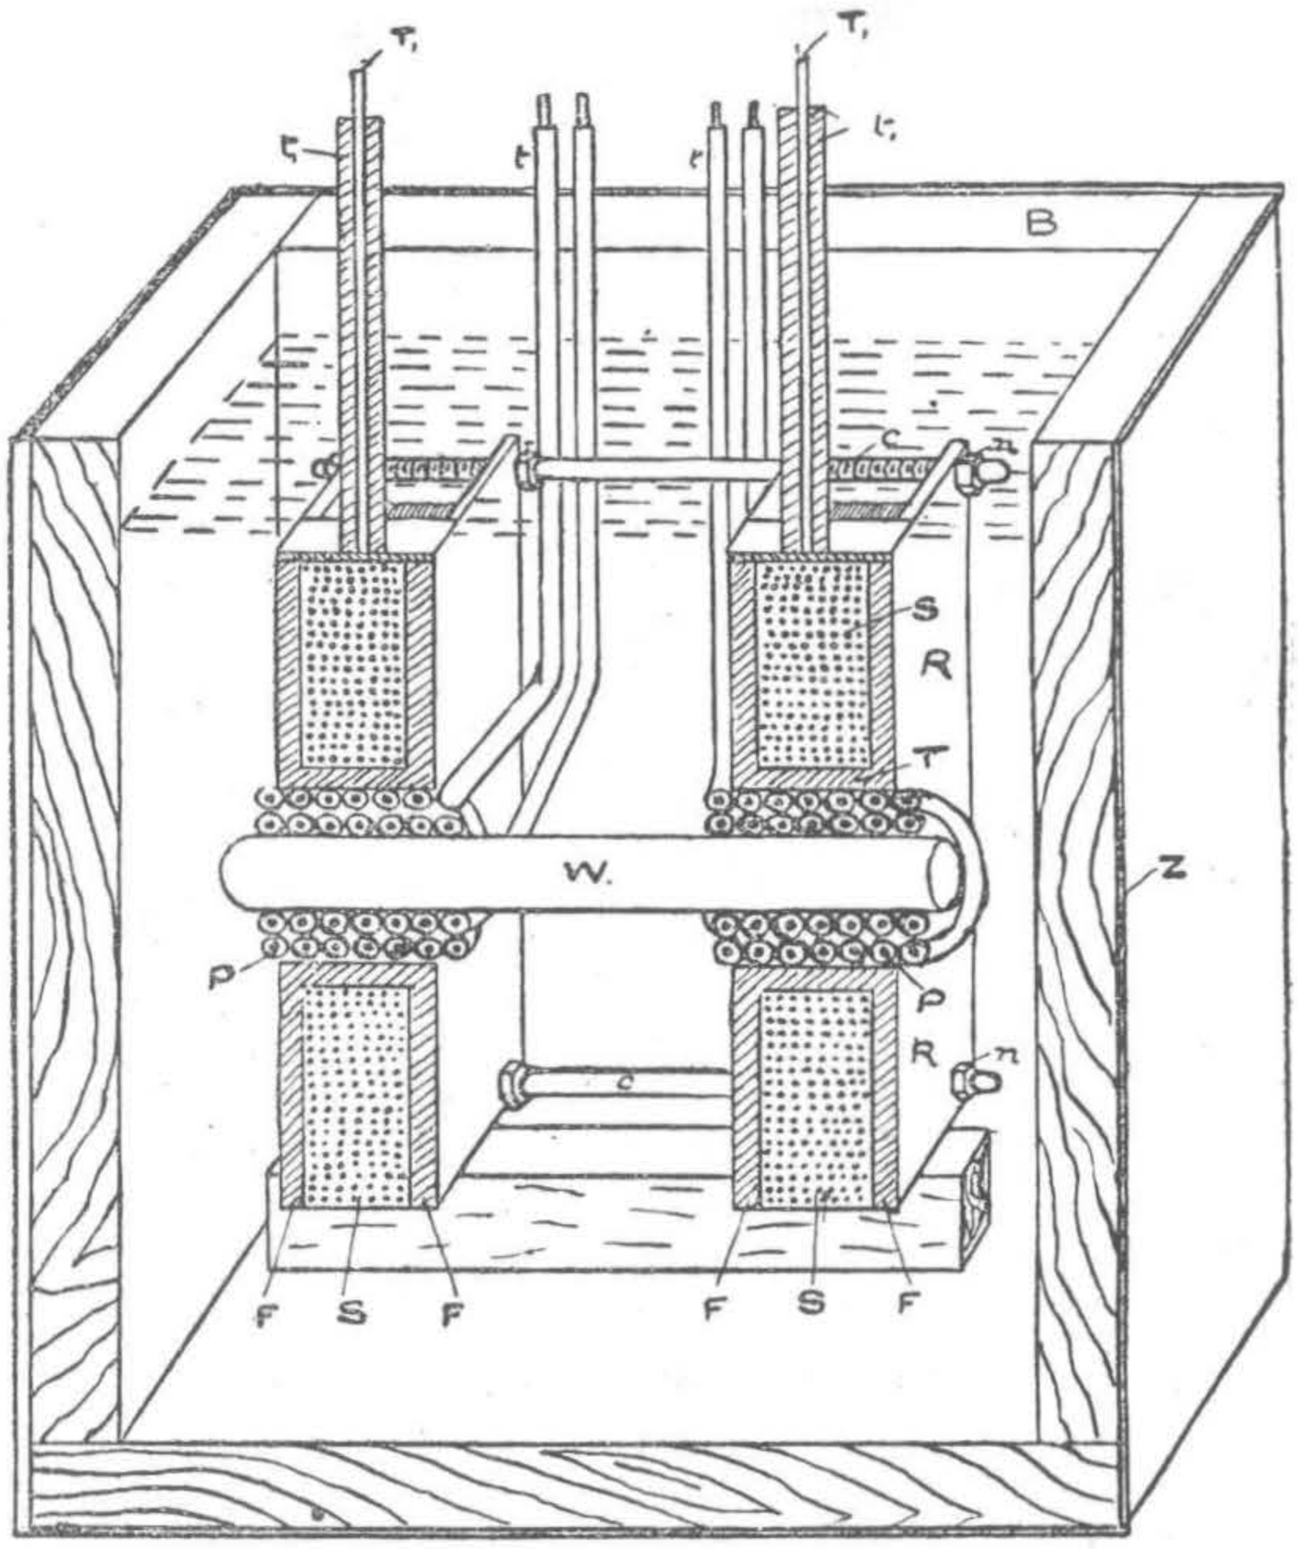


Fig. 17.

of lighter stamping, cutting, and milling tools. Between this shop and the warehouse is situated the power house, illustrated by Figs. 18 to 21. This is a very interesting part of the works, though it is as yet only half equipped, the arrangement being such that the plant can be duplicated, when the extension of the works renders this necessary. The building is divided into two parts, one for the engines, the other for the boiler-room. Along one side of the latter are ranged five boilers having a total capacity of 2500 horse-power, sufficient, including reserve, for the present requirements of the works. These boilers are of the Pierpoint water-tube type, and consist of three upper and three lower horizontal drums connected by inclined tubes 3½ in. in diameter; each boiler contains 5755 ft. of heating surface, and delivers its steam from the front and centre drums into a 20-in. steam main common to all the boilers. The fuel used is bituminous slack, delivered at the works at about 3s. a ton. Special appliances have been worked out and are in successful operation for storing and handling this coal, so that all labour is practically saved. The plant for this purpose is contained in a small building at one end of the power house. The coal is delivered by cars on a raised track into hoppers, after passing through a breaker. From the hoppers it is lifted by endless chains and buckets to a conveyor that delivers it into bins placed above the boilers; it then falls through delivery pipes from the bins to the receiver of a mechanical stoker; the ashes are collected and delivered into trucks almost automatically; the machinery for this part of the work is driven by a 30 horse-power motor. It was considered preferable not to adopt very large power units, and condensing engines were employed, the exhaust steam being used to heat the different buildings. There are five Westinghouse compound condensing engines, each of 500 horse-power, in the engine-room; they have cylinders 24 in. and 40 in. in diameter, with 18 in. stroke; their normal speed is 215 revolutions, and the steam pressure 125 lb. Each engine drives a separate generator, two of them being direct current, and the other three two-phase Tesla generators. These latter are driven at 215 revolutions, with 3000 alternations; the voltage is 230, and the loss is estimated at about 5 per cent. in the distribution of about 1000 ft. This power is distributed to a large number of motors throughout the entire works, as well as for lighting purposes and testing. For more detailed particulars of these magnificent works, the writer would refer your readers to the pages of the *Engineering Record*. In conclusion, he may mention that the Carnegie Steel Company, and the Shiffler Bridge Company, both of Pittsburg, supplied all the steel work for the buildings.

his lecture before the Royal Institution of Civil Engineers (Feb., 1892), Mr. Tesla thus described his coil:—"The coil consists of two spools of hard rubber, R R, held apart at a distance of 10cm. by bolts, *c*, and nuts, *n*, likewise of hard rubber. Each spool comprises a tube, T, of approximately 8cm. inside diameter, and 3mm. thick, upon which are screwed two flanges, F F, 24cm. square, the space between the flanges being about 3cm. The secondary, S S, of the best guttapercha-covered wire, has 26 layers, 10 turns in each, giving for each half a total of 260 turns. The two halves are wound oppositely, and connected in series, the connection between both being made over the primary. This disposition, besides being convenient, has the advantage that when the coil is well balanced—that is, when both of its terminals, $T_1 T_1$, are connected to bodies or devices of equal capacity—there is not much danger of breaking through to the primary, and the insulation between the primary and the secondary need not be thick. The primary P P is wound in two parts, and oppositely, upon a wooden spool, W, and the four ends are led out of the oil through the hard rubber tubes *t t*. The ends of the secondary $T_1 T_1$ are also led out of the oil through rubber tubes, $t_1 t_1$, of great thickness. The primary and secondary layers are insulated by cotton cloth, the thickness of the insulation, of course, bearing some proportion to the difference of potential between the turns of the different layers. Each half of the primary has four layers, 24 turns in each, giving a total of 96 turns. The coil is held in position in the oil on wooden supports, there being about 5cm. thickness of oil all round. The whole coil is immersed in boiled-out oil, contained in a box, B, of thick boards of hard wood, covered on the outside with a zinc sheet, Z, which is carefully soldered all round. The coil should be placed symmetrically to the metal cover, and the space between should not be too small; especially the two sides of the box, which are at right angles to the axis of the coil, should be sufficiently remote from the latter. Once the coil has been immersed, it should never be taken out of the oil for more than a few hours, else the guttapercha will crack up. The primary is No. 12, Brown and Sharpe gauge, ordinary line wire, with a thick cotton coating; the secondary is No. 24 Brown and Sharpe gauge wire, but the sections may be varied considerably. The kind of guttapercha wire in which the insulation sticks to the metal should be used, unless a special method is followed to expel all air. The coil is wound within an oil-tank, so that all interstices are filled up with oil. Paraffin or linseed oil may be used." W. C. Peake.

[87988.]—**Tesla Coil.**—"P. B. P." will find all he wants in "The Inventions, Researches, and Writings of Nikola Tesla," by T. C. Martin, published by the *Electrical Engineer*, New York; but in case he has not access to one of the large public libraries, I give some extracts from the book. In

TESLA WILL TRY TO CURE ROUSS

The Recorder Brings Electrician and Millionaire Together.

LAST HOPE OF THE BLIND MERCHANT

Has the Subtle Fluid Power to Restore His Fading Sight?

EXPERIMENT TO BE TRIED

With No Thought of Gain, but Simply to Help His Fellow Man, the Scientist Will, Under a Specialist's Supervision, Apply 100,000 Volts to the Sufferer's Optic Nerve.

Through the endeavors of a Recorder reporter two of the best-known characters in this country—Nikola Tesla, the greatest electrician the world has, perhaps, yet produced, and Charles Broadway Rouss, the multi-millionaire merchant—were brought together yesterday. The meeting had an important object. It resulted from a free-will offer on Mr. Tesla's part to place the results of his inventive genius at the disposal of the merchant for the sake of holding out to him the only possible chance for a recovery of his fast-waning eyesight.

Some time ago The Recorder reporter brought the fact of Mr. Rouss' sad plight to Mr. Tesla's notice and suggested the possible efficacy of the high-voltage currents. Mr. Tesla was at once interested, and quickly offered to place his apparatus at Mr. Rouss disposal.

"It cannot do him any harm, and it may possibly stimulate the optic nerves and awaken new life in them," he said, "and I am more than willing to render any service within my power."

The reporter found Mr. Rouss at first loth to consider the idea.

"That man's time is worth too much to be bothered about an old man's eyesight," he exclaimed with characteristic energy. "I wouldn't want to bother him. He is doing the whole world so much good that it would be wrong to make him stop to consider individuals. Why, I consider him the greatest man in the world."

When made to understand that Mr. Tesla had made the offer, and had even asked The Recorder reporter to bring Mr. Rouss to his laboratory, the merchant wellnigh broke down and said:

"Yes, I'll go with you any time; but I can't pay for it. I haven't money enough."

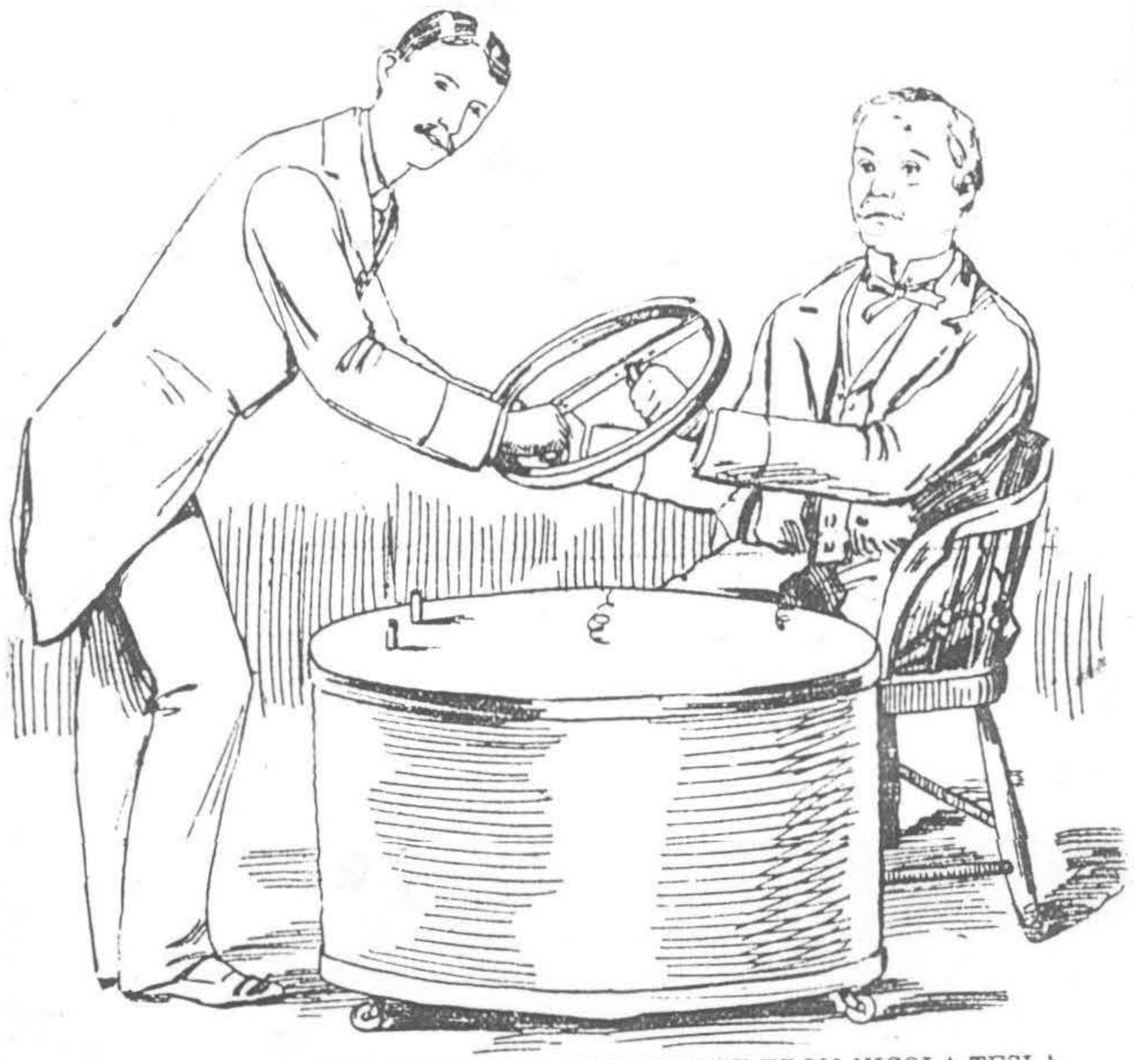
The reporter explained that Mr. Tesla would accept no remuneration for his services, but that his offer was prompted by sympathy and concern.

"But what are these currents like?" asked Mr. Rouss. "Maybe it will kill me!"

The reporter dispelled Mr. Rouss' fears by saying that he had had hundreds of thousands of volts passed through his own body at Mr. Tesla's laboratory without any ill effects.

"Take me to him!" cried Mr. Rouss. "I believe if there is one man in the world who can give me back my eyesight it's Tesla. And if he hasn't got any machine that will do it now, he'll invent one in a year or two!"

The meeting was arranged for yesterday afternoon at 3 o'clock, and when the reporter called at Mr. Rouss' great Broadway store the blind millionaire was anxiously awaiting his arrival.



Mr. Rouss took the reporter's arm, and they started up Broadway together, but had not got past the store even before a crowd of newsboys and street urchins almost blocked the sidewalk.

"Good afternoon, Mr. Rouss!"

"How-de-do, Mr. Rouss?"

"Buy a paper, Mr. Rouss?"

There did not appear to be a man, woman or child on Broadway who did not seem to know him and have a kind word of greeting for him. To rid himself of the crowd of newsboys and gamins that thronged around, Mr. Rouss would now and again thrust his hand into his pocket and bring forth a handful of pennies, which he would toss into the air. A wild scramble would follow as the boys darted between one's very legs almost after the

BROADWAY ROUSS RECEIVING TREATMENT FROM NICOLA TESLA.

TESLA WILL TRY TO CURE ROUSS

(Continued from First Page.)

rolling pennies.

Suddenly Mr. Rouss stopped short, and turned to the reporter.

"Have a drink?"

In spite of his almost total blindness, some occult sense seemed to tell Mr. Rouss of the proximity of a cafe, and in another minute they were both leaning over the bar, the best of friends imaginable.

"Give me the cheapest thing you've got in the house, and"—as the bartender turned toward the reporter—"he'll take the same."

The strangely ordered drink might have been far worse, for the bartender was evidently well posted in Mr. Rouss' wants, and proceeded to concoct a mock champagne a la Rouss.

"It tastes like champagne; it's as good as champagne, and it's so much cheaper," said Mr. Rouss by way of explanation.

For the benefit of the uninitiated, the formula for this rarest of drinks is herewith given: Half a teaspoonful of powdered sugar, one and a half tablespoonfuls of whisky; ginger ale ad libitum.

After this dissipation Mr. Rouss was taken directly to Mr. Tesla's laboratory and there introduced to the great inventor.

"I was so sorry to hear about your affliction," said Mr. Tesla, looking into Mr. Rouss' vacantly staring eyes with a look of genuine concern. "My poor fellow, how dreadful it must be for you! Oh, I do hope I have some means of helping you. Sit down. Before we do anything else I am going to show you some experiments, just to give you an idea of what my work is like."

Then, with the tenderness of a woman, Mr. Tesla led the great merchant to a chair, and in a trice his visitors were transported to Wonderland.

It would be impossible to describe the many wonderful things that the inventor showed Mr. Rouss and the reporter. Electricity no longer seemed a new force, but a living thing, capable of putting life and motion into even inanimate objects.

"If I could only see better, perhaps I would understand more," said Mr. Rouss, "and I would give anything if I could only see you, but it's a privilege to even shake hands with you. I want you to give me a pair of new eyes, and if you can't do it now, you will some day. I want them to be blue eyes, please."

"My poor fellow," answered Mr. Tesla, "I only wish I could. Why don't you go into the country? The green is so restful to the eyes. I am sure that just to be among the waving trees and fair green fields would do your eyes good."

"I wouldn't leave the store; no, not for the world!" said Mr. Rouss. "It would kill me. I get down at 6 o'clock every morning, I leave at 7, and go to bed at 8. No, I couldn't leave the store, even for my eyes. Why, what would you do if you gave up your work and loafed around in the saloons here for even ten days? Why, it would kill you!"

"Yes," sighed Mr. Tesla, "the wretched liquors they sell would, if nothing else."

Then the great table-like spool which gathers the electric currents which Mr. Tesla's dynamoes charge the air with was wheeled in front of Mr. Rouss' chair, and the wire ends began to crackle ominously with the intensity of the current. Mr. Tesla took a hoop of metal in his hands, holding it by one of two handles that were attached to the centre piece. Then, taking Mr. Rouss' one hand in his, he placed the millionaire's other hand on the second handle of the hoop and held it over the huge spool or coil. A lurid flame played about the connection of the handles and hoop, and almost without his feeling it 100,000 volts were shot through Mr. Rouss' body.

"Perhaps," he whispered to the reporter, "you've all got me here to kill me and take my money."

When informed of the intensity of the current he was enduring Mr. Rouss' wonderment knew no bounds.

"That is all," said Mr. Tesla, putting away the hoop. "I merely wanted you to see that there was no pain or danger in the current. I take it constantly myself; and, indeed, don't think I could live without it. Of course, not being a physician, I would not venture to undertake any personal treatment, but what facilities I have are at your disposal. Under the guidance of your specialist, these currents might do good."

Then Mr. Rouss and the reporter left, and when again in the shady cool of the saloon, discussing more fake champagne (the reporter managed to get his hand on the bottle before it left the bar), Mr. Rouss decided to place his case in Mr. Tesla's hands, under the guidance of Dr. William F. Mittendorf, the well-known ophthalmotologist of 140 Madison avenue.

Later, at Mr. Rouss' request, the reporter called on Dr. Mittendorf, and the latter expressed himself as most eager to test the efficacy of these wonderful currents.

"I doubt," said the doctor, "whether they will do much or any good in Mr. Rouss' case, but surely if there is any possible chance it lies in this one direction, and I will do my part with the utmost pleasure."

So the treatment is to be instituted, and the one slender straw that offers eyesight to the erratic millionaire has been held out through the efforts of The Recorder.

Is Tesla to Signal to the Stars?

During the past week a number of the New York dailies contained interviews with Nikola Tesla, which were printed under "scare heads," such as, "May Signal Stars," "We May Signal to Mars." We reprint the following interview from the New York *Sun:*

"I have had this scheme under consideration for five or six years, and I am becoming more convinced every day that it is based upon scientific principles, and is thoroughly practicable. We know that electric disturbances on the sun are productive of similar disturbances on the earth in the form of thunder showers. Now, why is it not equally conceivable that a disturbance on the earth's surface should produce some tangible effect on other planets? The transmission of disturbances on the sun shows beyond doubt that waves of electricity are propagated through all space.

"The objection may be put forward that sufficient electrical disturbance cannot be made on the earth's surface, and that we should be wholly dependent upon thunder storms and other phenomena of nature for the success of our experiment. But, on the contrary, we can make all the artificial thunder and lightning we want. There is no difficulty in making electric apparatus with a spark gap of a mile, and if that did not prove effective it could be increased.

"Do not get the impression," continued Mr. Tesla, "that the success of the experiment is in any way dependent upon the light, noise, or vibration accompanying such an electric discharge. It is wholly through the electricity waves, which are propagated through the atmosphere and the ether beyond, that we may hope to obtain any results. But if there are intelligent inhabitants of Mars or any other planet, it seems to me that we can do something to attract their attention.

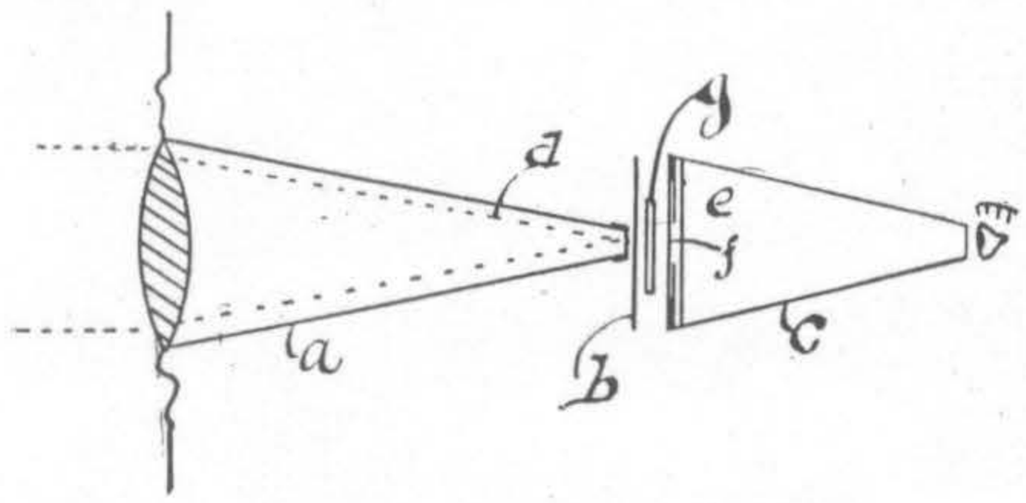
"This, of course, is the extreme application of this principle of the propagation of electric waves. The same principle may be employed with good effect for the transmission of news to all parts of the earth. It was formerly thought that in order to get any power out of electricity a conducting circuit must exist, but it has been shown that the same results may be accomplished with a single wire. It is perfectly possible to operate a motor or an electric light with just a single line of wire leading to the apparatus. It naturally occurred to me that, as the earth is a conductor, an electrical disturbance at one point, causing a change in the equilibrium of the earth's electricity, should be felt at all points on the earth's surface, and might be recorded by properly constructed instruments.

"The possibilities of such a transmission of intelligence cannot be exaggerated. Every city on the globe could be on an immense ticker circuit, and a message sent from New York would be in England, Africa and Australia in an instant. What a grand thing it would be in times of war, epidemic, or panic in the money market!"

Mr. Tesla, says the *Sun*, is at present engaged in finishing his calculations and perfecting the apparatus necessary for experiment in his new field of investigation, and he hopes soon to be able to show the practicability of his plan.

The following we abstract from an interview in the New York *Herald:*

"Years ago, in St. Louis, I delivered an address before the National Academy of Sciences. I then declared it would be possible to use economically the electricity in the atmosphere for lighting and heating, and, of course, for communication between different parts of the earth's surface. The problem was the conservation of electrical energy at the least possible cost to the other elements. That problem, I was confident then, I could solve by my oscillator. At present I am sure it can be done. From my most recent experiments I am convinced that within a very short time we shall be independent of the clumsy methods of generating electricity now in vogue. The electrical fluid in the atmosphere will give energy enough. The same electric envelope of the earth will enable us to send messages from one part of the globe to all other parts in an instant of time. The same element, which I believe to be finite and not confined to this atmosphere, may be used to communicate with the other planets."



The oscillator referred to, it may be explained, is a combined steam engine and alternating-current generator, the piston of the engine being direct-connected to the armature or field of the alternator and oscillating to and fro at a rapid rate. It is consequently difficult to see how the reporters should have imagined it to be capable of such sartling performances.

PHOSPHORESCENCE AS THE SOURCE OF X-RAYS.

BY EDWARD P. THOMPSON, M. E.

ONE of the most important facts necessary in order to determine the nature of the X-rays is that which will prove their source. In the first place Prof. Röntgen alleges that they radiate solely from the phosphorescent spot upon the Crookes tube. Dr. Morton's experiment indicates the same feature. M. Charles Henry thinks he obtained X-rays from a phosphorescent substance, which he exposed to the light. Niewenglowski finds that phosphorescent bodies increase the penetrating power of sunlight like the sulphide of zinc increases that of X-rays. Poincaré at an early date advanced the hypothesis that the rays are due to phosphorescence, whether produced by electrical or other means. Professors Thomson and Rowland maintain that they radiate from the anode. Tesla has obtained effects by a closed bulb without any electrodes. In one of Tesla's experiments, he employed only one and either electrode, while the other was away off in space somewhere, and yet he obtained penetrating power at great distances. He is convinced that phosphorescence is not the source, because he believes that aluminum X-ray tubes do not phosphoresce. He gave no other explanation. Silvanus P. Thompson thinks that certain of his experiments prove that the rays do not come from either the cathode or from the phosphorescent spot individually, but jointly from both.

I have obtained fluorescence from X-rays after they have passed through a fluorescent substance. Experiments have also proved, apparently, that there are no X-rays radiating from the arc light, sun, flames or other sources of light. Other experiments show that although a Crookes tube may phosphoresce, yet no X-rays can be detected. Sometimes the phosphorescent light is local, occuring in spots here and there. It may be near the cathode or anode, or between them, or as in a tube

DETERMINING THE SOURCE OF THE X-RAY.

with which I experimented, the light was practically uniform on the whole surface, and a fluorescent screen was illuminated by all parts of the Crookes tube equally. Experiment also shows that with a given Crookes tube, the penetrating power of the rays seems to depend upon the electromotive force of the electrical energy, all other things remaining the same. Tesla, with his apparatus, has projected them through the thickest part of the human body, so as to affect the photographic plate.

Upon first reading the statement of Prof. Röntgen as to the phosphorescent spot being the source, it occurred to me that phosphorescence by other means might also radiate X-rays, and I was anxious to learn in the most emphatic manner the truth of the matter, whether it ended in negative or positive results. I have, therefore, been carrying out a series of experiments to determine whether ordinary phosphorscence will produce X-rays. Although I obtained negative results, yet the conclusion should not be drawn to the effect that X-rays may not be obtained by phosphorescence produced otherwise than by electricity, because by no possible means imaginable could I cause light to produce upon a Crookes tube the phosphorescence obtainable by the current, which, as well known, is visible even by daylight. Parenthetically, the intensity of light spoken of in text books is a misnomer. The light considered as to its penetrating power at the focus of the lens is no more intense than elsewhere. It will not penetrate anything to any greater distance by being condensed. It merely appears brighter to the eye, because there is more of it upon a given area, or because more of it has penetrated a given substance. The volume alone is greater.

To determine the degree of phosphorescence obtainable upon a Crookes tube by direct sunlight, it was placed inside of a box having an opening covered by violet glass. When the box was looked into, so as to exclude all other light the tube did not even appear green. However, under the same circumstances, uranium glass, barium platino cyanide, also a screen of ammonium uranate, potassium platino cyanide and others, each appeared of a vivid green or yellowish green. The experiment was repeated with focused sunlight on a very large scale, the lens being about five inches in diameter and having a focus of sixteen inches, and provided also with a funnel, white inside, which brought to a focus much diffused sunlight. The small end of the funnel was located in a dark room. The light was condensed upon violet glass.

The light passed through the glass, and, upon striking the phosphorescent and fluorescent materials, its refrangibility was changed; while the substances were as vividly green as when produced by the radiations in the Crookes tube, and, light cannot cause the same phosphorescence upon a Crookes tube did not become green. Uranium glass seemed as bright as when forming a Crookes tube highly charged. The Crookes tube had been before tested, and showed a green phosphorescence with a high electromotive force. The experiment with violet glass, although perfectly simple, and although the results, perhaps, could have been conjectured, proves that sunlight cannot cause the same pohsphorescence upon a Crookes tube as that produced by the current.

Another experiment indicated somewhat otherwise. In the direct focus, without blue glass, a livid green (as when electrified) was discernible as a fringe around the focus.

Inasmuch as the other substances fluoresced better with the violet light than with the electrified Crookes tube, as far as the eye could remember, an experiment was performed with the apparatus shown in the accompanying diagram, in order to determine whether condensed sunlight would produce sufficient phosphorescence for the generation of X-rays. The funnel above described was closed at the small end successively by different phosphorescent and fluorescent substances, b. The instrument which has now become known as the fluoroscope was directed towards the substance, b, which was made phosphorescent or fluorescent by the condensed sunlight, d, in order to detect fluorescence upon the screen, e, within the fluoroscope, which was covered at the large end partly with one thickness, b, partly with two thicknesses, and on another portion by three thicknesses of black paper.

The fluorescent screen, f, appeared green only at the part covered with one thickness. It was brighter without screen, b, which seems to contradict Niewenglowski's result. If there had been X-rays of any appreciable extent, they would have caused fluorescence through the three thicknesses and through a block of wood, g, interposed between the two fluorescent screens outside of the fluoroscope, as illustrated in the diagram. It should be noticed that the fluoroscope was exceedingly sensitive, and yet the results were negative.

The same instrument was tried with a Crookes tube generating X-rays by a current, and it became uniformly luminous at a distance of six feet from the electrified Crookes tube; therefore, it may be concluded, I think, that X-rays cannot be obtained from phosphorescence produced by sunlight. It may be noted that the objects were not placed exactly in focus because they would burn. The funnel, a, was cut off so that the cross sectional area of the path of the condensed rays was about one-fourth of an inch in diameter, and in this case heat absorbing substances were not needed further than that of the lens itself.

Aluminum was substituted for the block of wood, g, but no fluorescence occurred with the fluoroscope. The experiment was modified in a great many different directions; for example, by using the focused light when reflected from the screen, b, although (as the latter was made of a mixture of pulverized fluorescent material and varnish) the fluorescence was caused by reflection from each particle when the light was transmitted by the screen, as well as when reflected therefrom. A gas flame was also employed as a source of light; also sunlight without a lens.

Remembering how a little daylight entering the eye while viewing fluorescence by X-rays nearly neutralized the effect, I thought, perhaps, persistence of vision prevented my seeing any fluorescence which might have been produced through the three thicknesses of black paper, and therefore I applied the most severe test. A photographic plate with a metal ring attached to it was wrapped closely in several folds of black paper and inclosed in an aluminum box, which, in turn, was wrapped in cloth. On the outside of all was fastened a plate of uranium glass, which was exposed to direct sunlight for over seven hours. No effect whatever was produced upon the photographic plate. With X-rays, an effect would have occurred through the same thickness in a few minutes.

A large glass plate covered with calcic sulphide, which remains luminous in a dark room after having been exposed to sunlight, was tested. I exposed the plate to the condensed sunlight, forming a bright, luminous spot, and at another time I exposed the whole plate to sunlight for an hour or more. When the fluoroscope was directed toward it in the dark and certain experiments performed, sufficient light was produced

to illuminate the screen in the fluoroscope, but not through even a single thickness of black paper, but only enough to cast a shadow. Here again the bluish brightness of the luminous paint is not visible in daylight, while a Crookes tube energized by electricity radiates green light abundantly and is easily visible in daylight.

While these experiments do not prove that the X-rays do not have their source alone in the phosphorescence of a charged Crookes tube, yet they form substantial evidence that X-rays are not obtained from phosphorescence by sunlight.

ON THE SOURCE OF THE ROENTGEN RAY.

BY

H. M. Stine

A series of experiments extending over the past six weeks has at length yielded conclusive evidence and enabled the source and distribution of the ray to be mapped out around the entire tube with great clearness. Penumbral shadows were repeatedly plotted back to the tube and invariably pointed to

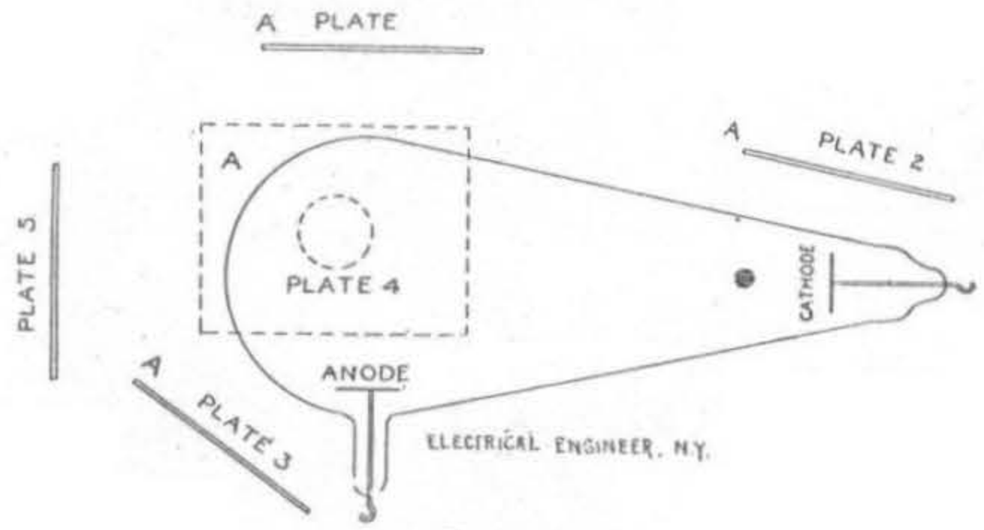


FIG. 1.

the area of the bulb opposite the cathode as the source of the distribution. These observations have already been published.[1]

It occurred to the writer that the best means to trace the ray distribution would be shadows cast by short metallic tubes. Half-inch lengths were cut from No. 18 gauge brass tubing, varying in diameter from ½ inch to 3 inches. In the first experiment, these were placed concentrically on a dry plate and placed parallel with the bulb in position marked 5 in Fig. 1,

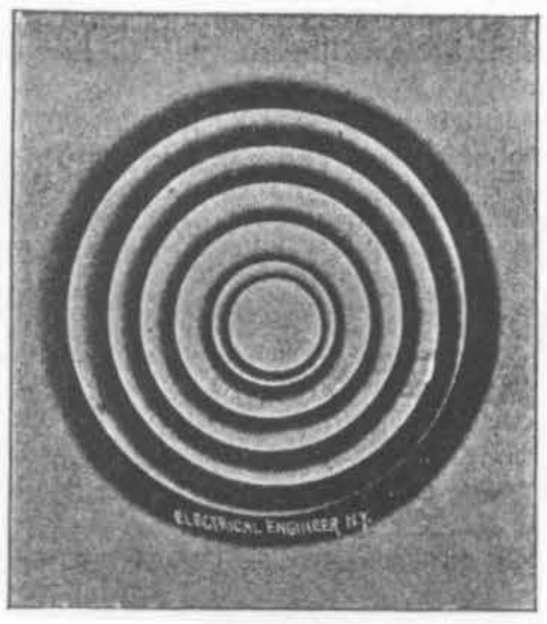

FIG. 2.

the distance of the plate from the bulb being 4 inches. The sciagraph is reproduced in Fig. 2.

Two separate effects are to be noted in all the sciagraphs of the tubes used. Both the length and direction of the shadow are clearly indicated and the vertical shadow of the metal itself. It will be noted that the latter seems to indicate the presence of rays which are more or less vertical. Plotting the shadows in Fig. 2 and noting that the vertical shadow does not appear beyond the third ring, we find that the source of the rays was on the surface of the bulb, and the area of the source was nearly or quite circular, and not much in excess of the diameter of the third ring, which was 1½ inches.

With such a clear and unmistakable result in possession, the next experiment was an attempt to decide whether this area was the only source of the ray. We were guided in this by some recently published emphatic statements that the ray was of anodic origin and did not, as popularly supposed, proceed

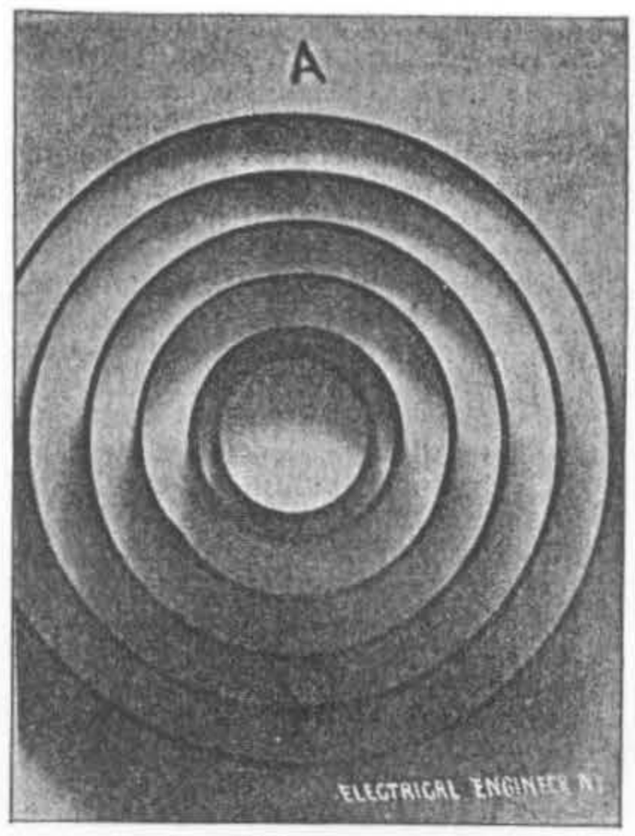

FIG. 3.

from the cathode. It was seen that while a screen could be misleading, the shadows cast by rings would be conclusive. Four plates were prepared for simultaneous exposure. The concentric rings were placed on one plate, and single rings, of 1 inch diameter and same height, were placed over the other plates. All these objects were placed as nearly as possible on the center of the plate. In Fig. 1 is shown the shape of the tube, the position of the electrodes and the plates, which were 3¼ by 4¼-inch in size, and placed 2½ inches from the bulb. The plates were marked with the letter "A" on the ends which were disposed as shown in the drawing. The resulting sciagraph from plate 1, is shown in Fig. 3, that from plate 2 in Fig. 4, from plate 3 in Fig. 5, and from plate 4 in Fig. 6.

To interpret the results, note first the sciagraphic effect of the rings, and second, the elliptical shadows of the intercepted inclined rays. If the latter be plotted, they all point to one area, the circular cathode imprint on the end of the bulb. We may now call this the prime source of the Röntgen ray. The vertical ring shadows, however, indicate numerous secondary and more or less weak sources. A general statement can then be made to the effect that about the entire surface of the tube is sciagraphically active. The four plates were developed to-

FIG. 4.

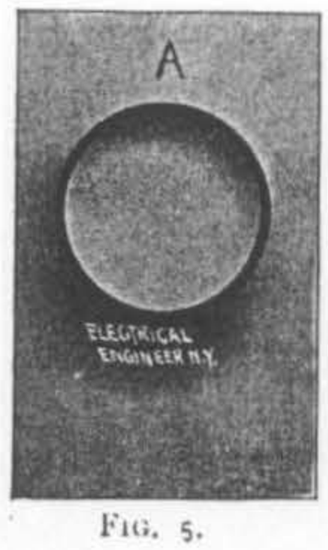

FIG. 5.

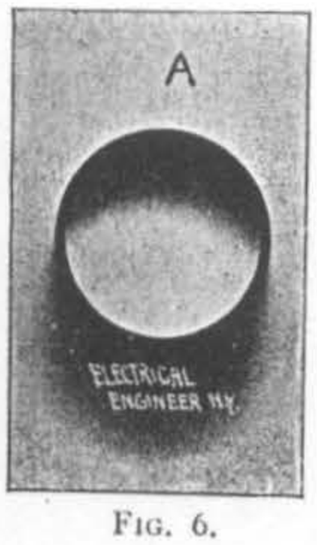

FIG. 6.

gether for an equal length of time. Plates 1 and 3 developed soonest, 4 a little slower, and the image on 2 was the last to appear. The resulting negatives are, however, all excellent and of about equal density. It is thus shown that a number of sciagraphs may be taken simultaneously if the entire tube be surrounded by plates. It might be added that the rings in Fig. 3 were held in concentric position with wedges of pine wood one-half inch thick, and since these do not show, they were entirely transparent for this length of exposure.

COMMENT ON TESLA'S WORK.

VIEWS OF EMINENT PHYSICIANS AND SCIENTISTS ON TESLA'S ARTICLES ON ROENTGEN RAYS.

The articles from the pen of Nikola Tesla that have appeared in the ELECTRICAL REVIEW attracted a great deal of attention, particularly in the scientific world. They were widely quoted in the press of this country and abroad, and were probably seen by every person in the world interested. The New York *Times* interviewed a number of gentlemen in relation to Tesla's discoveries, and we quote below from its columns.

Dr. Cyrus Edson, formerly health commissioner of New York, when asked by the reporter about Tesla's deductions, said that he had been much interested in the subject and had given it considerable attention. Said he:

It is an undoubted fact that you can decompose certain chemicals by means of light. The principle of photography rests upon this fact. These X rays decompose the chemicals with which the film is sensitized and effects this decomposition through what have hitherto been regarded as opaque bodies, such as the hand, for instance. Light in vibration, and it has been demonstrated that these X rays, will pass through an opaque body. That these vibrations in passing through the skull should affect the delicate nerve tissues of the brain and stimulate them is a perfectly natural result. This accounts for the sensations experienced by Tesla when he exposed his head to a powerful radiation. But there is no more reason to believe that the X rays will carry a medicinal agent through the body and into the distant spot, the seat of disease, than that a ray of light will be able to project such a chemical on to the surface of the body.

The theory of the vibrations of light is not a new one. It originated with Sir Isaac Newton, who believed that luminous bodies shot out infinitely small particles in straight lines, which, by penetrating the transparent parts of the eye and falling on the nervous tissue, produced vision. Other philosophers drew a parallel between the properties of light and those of sound, and considered that, as sound was certainly the effect of vibrations, or little waves projected through elastic bodies, so light might be nothing more than the consequence of similar vibrations transmitted with inconceivable velocity through a highly elastic medium. The wave hypothesis of light is at present generally adopted simply because it is in harmony with all the known phenomena discovered since the time of Newton. The deductions of Tesla as the result of his experiments are absolutely in harmony with the Newtonian theory. We can certainly expect some marvelous results from the X rays—things not even dreamed of yet. I believe that they will prove a valuable adjunct to medical science, and I think that the ultra-violet rays will be sooner or later obtained by passing ordinary sunlight through certain media, without the agency of electricity.

Dr. J. Mount Bleyer, who has taken great interest in determining the effects of all light rays on animal and vegetable life, said:

I am not at all surprised at the results of Tesla's experiments. I have been experimenting for some time with the associated-light rays—the sunlight and the different colors, such as blue, red and orange—in connection with the treatment of infectious diseases and vegetations. The results obtained by Tesla are simply marvelous, but are just what I expected. I have contended from the beginning, and it has now been proved beyond a doubt by Tesla, that this bombardment of particles does pass through glass and other materials at an enormous velocity. As far as the therapeutic effects of the rays are concerned, they may be likened in some way to a massage effect, if they do not form a high class of bactericidal agent. Solariums for the treatment of infectious diseases, with associated-light rays, will no doubt be the next advance in hospital architecture. I have made a number of experiments with the associated-light rays in hospitals and among my private patients in cases of phthisis and tuberculosis. I have resorted to the treatment wherever it was possible, and never failed to obtain the best results. Ordinary light is one of the main factors in the growth of animal life. We know that sunlight is essential for the growth and development of both animal and vegetable tissue. We have in light a therapeutic agent that has been underestimated and neglected, and which should be taken up and thoroughly studied.

Ogden N. Rood, professor of physics in Columbia College, after glancing through the article by Nikola Tesla, dictated to a New York *Times* reporter the following statement of his views:

It is never proper to frame a new hypothesis in order to account for discoveries when an old and well-established theory is capable of giving them an explanation. Our knowledge of the waves of light, of radiant heat, and of the ultra-violet rays is confined within narrow limits. Thus far, according to our previous experience, the shorter the length of the wave the more it will be bent or refracted by substances in general. It, however, does not at all follow that this will hold good if the length of the wave is shortened to a degree beyond our experience. On the other hand, it is highly probable that, if this shortening process goes on till the length of the wave has become of the same order of magnitude with the molecules of matter, the effect in the matter of refraction will diminish. This would account for the fact that no one has succeeded thus far in refracting or reflecting the Roentgen rays. In my own experiments I have so far found them to act in the same general way with waves of ordinary light, and I am inclined to believe that they are simply waves of light of unprecedented shortness. This view necessarily excludes all idea of a molecular bombardment outside of the Crookes tube. I believe that it will be eventually demonstrated that the Roentgen rays are capable of reflection and refraction, although it will require more delicate work than has thus far been extended in this direction.

[*From the Western Electrician, March 21, 1896.*]

To many investigators who have been experimenting with X rays, the most important feature of Tesla's communication in the ELECTRICAL REVIEW last week was his reference to the influence of these rays upon a living subject. He said:

By exposing the head to a powerful radiation strange effects have been noted. For instance, I find that there is a tendency to sleep and the time seems to pass away quickly. There is a general soothing effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time.

This is a point that has been noted by other experimenters, and it has led to much speculation as to the possible effect of these rays upon the physical organism, although the subject has not received the consideration which it seems to be entitled to. But now that Tesla has called attention to it there is a probability that it will be given more attention, especially as he suggests that "it may be possible by these strange appliances to project a suitable chemical into any part of the body." He is not confident by any means of the correctness of his views, though, as he says, "Should these remarkable effects be verified by men with keener sense of observation, I shall still more firmly believe in the existence of material streams penetrating the skull."

The announcement of these conclusions by Tesla has already excited comment. Professor Stine does not agree with his eastern contemporary, and in an interview takes the ground that thus far not a single experiment has been made to show that the X ray has any physiological effect. He says that it has been tried on microbes without apparent result, and claims that the peculiar vibratory motion and the heat Tesla speaks about are much more noticeable when the tube does not give off the X ray than when it is in perfect working order. His conclusion is that "the pulsations one feels when making a sciagraph of the hand, for instance, are no doubt the effect of heat and the external change of electricity on the air." Concerning the suggestion that the X ray may be utilized to project chemicals into the human system, Professor Stine says that he can find no authority for such an opinion in the accepted theories of to-day.

[*From Leslie's Weekly, New York, April 2, 1896.*]

None of the scientists who have made practical investigations as to the scope and value of the Roentgen ray discovery have reached more important or wonderful results than Nikola Tesla, the well known inventor. Communication from him, recently published in the ELECTRICAL REVIEW, which is the organ of the best scientific thought and literature of the time, mentions some of the results of his experiments in radiography.

[*From The Independent, New York, March 26, 1896.*]

We might expect from Nikola Tesla the most intelligent discussion of the new Roentgen rays, but we were not prepared for his announcement in the last week's ELECTRICAL REVIEW. He says he is now producing strong shadow pictures at a distance of 40 feet, and he finds it necessary to guard the plates in his photographic department on the floor above, and 60 feet away, from being spoiled by long exposure to strong rays. * * * In the rapid development, by the concurrent labors of hundreds of students, of the discovery of Professor Roentgen, we see the advantage which comes, in science, from that fine and generous ambition which leads scholars to hasten to give to the world the results of their discoveries, that others may make applications and improvements.

RADIOGRAPHY.

The ELECTRICAL REVIEW presents to its readers this week an unusually brilliant symposium of literature on the latest developments in radiography. Mr. Tesla supplements his previous communications to this journal with further remarks on his very interesting and valuable scientific work. The results achieved by Professor Enrico Salvioni, of Perugia, Italy, are chronicled by a well-known newspaper man who interviewed him for the ELECTRICAL REVIEW. Messrs. Scribner and McBerty, of Chicago, send us an important communication on the source of the X rays, on which Prof. Elihu Thomson makes some very interesting comments, and at the same time refers to his own work in a similar direction. Altogether, the past week has been a very interesting one as far as the X rays are concerned, and as usual the ELECTRICAL REVIEW presents the latest thought and achievement of the brightest minds that are at work on this very interesting topic. Our readers will appreciate the fact that while the real source and nature of the X ray are still a matter of speculation and doubt, important practical results have already been achieved in the development of Salvioni's cryptoscope and Edison's fluoroscope. These are probably but the primary steps in the evolution of a device which will be of untold value in the future practice of surgery and medicine. In the meantime the ablest minds in the electrical field are steadily at work endeavoring to determine the nature of a phenomenon which, according to at least one experimenter, enables solids to pass through solids.

Hardly had Tesla announced the important results of his investigations on reflection when he followed it up with a practical demonstration of the value of these results, as will be seen from the illustration on another page. The time is materially reduced, and a distance of four feet is, for such a radiograph, really remarkable, and shows the extraordinary performances of the Tesla coil. While the results which he describes in his present communication are very wonderful, there is still to be considered his statement, before made, that he is availing himself at the present time of only a small part of the capacity of his apparatus. The impressions obtained with short exposures by the help of a phosphorescent powder are not the less interesting and remarkable.

TESLA ON ROENTGEN RADIATIONS.

To the Editor of Electrical Review:

Having observed the unexpected behavior of the various metals in regard to the reflection of these radiations, as communicated in your issue of April 1, I have endeavored to settle several still doubtful points. As, for the present, it appeared chiefly desirable to establish the exact order of the metals, or conductors, in regard to their powers of reflection, leaving for further investigation the determination of the magnitude of the effects, I modified slightly the apparatus and procedure described in my communication just referred to. The reflecting plates were not made each of one metal, as before, but of two metals, the reflective power of which was to be compared. This was done by fastening upon a plate of lead the two metal plates to be investigated, so that the reflecting surface was divided in two halves by the joining line. Furthermore, to prevent any spreading and mingling of the rays reflected from both halves, I divided the lead box into two compartments by a thick lead plate through the middle. Care was taken that the density of the rays falling upon the reflecting surfaces was as uniform as possible, and with this object in view the glass tube surrounding the bulb was lifted up so as to just expose the half-spherical bottom of the latter. The bulb was placed as exactly as it was practicable in the center, so that both halves of the reflecting plate were equally exposed to the radiations.

Having failed to obtain, in former experiments, a record for iron owing to an oversight, I tried to ascertain its position in the series by comparing it with copper, using a plate made up of iron and copper. The experiments showed that iron reflected about as much as copper, but which metal reflected better was impossible to determine with safety by this method. Next I endeavored to find whether tin or lead was a better reflector, by the same method. Three experiments were performed, and in each case the metals behaved nearly alike, but tin appeared just a trifle better. Finally I investigated the properties of magnesium as compared with zinc. In fact, the experiments showed that magnesium reflected a little better.

I am not yet satisfied, in view of the importance of this relation of the metals with the means employed, and will try to devise an apparatus which will do away with all the defects of the present. The time of the exposure I have found practicable to reduce to a few minutes by the help of a fluorescent paper.

In my previous communications I have barely hinted at the practical importance of the use of suitable reflectors. One would be apt to conclude that, since, under the conditions of the previously described experiments, zinc, for instance, reflected only three per cent of the incident rays, the gain secured by the employment of such zinc reflector would be small. This, of course, would be an erroneous conclusion. First of all it should be remembered that in the instances mentioned before the angle of incidence was 45 degrees, and that for larger angles a much greater portion of the rays would be reflected. The exact law of reflection is still to be determined. Now, let us suppose the shadow of an object is taken at a distance, D. In order to get a sharp shadow we must take this distance not less than two feet, and I am finding it more and more necessary to adopt a still greater distance. If, for the sake of simplicity, we assume a spherical bulb and electrode, the radiation will be uniform on all sides, and any element of a surface of a sphere of radius D, drawn around the electrode, will receive an equal quantity of rays. The total surface of this sphere will be $4\pi D^2$. The object, the shadow of which is to be taken, may have a small area a, which gets only an insignificant part of the total rays emitted, this part being given by the proportion $\frac{a}{4\pi D^2}$. In reality we can not assume less than $\frac{a}{D^2\pi}$ as effective ratio, but even then, if D is very large and the object, that is, the area a, small, this ratio may be still so small that evidently, by the use of a proper reflector, we can easily concentrate upon the area a an amount of rays several times exceeding that which would fall upon it without the use of a reflector, in spite of the fact that we are able to reflect only a few per cent of the *total* incident rays.

As an evidence of the effectiveness of such a reflector, the annexed print of the shoulder and ribs of a man is shown. A funnel-shaped zinc reflector, two feet high, with an opening of five inches on the bottom and 23 inches at the top, was used in the experiment. A tube, similar in every respect to those previously described, was suspended in the funnel, so that just the static screen of the tube was above the former. The exact distance from the electrode to the sensitive plate was four and one-half feet. The distance from the end of the tube to the plate was three and one-half feet. The exposure lasted 40 minutes. The plate showed very strongly and clearly every bone, and shoulder and ribs, but I can not tell how clearly they will appear in the print. I selected the same object as in my first report in your columns on this investigation, so as to give a better idea of the progress made. The advance will be best appreciated by stating that the distance in this case was much more than double, while the time of exposure was less than one-half. The chief importance of a reflector consists, however, in this, that it allows the use of many bulbs without sacrifice of precision and clearness, and also the concentration of a great quantity of radiation upon a very small area.

Since the use of phosphorescent or fluorescent bodies in connection with the sensitive film has been suggested by Professors Henry and Salvioni, I have found it an easy matter to shorten the time of exposure to a few minutes, or even seconds. So far, it seems that the tungstate of calcium, recently introduced by Edison, and manufactured by Messrs. Aylsworth & Jackson, is the most sensitive body. I obtained a sample of it and used it in a series of tests. It fluoresces decidedly better than barium-platinocyanide, but, owing to the size of the crystals and necessarily uneven distribution on the paper, it does not leave a clean impression. For use in connection with the sensitive films, it should be ground very fine, and some way should be adopted of distributing it uniformly. The paper also must adhere firmly to the film all over the plate, so as to get fairly sharp outlines. The fluorescence of this body seems to depend on a peculiar radiation, because I tested several bulbs, which otherwise worked excellently, without producing a very good result, and I almost gained a false impression. One or two of the bulbs, how-

(Concluded on page 186.)

TESLA ON ROENTGEN RADIATIONS.

(*Concluded from page 183.*)

ever, effected it very powerfully. An impression of the hand was taken at a distance of about six feet from the bulb with an exposure of less than one minute, and even then it was found that the plate was overexposed. I then took an impression of the chest of a man at a distance of 12 feet from the end of the tube, exposing five minutes. The developed plate showed the ribs clearly, but the outlines were not sharp. Next, I employed a tube with a zinc reflector, as before described, taking an impression of the chest of an assistant at a distance of four feet from the bulb. The latter was strained a little too much in this experiment and exploded, in consequence of the great internal pressure against the bombarded spot. This accident will frequently occur when the bulb is strained too high, the preceding outward sign being an increased activity and vapor-like appearance of the gas in the bulb and rapid heating of the latter. The process causing the abnormal increase in the internal pressure against the glass wall seems to be due to some action opposite to that noted by Crookes and Spottiswoode, and is very rapid, and for this reason the experimenter should watch carefully for these ominous signs and instantly reduce the potential. Owing to the untimely end of the bulb in this last described experiment, the exposure lasted only one minute. Nevertheless, a very strong impression of the skeleton of the chest, showing the right and left ribs and other details, was obtained. The outlines, however, were again much less sharp than when the ordinary process without the phosphorescent intensifier was followed, although care was taken to press the fluorescent paper firmly against the film. From the foregoing it is evident that, when using the above means for shortening the time of exposure, the thickness of the object is not of very much consequence.

I obtained a still better idea of the quality of tungstate of calcium by observing the effect upon a fluorescent screen made of this chemical. Such a screen, together with a paper box, has been termed with the fanciful name "fluoroscope." It is really Salvioni's Cryptoscope with the lens omitted, which is a great disadvantage. To appreciate the performances of such a screen, it is necessary to work at night, when the eye has for a long time been used to the darkness, and made capable of noting the faint effects on the screen. In one instance the performance of this screen was particularly noteworthy. It was illuminated at a distance of 20 feet, and even at a distance of 40 feet I could still observe a faint shadow passing across the field of vision, when moving the hand in front of the instrument. Looking at a distance of about three feet from the bulb through the body of an assistant, I could distinguish easily the spinal column in the upper part of the body, which was more transparent. In the lower part of the body the column and the rest were practically not perceptible. The ribs were only very faintly seen. The bones of the neck were plainly noticeable, and I could see through the body of the assistant very easily a square plate of copper, as it was moved up and down in front of the bulb. When looking through the head I could observe only the outline of the skull and the chin-bone, yet the field of vision was still bright. Everything else appeared indistinct. This shows that improving of fluorescence will not aid us very much in the examination of the internal parts of the body. The solution rather will come through the production of very powerful radiations, capable of producing very strong shadows. I believe I have indicated the right way to secure this result. Although it must be admitted that the performance of such a screen is remarkable with the appliances I have used, I have, nevertheless, convinced myself of its still limited value for the purpose of examination. We can distinguish the bones in the limbs, but not nearly as clearly as a photographic impression shows it. Eventually, however, with the help of strong radiations and good reflectors, such fluorescent screens may become valuable instruments for investigation. A few weeks ago, when I observed a small screen of barium-platino-cyanide flare up at a great distance from the bulb, I told some friends that it might be possible to observe by the aid of such a screen objects passing through a street. This possibility seems to me much nearer at present than it appeared then. Forty feet is a fair width for a street, and a screen lights up faintly at that distance from a single bulb. I mention this odd idea only as an illustration of how these scientific developments may even affect our morals and customs. Perhaps we shall shortly get so used to this state of things that nobody will feel the slightest embarrassment while he is conscious that his skeleton and other particulars are being scrutinized by indelicate observers.

Fluorescent screens afford some help in getting an idea of the condition of the bulb when working. I hoped to find some evidence of refraction by means of such a screen, placing a lens between it and the bulb, and varying the focal distance. To my disappointment, although the shadow of the lens was observable at a distance of 20 feet, I could see no trace of refraction. The use of the screen for the purpose of noting the effects of reflection and diffraction proved likewise futile.

NIKOLA TESLA.

New York, April 6.

TESLA'S RADIOGRAPH OF A MAN'S SHOULDER AND RIBS THROUGH CLOTHING BY MEANS OF A REFLECTOR.—EXPOSURE FORTY MINUTES, DISTANCE FOUR FEET.—IMPRESSION PRODUCED WITHOUT A PHOSPHORESCENT INTENSIFIER. (SHIRT BUTTON ON TOP OF SHOULDER PLAINLY SHOWN.)

The New York Tribune April 9, 1896

MADE WITH REFLECTED X RAYS

MR. TESLA GETS SOME REMARKABLE PICTURES—IMPROVED METHODS.

Undeterred by Professor Röntgen's statement that he had been unable to change the course of the X rays when the latter had once been generated, many other scientists have undertaken to do so. Several weeks ago Nikola Tesla reported that he had succeeded in such an attempt. Only about 2 per cent of the invisible radiance was reflected from the copper plate employed by Mr. Tesla; the rest of it proceeded uninterruptedly. Since that time he has experimented with several other metals, and he tells "The Electrical Review" (New-York) this week that a surface of magnesium or zinc held at an angle of 45 degrees with the path of the rays will reflect about 3 per cent. "For larger angles," he adds, "a much greater portion of the rays would be reflected."

An important practical application of this discovery has been made by Mr. Tesla. Instead of using a flat plate he shapes his zinc into a funnel. Such a reflector, of course, works very much like a concave mirror. The vacuum tube by means of which the X rays developed was placed very near the centre of the mouth of the funnel. In this way he concentrated the radiance upon the object to be photographed, and produced not only a sharper image, but more rapid results than if no reflector had been employed. He estimates that there is a smaller waste of energy under these circumstances.

One of the pictures taken by Mr. Tesla with reflected X rays shows the ribs, collar-bone, shoulder-blade and upper arm of a man with great distinctness. The plate was exposed for forty minutes, which is only half the time required for an earlier photograph of the same subject at a shorter distance, but without a reflector. In the more recent skiagraph, moreover, the bones are clearly outlined, instead of being hazy streaks. Obviously, for purposes of surgical diagnosis, this is a notable gain.

The New York Herald April 10, 1896

CAN SEE THROUGH A MAN.

Nikola Tesla's Remarkable Achievements with the X Rays and a Luminous Screen.

Nikola Tesla, who was among the first to experiment with the Roentgen rays and who achieved some remarkable results, has an interesting article in the current number of the Electrical Review, in which he describes in detail his recent experiments. As a result of them he says he can see clear through the human body.

Tesla's ambition has been to develop electrical power enough to enable the rays to fully illumine the human body, and thus enhance their value to surgery. He shadowgraphed a man's ribs and the bones of his shoulder and arms some time ago, but he was not satisfied with the picture, because it failed to show the bones distinctly. This result, he says in his article, he has just obtained, and he has a shadowgraph in which the bones appear clearly outlined. This picture was taken four feet from the vacuum tube and after a comparatively short exposure.

An equally satisfactory shadowgraph, Mr. Tesla says, was obtained at a distance of twelve feet from the vacuum tube and after an exposure of only five minutes.

But the interesting portion of Mr. Tesla's article is that in which he tells how he was enabled to see through a man's body. He did this with the aid of a luminous screen, somewhat on the principle of Edison's fluoroscope, recently described in the HERALD. In the fluoroscope Edison used tungstate of calcium crystals only; in his luminous screen Tesla used these crystals, with barium platinum cyanide. The man through whom Tesla looked was placed between the luminous screens and the vacuum tube. Tesla says that when he looked at the screen it made the man's body luminous, so that he distinctly saw his backbone and all the details of his skeleton. A metal plate placed on the man's back and a coin were also, he says, revealed. This screen, he says, fluoresces at a distance of twelve feet from the rays.

Mr. Tesla says these remarkable effects were produced by reflecting the rays and contracting them in a funnel. Mr. Tesla is still pursuing his researches and expects to obtain even more sensational results soon.

Electrical Progress.

NICOLA TESLA is credited with a statement last week that he was satisfied he had a machine, which, when perfected, would enable him to make practical experiments in distributing electric waves about the earth so that messages might be conducted to all parts of the globe simultaneously. He believed that electric waves might be propagated through the atmosphere and even the ether beyond, a disturbance of the waves at any point being instantly felt at every point along them. He declared that he believed that the transmission of news about the earth by electric waves in the place of wires was no longer a dream.

Louisville Courier Journal April 12, 1896

Three Great Inventors.

What Is Going On In the Laboratories of Edison, Tesla and Moore Great Improvements In Electric Lighting Are Promised—Cheap and Effective Illumination.

(Correspondence of the Courier-Journal.)

New York, April 10.—We are soon to have electric lights so cheap that any one can afford to have them. At least, this is the promise of three noted electricians who have been working on the problem for some time past. The fact that Thomas A. Edison and Nikola Tesla are two of the three referred to, gives strong assurance that we may look for a revolution in our system of illumination in the near future. It begins to look as if the gas companies would be distanced this time, despite the discovery of the new method of producing acetylene, and will not be able hereafter to manufacture light for the million, as they have done in days gone by.

I had occasion to pay a number of visits to the laboratory of Mr. Edison near Llewellyn Park, N. J., within the past month, in order to find out how he was progressing in his experiments with the wonderful Roentgen rays, which seem to respect neither substance or shadow but go through everything. It was on one of these trips that I learned from Mr. Edison' own lips how he had practically succeeded in improving his incandescent lamp so that he could run twenty of them for each horse-power used. This is a distinct gain of 33 1-3 per cent., as at present only fifteen lamps can be run per horse-power.

"I started out with ten incandescent lamps per horse-power," said the Wizard, "and after a while succeeded in bringing these up to such a state of perfection as to string fifteen of them on a line for each horse-power employed. Now I have practically succeeded in improving my incandescent lamp so that I can put twenty lamps where I could use only fifteen before."

"Then you are not experimenting with etheric or phosphorescent lighting." I said.

"No," replied Mr. Edison. "I believe that the incandescent lamp can be improved so that it will give as good light at as small a cost as anything in the market. Besides, I don't take any stock in these graveyard lights that some electricians are experimenting with. The incandescent lamp sends out as soft and mellow a light as could be expected; it is quite adequate for all practical purposes."

"Would you care to say just how you have improved your new lamp?"

"Not just yet. I have still some finishing touches to make on it. You see, when Prof. Roentgen made his wonderful discovery of the X rays, I dropped everything in order to repeat the experiments here. These rays open up wonderful possibilities in the electrical world, and may make it necessary for us to completely reconstruct the undulatory theory of light. Just think where we are now! Photographing through wood and metal, talking by telephone a thousand miles away, telegraphing under the ocean despite of storm and tempest—why, one of these days we shall perhaps see by electricity."

Of course, it is idle to look for the improved incandescent lamp until Mr. Edison gets tired of his investigation of the Roentgen rays. The truth is, when the great electrician begins to experiment in any one line, he sticks to his work as close as a hen does to her nest, when she is hatching out a lot of eggs. He has eyes and ears only for the subject in hand, and nothing can take him away from his work. He even dreams over his theories—that is, when he takes time to sleep, for sometimes he will continue right along in his laboratory for three days at a stretch without shutting an eye.

"You will keep your carbon filament in the improved incandescent lamp, and not dispense with it as Tesla proposes to do?" I asked.

"Oh, yes," he replied. "No need of changing that now. I had quite a time finding it; I searched all over creation. They are using cellulose now, but it isn't much cheaper than the Japanese bamboo splints that I first used."

"Then you think your latest improvements will cheapen electric lighting?" I asked again.

"I don't see how it can help it," replied Mr. Edison. "If I can run twenty lamps where I now use only fifteen, don't you see that there will be considerable saving."

"Have you taken out your patents yet?"

"No—nor shall I. I don't believe in getting things patented any more. It doesn't protect you. The only safe way is to keep the secret yourself as far as possible."

And the great electrician hereupon began to experiment with a telephone, in the hope of transmitting the Roentgen rays by wire to any distance, just as in the case of sound waves. As he did so, he added:

"Faraday could only turn the most delicate needle at first with his electrical current; yet to-day an electrical engine is hauling a train of forty cars. You must not despise the day of small beginnings."

Nikola Tesla is almost as prominent a figure in the electrical world as the "Wizard of Menlo Park." He is the man who allowed 250,000 volts to pass through his body, who discovered the art of transmitting electricity without a wire, and who has promised to make sunshine as soon as he can safely care for the 8,000,000 volts necessary for that purpose. His laboratory on South Fifth avenue was burned down a year ago, and he lost a great many valuable instruments for experimental purposes, some of which can never be replaced. This is why the world has not heard so much of Mr. Tesla during the past year. Those of his friends who have been permitted to witness his late experiments at the new laboratory on East Houston street, say that he has made some remarkable discoveries which will soon be announced.

I had a pleasant chat with Mr. Tesla the other day, and learned from him that he has about perfected his new phosphorescent light, which will come as near artificial daylight as anything yet attempted. There will be no filament in the glass bulb; nevertheless, it will glow with all the brilliancy of an arc light. The current employed will be of low voltage, but it will be changed into one of high potential by induction coils. In this way three improvements will be affected over the present incandescent lamps—brighter illumination, no deadly wires and cheaper cost.

Mr. Tesla is not yet ready to give to the public the details of his wonderful invention, but those who have seen the new light say that it will work a revolution in methods of illumination. Some remarkable photographs have already been obtained from it. It is stated that the cost will be scarcely one-half of the rates that at present prevail.

Mr. Tesla had a somewhat amusing experience not long ago in this connection. In the course of his experiments he accidentally discovered that rapid vibration has physiological effects on the human body. That a sick man, for example, may be so shaken up as to be cured of his ailments. Mr. Tesla thereupon made an "oscillator" a sort of platform which produces very rapid mechanical vibrations, and tried it upon some of his friends, Hon. Abram S. Hewitt among others. The "oscillator" worked like a charm, and some one put a squib in the papers about it which went the rounds of the country. Very soon Mr. Tesla was deluged with letters by people who wanted to be "shaken up." It seemed as if half the human family had torpid livers.

Mr. Tesla's experience in this respect was duplicated by Mr. Edison. As soon as it became generally known that the Wizard had been able to photograph through boards and the human body, letters poured into Llewellyn Park from all over the country, stating that the writers had needles, bullets or foreign substance in them. "I had no idea," said Mr. Edison, "that the country had so many patriots with bullets in their bodies. It seems from my mail as if every other person must have got hit with a stray shot."

The third electrician who is grappling with the problem of cheap illumination is Mr. D. McFarlan Moore, who claims to have solved the secret of the fire-fly. Following close upon the heels of Roentgen's rays, the discovery promises to work a revolution in electric illumination, and foreshadows an era of one unbroken day.

Mr. Moore is comparatively unknown to fame. For several years past he has been quietly at work in his Newark laboratory—which, curiously enough, is within a stone's throw of Edison's old place—and success seems at last to have crowned his efforts. He calls the new kind of illumination "etheric lighting" for want of a better name, and employs only the most simple apparatus to manufacture it. Indeed, like Roentgen's rays, the wonder is that some electrician has not before this time hit upon Mr. Moore's discovery. It is certainly as simple as it is remarkable in the effects produced. Not only is it the nearest approach to the production of light without heat that the world has yet seen, but the whole illumination is obtained from an ordinary current of low voltage.

There are no hairpin filaments in Mr. Moore's system, as with the incandespoint his walking stick in the air in any direction, as Franklin did with his lightning rod, and the electric fire will come down and illuminate the place. It doesn't matter which way the stick is pointed, he will be sure to get light sufficient to find his way upstairs.

Neither of the inventions I have just described has been placed on the market as yet, but they are liable to make their appearance almost any day. Meanwhile the oil trusts, the acetylene trusts and some of the big electric light companies would do well to be on the lookout for cheap illumination, for it is bound to come. Three electric experts have said it, and it is greatly to their credit. Perhaps we shall soon be even better off than the people at the North Pole. They have daylight half the year, whereas we are now promised artificial daylight for every hour in the twenty-four.

FRANCIS LEON CHRISTMAN.

ROENTGEN RAY LAMPS AND OTHER EXPERIMENTS.

BY

Thomas A. Edison.

A VACUUM tube, the inner portion of which has fused to it crystals of tungstate of calcium when exhausted to the X-ray stage, gives out scarcely any of the rays; on the other hand, the tubes shine with a splendid white fluorescence. We have here a true fluorescent lamp, possibly commercial, as a very small bulk gave in the photometer 2½ candle power with an extremely small amount of energy. The white light is of a character not unpleasant, but quite the contrary. The spectroscope reveals the reason; the spectrum has strong red rays.

Tubes with aluminum electrodes become coated with transparent aluminum, which, as time goes on, gets so thick as to become visible. The X-ray is greatly diminished, not, I think, so much on account of absorption of the wave after generation, but through lack of elasticity, the concussive action or energy being absorbed by deforming the aluminum.

Silicon carbide is a conductor for high-tension current, a fact previously noted by Tesla. It is a very good conductor. I have substituted pieces of the carbide for aluminum; no air comes therefrom; it does not absorb air; it cannot be melted, nor does it blacken the glass. The voltage can be increased to a point where the glass melts. It may possibly prove the most practical substance for electrodes in high vacua. The only difficulty is the contact between the carbide and platinum wire.

With all glass used for making bulbs the sodium line shows in the spectroscope; there is evidently a decomposition due to the current, electrolytic or otherwise. Combustion tube glass has the least; lime soda glass, that is, the glass used for dry plate photography, has the most. This latter glass is the most transparent to the X-ray, but the continuous decomposition of the glass makes it almost impossible to maintain a vacuum except when connected to the pump, and even then the effect of the current is greater in producing gas than the capacity of the pump to exhaust, but the ray is very powerful.

Experiments were made with over twelve hundred substances in the form of crystals and precipitates. Not one fluoresces through thick cardboard when the sources of energy are the arc light, a six-inch spark in air, a vacuum tube with vacuum so high that a ten-inch spark leaves it dark, and the direct rays of the sun from 11 till 2 p. m.

Another fact supporting the theory that the X-ray is a wave due to concussion is that crystals of calcium tungstate are very sensitive to agitation or slight friction, giving off light. It is also of interest to note that by a properly arranged sensitive flame and phonographic listening tubes, my assistants have made it responsive to the X-ray.

ARE ROENTGEN RAY PHENOMENA DUE TO SOUND WAVES?

BY PROF. WM. A. ANTHONY.

THE observations of Mr. Edison, recorded in his article in The Electrical Engineer of April 8, do not appear to me to warrant the conclusion at which he arrives. It is well known that sound shadows are not as sharply defined as light shadows and the reason is that the wave lengths of sound are very great compared to those of light. The shorter the wave lengths the sharper should be the shadows; that is, the less should the geometrical shadow be encroached upon by the radiant energy. Now the geometrical shadows for apparatus arranged as in Edison's Fig. 1 would be included between the lines a a'. Rays deflected into the shadow, as shown in that figure, could not have been due to a true difraction, but must have been due to some other cause.

The experiments of Le Conte, to which Mr. Edison refers, so far from warranting the conclusion that Edison draws from his own experiment seem to me to show that Edison's result could not be due to diffraction, and therefore has no bearing upon the question as to the nature of the Röntgen radiations. Le Conte's experiments show comparatively sharp sound shadows. Even at a distance of twelve feet from the pile, only one foot in diameter, casting the shadow, there was no apparent penetration within the geometrical boundary. If any such effect as Edison shows had occurred, the shadows should have been completely obliterated at one foot behind the pile.

The beautiful experiments of Professor Stine and of Scribner and M'Berty indicate a straight line propagation of the Röntgen radiations, and go far to prove that the result obtained by Edison must have been due to some other cause than that to which he ascribes it. These experiments were admirably adapted to demonstrate th source of the Röntgen rays, and led us back to the conclusion originally announced by Röntgen himself, which has always seemed to me to be the true one, notwithstanding all the different conclusions that have been drawn from later experiments. These results go to show how carefully Röntgen had studied the phenomena before making his original announcement.

These experiments seem to demonstrate conclusively that the source of the Röntgen radiations is the bombarded surface of the glass. It is probable, as suggested by Professor Elihu Thomson, that this bombardment produces two effects, one the Röntgen radiations and the other phosphorescence of glass, and that the greater the phosphorescence, the less the Röntgen rays.

I have always wondered why some of the various experimenters upon these phenomena have not made experiments to demonstrate, first, whether the Röntgen radiations are propagated as waves, or are flying particles shot off from the source, and, second, if waves, what is the wave length? If they are wave motions, whether the vibrations are longitudinal or transverse, the fact should be capable of demonstration by diffraction phenomena. Professor Snow, of the Wisconsin University, has suggested a method by which the test could be made.

A parallel beam of rays might be obtained by allowing the vibrations to pass successively through two narrow slits in lead screens placed a little distance apart. This beam being received upon a grating consisting of finer copper wires laid parallel to each other, should, if the radiations are wave motions, give diffraction phenomena that would demonstrate the fact, and also furnish data for computing the wave length, if the radiations consist of a few definite wave lengths only. The question whether those radiations are wave motions or an actual translation of particles, seems to me the most important one to be settled at this stage of the investigation, and I hope some one will take the matter up.

CANDLE POWER OF THE X-RAYS.

BY EDWARD P. THOMPSON.

I USED the following method in order to obtain a rough idea as to the strength of the Röntgen rays as compared with those of a candle. The process, of course, will not give the true candle-power, for the simple reason that the X-rays are not visible, but nevertheless, what may be termed the equivalent of the candle-power may be measured, so that the result impresses one with the extreme weakness of the rays in one sense, although they have so great a penetrating power.

In order to obtain the best results roughly, I receded from the Crookes' tube while looking into the skiascope, until the luminosity disappeared, and then measured the distance between the screen and the Crookes tube. It was about six feet. This represents about the usual power of X-rays, except in Tesla's results where he obtains fluorescence of calcic tungstate at 40 feet. Of course, the luminous rays of the Crookes tube were extinguished by the double thickness of black paper between it and the fluorescent screen.

I then held the skiascope (the name suggested by Prof. Magie, and which I think is by far the best) so as to face the candle, and I walked away from the same until the luminosity of the screen disappeared. The distance was likewise measured. In this case there should be no opaque substance between the candle and the screen. When it is between the Crookes tube and the screen, it has practically no effect upon the X-rays, whereas it would cut off all the rays from the candle. The distance in the latter case was about 120 feet. If the power of X-rays varies inversely as the square of the distance, a candle is 400 times more powerful in producing fluorescence than the X-rays, particularly from a Crookes tube that I employed and charged with the particular apparatus. In the same manner the candle-power of the X-rays from any Crookes tube could be measured.

It is assumed that the fluorescent screen represented the total energy for producing fluorescence as far as the X-rays were concerned. However, the candle rays are not all converted into fluorescent light; for those below the green, including yellow, orange, red and infra-red rays, produce no luminosity upon the fluorescent screen; therefore this method does not compare all the energy of the X-rays with the energy of the candle rays, but it serves to give a rough comparison. It is assumed that the fluorescent screen converted all the ultra-violet rays, violet, indigo, blue and green rays into luminous rays. This assumption may cause unknown errors in the result.

Neither would a corresponding photographic method be exact, because the silver compound would not be chemically acted upon by the infra-red rays. It should be noticed also that both methods are based upon the assumption that all the rays in both cases are converted into green rays of light by means of the fluorescent screen and into chemical energy by the photographic plate.

It remains a fact, however, that as far as we are able to transform the energies, the X-rays are weak as compared with those from the candle. Both will produce fluorescence and chemical action, but the candle very much more powerfully than the X-rays. When the two sets of rays are compared on other grounds, the Röntgen rays are more powerful, as, for for example, in reducing the sparking distance either for a positively or negatively charged insulated plate. Again, from another point of view, the candle rays can be turned out of their course by reflection or refraction. It still remains true, however, in the rough, that inasmuch as fluorescence and chemical action are both produced by the two forms of energy, therefore, these phenomena serve as a standard upon which to operate in order to obtain what may properly be called candle-power, with the restriction that it is not the true candle-power, because things of exactly the same nature are not compared. In the case of the candle-power of the sun, arc light, oxy-hydrogen flame, the incandescent lamp, gas flame, etc., their natures are the same as that of the candle, namely, all have all the luminous rays of the spectrum, but some more than others, so that in these cases we are comparing the rays of similar natures.

DIFFUSIVE REFLECTION OF ROENTGEN RAYS.*

BY DR. M. I. PUPIN.

The following communication contains a brief description of a series of experiments with Roentgen radiance which were conducted during the last six weeks. The results of these experiments seem to possess a sufficient scientific and practical importance to merit notice. The most important refer to diffuse reflection or scattering of Roentgen radiance. It seems desirable to state first, briefly, the disposition of the apparatus and the method of experimentation.

Induction Coil and Interrupter.—A powerful coil was found indispensable for strong effects and satisfactory work. The vibrating interrupter is too slow and otherwise unsatisfactory, and it was replaced by a rotary interrupter consisting of a brass pulley 6 inches in diameter and 1¼ inches in thickness. A slab of slate ¾ inch thick was inserted and the circumference was kept carefully polished. This pulley was mounted on the shaft of a Crocker-Wheeler ⅛ H. P. motor giving 30 revolutions and therefore 60 breaks per second. Two adjustable Marshall condensers of 3 microfarads each were connected in shunt with the break and the capacity adjusted carefully until the break spark was a minimum and gave a sharp cracking sound. Too much capacity will not necessarily increase the sparking, but it will diminish the inductive effect which is noticed immediately in the diminished intensity of the discharge. A powerful coil with a smoothly working rotary interrupter will be found a most satisfactory apparatus in experiments with Roentgen radiance.

Edison's Fluoroscope.—A fluorescent screen, made by Aylsworth & Jackson of East Orange, N. J., according to Mr. Edison's directions, will be found an indispensable aid in these experiments. The salt employed is tungstate of calcium, and it is so powerful that with a satisfactorily working tube it will show a noticeable fluorescence at a distance of *over 30 feet*. Those who have struggled with barium-platino-cyanide screens will appreciate fully Mr. Edison's improvement. This fluorescent screen was employed successfully for three distinct purposes. First, to study the operation of the vacuum tube un-

*Presented before the New York Academy of Sciences, April 6, 1896.

der various conditions; secondly, to shorten the time of exposure in photography; and thirdly, to study the phenomena of diffuse reflection or scattering of Roentgen radiance.

The Most Efficient Working of the Tube—The Critical Temperature.—The tubes employed were an old pear-shaped Crookes tube with a cross and several pear-shaped German tubes imported some time ago by Eimer & Amend, of New York. They all had disks at each electrode. Very satisfactory tubes are also being made now at the lamp works of the General Electric Company at Harrison, N. J. These were also employed in my experiments with completely satisfactory results. No fresh tube works quite satisfactorily with a powerful coil and a rapid rate of interruptions; it heats too much, and the vacuum becomes thus rapidly impaired and the intensity of the Roentgen radiance is very much diminished. This is true even of larger tubes. Each new tube must undergo first an electric treatment. I described this matter at some length at the meeting of the Academy on March 2. Since that time I have investigated it more fully and brought it to a satisfactory termination. Mr. Tesla has also in the meantime discussed this matter, but in what appears to me to be a somewhat fanciful way. He imagines that the vacuum of a Crookes tube becomes more and more attenuated by the passage of current through it on account of the expulsion of the gas through the walls of the bulb. He maintains that he even succeeded in piercing electrically a small hole in the tube through which the gas from the vacuum was expelled with so enormous a velocity as to prevent the outside air from rushing in. This marvelous experiment does certainly support Mr. Tesla's favorite molecular bombardment theory, but it seems to leave us with the gloomy prospect of having to refill our tubes from time to time with a fresh vacuum. The following experiments, however, lead to the conclusion that this necessity will probably never arise and that Mr. Tesla's interpretation of the cause of variation of the vacuum during the discharge is probably wrong. The electrical treatment of the tube is simply this: Pass a sufficiently strong current until the tube becomes so hot as to lose much of its Roentgen radiance. Stop then and let it cool. Repeat the operation, and observe that after each operation the vacuum has gone up and that the Roentgen effect becomes stronger. It is not advisable to drive the vacuum much beyond the sparking distance between the electrodes on the outside. But even if this point has been reached, then a judicious application of the Bunsen flame to the tube will enable the coil to force and maintain a strong enough current through the tube so as to heat it gradually, which increases the facility with which the discharge passes through the tube. The fluoroscope tells us that there is then a perfectly definite temperature at which the tube will work most efficiently, and it is desirable to operate the tube at this temperature. This can be easily done by directing currents of air against those parts of the tube where it heats most, that is, against the parts opposite to the electrodes. By a suitable regulation of the air currents, and a careful watching with the fluoroscope, the tube can be kept steadily at the temperature of its highest efficiency for hours. A deviation above or below this point will produce a very large diminution in the Roentgen effect. This temperature of highest efficiency is so sharply defined that it looks very much like a critical point in the discharge. Below this temperature the discharge is in straight lines from the cathode, and the portion of the glass opposite to the cathode fluoresces much more intensely than the rest. Above this temperature the discharge begins to spread in all directions from the cathode and the whole tube fluoresces strongly. There is then considerable flickering until the temperature is sufficiently above the critical temperature. The tube heats then rapidly and a yellowish mist begins to rise from the anode. As soon as the air blast begins to cool the tube, this mist begins to clear away and the whole tube regains a clear transparence. If the tube is made too cool the discharge becomes too faint; there is very little heating, because the coil fails to force a strong enough current. The Bunsen burner will aid the coil then to force a sufficiently strong discharge again. The blackening of the tube by the disintegration of the electrodes seems to be the only thing that will determine the length of its life.

The Combination of a Fluorescent Screen with a Photographic Plate—Photography at a Long Distance from the Tube and Through the Heavier Parts of the Human Body.—With an arrangement of apparatus as described above it was found possible to produce very much stronger photographic effects, but not sufficiently strong for penetration through the thigh and the trunk of the human body at reasonably short exposures and at long enough distances from the tube to obtain the desirable clearness in the pictures of these massive parts. A completely successful application of Roentgen's beautiful discovery to surgery depends for the present on a successful solution of the problem just mentioned. I have obtained one satisfactory solution with the method which I first described before the Academy on March 2. It consists in placing in contact with the photographic plate a fluorescent screen and thus transforming most of the Roentgen radiance into visible light before it reaches the sensitive film. Photographs of the hand were thus obtained at a distance of 25 feet from the tube with an exposure of half an hour. At the distance of four inches the hand can be photographed by an exposure of a few seconds. It was in this manner only that I succeeded in photographing on a single plate the whole chest, shoulders and neck of my assistant with an exposure of seventy minutes and at a distance of three feet between the plate and the tube. The collar button and the buttons and clasps of the trousers and the vest show very strongly through the ribs and the spinal column. This result seems to prove beyond all reasonable doubt the applicability of radiography to a much larger field in surgery than was expected a few weeks ago.

Diffuse Reflection of the Roentgen Radiance.—The question of reflection and refraction of the X-rays is a very important one. I was discussed by Prof. Roentgen in sections 7 and 8 of his original essay. Neither by photography nor by the fluorescent screen could he detect an appreciable refraction with certainty. A reflection from metallic surfaces in the immediate vicinity of a photographic film was detected, "but," quoting Roentgen's own words, "if we connect these facts with the observation that powders are quite as transparent as solid bodies and that, moreover, bodies with rough surfaces are in regard to the transmission of X-rays, as well as in the experiment just described, the same as polished bodies, one comes to the conclusion that regular reflection, as already stated, does not exist, but that the bodies behave to the X-rays as muddy media do to light."

In face of these observations made by Prof. Roentgen, Prof. Rood's and Mr. Tesla's experiments must be interpreted as a confirmation of Prof. Roentgen's results, and not as a demonstration of the existence of a regular reflection. If I understood Prof. Rood's words correctly, no claim is made by him of a discovery of regular reflection, for he says: "These facts and the character of the deformations point very strongly to the conclusion that in the act of reflection from metallic surfaces the Roentgen rays behave like ordinary light." Mr. Tesla, however, infers with much confidence regular reflection from his theory of bombardment. His method is the same as that of Prof. Rood, that is, he places a reflecting plate at an angle of 45 degrees to the direct ray and then places the photographic plate at right angles to the direction in which the reflected ray should pass if regular reflection existed. On account of the greater power of his apparatus his time of exposure was one hour, whereas that of Prof. Rood was ten hours. It is evident, however, that an effect upon the photographic plate does not prove the existence of regular reflection, as Mr. Tesla maintains with much assurance and with much rejoicing over the realization of the prophecy which he made, inspired by his molecular bombardment theory.

In my experiments on reflection I aimed at getting rid of the photographic plate and substituting the fluorescent screen in its place. Two conditions had to be fulfilled to make this substitution possible. First, a very powerful and perfectly steady discharge had to be maintained; secondly, a very sensitive fluoroscope had to be employed. The first was accomplished by the apparatus and the operations described above. The second was found in Mr. Edison's tungstate of calcium fluoroscope. The tube was placed between two thick planks of pine coated with sheet lead one-sixteenth of an inch thick. This screening was found to be somewhat insufficient when the tube operated at maximum efficiency, and another screen, consisting of a thick copper plate, had to be employed. The planks were placed so as to form a wedge around the tube. The cathode streamer was horizontal and passed through a vertical slit formed by the edges of the two screening lead-covered planks. In front of this slit was a fixed pivot on which a mirror could be rotated. The mirror consisted of a polished sheet of platinum pasted upon a rectangular piece of pine board of nearly the same area as the platinum sheet and about one inch thick. The slit was made one-sixteenth inch wide and its image was examined by means of the fluoroscope. The tube was six inches from the slit.

a. Quite near the slit the image was sharp and intense. But as the fluoroscope was gradually moved away from the slit its image broadened out somewhat, and there was at each side of it a diffuse border. At about two inches from the slit the image of the slit looked like a wide spectral line upon the less luminous background of a wide band which shaded off gradually into the dark space of the screen. With increase of distance the relative intensities of the two grew more and more equal, and at about six inches from the slit the whole fluorescent screen (about 6 ins. by 4 ins.) was uniformly illuminated. There was evidently a diffuse scattering of the X-rays in their passage through the air. This inference was confirmed by other experiments which will be discussed presently. Various well-known devices were employed to concentrate the cathode rays along the axis of the tube, as, for instance, wrapping tinfoil around the tube. This, however, did not diminish the gradual diffusion of the image of the slit on the fluorescent screen when the distance between the slit and the fluoroscope was gradually increased. Up to about three inches from the slit the real image of the slit could still be distinguished easily from the diffuse background as a band of maximum intensity.

b. The platinum mirror was now placed quite near the slit and at a convenient angle to the direction of the ray and the fluoroscope was placed quite near the mirror. There was a faint illumination of the fluorescent screen, but it was perfectly uniform. Not the slightest indication of an image of the slit could be detected, although the distance between the slit and the mirror plus the distance between the mirror and the fluorescent screen was less than the distance at which the image of the slit on the fluorescent screen appeared as a band of maximum intensity when observed directly. A change in the angle of the mirror produced but a small change in the fluorescence of the screen, and then the change seemed to be such as to approach a maximum when the mirror and the fluorescent screen were parallel to each other. The same experiment was repeated with other metals and with the same result. This experiment, therefore, does not speak in favor of regular reflection.

c. Turning the mirror completely around, so that the face of the wooden block on which the metal plate was fastened served as a mirror, it was found that the fluorescent effect upon the screen was

stronger than with the platinum. A pad of paper of about the same size as the wooden block acted more strongly than the platinum or any other metal. Various substances were tried, like glass, vulcanite, the hand, various metals, and they all produced a diffuse reflection of varying intensity, and at all angles of inclination. In all cases the maximum effect seemed to take place when the broadest side of the reflecting object was about parallel to the fluorescent screen. But the fluorescence was very weak as long as the slit was narrow.

d. The slit was now made wider, and the same series of experiments was repeated with various widths of the slit. The fluorescence of the exploring screen increased, of course, with the width of the fluorescent screen. The observations made with the narrow slit were confirmed. In every case the maximum intensity on the exploring screen was obtained when the broadest side of the reflecting object was about parallel to the screen. Wood and other transparent insulators produced in general a stronger effect than metals. No accurate quantitative comparisons have yet been made. Among the insulators experimented with, wood produced the strongest effect, and among the metals aluminum was the weakest. The thickness of the reflecting plate increases the effect; this increase will go on until the reflecting plate is several inches thick if this plate is an insulator. In the case of metals, however, like sheets of iron or copper, the increase in the fluorescent effect ceases as soon as the reflecting plate becomes thick enough to be practically opaque to the direct ray.*

e. The human body when in the path of the X-rays will act as a reflector. It is quite an easy matter to detect a person walking across the room in the vicinity of the slit, for as soon as a person crosses the path of the X-rays the fluoroscope will light up. While making this particular observation, I noticed that when the tube was operating especially well a faint fluorescence was still present even if no reflecting body was in front of the slit. Precautions were observed to exclude any radiance that might reach the fluoroscope directly by a sort of diffraction around the edges of the slit, but still the fluorescence in the fluoroscope persisted. There was evidently a diffuse scattering of the Roentgen radiance in the air itself. This, however, was so small that it was distinctly noticeable only when the tube operated so powerfully that a strong image of the hand on the fluorescent screen could be obtained by the radiance reflected from a pine board two inches thick and sixteen inches squared, placed at a distance of six inches from the slit. With a good-sized tube of proper vacuum and working at the temperature of highest efficiency, this intensity is not at all difficult to obtain, provided, of course, that one has sufficient electric power to excite the tube.

These experiments prove beyond all reasonable doubt that the Roentgen radiance is diffusely scattered through bodies, gases not excepted. We may call it diffuse reflection if we choose, provided that we do not imply thereby that we must necessarily assume an internal intermolecular regular reflection in order to explain the phenomenon. For if a puff of smoke be forced through a pile of wood some of it will come out pretty well scattered, although we cannot speak here of a reflection in the ordinary sense, but rather of deflection, reserving the term "reflection" for those particular cases in which the angle of incidence is equal to the angle of deflection. It might turn out, for instance, that the X-rays are due to a circulating motion of ether, and that the stream lines are partially deflected and diffusely scattered within the molecular interstices of ponderable substances. Appearances seem to speak more in favor of this view than in favor of a wave motion of ether.

The diffuse scattering of the Roentgen radiance by bodies placed in its path may be also described by saying that *every substance when subjected to the action of the X-rays becomes a radiator of these rays*. This statement will be more complete than the statement that a diffuse reflection takes place, if my observation should prove correct that the maximum effect in the fluoroscope is obtained when the largest surface of the body acted upon by the Roentgen radiance is placed parallel to the fluorescent screen. For in that case the secondary radiation due to the diffuse scattering will proceed normally to the surface of the intercepting body.

The fact that opaque bodies like metals are less effective in producing this secondary radiation leads to the conclusion that there is in these bodies an internal dissipation of the Roentgen radiance much greater than in the case of transparent dielectric substances. A properly constructed bolometer should give us much information on this point, and it is my intention to take up this subject as soon as time and facilities will permit.

These diffusion effects, which are present even in air, bring the Roentgen radiance into still closer resemblance to the principal features of the cathode rays which were studied by Prof. Lenard. The difference in their behavior towards magnetic force is still to be explained. Is it not possible that this magnetic effect in air is marked by the diffuse scattering of the X-rays?

In conclusion, I wish to observe that among the several theories proposed to account for the properties of the X-rays we may insert one which can be easily inferred from the somewhat neglected essay which the late Prof. von Helmholtz wrote toward the closing days of his life. It is the essay, "Inferences from Maxwell's Theory Concerning the Motion of Pure Ether" (Wissenschaftliche Abh., B. III, p. 526; Wied. Ann., Vol. LIII, pp. 135–143).

Postscript.—My attention has just been called to an investigation published by MM. A. Imbert and H. Bertin-Sans in the *Comptes Rendus* of March 2, pp. 524–525, in which experiments almost identical with those of Prof. Rood and Mr. Tesla were described, and the inference drawn that the X-rays are diffusively reflected and that the amount of this reflection depends much more on the nature of the reflecting substance than on the degree of its polish.

In an article in the *Electrical Review* of April 8, Mr. Tesla states that he also employed recently a fluorescent screen for the purpose of shortening the time of exposure in photographing with the X-rays. He attributes the suggestion of this method to Salvioni, of Italy, and Charles Henry, of France. This calls for a comment on my part. I have been unable to locate Mr. Tesla's source of Italian information. The French source is in *Comptes Rendus* of February 10, p. 312. There is no explicit statement there, nor a suggestion that a fluorescent screen would be practicable in connection with X-ray photography, but I admit that this can be easily inferred. There is no doubt that the idea of employing the fluorescent screen must have occurred to a great many people as soon as they received full information concerning Roentgen's discovery, as it occurred to me. I made the first successful experiment on February 7, and have the plates still in my possession, signed by a gentleman who was experimenting with me on that day. On February 8, I wrote an article which appeared in *Science* of February 14. In this article the following sentence will be found: "A fluorescent screen placed in front of the sensitive plate for the purpose of shortening the time of exposure gave encouraging results." The same sentence occurs in an article published in ELECTRICITY of February 12. Ever since that time I worked faithfully on this matter, and how successful I was may be inferred from the following letter which Prof. Arthur G. Webster, of Clark University, wrote to the Worcester *Gazette* of March 2:

To the Editor of the *Gazette*.

Sir: In case the interest in the Roentgen rays still holds out it may not be an intrusion to your columns if I describe an experiment which I saw made yesterday morning. My own supply of glass tubing having run out, and my efforts to procure some from New York having been of no avail, I ran down to New York to procure some supplies and to talk over matters with my friend, Professor Pupin of Columbia College, who has obtained some of the best results in this country.

Sunday morning I went with Professor Pupin to his laboratory to try the effect of a fluorescent screen in front of the plate. I placed my hand under the bulb and in five minutes the current was stopped. I was skeptical as to anything appearing on the plate, but as I have been skeptical with regard to many things connected with this matter which have turned out to be true, I was not greatly surprised when the plate developed up plainly. The res of was the best plate that I have yet seen. All the bones of the hand showed with extreme sharpness, even the small bones of the wrist being perfectly plain, in marked contrast to most of the pictures that have been published. Whereas the time of five minutes may not seem wonderful to those who have read the report of the five seconds' exposure at Harvard, it is necessary to have compared the results in order to make a fair comparison. One who has tried the experiments and seen how long it takes to obtain a good result can judge of an improvement. Whereas the idea of a fluorescent screen is one that must have occurred to many, as it did to the writer, I think that Dr. Pupin should enjoy the credit of having actually carried it ou and shortened the time of exposure ten and twenty time thereby.

Very truly yours,

ARTHUR G. WEBSTER.

On the same day I described this method at considerable length before the New York Academy of Sciences. Within the last few weeks, since Messrs. Aylsworth & Jackson succeeded in making just the screens which I wished to have, my success of Roentgen ray photography has been all that I could wish for it.

My only object in working on the improvement of the Roentgen ray photography was for the purpose of widening its scope of application to surgical diagnosis. I think that I have succeeded completely in it and I wish full credit for the work done.

M. I. PUPIN.

Columbia University, April 14, 1896.

---

*The effect of varying the thickness of interposed metals appears to give sometimes anomalous results. Thus two sheets of polished tin appeared to give less of the scattering effect than one. This point needs additional inquiry.

THE ROENTGEN RAYS.*

By Edwin J. Houston, Ph.D., and A. E. Kennelly, Sc.D.

THE announcement of a scientific discovery has seldom produced so intense an excitement throughout the civilised world as has that made in December last, by Prof. W. C. Röntgen, of Würzburg, Bavaria, concerning his ability to obtain a photograph of the bones of an animal through its living integument. His announcement, indeed, has created so intense an excitement and enthusiasm that, although the discovery is practically only a few weeks only, yet his experiments have been repeated in all parts of the world.

The authors have been requested, by the Franklin Institute, to present to its members a *rèsumé* of the facts that are known concerning Röntgen's discovery, as well as of some of the theoretical explanations which have been offered in connection therewith.

The paper in which Prof. Röntgen announced his discovery was addressed to the Würzburg Physico-Medical Society in December last. Prof. Röntgen describes in this paper the method he adopted for obtaining the peculiar form of radiant energy now generally known as the Röntgen rays, and for which he proposed the provisional name of X rays. On passing the discharge from a large Ruhmkorff coil through a suitably exhausted tube of the Hittorf, Lenard, or Crookes type, a peculiar effect, invisible to the eye, is produced in the region outside the tube. This effect, however, can be rendered visible by the fluorescence excited in a paper screen, painted with a solution of barium-platino-cyanide. In vacuum tubes of the type referred to, the passage of the proper discharge is attended by the production of rays, called cathode rays—that is, rays projected in straight lines from the cathode, or negative electrode, of the vacuum tube.

It was observed by Crookes that these cathode rays were not produced to an appreciable degree until a certain high vacuum was reached. Crookes showed by his experiments that, in so high a vacuum, matters could be regarded as existing in a fourth state or condition, to which he gave the name of the

Radiant or Ultra-Gaseous State.

The highly rarefied matter contained in these vacua is capable of producing characteristic effects when subjected to heat or electrification. For example, when an electric discharge is passed through the residual atmosphere in the tubes, the molecules are shot off in rectilinear paths from the cathode, and wherever they strike the walls of the glass tube, or suitable bodies placed in the tube, they produce a faint fluorescent light. Crookes showed that these cathode rays were capable of being deflected from their original rectilinear paths by the action of a magnet. They thus behave in conformity with the view that they consist of streams of negatively charged molecules, the deflecting action being merely a particular kind of electro-magnetic action, well seen in the deflection of a voltaic arc by a magnet, or in the electro-magnetic motion of the armature of the electric motor.

Hertz discovered that the cathode rays readily pass through thin films or screens of mica, or even of metal. He showed that, in fact, metallic films were even more transparent to the cathode rays than films of mica. For example, when such metallic screens were interposed in the vacuum tube between the cathode and the glass walls on the tube opposite the cathode, fluorescence was still developed in portions of the tube which would have corresponded to the shadow of the screen, had it been opaque.

Lenard, at one time an assistant of Hertz, took the matter up, and showed that fluorescence could be produced by the cathode rays outside the glass vacuum tube. For this purpose, he placed a small window of aluminium in the walls of his vacuum tube, so that the stream of cathode rays would impinge upon this window. A change of some sort appeared to occur at the window. While in the tube the rays proceeded along straight lines, unless deflected by a magnet; outside the window they preserved rectilinear paths, but radiated in all directions from the window as a source. These rays, produced outside the vacuum tube by the cathode rays within the vacuum tube, may be called

The Lenard Rays.

In common with the cathode rays, the Lenard rays possess the power of producing fluorescence in fluorescent substances upon which they impinge. They differ from the cathode rays in the fact that, in the air, they are visible to the eye as a faintly glowing stream or pencil, which rapidly diminishes in intensity, at comparatively short distances from the window. All the effects of the Lenard rays became lost at a distance of a few centimetres from the window, so rapid is their absorption in the air or other media. Hydrogen was found to be the least absorptive—that is, the most transparent medium; but hydrogen, under great pressure, becomes more opaque. Lenard showed that many of the metals are partially transparent to his rays, and that sensitive photographic plates, or films, are quickly blackened by their influence. In fact, Lenard took shadow photographs of opaque or semi-opaque bodies, by interposing them in the path of the rays before they impinged upon the sensitive photographic plate held in a light-tight box, provided with an aluminium cover or slide. Lenard found that the opacity of different substances to his rays varied, approximately, with their density.

In the paper before referred to, Röntgen announced that, when a suitably exhausted vacuum tube is placed under a cover of blackened pasteboard, fluorescent effects can be obtained, not merely at a distance of a few centimètres, but even at a distance of two metres, in air. He employed for this purpose a paper screen painted with a solution of barium-platino-cyanide. The Röntgen rays, unlike the Lenard rays, are invisible to the eye, even close to the vacuum tube. No window is necessary in the vacuum tube to produce the Röntgen effect, although Röntgen has produced the effect through an aluminium window. As in the case of the Lenard rays, the Röntgen rays are radiated in rectilinear paths in all directions from the portions of the walls of the tube subjected to the bombardment of the cathode rays.

It will thus be seen that a similarity exists between the Lenard and the Röntgen rays, so far as their method of production is concerned. In each, the source of the rays is to be traced to the impact of the cathode rays upon the wall of the vacuum tube in which they are produced. In each, the rays possess the power of exciting fluorescence in suitable bodies on which they impinge; in each, they possess the power of passing through substances opaque to ordinary light, the opacity in each case increasing apparently with the density, although not in direct proportion.

The Röntgen rays appear to differ from the Lenard rays in the fact that they are not so readily absorbed by air or other media. If no absorption existed, the intensity of the rays would, of course, diminish as the square of the distance from their source. Röntgen claims that he has observed that this rate of diminution in the intensity of his rays does exist within the limits of observational error. This peculiarity of the Röntgen rays has greatly enhanced their practical value.

Similarity of the Lenard and Roentgen Rays.

It will be seen, therefore, that the difference between the Lenard and the Röntgen rays is not marked. The difference appears to be one of degree rather than one of kind. There is, however, at least one difference in the rays under discussion. Lenard found that his rays are not appreciably deflected by a magnet when passing through air, but that deflection does occur when his rays were allowed to traverse a highly-exhausted chamber. Röntgen mentions that, up to the present time, he has not been able to produce any deflection of his rays by a magnetic field. This has been confirmed by Dr. Oliver Lodge. Röntgen is also experimenting with the action of an electrostatic field, but we believe he has not as yet announced any result.

The curious fact pointed out by Röntgen in the paper before referred to of the ability of his rays to produce upon a sensitive photographic plate photographs of the shadows of, say, the bones of the hand in the living subject, has naturally caused great popular excitement and interest. There can be no doubt that this fact will prove of great value to the surgeon, especially if, as would seem probable, means are perfected for the production of these rays with increased power.

Röntgen states, as a result of observation, that his rays are apparently incapable of reflection, refraction, or interference. If refraction does exist, it must be of very limited amount. These facts have led Röntgen to suggest that his rays are not light in the ordinary physical sense of the term; that is, that they do not consist of a transverse vibration propagated in the ether, according to electro-magnetic laws, but that possibly they may be a longitudinal motion propagated in the ether, a condition which Prof. S. P. Thompson has happily named "ultra-violet sound," and which others have called "ethereal sound" and "longitudinal light."

The details of the method for producing Röntgen rays do not appear yet to have been published by Prof. Röntgen. Physicists, however, have very generally reproduced them, although thus far the shddowgraphs obtained in this country do not present the sharpness and depth which apparently characterise Prof. Röntgen's shadowgraphs.

Modus Operandi.

The authors have successfully obtained Röntgen rays by the use of a large induction coil excited directly by storage cells through an interrupter, the secondary terminals of the induction coil being led directly to the terminals of the Crookes tube. In this case the cathode is the source of cathode rays in the tube, and the surface of the glass opposite to the cathode, where fluorescence is produced, is the source of the Röntgen rays. We have found, however, as others have done, that by far the best results are obtained by using a high-frequency discharge through the Crookes tube. This is conveniently done by exciting the primary of the induction coil from a 50-volt alternating-current circuit, such as is employed for supplying incandescent lamps on commercial alternating-current circuits at, say, 15,000 alternations per minute. The secondary terminals of the induction coil are led to a battery of Leyden jars through the primary coil of a Tesla induction coil immersed in oil. The secondary terminals of the Tesla coil are then connected directly to the Crookes tube. Under these conditions torrents of high-frequency discharges pass between the discharging knobs of the induction coil, which are separated to a distance of perhaps five millimètres, the frequency being determined by the capacity and inductance of the Leyden-jar circuit, including the Tesla primary. These high-frequency discharges induce in their turn high-frequency and high-tension discharges in the Crookes tube. In such cases both electrodes of the Crookes tube are alternately cathodes, and the glass wall opposite to each electrode becomes fluorescent, and, therefore, the source of Röntgen rays.

The practical difficulties in connection with the production of the Röntgen rays arise from the fact that the Crookes tubes, as ordinarily constructed, are not designed to stand the molecular bombardment of the cathode rays, when of fairly great power, for any considerable length of time. Since the ordinary Röntgen shadowgraphs require exposures lasting usually half an hour, and sometimes several hours, a great liability exists to excessive heating of the tubes and the destruction of their vacua. Indeed, at times, the heat produced by the molecular bombardment of the cathode rays is sufficient to melt the glass walls of the tubes, as the authors, most probably in common with others, have ascertained to their loss.

Since the high-frequency discharges obtained by the use of a Tesla coil are not characterised by such marked heating effects, either at the walls of the tubes or in the electrodes, they are greatly to be preferred for producing shadowgraphs. Independently of this, however, they appear to produce a more powerful image. Possibly the velocity with which the molecules are projected from the cathode, or their number, or both, are increased.

Tesla Coil.

A simple form of Tesla coil may be made by winding a primary of about eighty turns of No. 19 A.W.G. cotton-covered copper wire over a glass tube about ¾in. in diameter, and inserting this inside a slightly larger glass tube, over the surface of which has been wound a secondary of about 400 turns of about No. 31 A.W.G. fine silk-covered copper wire. The coil is then immersed in some high insulating oil, such as rosin oil.

In the shadowgraph of such portions of the human body as, for example, the hand, the bones cast the most marked shadows, and the surrounding tissues produce shadows intermediate in intensity. The density of the shadow which is cast upon the plate depends apparently upon the total quantity of matter which the rays have to traverse. Thus, a short passage through a dense substance produces the same depth of shadow as a long passage through a rare medium. In order to obtain sharp definition, the use of a diaphragm is recommended. An iron or lead plate provided with a suitable aperture, and placed between the tube and the photographic plate, is suitable for the purpose.

It is stated by Prof. Silvanus P. Thompson that distinct shadow photographic effects have been produced by the ordinary arc light, so that it would appear that some Röntgen effect is produced by the voltaic arc.

It has recently been discovered by Prof. Pupin and others that, in order to obtain the cathode rays in a vacuum tube, it is not necessary to employ electrodes within the tube itself; but if pieces of tinfoil are placed outside the vacuum tube, and the terminals of the high tension coil are connected therewith, discharges are produced in the vacuum tube by electrostatic induction. These discharges produce fluorescence in the tube, and the fluorescent glass is again the region of Röntgen rays.

Molecular Bombardment.

This would appear to show that the Röntgen rays are produced by molecular bombardment by the molecules of the residual atmosphere of the high vacuum, and that the metallic cathode is only to be regarded as an auxiliary means for producing this bombardment.

Prof. J. J. Thomson has recently made the extremely important discovery that the Röntgen rays tend to discharge an electrified body on which they impinge, and this whether the charge of the body be positive or negative. Prof. Thomson finds that a charged body constitutes a more sensitive test for the presence of the Röntgen rays than is afforded by either a sensitive photographic plate or a fluorescent screen. This effect takes place whether the charged body be covered by a layer of paraffin, sulphur, or vulcanite. In other words, as Prof. Thomson points out, the remarkable fact exists that

* From the *Journal* of the Franklin Institute.

an insulating layer becomes electrically leaky while being traversed by the Röntgen rays.

Hitherto no means have been known, beyond mere thermal influence, for altering the electrical insulating power of solid materials by radiant energy of any character. The discovery of this property of effecting electric discharge makes the ray far more wonderful and important to physicists than its property of penetrating opaque solids as displayed in shadowgraphs.

The degree of exhaustion in the vacuum tube, which is the source of the Röntgen rays, appears to be that required for rectilinear molecular bombardment. Edison has shown, experimentally, that below a certain exhaustion the Röntgen effect is negligibly small, while above a certain exhaustion the intensity of the effect again decreases. In general, it may be said that a vacuum which produces a bluish violet light on the passage of the discharge is too low to produce the Röntgen effect. The best results are obtained when little or no discharge is visible within the tube; but the walls are rendered fluorescent with a peculiar greenish tinge. This is usually obtained at about one-millionth of an atmosphere.

Since the Röntgen effect is evidently due to molecular bombardment, and varies with the degree of the vacuum, it would appear that good experimental work can be conducted, both by ascertaining the best degree of vacuum in tubes containing rarefied air, and by ascertaining whether gases other than air will produce, in such tubes, better results. It would appear that the Röntgen rays must be either a material propagation or an ethereal propagation. A material propagation would require either that ordinary matter be projected rectilinearly as a whole along the rays, or that some disturbance in matter is projected along them.

The burden of probability seems to be against the assumption that the Röntgen rays consist of a material propagation, since they not only traverse opaque, dense substances, but also appear to be unaffected by a magnet. Assuming, therefore, that the Röntgen rays are an ethereal propagation, they must either consist of a translatory movement of the ether, or of some disturbance propagated along it. Such a disturbance would, probably, have to be periodic or vibratory. The vibrations might be transverse, or they might be longitudinal to the path of the ray. Physical science is acquainted with transverse ethereal vibrations, such being, in fact, electro-magnetic vibrations, or ordinary light. These vibrations differ in their frequency, and hence in their wave-lengths, but are not known to differ in their speed through free ether. In the ether within material substances their velocity of propagation is reduced, as is evidenced by their refrangibility. This is true of all known transverse vibrations from the lowest frequency, far below the red, produced by the discharge of a Leyden jar, and detected only by electrical methods; through the higher-frequency waves, still in the infra-red and constituting direct heat; throughout the limits of the visible spectrum, and beyond the violet in that frequency which is detectable only by chemical or by electric eyes. The marked characteristics of these transverse vibrations are their refrangibility, their reflectibility, and their possibility of interference—characteristics which are all apparently wanting in the Röntgen rays.

It would, therefore, appear that the Röntgen rays are not transverse vibrations of the ether. If they are, they do not appear to lie within the range of frequency hitherto explored, a range extending from about 100,000 to about 1,000,000,000,000,000 (a quadrillion) waves per second. There is reason to believe that, if they have a wave-length, this wave-length is long, compared with that of visible light, since they pass through appreciable distances of gross matter, distances measured in centimètres or hundredths of a mètre, rather than in microns or millionths of a mètre. Such waves would correspond to dark heat-waves, in the infra-red.

It is known that ultra-violet light possesses the power of discharging a negatively charged body upon which it falls directly, while, as Prof. J. J. Thomson has discovered, the Röntgen rays can discharge bodies either positively or negatively charged, even while imbedded in a layer of highly insulating material.

Longitudinal Ethereal Vibrations.

Dr. Lodge has shown that, when polarised ultra-violet light strikes such a negatively charged polished plate, it is most effective in producing discharge when striking at an angle, instead of perpendicularly, and, consequently, the discharge may, perhaps, be effected by a longitudinal component of the impact. This seems to favour the supposition that the Röntgen rays are longitudinal ethereal vibrations.

The material substances with which we are familiar, and which are capable of transmitting vibrations transversely to the direction of propagation, are also capable of transmitting longitudinal vibrations. The fact that longitudinal vibrations in the ether have hitherto remained undiscovered has caused no little inconvenience in the framing of hypotheses concerning the action and properties of the ether. If ether resembles material substances, its velocity of propagation for longitudinal vibrations would be much greater than that of its velocity of propagation for transverse vibrations; consequently, for any given frequency of vibration, the wave-length would be greater than that of light waves.

Summing up, then, while it is far too early to form a reliable conclusion concerning the nature of the Röntgen rays, such evidence as does exist would appear to favour the theory of longitudinal vibrations in the ether.

Whatever may be the future of the Röntgen rays, so far as their practicable applicability or scientific value is concerned, great praise must be accorded to Prof. Röntgen for the exceedingly interesting and important contribution he has made to this branch of molecular physics.

Röntgen Rays.—The *Elec. Rev.*, April 1, contains another communication from Mr. Tesla, the greater part of which is descriptive of his researches with the reflection of Röntgen rays, including an illustration of the apparatus used. His researches have strengthened his conviction that the rays are streams of material particles possessing a great velocity, and they should therefore be capable of being reflected; he describes and shows a form of tube which consists of a cylinder of very thick glass, the bottom of which is made very thin, and the top of which contains the single electrode which should be of aluminum, as platinum gives inferior results, and the bulb is disabled in a comparatively short time; he describes briefly how a fairly constant vacuum may be maintained and produced electrically. It is not literally true that the Crookes vacuum is not high enough for producing the Röntgen phenomena, which manifest themselves even with poor vacua, provided the potential is high enough; to prevent overheating when the potential is raised, the number of impulses or their duration should be reduced, and it is therefore well to use a rotating commutator in connection with the ordinary coil instead of a vibrating make-and-break; with this rotating commutator the conditions may be adjusted to suit the degree of the vacuum and the potential. In his experiments with reflection he used a T-shaped box of lead, which was found to be entirely impervious; the bulb was placed at one end of the straight piece, and the sensitive plates were placed over both of the other ends, the reflecting plate being secured at the proper angle in the middle; one plate would therefore be affected by transmitted rays and the other by those which are reflected; images which were exactly alike were placed over the two plates. The results of the observations are given in a table for 12 different materials most of which were metals, and approximate calculations were made to show the relative impression by reflected rays, which appears to have varied from 0 per cent. for aluminum to 3 per cent. for zinc, the percentage being based on the impression by direct action; he considers these figures fairly correct as relative values; arranging the metals according to these values, he arrives at the following order: zinc, lead, tin, copper, silver; this order is precisely that in the contact-series of metals in air, which if true he considers an extraordinary fact; the one possible explanation he thinks is that the bulb throws out streams of matter in some primary condition and that their reflection depends on some fundamental and electrical properties of the metals; this seems to infer that these streams must be of uniform electrification, that is, anodic or cathodic, but not both. He does not agree with the statement that the streams are anodic, as he finds that both affect the plate; also that the phosphorescence of the glasses has nothing to do with the photographic impressions, for when aluminum vessels are used there is no phosphorescence. In connection with induction coils, both terminals of a tube are acted upon alike, as long as the tube is not very highly exhausted; at a high degree of exhaustion both electrodes act practically independently and the coil is then unbalanced; a hot anode emits a more intense stream than a cool cathode. He found that a brass plate of $\frac{1}{16}$ inch thickness proved fairly transparent while copper and zinc plates of the same thickness were entirely opaque. With the use of proper reflectors he produced stronger effects; by surrounding a bulb with a thick glass tube the effect may be considerably increased; the use of a zinc reflector showed an increase of about 40 per cent.; by the proper use of reflectors any number of bulbs may be used, thus producing any desired intensity of radiation. He has failed so far in his efforts to demonstrate refraction, although he tried a great many experiments. The issue of April 8 contains another communication from him. In making further experiments with reflection he used two metallic plates simultaneously, placed next to each other, so as to compare their reflecting power; a thick lead plate divided the box into two halves to prevent the rays from intermingling; the result showed that iron reflected about as much as copper, and that tin was a trifle better than lead, also that magnesium was a little better than zinc. He found it possible to reduce the time of exposure of plates to a few minutes with the aid of fluorescent paper placed near the sensitive film. Although zinc reflected only 3 per cent. of the rays when the angle was 45 degrees, the amount would be much greater for larger angles, and as such a large proportion of the rays radiate out into space, a reflection of even a small proportion of them may increase the effect several times; as an evidence of the effectiveness of such a reflector, he shows a print of the shoulders and ribs of a man which was obtained with the aid of a funnel-shaped reflector in connection with the tube; the exposure was 40 minutes, and the plate showed very strongly every bone and rib; the chief use of the reflector is that it allows the use of many bulbs without sacrifice of precision, as also a concentration on a small area. By the use of fluorescent bodies in connection with a sensitive film, he has shortened the time of exposure to even a few seconds; owing to the large size of the crystals of tungstate of calcium, the impression is not very clear; for use in connection with sensitive films it should therefore be ground very fine and distributed uniformly and the paper should adhere firmly to the film all over the plate. The fluorescence of this body seems to depend on a peculiar radiation, as it was different with different bulbs, which otherwise worked very successfully; an impression of a hand was taken at six feet in less than a minute, and even then it was over-exposed; the bulbs are very apt to explode, owing to the great internal pressure against the bombarded spot; when using phosphorescent paper in connection with the film the time of exposure is reduced so much that the thickness of the object is not of very much consequence. The fluoroscope of Edison, he states, is really Salvioni's cryptoscope with the lens omitted, which he thinks is a great disadvantage; with it he could easily distinguish the spinal column in the upper part of the body, which is more transparent than the lower, at a distance of about three feet from the bulb; through the body he could easily see the shadow of a square plate of copper; he thinks that improving the fluorescence will not add much in the examination of the internal parts of the body, and that the solution will probably come through the production of very powerful radiations; the fluoroscope does not give nearly as clear impressions as the photograph; the use of the screen for noting the effects of reflection, refraction and diffraction proved futile. The same journal publishes some comments on Tesla's work, by others, which, however, contain nothing of importance, technically.

The same journal contains an interview with Prof. Salvioni. He mentions briefly that he endeavored to find the velocity of the rays, so as to decide whether they are light or matter, and the conclusions so far obtained lead him to believe that they are matter, but he is not sure of the result; he also attempted to find whether objects present color phenomena analogous to those of light, and the results so far have been negative, giving support to the supposition that the rays are projected matter, but he has not yet reached definite conclusions. In the impression of a frog, if over-exposed, the ribs disappeared, showing the lungs, heart and another organ corresponding to the spleen. He also studied the transparency of the eye, arriving at the conclusion that it is hardly transparent. He describes his cryptoscope (see *Digest*, March 14). In an experiment he noticed that when he touched the tube with the hand, the luminous aspect varied, the tube first losing its fluorescence, which is then re-excited, reaching a great maximum, and is then relegated to the anode; it is sufficient to bring a metallic point connected with the earth or with the cathode, in contact with the tube, to obtain a very intense fluorescence confined to about one square centimetre, opposite to the place at which the tube is touched; "with this system the exhaustion of the tube can also be avoided, as with the metallic point the fluorescent zone can be successively displaced."

McClure's Magazine contains an interview with Prof. Röntgen by a reporter of that journal, which is reprinted in the *Elec. Rev.*, April 1; parts of it are interesting, although it does not contain anything of importance scientifically.

The *Elec. Eng.*, April 8, contains a short article by Mr. Edison suggesting that the X-ray was a sound wave of very small wave length, and that the shadows were sound shadows; he refers to an article by LeConte in the *Phil. Mag.*, Feb., 1882, a reprint of which with illustrations accompanies the article, on experiments with sound shadows. Edison describes an experiment in which the source of X-rays was placed on one side of a steel plate and on the other side it was noticed by means of the fluoroscope, that the rays seem to be refracted or bent around the edges of the plate. In another experiment which he believes tends to confirm the theory, he found that liquids do not fluoresce, while crystals alone do, crystal being "resonant to the wave." In another experiment he found that a tube with too low a vacuum, which ordinarily produces no X-rays, can be made to generate them by a powerful blast of air on the spark of the break wheel, and a spark gap in the secondary. Another observation was that the sharpness of the shadow depends on the abruptness of the break. With Sprengel pumps used for incandescent lamps, the vacuum is too high for the best results; if a definite amount of air is allowed to enter the bulb, the rays will flash out with great brilliancy, diminishing again as the exhaustion is continued.

The same journal contains an article by Dr. Morton, in which he gives an illustrated description of a bulb with a piece of fluorescent material mounted in it, and from this he believes the X-rays proceed. He also describes another form of tube, consisting of a glass cylinder with rounded ends, having an external electrode in the form of a disc of aluminum at one end, and a cap of aluminum covering the other end and the greater part of the walls of the tube, the edges nearest the other electrode being serrated, to provide for possible sparking between the electrodes and thus prevent perforation of the tube; the rays pass through the large cap-shaped anode, the cathode being the smaller one; this bulb is said to work well with a static machine.

The same journal contains an article by E. P. Thompson, describing experiments to determine whether ordinary phosphorescence will produce these rays; while his experiments do not prove that the rays do not have their source alone in the phosphorescence of a charged tube, yet he believes that they form substantial evidence that the rays are not obtained from phosphorescence by sunlight. There is also published in the same issue a reprint of a Röntgen photograph of 29 different objects, made by Prof. Terry, of the U. S. Naval Academy.

According to the *Amer. Jour. of Science* for April, DOELTER showed that different gems may be distinguished from each other and from their imitations by means of the X-rays; the true diamond may be distinguished from the false one; rock crystal, topaz, strass and spinel are opaque to the rays, while the varieties of the corundum, such as the ruby and sapphire, transmit them to some extent; among the minerals there are

exceptions to the accepted relation between the opacity and the density; sulphur, realgar, quartz and fluorite are quite opaque; corundum transmits somewhat, while diamond and graphite transmit much better; silicates are opaque, which is also true of mica in layers of one mm; in sections of about one third mm it is possible to distinguish between the transmissive powers of amphibole, garnet, quartz, mica and feldspar.

The *Sc. Amer.*, April 4, contains a brief description of some of Edison's experiments.

Electricity as an Exact Science. CROCKER. *Elec. Eng.*, April 1.—A brief report of a recent lecture before the Franklin Institute. He showed that electricity was one of the exact of the known sciences, being second only to astronomy; the most important test of the science is the power of prediction; a dynamo or motor can to-day be calculated from drawings before the machine is built, more nearly than by a test made of the machine itself; this assertion cannot be made of a steam engine or other like machines; other illustrations of the exactness of the science are given.

The New York Herald April 18, 1896

SAW THROUGH THREE MEN.

Nicola Tesla Has a Tube by Which He Looks Through Three Bodies.

Nicola Tesla was very busy with his experiments when I called yesterday afternoon at his laboratory in Houston street. He had a very elaborate apparatus at one end of the laboratory for the generation of the X rays. The vacuum tube was more than four feet long, and so great was the electrical power applied to it that it was filled with a brilliant fluorescence for its entire length.

With this big, brilliant tube and his fluorescent screen, which is simply cloth coated with tungstate of calcium crystals, Mr. Tesla is able to see clear through a human body, and the other day, when he put three of his workmen in a row, he saw through them all.

The New York Tribune April 18, 1896

NIKOLA TESLA'S EXPERIMENTS.

THE X RAYS DO NOT REVEAL OBJECTS PLAINLY TO HIM AS YET.

In his laboratory, which occupies two floors of the building at No. 46 East Houston-st., Nikola Tesla is delving day after day in the mysteries of the X rays, whose discovery has set the world talking. His article published recently in "The Electrical Review," with reference to the progress he had made by using a conical reflector was read with great interest by all the experts.

Since then he has made still further progress. To a Tribune reporter who found him at his laboratory yesterday afternoon Mr. Tesla said: "The reports that have been printed regarding my work have sometimes been inaccurate and exaggerated. The statement that I have succeeded in seeing plainly through the bodies of three of my assistants at one time is rather too strong. I have no time to spare my assistants for any foolish experiments. Still, I have no doubt that the light of the X rays, as I reflect them, would be seen through three bodies at one time. But as yet I have not been able to define with sufficient clearness the organs of the body. They still remain too vague and shadowy.

"Since the publication of my article in 'The Electrical Review' I have made some progress. I am working steadily, and I have great hopes for the future. It can safely be said that the subject has great possibilities.

"As for the talk of my rivalry with Mr. Edison, that is all rubbish. We have always been on the most friendly terms. We are working with the same end in view, namely, the development of the subject to its fullest."

Tesla's latest investigations of the many interesting scientific questions arising from the Roentgen ray discovery are published in this issue. No step in the various stages that he has so far presented to the readers of the ELECTRICAL REVIEW is more interesting or suggestive. The relation which he demonstrates to exist between the series obtained by arranging the metals according to their reflective power and Volta's contact series in air, proves that the rays emitted from the bulb are not an isolated phenomenon, but are emitted everywhere. Particularly suggestive is the observation that all conductors emit streams similar to those discovered by Roentgen, and that the sun and other sources of radiant energies must pour forth rays of the nature of the cathode. To those devoted chiefly to the practical applications of Roentgen's discovery, Tesla's latest observations with a fluorescent screen, showing that even the heart can be seen, will appear most promising, while his investigation of the important effect discovered by Prof. J. J. Thomson (who has contributed so much to the advancement along these lines) can not fail to be of the greatest interest to scientific men.

TESLA'S LATEST ROENTGEN RAY INVESTIGATIONS.

To the Editor of Electrical Review:

Further investigations concerning the behavior of the various metals in regard to reflection of these radiations have given additional support to the opinion which I have before expressed; namely, that Volta's electric contact series in air is identical with that which is obtained when arranging the metals according to their powers of reflection, the most electro-positive metal being the best reflector. Confining myself to the metals easily experimented upon, this series is magnesium, lead, tin, iron, copper, silver, gold and platinum. The last-named metal should be found to be the poorest, and sodium one of the best, reflectors. This relation is rendered still more interesting and suggestive when we consider that this series is approximately the same which is obtained when arranging the metals according to their energies of combination with oxygen, as calculated from their chemical equivalents.

Should the above relation be confirmed by other physicists, we shall be justified to draw the following conclusions: *First*, the highly exhausted bulb emits material streams which, impinging on a metallic surface, are reflected; *second*, these streams are formed of matter in some primary or elementary condition; *third*, these material streams are probably the same agent which is the cause of the electro-motive tension between metals in close proximity or actual contact, and they may possibly, to some extent, determine the energy of combination of the metals with oxygen; *fourth*, every metal or conductor is more or less a source of such streams; *fifth*, these streams or radiations must be produced by some radiations which exist in the medium; and *sixth*, streams resembling the cathodic must be emitted by the sun and probably also by other sources of radiant energy, such as an arc light or Bunsen burner.

The first of these conclusions, assuming the above-cited fact to be correct, is evident and uncontrovertible. No theory of vibration of any kind would account for this singular relation between the powers of reflection and electric properties of the metals. Streams of projected matter coming in actual contact with the reflecting metal surface afford the only plausible explanation.

The second conclusion is likewise obvious, since no difference whatever is observed by employing various qualities of glass for the bulb, electrodes of different metals and any kind of residual gases. Evidently, whatever the matter constituting the streams may be, it must undergo a change in the process of expulsion, or, generally speaking, projection—since the views in this regard still differ—in such a way as to lose entirely the characteristics which it possessed when forming the electrode, or wall of the bulb, or the gaseous contents of the latter.

The existence of the above relation between the reflecting and contact series forces us likewise to the third conclusion, because a mere coincidence of that kind is, to say the least, extremely improbable. Besides, the fact may be cited that there is always a difference of potential set up between two metal plates at some distance and in the path of the rays issuing from an exhausted bulb.

Now, since there exists an electric pressure or difference of potential between two metals in close proximity or contact, we must, when considering all the foregoing, come to the fourth conclusion, namely, that the metals emit similar streams, and I therefore anticipate that, if a sensitive film be placed between two plates, say, of magnesium and copper, a true Roentgen shadow picture would be obtained after a very long exposure in the dark. Or, in general, such picture could be secured whenever the plate is placed near a metallic or conducting body, leaving for the present the insulators out of consideration. Sodium, one of the first of the electric contact series, but not yet experimented upon, should give out more of such streams than even magnesium.

Obviously, such streams could not be forever emitted, unless there is a continuous supply of radiation from the medium in some other form; or possibly the streams which the bodies themselves emit are merely reflected streams coming from other sources. But since all investigation has strengthened the opinion advanced by Roentgen that for the production of these radiations some impact is required, the former of the two possibilities is the more probable one, and we must assume that the radiations existing in the medium and giving rise to those here considered partake something of the nature of cathodic streams.

But if such streams exist all around us in the ambient medium, the question arises, whence do they come? The only answer is: From the sun. I infer, therefore, that the sun and other sources of radiant energy must, in a less degree, emit radiations or streams of matter similar to those thrown off by an electrode in a highly exhausted inclosure. This seems to be, at this moment, still a point of controversy. According to my present convictions a Roentgen shadow picture should, with very long exposures, be obtained from all sources of radiant energy, provided the radiations are permitted first to impinge upon a metal or other body.

The preceding considerations tend to show that the lumps of matter composing a cathodic stream in the bulb are broken up into incomparably smaller particles by impact against the wall of the latter, and, owing to this, are enabled to pass into the air. All evidence which I have so far obtained points rather to this than to the throwing off of particles of the wall itself under the violent impact of the cathodic stream. According to my convictions, then, the difference between Lenard and Roentgen rays, if there be any, lies solely in this, that the particles composing the latter are incomparably smaller and possess a higher velocity. To these two qualifications I chiefly attribute the non-deflectibility by a magnet which I believe will be disproved in the end. Both kinds of rays, however, affect the sensitive plate and fluorescent screen, only the rays discovered by Roentgen are much more effective. We know now that these rays are produced under certain exceptional conditions in a bulb, the vacuum being extremely high, and that the range of greatest activity is rather small.

I have endeavored to find whether the reflected rays possess certain distinctive features, and I have taken pictures of various objects with this purpose in view, but no marked difference was noted in any case. I therefore conclude that the matter composing the Roentgen rays does not suffer further degradation by impact against bodies. One of the most important tasks for the experimenter remains still to determine what becomes of the energy of these rays. In a number of experiments with rays reflected from and transmitted through a conducting or insulating plate, I found that only a small part of the rays could be accounted for. For instance, through a zinc plate, one-sixteenth of an inch thick, under an incident angle of 45 degrees, about two and one-half per cent were reflected and about three per cent transmitted through the plate, hence over 94 per cent of the total radiation remain to be accounted for. All the tests which I have been able to make have confirmed Roentgen's statement that these rays are incapable of raising the temperature of a body. To trace this lost energy and account for it in a plausible way will be equivalent to making a new discovery.

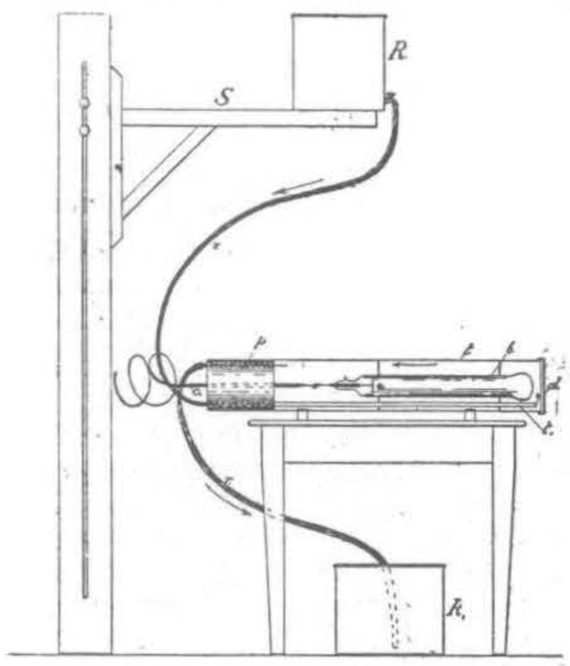
Since it is now demonstrated that all bodies reflect more or less, the diffusion through the air is easily accounted for. Observing the tendency to scatter through the air, I have been led to increase the efficiency of reflectors by providing not one, but separated successive layers for reflection, by making the reflector of thin sheets of metal, mica or other substances. The efficiency of mica as a reflector I attribute chiefly to the fact that it is composed of many superimposed layers which reflect individually. These many successive reflections are, in my opinion, also the cause of the scattering through the air.

In my communication to you of April 1, I have for the first time stated that these rays are composed of matter in a "primary" or elementary condition or state. I have chosen this mode of expression in order to avoid the use of the word "ether," which is usually understood in the sense of the Maxwellian interpretation, which would not be in accord with my present convictions in regard to the nature of the radiations.

An observation which might be of some interest is the following: A few years ago I described on one occasion a phenomenon observed in highly exhausted bulbs. It is a brush or stream issuing from a single electrode under certain conditions, which rotates very rapidly in consequence of the action of the earth's magnetism. Now I have recently observed this same phenomenon in several bulbs which were capable of impressing the sensitive film and fluorescent screen very strongly. As the brush is rapidly twirling around I have conjectured that perhaps also the Lenard and Roentgen streams are rotating under the action of the earth's magnetism, and I am endeavoring to obtain an evidence of such motion by studying the action of a bulb in various positions with respect to the magnetic axis of the earth.

In so far as the vibrational character of the rays is concerned, I still hold that the vibration is merely that which is conditioned by the apparatus employed. With the ordinary induction coil we have almost exclusively to deal with a very low vibration impressed by the commutating device or brake. With the disruptive coil we usually have a very strong superimposed vibration in addition to the fundamental one, and it is easy to trace sometimes as much as the fourth octave of the fundamental vibration. But I can not reconcile myself with the idea of vibrations approximating or even exceeding those of light, and think that all these effects could be as well produced with a steady electrical pressure as from a battery, with the exclusion of all vibration which may occur, even in such instance, as has been pointed out by De La Rive. In my experiments I have tried to ascertain whether a greater difference between the shadows of the bones and flesh could be obtained by employing currents of extremely high frequency, but I have been unable to discover any such effect which would be dependent on the frequency of the currents, although the latter were varied between as wide limits as was possible. But it is a rule that the more intense the action the sharper the shadows obtained, provided that the distance is not too small. It is furthermore of the greatest importance for the clearness of the shadows that the rays should be passed through some tubular reflector, which renders them sensibly parallel.

In order then to bring out as much detail as possible on a sensitive plate, we have to proceed in precisely the same way as if we had to deal with flying bullets hitting against a wall composed of parts of different density with the problem before us of producing as large as possible a difference in the trajectories of the bullets which pass through the various parts of the wall. Manifestly, this difference will be the greater the greater the velocity of the bullets; hence, in order to bring out detail, very strong radiations are required. Proceeding on this theory I have employed exceptionally thick films and developed very slowly, and in this way clearer pictures have been obtained. The importance of slow development has been first pointed out by Professor Wright, of Yale. Of course, if Professor Henry's suggestion of the use of a fluorescent body in contact with the sensitive film is made use of, the process is reduced to an ordinary quick photographic procedure, and the above consideration does not apply.



It being desirable to produce as powerful a radiation as possible, I have continued to devote my attention to this problem and have been quite successful. First of all, there existed limitations in the vacuum tube which did not permit the applying of as high a potential as I desired; namely, when a certain high degree of exhaustion was reached a spark would form behind the electrode, which would prevent straining the tube much higher. This inconvenience I have overcome entirely by making the wire leading to the electrode very long and passing it through a narrow channel, so that the heat from the electrode could not cause the formation of such sparks. Another limitation was imposed by streamers which would break out at the end of the tube when the potential was excessive. This latter inconvenience I have overcome either by the use of a cold blast of air along the tube, as I have mentioned before, or else by immersion of the tube in oil. The oil, as it is now well known, is a means of rendering impossible the formation of streamers by the exclusion of all air. The use of the oil in connection with the production of these radiations has been early advocated in this country by Professor Trowbridge. Originally I employed a wooden box made thoroughly tight with wax and filled with oil or other liquid, in which the tube was immersed. Observing certain specific actions, I modified and improved the apparatus, and in my later investigations I have employed an arrangement as shown in the annexed cut. A bulb *b*, of the kind described before, with a leading-in wire and neck much longer than here shown, was inserted into a large and

(Concluded on page 211.)

TESLA'S LATEST ROENTGEN RAY INVESTIGATIONS.

(*Concluded from page 207.*)

thick glass tube *t*. The tube was closed in front by a diaphragm *d* of pergament, and by a rubber plug P in the back. The plug was provided with two holes, into the lower one of which a glass tube t_1, reaching to very nearly the end of the bulb, was inserted. Oil of some kind was made to flow through rubber tubes *r r* from a large reservoir R, placed on an adjustable support S, to the lower reservoir R_1, the path of the oil being clearly observable from the drawing.

By adjusting the difference of the level between the two reservoirs it was easy to maintain a permanent condition of working. The outer glass tube *t* served in part as a reflector, while at the same time it permitted the observation of the bulb *b* during the action. The plug P, in which the conductor *c* was tightly sealed, was so arranged that it could be shifted in and out of the tube *t*, so as to vary the thickness of the oil traversed by the rays.

I have obtained some results with this apparatus which clearly show the advantage of such disposition. For instance, at a distance of 45 feet from the end of the bulb my assistants and myself could observe clearly the fingers of the hand through a screen of tungstate of calcium, the rays traversing about two and one-half inches of oil and the diaphragm *d*. It is practicable with such apparatus to make photographs of small objects at a distance of 40 feet, with only a few minutes exposure, by the help of Professor Henry's method. But, even without the use of a fluorescent powder, short exposures are practicable, so that I think the use of the above method is not essential for quick procedure. I rather believe that in the practical development of this principle, if it shall be necessary, Professor Salvioni's suggestion of a fluorescent emulsion, combined with a film, will have to be adopted. This is bound to give better results than an independent fluorescent screen, and will very much simplify the process. I may say, however, that, since my last communication, considerable improvement has been made in the screens. The manufacturers of Edison's tungstate of calcium are now furnishing screens which give fairly clean pictures. The powder is fine and it is more uniformly distributed. I consider, also, that the employment of a softer and thicker paper than before is of advantage. It is just to remark that the tungstate of calcium has also proved to be an excellent fluorescent in the bulb. I tested its qualities for such use immediately and find it so far unexcelled. Whether it will be so for a long time remains to be seen. News reaches us that several fluorescent bodies, better than the cyanides, have been discovered abroad.

Another improvement with a view of increasing the sharpness of the shadows has been proposed to me by Mr. E. R. Hewitt. He assumed that the absence of sharpness of the outlines in the shadows on the screen was due to the spread of the fluorescence from crystal to crystal. He proposed to avoid this by using a thin aluminum plate with many parallel grooves. Acting on this suggestion, I made some experiments with wire gauze, and, furthermore, with screens made of a mixture of a fluorescent with a non-fluorescent powder. I found that the general brightness of the screen was diminished, but that with a strong radiation the shadows appeared sharper. This idea might be found capable of useful application.

By the use of the above apparatus I have been enabled to examine much better than before the body by means of the fluorescent screen. Presently the vertebral column can be seen quite clearly, even in the lower part of the body. I have also clearly noted the outlines of the hip bones. Looking in the region of the heart I have been able to locate it unmistakably. The background appeared much brighter, and this difference in the intensity of the shadow and surrounding has surprised me. The ribs I could now see on a number of occasions quite distinctly, as well as the shoulder bones. Of course, there is no difficulty whatever in observing the bones of all limbs. I noted certain peculiar effects which I attribute to the oil. For instance, the rays passed through plates of metal over one-eighth of an inch thick, and in one instance I could see quite clearly the bones of my hand through sheets of copper, iron and brass of a thickness of nearly one-quarter of an inch. Through glass the rays seemed to pass with such freedom that, looking through the screen in a direction at right angles to the axis of the tube, the action was most intense, although the rays had to pass through a great thickness of glass and oil. A glass slab nearly one-half of an inch thick, held in front of the screen, hardly dimmed the fluorescence. When holding the screen in front of the tube at a distance of about three feet, the head of an assistant, thrust between the screen and the tube, cast but a feeble shadow. It appeared some times as if the bones and the flesh were equally transparent to the radiations passing through the oil. When very close to the bulb, the screen was illuminated through the body of an assistant so strongly that, when a hand was moved in front, I could clearly note the motion of the hand through the body. In one instance I could even distinguish the bones of the arm.

Having observed the extraordinary transparence of the bones in some instances, I at first surmised that the rays might be vibrations of high pitch, and that the oil had in some way absorbed a part of them. This view, however, became untenable when I found that at a certain distance from the bulb I obtained a sharp shadow of the bones. This latter observation led me to apply usefully the screen in taking impressions on the plate. Namely, in such case it is of advantage to first determine by means of the screen the proper distance at which the object is to be placed before taking the impression. It will be found that often the image is much clearer at a greater distance. In order to avoid any error when observing with the screen, I have surrounded the box with thick metal plates, so as to prevent the fluorescence, in consequence of the radiations, reaching the screen from the sides. I believe that such an arrangement is absolutely necessary if one wishes to make correct observations.

During my study of the behavior of oils and other liquid insulators, which I am still continuing, it has occurred to me to investigate the important effect discovered by Prof. J. J. Thomson. He announced some time ago that all bodies traversed by Roentgen radiations become conductors of electricity. I applied a sensitive resonance test to the investigation of this phenomenon in a manner pointed out in my earlier writings on high frequency currents. A secondary, preferably not in very close inductive relation to the primary circuit, was connected to the latter and to the ground, and the vibration through the primary was so adjusted that true resonance took place. As the secondary had a considerable number of turns, very small bodies attached to the free terminal produced considerable variations of potential on the latter. Placing a tube in a box of wood filled with oil and attaching it to the terminal, I adjusted the vibration through the primary so that resonance took place without the bulb radiating Roentgen rays to an appreciable extent. I then changed the conditions so that the bulb became very active in the production of the rays. The oil should have now, according to Prof. J. J. Thomson's statement, become a conductor and a very marked change in the vibration should have occurred. This was found not to be the case, so that we must see in the phenomenon discovered by J. J. Thomson only a further evidence that we have to deal here with streams of matter which, traversing the bodies, carry away electrical charges. But the bodies do not become conductors in the common acceptance of the term. The method I have followed is so delicate that a mistake is almost an impossibility.

NIKOLA TESLA.

New York, April 20.

The New York Herald April 22, 1896

SAW A MAN'S HEART.

Nicola Tesla Makes Two Important Announcements of His Ray Experiments.

Nicola Tesla is devoting much time to the scientific investigation of the Roentgen ray effects. In a communication to the Electrical Review he announced among others two interesting results he has achieved. One of these is that if a sensitive film be placed between two plates, say of magnesium and copper, a true Roentgen radiograph would be obtained after a very long exposure in the dark. Another wonderful result Tesla has obtained is that by the use of a new type of fluorescent screen, devised in his laboratory, he has been able to greatly increase the sharpness of the outlines in a shadow on the screen and to actually see the human heart., Regarding this, Tesla says:—

"By the use of this apparatus I have been enabled to examine much better than before the body by means of the fluorescent screen. Presently the vertebral column can be seen quite clearly, even in the lower part of the body. I have also clearly noted the outlines of the hip bones. Looking in the region of the heart, I have been able to locate it unmistakably. The background appeared much brighter, and this difference in the intensity of the shadow and surrounding has surprised me. The ribs I could now see on a number of occasions quite distinctly, as well as the shoulder bones. Of course there is no difficulty whatever in observing the bones of all the limbs."

This latter discovery, he thinks, is capable of extensive practical application.

TESLA AND ROENTGEN RAYS

BEHAVIOR OF METALS ON THE SCALE OF CHEMIC AFFINITY.

Every Metal or Conductor Is More or Less a Source of Such Streams—These Streams or Radiations Must Be Produced by Some Radiations Which Exist in the Medium.

Nikola Tesla, in the present number of the *Electrical Review*, gives the results of his latest Röntgen ray investigation. He says that the behavior of the various metals in regard to reflection of these radiations gives additional support to his previously expressed opinion that Volta's electric contact series in air is identical with that which is obtained when arranging the metals according to their powers of reflection—the most electro-positive metal being the best reflector. He confined himself to the following metals most easily experimented upon, viz.: Magnesium, lead, tin, iron, copper, silver, gold and platinum. Tesla decides that it is fair to draw the following conclusions:

First, the highly exhausted bulb emits material streams which, impinging on a metallic surface, are reflected; second, these streams are formed of matter in some primary or elementary condition; third, these material streams are probably the same agent which is the cause of the electro-motive tension between metals in close proximity or actual contact, and they may possibly, to some extent, determine the energy of combination of the metals with oxygen; fourth, every metal or conductor is more or less a source of such streams; fifth, these streams or radiations must be produced by some radiations which exist in the medium; and, sixth, streams resembling the cathodic must be emitted by the sun and probably also by other sources of radiant energy, such as an arc light or Bunsen burner."

Tesla then proceeds to give his reasons for arriving at these conclusions.

In explanation of the fact that there exists an electric pressure or difference of potential between two metals in close proximity or contact, he says:

"We must, when considering all the foregoing, come to the fourth conclusion, namely, that the metals emit similar streams, and I therefore anticipate that, if a sensitive film be placed between two plates, say, of magnesium and copper, a true Röntgen shadow picture would be obtained after a very long exposure in the dark. Or, in general, such picture could be secured whenever the plate is placed near a metallic or conducting body, leaving for the present the insulators out of consideration. Sodium, one of the first of the electric contact series, but not yet experimented upon, should give out more of such streams than even magnesium.

"Obviously, such streams could not be forever emitted, unless there is a continuous supply of radiation from the medium in some other form; or possibly the streams which the bodies themselves emit are merely reflected streams coming from other sources. But since all investigation has strengthened the opinion advanced by Röntgen that for the production of these radiations some impact is required, the former of the two possibilities is the more probable one, and we must assume that the radiations existing in the medium and giving rise to those here considered partake something of the nature of cathodic streams.

"But if such streams exist all around us in the ambient medium, the question arises, whence do they come? The only answer is: From the sun. I infer, therefore, that the sun and other sources of radiant energy must, in a less degree, emit radiations or streams of matter similar to those thrown off by an electrode in a highly exhausted inclosure. This seems to be, at this moment, still a point of controversy. According to my present convictions, a Röntgen shadow picture should, with very long exposures, be obtained from all sources of radiant energy, provided the radiations are permitted first to impinge upon a metal or other body.

"The preceding considerations tend to show that the lumps of matter composing a cathodic stream in the bulb are broken up into incomparably smaller particles by impact against the wall of the latter, and, owing to this, are enabled to pass into the air. All evidence which I have so far obtained points rather to this than to the throwing off of particles of the wall itself under the violent impact of the cathodic stream. According to my convictions then, the difference between Lenard and Röntgen rays, if there be any, lies solely in this, that the particles composing the latter are incomparably smaller and possess a higher velocity. To these two qualifications I chiefly attribute the non-deflectibility by a magnet, which I believe will be disproved in the end. Both kinds of rays, however, affect the sensitive plate and fluorescent screen, only the rays discovered by Röntgen are much more effective. We know now that these rays are produced under certain exceptional conditions in a bulb, the vacuum being extremely high, and that the range of greatest activity is rather small."

Tesla believes that the Röntgen rays are incapable of raising the temperature of the body. He adds that to trace the lost energy which amounts to 94 per cent. and account for it in a plausible way will be equivalent to making a new discovery.

By the use of certain apparatus which he describes, Tesla says:

"I have been enabled to examine much better than before the body by means of the fluorescent screen. Presently the vertebral column can be seen quite clearly, even in the lower part of the body. I have also clearly noted the outlines of the hip bones. Looking in the region of the heart I have been able to locate it unmistakably. The background appeared much brighter and this difference in the intensity of the shadow and surrounding has surprised me. The ribs I could see on a number of occasions quite distinctly, as well as the shoulder bones. Of course, there is no difficulty whatever in observing the bones of all limbs. I noted certain peculiar effects which I attributed to the oil. For instance, the rays passed through plates of metal over one-eighth of an inch thick, and in one instance I could see quite clearly the bones of my hand through sheets of copper, iron and brass of a thickness of nearly one-quarter of an inch. Through glass the rays seemed to pass with such freedom that, looking through the screen in a direction at right angles to the axis of the tube, the action was most intense, although the rays had to pass through a great thickness of glass and oil. A glass slab nearly one-half of an inch thick, held in front of the screen, hardly dimmed the fluorescence. When holding the screen in front of the tube at a distance of about three feet, the head of an assistant, thrust between the screen and the tube, cast but a feeble shadow. It appeared some times as if the bones and the flesh were equally transparent to the radiations passing through the oil. When very close to the bulb, the screen was illuminated through the body of an assistant so strongly that, when a hand was moved in front, I could clearly note the motion of the hand through the body. In one instance I could even distinguish the bones of the arm.

"Having observed the extraordinary transparence of the bones in some instances, I at first surmised that the rays might be vibrations of high pitch, and that the oil had in some way absorbed a part of them. This view, however, became untenable when I found that at a certain distance from the bulb I obtained a sharp shadow of the bones. This latter observation led me to apply usefully the screen in taking impressions on the plate. Namely, in such cases it is of advantage to first determine by means of the screen the proper distance at which the object is to be placed before taking the impression. It will be found that often the image is much clearer at a greater distance. In order to avoid any error when observing with the screen, I have surrounded the box with thick metal plates, so as to prevent the fluorescence, in consequence of the radiations, reaching the screen from the sides. I believe that such an arrangment is absolutely necessary if one wishes to make correct observations."

Tesla decides finally that the announcement of Prof. J. J. Thomson that all bodies traversed by Röntgen radiations became conductors of electricity in the common acceptation of the term conductor is not true. Tesla concludes his article by saying that the method that he (Tesla) has followed is so delicate that a mistake is almost an impossibility.

HUMAN HEART STANDS REVEALED

With the Aid of a Fluorescent Screen Nikola Tesla Can See It in a Living Subject.

NATURE FULL OF X RAYS.

The Sun and Other Sources of Radiant Energies Have All Anticipated Roentgen.

SOME STARTLING DEDUCTIONS.

NIKOLA TESLA'S latest experiments with the cathode rays have enabled him to reach and reveal to human eyesight the human heart in a living subject.

This is an extraordinary fact. To our ancestors it would have seemed a miracle that could be ascribed only to some supernatural agency—preferably to that of the devil, for, in the gloomy mood which they carefully cultivated, the devil appeared to be a more potent agent in mundane affairs than Divinity itself. Even to us of the present, who have carefully eliminated the supernatural, either in the form of God or devil, and who have been calloused to the marvels of the natural world by the thick coming sensations which, day by day and even hour by hour, crowd upon our senses, this is an event altogether out of the common. But we still preserve some of the failings of our devil haunted progenitors. After the first stunning effect of an announcement of this sort we rebound into an unreasonable state of expectancy. We are not content with the marvel of the moment. We would anticipate the future. We would outstrip nature and plunge into the supernatural. We exaggerate, we augur the utmost. We are disappointed if our fondest anticipations are not immediately realized.

There are people who imagine at once that the human heart would be revealed as utterly and clearly as though it were laid bare by the surgeon's scalpel. Perhaps some go so far as to hope to see that living heart inscribed legibly with its secrets. Queen Mary said that when she was dead the word Calais would be found indelibly engraved on her heart. Some folk would not be satisfied unless Nikola Tesla revealed to them the very letters of such an inscription.

TESLA IS SILENT.

Mr. Tesla himself is sensible of this overweening expectation. So for the moment he has determined to make no further revelations. He will wait patiently until the future has arrived and the revelations expected in the present have been approximately realized. He knows how unreasonable are the demands of the public after the first burst of startled incredulity is over. Belief will succeed that incredulity if the facts warrant belief, but that belief becomes utterly importunate and unreasonable.

"If I tell people," complained Mr. Tesla when I saw him in his laboratory yesterday, "that science has gone so far and no further they are disappointed. Because they expect everything they do not realize that even a very little is an immense advance. By the aid of the Roentgen rays I have, it is true, been able to examine much better than before the interior of the body. I have been able to locate by ocular inspections the region of the heart. But when I explain that it is simply a dim adumbration and not a clear vision people turn away disappointed. Therefore at present I deem it best not to add anything to the article just published in the Electrical Review. I shall wait until I have something to report that will approximately meet the o'erleaping expectations of the public."

THE SUN EMITS X RAYS.

"The revelations of that article are astounding enough, in all conscience. Tesla demonstrates that what are known as the Roentgen rays are not an isolated phenomenon, but are emitted everywhere. All conductors emit streams similar to those discovered by Roentgen. The sun itself and other sources of radiant energies pour forth rays similar to those emitted by an electrode in a highly exhausted enclosure. His present conviction is that a Roentgen shadow picture should, with very long exposure, be obtained from all sources of radiant energy, provided the radiations are permitted first to impinge upon a metal or other body. Hence he has been led to increase the efficiency of reflectors by providing, not one, but separated successive layers for reflection, by making the reflectors of thin sheets of metal, mica or other substances.

To scientists interested in the practical application of Roentgen's discovery Tesla's latest observations with a fluorescent screen will seem most promising. The ordinary reader will be better satisfied with results than with technical explanations of his method. Here, briefly, are the results as he has chronicled them:—

WHAT TESLA HAS DONE.

He has succeeded in gaining a clear view of the vertebral column, even in the lower part of the body. He has also clearly noted the outlines of the hip bones. Looking in the region of the heart he has been able to locate it unmistakably.

"The background appeared much brighter, and this difference in the intensity of the shadow and surrounding has surprised me." The ribs he could now see on a number of occasions quite distinctly, as well as the shoulder bones. Of course, there is no difficulty whatever in observing the bones of all limbs. In one instance he could see quite clearly the bones of his hand through sheets of copper, iron and brass of a thickness of nearly one-quarter of an inch. Through glass the rays seemed to pass with such freedom that, looking through the screen in a direction at right angles to the axis of the tube, the action was most intense, although the rays had to pass through a great thickness of glass and oil. A glass slab nearly one-half of an inch thick, held in front of the screen, hardly dimmed the fluorescence.

When holding the screen in front of the tube, at a distance of about three feet, the head of an assistant thrust between the screen and the tube cast but a feeble shadow. It appeared sometimes as if the bones and the flesh were equally transparent to the radiations passing through the oil. When very close to the bulb the screen was illuminated through the body of an assistant so strongly that when a hand was moved in front Mr. Tesla could clearly note the motion of the hand through the body. In one instance he could even distinguish the bones of the arm.

You cannot arrest time in its flight or roll it backward. Therefore you cannot say what a past generation would have thought of these manifestations. But you can do the next best thing. If you have a grandmother who has not kept up with the trend of events seek her out and explain to her in simple language just what Tesla has effected. As the supposition is that she has never heard of Tesla's name, and as she may not know Latin, you cannot expect her to say, "Aut Diabolus aut Tesla." But in her simple retrograde manner she may allude to Diabolus alone in the vernacular terminology.

The New York Herald April 27, 1896

NIKOLA TESLA BURNED.

Touched a Heavily Charged Wire While Engaged in Experiments.

Nikola Tesla, whose interesting experiments with a fluorescent screen, as showing the action of a man's heart, were described in the Sunday HERALD, has one hand swathed in bandages these days.

This is the result of an accident while conducting his experiments in his laboratory. He was deeply interested in his work, and perhaps became somewhat careless. At any rate, his hand touched a wire charged with a large amount of electric fluid. It was only for an instant. but that was long enough for the flesh of the fingers to be badly seared, while the ends, around the nails, were seriously burned.

While painful, the wounds were not dangerous and he will be all right in a few days.

Professor Roentgen's New Discoveries.

[*Cable to the Sun, New York, April 26.*]

Professor Roentgen has published several important new discoveries connected with the X rays. He has ascertained that all solid bodies can generate them under the influence of cathode rays, the only difference being as regards intensity. The most intense are produced by platina. He further says that the insertion of the Tesla apparatus between the ray-producing apparatus and the Ruhmkorff apparatus is highly advantageous. He has made several experiments which confirm his observation that X rays can discharge electric bodies, and that air illuminated by the rays can do the same. He further declares that electric bodies surrounded not by air, but by hydrogen or by highly rarefied air, are also discharged by the rays, though much more slowly.

RECENT WORK WITH RÖNTGEN RAYS.

IN our last week's number, Prof. J. J. Thomson brought together and discussed observations of prime importance selected from the mass of material recently published on Röntgen rays. As a supplement to this, and in continuation of the general summaries which have already appeared in NATURE, we present the following notes on papers and communications received during the past few days.

Prof. Oliver Lodge has sent us the following announcement, dated April 20.

"It has been asserted that the action of X-rays on a film is a photographic one, depending on the fluorescence of the glass backing. The truth is that a film on a ferrotype plate is just about as rapid as a similar film on glass. Thick films are much better than thin. It may be further interesting to state that if the platinum disk on which the kathode rays inside the bulb are converged is connected to the kathode, it fails to act as a source; if it be insulated, it acts fairly; while if it is connected to the anode, it constitutes a vigorous source."

It will be remembered that Prof. Röntgen found that "films can receive the impression as well as ordinary dry plates" (NATURE, January 23, p. 274), but he was doubtful whether the photographic effect was secondary or not.

From a number of papers dealing with various properties of Röntgen's rays, we learn that Herren V. Novák and O. Sulc (Prague) have observed the relative opacity for X-rays of different substances, both simple and compound (*Zeitschrift für Physikalische Chemie*, xix. 3). They conclude that the absorbing powers of the chemical element depend on their atomic weight alone, and that the absorbing power of a compound depends only on the atomic weights of the elements of which it consists, and not on the complexity of its molecules. It seems probable that the *average* atomic weight of a compound affords an index of its absorbing power. In the *Jenaische Zeitschrift für Naturwissenschaft*, Dr. A. Winkelmann and Dr. R. Straubel (Jena) have investigated the refraction of Röntgen rays, and by using prisms of various metals, obtain in each case a value of about 1 : 0·0038 referred to air. They also have measured the reflection produced by a sheet of tinfoil, and the relative transparency of different kinds of glass to Röntgen radiations. All glasses made with lead are found to be comparatively opaque. The same writers have experimented on the action of fluor-spar in intensifying the actinic effects of X-rays, and have found that the best results are obtainable with a coarse powder of the fluor-spar; finer powders producing a less marked effect. This effect is due to fluorescence, the spar emitting radiations whose index of refraction is about 1·48; indicating a wave-length of 219×10^{-6}. The March number of the *Atti della Reale Accademia dei Lincei* contains two papers, one by Signor Augusto Righi, and the other a joint paper by Drs. A. Fontana and A. Umani (Rome), both of which deal with the effect of Röntgen rays in stopping the action of Crookes' radiometer. The effect is found to be purely electrostatical, and to be due to the electrification of the glass bulb containing the radiometer; when the bulb is wetted, or electrification prevented by the interposition of a conducting screen, the radiation from a Crookes' tube does not affect the radiometer in any way whatever.

Mr. A. W. Isenthal has sent us the following letter, *à propos* of Winkelmann and Straubel's paper. He says:—"It may be of interest to your readers to learn that, within the last few weeks, Prof. Dr. Winkelmann and Dr. Straubel, of Jena University, have been successful in reducing the exposure required for the production of radiograms to a few seconds only. Acting on the few directions given, I have made a few preliminary trials, the result of which is very promising. By simply backing the sensitive plate with a most inexpensive material, I have obtained fair negatives of the finger-bones in about ten seconds, using only a 3-inch spark. As the rays in this method have first to pass through the glass of the sensitive plate, there is a probability of still further reducing the necessary exposure by substituting sensitive films (on celluloid) for the ordinary photographic plate."

With reference to the use of fluorescent screens in reducing the time of exposure, we have received the following letter from Dr. H. Van Heurck, of the Botanical Gardens, Antwerp, through Dr. Wynne E. Baxter:—

"I notice in your issue of April 16, that Messrs. L. Bleekrode and J. William Giffcrd announce that they have been able to reduce the time of exposure in radiography by the use of a fluorescent screen. Mr. Basilewski communicated the same fact to the Paris Académie des Sciences on March 23 last. Allow me, however, to lay claim to priority in this application of fluorescent screens, as the same was announced by me in various Antwerp journals on March 8, and again on the 12th of that month, in the *Annales* (*Belges*) *de Pharmacie*, an extract from which, in pamphlet form, I send herewith. You will also find described therein a chemical substance, viz. a newly-discovered double fluoride of uranyl and ammonium, with which screens can be made, at a nominal cost, of a luminosity and of a clearness superior to that of any screen now known to exist."

The combination of a fluorescent screen with a photographic plate was one to which every worker with Röntgen rays would naturally be led. Prof. M. L. Pupin gave a description of the combination before the New York Academy of Sciences on March 2. At a meeting of the Academy on April 6, reported in *Science* of April 10, he described an arrangement of apparatus by means of which it was found possible to produce very strong photographic effects, "but not sufficiently strong for penetration through the thigh and the trunk of the human body at reasonably short exposures and at long enough distances from the tube to obtain the desirable clearness in the pictures of these massive parts. A completely successful application of Röntgen's beautiful discovery to surgery depends for the present on a successful solution of the problem just mentioned. I have obtained one satisfactory solution with the method which I first described before the Academy on March 2. It consists in placing in contact with the photographic plate a fluorescent screen, and thus transforming most of the Röntgen radiance into visible light before it reaches the sensitive film. Photographs of the hand were thus obtained at a distance of twenty-five feet from the tube with an exposure of half an hour. At the distance of four inches the hand can be photographed by an exposure of a few seconds. It was in this manner only that I succeeded in photographing on a single plate the whole chest, shoulders, and neck of my assistant, with an exposure of seventy minutes and at a distance of three feet between the plate and the tube. The collar-button and the buttons and clasps of the trousers and the vest show very strongly through the ribs and the spinal column. This result seems to prove beyond all reasonable doubt the applicability of radiography to a much larger field in surgery than was expected a few weeks ago."

A communication on the same branch of the subject has been received from Mr. A. A. C. Swinton, under date April 22. We print his letter in full.

"The chemical action of the Röntgen rays upon a photographic film may be either a direct action or may be a secondary effect, due to the fluorescence produced in the support, or in the gelatine and silver bromide of the film itself. Be this as it may, the fact that an ordinary photographic film supported on celluloid is almost completely transparent to the rays, as may easily be proved with a cryptoscope, and also the fact that it is possible to simultaneously impress many super-imposed films, show that only a very small fraction of the energy in the rays is utilised under ordinary circumstances.

"As long ago as January 30, in some remarks that I made at the close of Mr. Porter's demonstration at University College, I suggested as a means of more completely utilising the energy in the rays, and thereby shortening the necessary exposure, the use of suitable fluorescent material applied either in the form of a screen behind the photographic film, or introduced into the substance of the film itself.

"Since I first made this suggestion, I have tried numerous experiments in the direction indicated. These were at first unsuccessful owing to the screens used not having been properly prepared. Some weeks ago, however, on renewing the experiments with a screen thickly coated with potassium platino-cyanide and gum, placed behind a celluloid photographic film, I obtained conclusive evidence that by this means the necessary exposure could be greatly shortened, and that in a less degree the same result could be accomplished by the employment of a screen thickly covered with powdered fluor-spar.

"The chief objection to this method lies in the fact that it is very difficult to avoid granular results. Unless the fluorescent material be in a very fairly divided condition, its grain shows distinctly and mars the detail of the finished picture. The platino-cyanide does not work so efficiently when finely powdered as when in moderately coarse crystals, but good results can be obtained by thickly coating a thin celluloid film with an emulsion of this salt ground to fine powder in collodion, and using the screen so prepared with its celluloid surface in contact with the

sensitive surface of the photographic film. I have obtained considerably better results with a finely ground sample of tungstate of calcium, prepared for me by Messrs. Hopkin and Williams. This may be used either in loose powder or made up with gum into a paste and dried.

"With this substance it is easy to obtain sharp and fully-exposed negatives of the hand in from five to ten seconds with a moderately excited tube, with which, with ordinary arrangements, one to two minutes' exposure would be necessary.

"I have also tried some special plates prepared for me by Messrs. Marion, into the sensitive emulsion of which fluorescent substances such as powdered fluor-spar and calcium tungstate were introduced before application to the glass. Though the results so far obtained by this method are not very satisfactory owing to granularity, the presence of the fluorescent substance in the photographic film appears undoubtedly to increase its sensitiveness to the rays.

"There is a wide field for further research on the lines above indicated, both with regard to suitable fluorescent substances and the best method for their application."

A paper by Dr. Ferdinando Giazzi, of the Regio Istituto Tecnico, Perugia, is of importance in this connection, and the following translation of it, by Mr. G. H. Baillie, will be useful to chemists who are preparing fluorescent salts for use with Röntgen rays:

"Some days ago Prof. Ruata called my attention to the telegram sent by Edison to Lord Kelvin, and published in NATURE, according to which calcium tungstate, when suitably crystallised, showed fluorescent phenomena under the action of X-rays in a far more marked degree than barium platino-cyanide.

"I immediately consulted Prof. Bellucci, who informed me that calcium tungstate could be easily obtained from either sodium tungstate or tungstic acid, two commercial products selling at a low price. Having obtained these from the firm of Bonavia of Bologna, I set to work and produced some calcium tungstate, but in an amorphous form, which was, as far as I could test with the coil at my disposal, insensible to X-rays. I shall not describe all the attempts I made by wet and dry processes to obtain the salt in the desired form. I merely say that I never have dealt with a body so intractable. The following is the process I finally adopted in preparing it for surgical purposes. I treated a dilute aqueous solution of sodium tungstate with a solution of calcium chloride, given to me by my colleague Prof. Corneliani; I thoroughly washed the resulting pure white precipitate, and dried it at a gentle heat in a porcelain capsule. Next I made a small hole in a piece of fresh retort-carbon, and filled it with the precipitate, which I fused and boiled by means of a small flame from an oxyhydrogen blowpipe. After boiling for some seconds (at a bright white heat), I gradually removed the substance from the hottest parts of the flame, so that solidification took place only after a few minutes. In this way I obtained five globules of calcium tungstate of the required structure. I powdered them in an iron mortar and sifted the powder on to a gummed card, which I exposed in the camera to Röntgen rays. The result was most striking; I saw at once the shadow of the skeleton of my hand more clearly than I ever have with other preparations. A surgeon with this product, good Crookes' tubes, a large coil, and an apparatus such as I have arranged, could certainly dispense with the tedious process of photography.

"I publish this note for the assistance of those who perchance have not yet succeeded in preparing the invaluable tungstate in the desired form."

So far as the utility of the method of reducing exposure by means of fluorescent screens is concerned, the advantage gained must be understood only in a comparative sense. Some investigators obtain excellent results without the use of the screen in less time than others with a screen. Dr. John Macintyre, who has sent us several communications previously upon his work with Röntgen rays, has something to say about the reduction of exposure by screens, in a letter just received. He remarks:

"The object of this note is not to minimise the importance of any aid which the physicist may place in the hand of the surgeon. I have been aware of this new method, but my experience in practice has not encouraged me meantime to pursue it largely, because of want of time in developing what I consider of greater importance, viz. a better Crookes' tube. In surgery what we require may be divided into two parts: (1) rapid views of objects, and (2) permanent records. In practice we must have for the former not photographs but direct vision, and for the second, of course, rapid exposures. Now it may occasionally happen that a permanent record is desirable o. what must be done almost instantaneously. That point I think ought to be reached ere long.

"Some weeks ago I recorded a photo of the elbow-joint in 1¾ minutes, and that at a time when we did not understand the tubes as well as now. Since then I have obtained records of metallic objects in half a second, and the bones of the hand in six seconds, without the aid of fluorescent screens. What we desire most, however, in practice is a better Crookes' tube for fluorescent screens in direct vision. At present I go while the tube is being exhausted, and test the result before it is taken off the pump. When I am examining an object with the screen, or about to photograph, I heat the tube and keep the current passing through until the maximum effect is obtained. I have now seen by this means the different bones of the extremities and joints; moreover, I have no difficulty in seeing through the body itself. The spine ribs, sternum, clavicle and scapula can be seen; and I have shown to several medical men the shadow of a coin in the gullet (impacted for six months), opposite the fourth dorsal vertebra. Foreign bodies in the extremities are, as a rule, easily seen.

"For the examination of the cavities inside the head, *e.g.* the antrum, or mouth, or pharynx, also the teeth, I now place fluorescent screens in the mouth, and the Crookes' tube outside, either above or below the level of the buccal cavity as required, and sharp images are thus obtained on the screen of not only foreign bodies, but also of the bones of the face, and roots of the teeth as well.

"Other tissues than the bones are now yielding. I have photographed the side of the neck, and shown the tongue, hyoid bone, the pharygeal cavity, cartilages of larynx and trachea of the living adult subject.

"At present we cannot afford to ignore any aid, and hence we are glad to have such hints as the fluorescent screens in photography; but it is not unlikely that all such will be more or less dispensed with as a better source of the X-rays is obtained, viz. a still better Crookes' tube."

Since the above was written, and in consideration of the question at issue, Dr. Macintyre informs us that he has made a further series of experiments on the question of rapid exposures. The tube used was one of the now well-known ordinary focus tubes, made in Glasgow. He has obtained a well-defined image of metallic objects, and distinct, though faint, image of the bones of the fingers with one flash of the Crookes' tube, produced by a single vibration of the mercury interrupter, a large coil giving an eleven-inch spark, and, of course, without using any fluorescent screen. What the extent of the time of exposure was cannot be said, but he describes it as an unknown, unmeasured, small fraction of a second. In another experiment he was able to obtain a distinct image of the bones of the forearm with sixty similar flashes of the tube.

Prof. O. N. Rood found indications of reflection of Röntgen rays from a platinum surface on March 9, and on March 13, after an exposure of ten hours, he obtained a good negative, capable of furnishing prints, of a piece of iron wire netting reflected from a sheet of ordinary platinum foil and through a plate of aluminum (*Science*, March 27). The conclusion he arrived at from inspection of the image was that "in the act of reflection from a metallic surface the Röntgen rays behave like ordinary light." Experiments made to ascertain the percentage of the rays reflected, indicated that platinum foil reflected the 1/260th part of the X-rays incident on it at an angle of 45°.

Upon the question of reflection and refraction of Röntgen radiance, Prof. Pupin pointed out in his paper read before the New York Academy of Science, on April 6, that it was discussed by Prof. Röntgen in Sections 7 and 8 of his origina essay. Neither by photography nor by the fluorescent screen could Prof. Röntgen detect an appreciable refraction with certainty. A reflection from metallic surfaces in the immediate vicinity of a photographic film was detected, "but," translating Röntgen's own words, "if we connect these facts with the observation that powders are quite as transparent as solid bodies, and that, moreover, bodies with rough surfaces are, in regard to the transmission of X-rays, as well as in the experiment just described, the same as polished bodies, one comes to the conclusion that regular reflection, as already stated, does not exist, but that the bodies behave to the X-rays as muddy media do to light." "In face of these observations," continues Prof. Pupin, "Prof. Rood's and Mr. Tesla's experiments must be interpreted as a confirmation of Prof. Röntgen's results, and not as a

demonstration of the existence of a regular reflection. Mr. Tesla infers regular reflection from his theory of bombardment. His experimental method is the same as that of Prof. Rood; that is, he places a reflecting plate at an angle of forty-five degrees to the direct ray, and then places the photographic plate at right angles to the direction in which the reflected ray should pass if regular reflection existed. On account of the greater power of his apparatus, his time of exposure was one hour, whereas that of Prof. Rood was ten hours. It is evident, however, that an effect upon the photographic plate does not prove the existence of regular reflection."

In his own experiments on reflection, Prof. Pupin aimed at getting rid of the photographic plate and substituting the fluorescent screen in its place.

He concludes as follows :—"These experiments prove beyond all reasonable doubt that the Röntgen radiance is diffusely scattered through bodies, gases not excepted. We may call it diffuse reflection, if we choose, provided that we do not imply, thereby, that we must necessarily assume an internal inter-molecular regular reflection, in order to explain the phenomenon. For if a puff of smoke be forced through a pile of wood, some of it will come out pretty well scattered, although we cannot speak here of a reflection in the ordinary sense, but rather of deflection, reserving the term 'reflection' for those particular cases in which the angle of incidence is equal to the angle of deflection. It might turn out, for instance, that the X-rays are due to a circulating motion of ether, and that the stream lines are deflected and diffusely scattered within the molecular interstices of ponderable substances. Appearances seem to speak more in favour of this view than in favour of a wave motion of ether. The diffuse scattering of the Röntgen radiance by bodies placed in its path may be also described by saying that *every substance when subjected to the action of the X-rays becomes a radiator of these rays*. . . . The fact that opaque bodies, like metals, are less effective in producing this secondary radiation, leads to the conclusion that there is in these bodies an internal dissipation of the Röntgen radiance much greater than in the case of transparent dielectric substances. A properly constructed bolometer should give us much information on this point, and it is my intention to take up this subject as soon as time and facilities will permit. These diffusion effects, which are present even in air, bring the Röntgen radiance into still closer resemblance to the principal features of the kathode rays which were studied by Prof. Lenard. The difference in their behaviour towards magnetic force is still to be explained. Is it not possible that this magnetic effect in air is masked by the diffuse scattering of the X-rays?"

Our American correspondent says :—"Tesla has found that the X-rays are reflected from certain metals tested in the same order as in Volta's electric contact series in air. Zinc reflects 3 per cent. at an angle of 45°. Below it stand lead and tin, but his observations do not yet show which reflects more highly. Below these in order come copper and iron about the same, then silver. His first observations led him to infer that magnesium would reflect still more than zinc, and sodium most of all. Subsequent experiment has verified the conjecture as to magnesium; but sodium has not yet been tested. By availing himself of the reflection from a zinc cone, he has taken a picture of the ribs of an assistant at a distance of four feet from the vacuum tube, and with an exposure of forty minutes. His apparatus is so constructed that the bulb or bulbs are at the large end of the cone, and the subject at the small end, where the rays are concentrated. The cone or funnel is constructed at an angle less than 30°, so that the incident rays are reflected more than 3 per cent; and especially more the small end of the funnel the rays approach within a very few degrees of parallelism with the reflecting zinc. Prof. Tesla thinks the theory that the X-rays consist of streams of radiant matter, is confirmed by these results. He has not yet been able to detect any refraction of the X-rays."

In the summary of work done in connection with Röntgen rays (page 522), we give an account of experiments made by Prof. Joly, which demonstrate the existence of reflection.

"In confirmation of these experiments," writes Mr. Alfred W. Porter, "may I point out that a similar phenomenon to that described by Prof. Joly has been present on all my skeletal radiographs. Immediately surrounding the sharp geometric shadow of the flesh of the fingers a black line exists on the *negative*. This is especially noticeable where two fingers overlap one another; the partial shadow cast by one finger preventing the deposit on the plate from becoming so dense as to obscure the presence of the black line. I enclose a *positive* which shows the presence of the corresponding white line very clearly. M attention was first called to the presence of this line on my pictures on January 28, by Mr. John T. Morris, of this College. I believe that the prominence of the finger-nails is due to the same cause. I have also taken graphs of over-lapping wood, metal, and ivory objects which exhibit the same phenomena."

We have received the prints referred to by Mr. Porter, and they entirely bear out his description of the appearance presented.

For some time past Prof. FitzGerald and Mr. Fred. T. Trouton, at Trinity College, Dublin, have sought evidence of crystalline action, both on transmission and reflection at grazing incidence of Röntgen rays. Though so far this has been without success, we learn that they have noticed a marked scattering of the rays in transmission through some substances. The following arrangement is convenient for showing this. "On a plate of lead, which has a slit cut in it, is placed a sheet of, say, solid paraffin 2 or 3 m.m. thick, so as to cover one end of the slit; over this is laid a strip of lead—but slightly wider than the slit—so as to just entirely cover the slit. No direct radiation then can pass from a Crookes' tube, placed vertically over the slit, to a sensitive plate placed behind the lead; but with a lengthened exposure (20 to 30 minutes) with a focus tube, a darkening is found on developing at the end where the paraffin is placed. If the paraffin be then moved to the centre or other end, so as to eliminate accidental effects, on again exposing the darkening action is found to follow the paraffin. Some darkening always occurs even where there is no solid body. How much of this is due to successive reflections from the lead sheet and strip, or how much is due to scattering of the rays by air, is not easy to say."

Mr. Dayton C. Miller has obtained some good results at Case School of Applied Science in Cleveland, Ohio, U.S.A., but the exposures he finds necessary are longer than those given by the foremost workers in Great Britain. The tube used by him is spherical in shape, and about five inches in diameter. The coil gives a six-inch spark in air, and is excited by a current of about sixty watts, obtained from fifteen cells of storage battery. The voltage used varies from twelve to twenty. With this apparatus and power, Mr. Miller says :—

"The bones of the fingers are distinctly shown with exposures of ten seconds, while exposures varying from two to ten minutes are regularly used in locating bullets and shot in the hand, and in examining injured or deformed hands. An excellent picture of a hand and fore-arm, placed diagonally across an 11 × 14 plate, has been made with twenty minutes' exposure. The entire detail of the lettering and design of an aluminium medal has been taken in five minutes. Numerous interesting surgical cases of fractured and diseased arm-bones have been examined with satisfactory results. Photographs of the chest and head have been made with exposures of one hour in each case. A surprising amount of detail is visible. The chest picture shows the shoulder-joint, the collar-bone, the spinal column with its articulations, and a dark streak along its length corresponding to the spinal cord, and eight ribs on each side of the spine. In the region of the heart the detail is less conspicuous, indicating that the heart is more opaque than the lung tissue."

Mr. W. L. Goodwin, of the School of Mining, Kingston, Canada, has sent us the results of experiments made to determine the relative opacities of various substances to Röntgen rays. The only details as to the method employed is that the results were obtained "by photography with a small Crookes' tube similar in shape to a radiometer, but constructed to show the revolution of a platinum vane covered on one side with mica." The relative opacities thus determined are as follows :—

I. SOLIDS :—

Transparent: Paraffin wax, wood charcoal, coke (in part), asphalte, albertite, starch, diamonds.

Fairly transparent: Citric acid, jet, anthracite, amber, natrolite, caustic potash, caustic soda, borax, soda crystals.

Somewhat transparent: Silicified wood, Epsom salts, serpentine, staurolite, stilbite, lazulite, $H_2(NH_4)PO_4$, cryolite, Mohr's salt, analcite, Na_2CO_3, borax glass, nitre, Rochelle salt.

Somewhat opaque: Mica, tourmaline, wulfenite, axinite, spinel, calcite, aragonite, kaolin, $NiSO_4(NH_4)_2SO_4.6H_2O$, $NiSO_4.K_2SO_4.6H_2O$, &c.

Opaque: Roll sulphur, crystal of rhombic sulphur, fluor-spar, topaz, beryl, ruby, quartz, NaCl, chalco-pyrite, $H_2(NH_4)AsO_4$, H_2KAsO_4, K_3FeCy_6, $K_2Cr_2O_7$, orpiment, anhydrite, celestine, barite.

Sulphuric acid is as opaque as the same thickness of sulphur. Water is more opaque than paraffin wax.

A number of crystals of about the same thickness were photographed on the same plate, and an attempt made to judge of their relative transparency with a scale from 1 to 10, with the following results:—

H_2KAsO_4	1
$H_2(NH_4)AsO_4$...	2
$NiSO_4.(NH_4)_2SO_4.6H_2O$	3
$MgSO_4.K_2SO_4.6H_2O$...	3
$NiSO_4.K_2SO_4.6H_2O$	3·5
$MgSO_4.(NH_4)_2SO_4.6H_2O$	4
$ZnSO_4.(NH_4)_2SO_4.6H_2O$	4
$CoSO_4.K_2SO_4.6H_2O$	4
$CoSO_4.(NH_4)_2SO_46H_2O$	4
$H_2(NH_4)PO_4$	5
Paraffin wax	10

The different values of arsenic and phosphorus in the isomorphous acid arseniates and phosphates are to be remarked.

Thin sections of a granite composed principally of quartz and feldspar and of a hornblende-gabbro were photographed. In both cases the feldspar was found to be distinctly more transparent than the other constituents.

Prof. E. Doelter, of Graz, has communicated to the *Naturwissenschaftliche Verein für Steiermark* some observations relating to the opacity of different rocks and minerals for the Röntgen rays, and their use as providing a test of the genuineness of precious stones. Dr. Doelter finds that (1) the opacity does not always increase with the density, although minerals having a specific gravity greater than 5 are relatively opaque; (2) the complexity of the chemical constitution of a mineral affects its opacity, but no general law of relationship can be enunciated; (3) dimorphous minerals exhibit but slight differences in their behaviour with regard to the rays in their different forms; (4) in most crystals, the amount of absorption does not depend sensibly on the direction of the incident rays; (5) all minerals naturally fall into about eight well-defined groups, according to their opacity, the order being as follows: diamond, corundum, talc, quartz, rock-salt, Iceland spar, &c. The diamond is ten times as transparent as corundum, and 200 times as transparent as tinfoil.

Mr. W. Ackroyd and Mr. H. B. Knowles have systematically examined the opacity of a number of substances for Röntgen rays, with a view to determining whether it bears any relation to molecular weight (*Journal* of the Society of Dyers and Cleaners, April).

With this view they have compared the isomorphous sulphates, $RSO_4, 7H_2O$ of the eighth group of metals, iron, nickel, and cobalt; the oxides, RO, of some members of the second natural group, viz. magnesium, zinc, and mercury; the isomorphous oxides, R_2O_3, of the metals aluminium, chromium, and iron. In each of these series there are presumably similarly shaped molecules for comparison, and the disturbing factor is the difference of molecular weight. The result of an hour and a half's exposure showed that the alumina was practically transparent, the chromium sesquioxide semi-transparent, while the ferric oxide was opaque. In other words, the opacity of the substance was in some direct relation to the molecular weight. There are here marked differences with big jumps in molecular weights. The same observation applies to the oxides of magnesium, zinc, and mercury. The isomorphous sulphates of iron, nickel, and cobalt are extremely interesting, because of the nearness of the specific gravity numbers, and also of the molecular weights. The iron compound, with lower specific gravity and molecular weight, appears to be the least opaque of the three, while the nickel and cobalt compounds of nearly the same specific gravity and molecular weight have approximately the same degree of opacity. The following table correlates these facts with other properties:—

Compound.	Sp. gr.	Molecular weight.	Colour.	Behaviour to Röntgen rays.
$FeSO_4, 7H_2O$	1·85	278	Light green	Slightlyless opaque than others in this group.
$NiSO_4, 7H_2O$	1·95	280	Deep green	About the same relative opacity.
$CoSO_4, 7H_2O$	1·92	281	Pink	
Al_2O_3	4·00	103	White ...	Transparent.
Cr_2O_3	4·99	153	Green ...	Semi-opaque.
Fe_2O_3	5·13	160	Brown ...	Opaque.
MgO	3·42	40	White ...	Transparent.
ZnO	5·47	81	White ...	Semi-opaque.
HgO	11·13	216	Red	Opaque.

The foregoing figures, conclude the authors, demonstrate the weakness of an unqualified law of density, as the denser oxide of zinc is more transparent than the less dense ferric oxide. But they point out that, adopting the legitimate method, which they have initiated, of comparing only compounds with kinship, each of the above bodies conforms to the law of density as well as of molecular weight in relation to opacity.

Dr. A. Sella and Dr. Q. Majorana (*Rend. R. Accad. dei Lincei*) describe certain experiments on the influence of Röntgen rays on the sparks produced by the discharge of an induction coil in air. The sparking distance is found to be shortened by the Röntgen rays, this effect taking place whenever these rays fall on the positive pole. In this respect the phenomenon is the reverse of that obtained by Hertz with ultra-violet light, the effect of which is to lengthen the sparking distance whenever it falls on the negative pole. The authors found that the simultaneous actions of Röntgen rays and of ultra-violet light could be made to neutralise each other by arranging the coil to give a spark of suitable length (in their experiments about 30 mm.). When the sparking distance was less, the Hertz effect predominated; when the sparking distance exceeded 30 mm., the Röntgen rays had the greater influence.

Dr. Filippo Campanile and Dr. Emilio Stromei communicate to the *Rendiconto dell' Accademia delle Scienze fisiche e matematiche* (Naples) a note on the phosphorescence and the Röntgen rays in Crookes' and Geissler's tubes. The conclusions arrived at are as follows: (1) When in the circuit of an induction coil, containing a Crookes' tube, a spark is thrown off from the positive pole, the phosphorescence of the tube and the efficacy of the Röntgen radiations are augmented. (2) As the length of the spark increases the phosphorescence at first increases to a maximum, and then decreases. (3) If, on the other hand, the spark is thrown off from the negative pole, the phosphorescence and the Röntgen rays are thereby diminished. The same experimenters have also succeeded in obtaining Röntgen rays with an ordinary Geissler's tube. These radiations possessed all the characteristics of those which emanate from a Crookes' tube.

Signor E. Villari, writing in the same journal, considers that the phenomena of discharges in tubes seem to indicate the existence not only of kathodic but also of anodic rays. While the kathodic rays travel in straight lines and produce a negative charge wherever they strike the tube, the suggested anodic rays diffuse themselves all round the anode, and communicate a positive charge to the whole surface of the tube over which they are diffused.

The fundamental character of the new rays has led speculators to make various surmises as to a possible connection between these radiations and the phenomenon of gravitation, and two lengthy memoirs have been written on the subject by Rudolf Mewes.[1] In the second of these the author claims to have proved experimentally that gravitation is propagated through the ether with the velocity of light.

Finally, attention may profitably be called in this summary to the April number of the *Proceedings* of the Physical Society. In the admirable collection of abstracts of physical papers there published, will be found concise descriptions of the scope and results of no less than forty papers concerned with Röntgen rays.

[1] "Licht Electricitäts und X-Strahlen" (pp. 54); "Die Fortpflanzungs-Geschwindigkeit der Schwerkraftstrahlen" (pp. 93). (Berlin: M. Krayn, 1896.)

Röntgen Ray Investigations. TESLA. *Elec. Rev.*, April 22.—His investigations with reflection have confirmed his opinion that Volta's electric contact series in air are identical with the order of the metals arranged according to their power of reflection, the most electro-positive metal being the best reflector; platinum is the poorest and sodium one of the best; this order is approximately the same as that with reference to their energies of combination with oxygen; should this be confirmed by other physicists, the following conclusions would be justified; first, that highly exhausted bulbs emit material streams which are reflected from metallic surfaces; second, these streams are formed of matter in some primary or elementary condition; third, the streams are probably the same agent which is the cause of the electromotive tension between metals in close proximity; fourth, every metal or conductor is more or less a source of such streams; fifth, these streams must be produced by some radiations which exist in the medium; sixth, streams resembling the cathodic must be emitted by the sun, and probably also by other sources of radiant energy; these conclusions are discussed in detail. He predicts that if a sensitive film is placed between a magnesium and a copper plate, a true Röntgen shadow picture would be obtained after a long exposure in the dark; he thinks it probable that there is a continuous supply of such radiations from the medium in some form, and that they come from the sun, from which he concludes that with very long exposures Röntgen shadow pictures could be obtained from all sources of radiant energy, provided the radiations are permitted first to impinge upon a metal or other body; he suggests that the lumps of matter composing a cathodic stream in the bulb are broken up into small particles by impact against the walls of the tube and are thereby enabled to pass into the air; the difference between Röntgen and Lenard rays is that the particles composing the former are incomparably smaller and have a higher velocity, which he believes is the reason why they are not deflected by a magnet; he tried to find whether the deflected rays possessed distinctive features but could notice no difference; it is important to find out what becomes of the energy of these rays; his tests have confirmed Röntgen's statement that the rays are incapable of raising the temperature of a body. He has increased the efficiency of the reflectors by providing separate successive layers for reflection, by making the reflector of thin sheets of metal or mica. He recalls a former experiment in which a brush or stream issuing from a single electrode rotated very rapidly due to the earth's magnetism, and he thinks that perhaps the Lenard and Röntgen streams also rotate under the action of the earth's magnetism. He does not favor the idea of vibrations approximating those of light and thinks that all these effects could be produced with steady electrical pressure like that from a battery, with the exclusion of all vibrations; he found no effect due to changes of the frequency although it was varied between wide limits; to obtain clear shadows it is very important to pass the rays through some tubular reflector which makes them approximately parallel; clearer pictures were obtained by using very thick films developed very slowly. He has succeeded in making the radiation more powerful and describes and illustrates his new form of apparatus in which the rays were made to pass through various thicknesses of circulating oil; with this apparatus he claims to have obtained better results. By mixing a non-fluorescent powder with the fluorescent material for a screen he found that the general brightness was diminished, but that the shadows were sharper; the vertebral column could be seen quite clearly even in the lower part of the body, as also the outlines of the hip bones; he located the heart unmistakably, the background for which appeared to be brighter; the bones of the hand could be seen very clearly through sheets of copper, iron and brass nearly one fourth of an inch thick, and through glass the rays seemed to pass with great freedom, one half an inch of glass hardly dimming the fluorescence; it appeared sometimes as if the bones and flesh were equally transparent to radiations passing through the oil; the motion of a hand could be clearly seen through the body; it is of advantage to determine by means of the screen the proper distance at which an object should be placed before taking the photographic impression. The effect noticed by Prof. J. J. Thomson, that bodies traversed by these rays became conductors, was further investigated, but the conclusion could not be confirmed, and he (TESLA) claims that it is a further evidence of the existence of streams of matter, but not that the bodies become conductors in the common acceptation of the term.

NIKOLA TESLA'S WORK.

WONDERS HE HAS ACCOMPLISHED AND OTHERS HE PROMISES.

His Achievements in Electrical Research—Endless Possibilities of Problems He Is Now at Work Upon—His Experiments with the Roentgen Rays—His Personality

Nikola Tesla is a man about whom the general public knows very little. There have been magazine articles about him and books about him, and, since Prof. Roentgen made known his discoveries in X-ray photography, Tesla's experiments with the discoveries with experiments followed up the discoveries with experiments of his own, the papers from time to time have told how Tesla had "seen the human heart" and had "photographed the human brain" and done other wonderful things. His name has been on the tongues of many people, but not one man in a hundred could tell what Tesla had done for science, or very little if anything about him personally.

Tesla himself is responsible for the lack of popular knowledge of himself. He isn't one of the kind to hide his light under a bushel, but he likes the light shine and hides himself. He doesn't like to see his name in print. He doesn't like to be praised for what he has done or is doing. He wants, more than anything else, to be let alone. He discourages notoriety of any sort. When newspaper men call on him to ask him questions he is the quintessence of courtesy and politeness. He is willing to tell them anything they want to know about electricity or any of the other subjects on which he is well informed, but on one subject —Tesla—he is silent. When THE SUN reporter called on him early last week and told him that he had been instructed to write a story about Tesla and his inventions, the inventor said:

"Don't; there has been too much already," and he said it in a way that showed he meant it. It was only after a second visit and much earnest urging that he would consent to the publication of anything, and he surrounded his consent with conditions.

He was asked to tell which of his many inventions he considered the most useful and satisfactory to him, and he replied that first in the list was the transmission of power with the help of wires. This power was the alternating electric current now in use. Next he mentioned the motor that made possible the transmission of power with only a single wire. It used to be supposed that two wires were necessary to complete a circuit, one for the electricity to come back on. This motor does away with the extra wire, and lessens the expense and the waste. Third, he mentioned the thing which he hoped to accomplish: Doing away with that wire altogether, and using the earth. In a lecture delivered before the American Institute of Electrical Engineers in 1891, Tesla said:

"We are whirling through endless space, with an inconceivable speed, all around us everything is spinning. Everything is revolving. Everywhere is energy. There must be some way of availing ourselves of this energy more directly. With the power derived from it, with every form of energy obtained without effort, from the store forever inexhaustible, humanity will advance with giant strides. The mere contemplation of these magnificent possibilities expands our minds, strengthens our hopes and fills our hearts with extreme delight."

He had this third thing in mind when he delivered the lecture. He has been working now ten years to accomplish it, and he has had encouraging success with his experiments.

Of his inventions, in this talk with THE SUN reporter, he mentioned fourth the perfecting of an apparatus for the production of electric vibrations; fifth, the production of light without any carbon such as is required in the ordinary incandescent lamp. Light is produced by the means of electrical vibration. By the method proposed 200 times the light can be had with the same power. Sixth, he mentioned the evolution of the oscillator, a work on which he has been engaged five or six years and which is about ready to be put into general use. Then he says:

"Of the energy that goes to the making of a cubic light 95 per cent. is wasted. The oscillator, combined with the Niagara engine and the dynamo combined and in use it means the saving of the energy that is now wasted."

Of the problems he has worked on Tesla said:

"They affect humanity as a whole." The energy that is wasted must be saved, he said. He spoke of the utilization of the power of Niagara Falls and of its possibilities and the possibilities in nature elsewhere. He said the existing faults of society are to be overcome only by producing more energy; that energy was in nature and the problem of getting control of it and of utilizing it was the problem on which he worked. He covered a field of ordinary invention. He thought only of the great problems. He observed that they would be mastered and the whole world would benefit.

Tesla is a man of striking personality. He is unusually tall and his body is well proportioned and is crowned with jet-black hair. His manner is quick and impulsive. In speech he is earnest. He wastes few words. He has a bearing impressive, one with the fact that he is a man of action. He is only 39 years old. He was born in Smiljan, Lika, on the Military Confine of Austria-Hungary, of the Serbian race. His father was a clergyman in the Greek Church. His mother was a woman of great inventive invention. Tesla got his early education at Gospich in a public school, and later spent three years in the Higher Real Gymnasium at Carlstadt, Croatia. He saw his first steam engine while at the latter school. He inherited his mother's love of invention, and when he left school in 1873 he went to experimenting with electricity against the wish of his father, who wanted him to enter the ministry. He was not in the question, and then his father wanted him to become a college professor of mathematics and physics and with that purpose sent him to the Polytechnic School at Gratz.

In this school there was a grammne dynamo, and Tesla, with the notion that the brushes of a dynamo could be operated without commutator or brushes, such as this one was equipped with, began work that resulted in one of the ideas that later developed one of his great inventions, a rotating field motor.

The idea of becoming a professor vanished, and he took up the engineering curriculum. For the next few years he kept up his studies, and succeeded in inventing several things in connection with the telephone. Then he went to Paris, where he saw a wider field. After a few years there in the course of which he met many Americans, who told him of opportunities in his field of investigation here, he came to America. He hunted out Thomas A. Edison, and went to work in his laboratory. In Thomas Commerford Martin's book, "The Inventions, Researches, and Writings of Tesla," Tesla's connection with Edison is mentioned, and the author says:

"It was impossible, however, that with his own ideas to carry out, and with his own inventions to develop, Mr. Tesla could long remain in even the most delightful employ; and his work now attracting attention he left his Edison ranks to join a company intended to make and sell an arc lighting system based on some of his inventions in that branch of the art. With unceasing diligence he brought this system to perfection, and saw it placed on the market. But the thing which most occupied his time and thought, however, all through these years was his old discovery of the rotating field principle for creating current work, and the application of it in motors that have now become known the world over."

Up to this time the alternating current wasn't in favor with electrical engineers. They knew little about it and did not realize its value. It wasn't until 1886 that Tesla himself succeeded in perfecting a practical operation the idea he had conceived when he was a student at the Polytechnic Institute. It is the completion and perfection of several of this invention that will enable the Niagara Falls Power Company to transmit its power far from the falls where it is generated with the aid of the forces of nature.

But before telling what Tesla has done, more may be said about Tesla the man, his work and how he works. He is a man of very regular habits, wherein he differs from Edison, who works by spurting at the top speed for a stretch, sometimes longer, when he has on hand something that interests him. Tesla is up at noon, spurning at 6 o'clock. He has a lot of gymnastic exercises that he goes through with regularly. He has a light breakfast and then he loses little time getting to his work. He takes an hour for his lunch and for a bundle of the day and the afternoon is devoted to hard work. He usually works until 8 o'clock in the evening, but often it is midnight or thereabouts. His laboratory is at 46 East Houston street.

He has a clerk who attends to visitors. Keeps away cranks, keeps a record of callers, sees that everybody who has real business with the inventor is provided with the latest copy of some scientific paper which Mr. Tesla is engaged. He also has a dozen or more mechanics who are as loyal to him as Edison's men are to him; but the nature of his work and the magnitude of the problems he sets himself to solve do not permit of their rendering him the same sort of assistance that the Wizard's men furnish to their employer. A friend of Tesla's was asked what was the most interesting trait of his character. He replied:

"His love of humanity and his friendship for young men who are ambitious to succeed and love their work. Tesla would become misanthropic. He is jealous of no man. I believe if he worked on a problem twenty years, and was about realizing success just as another succeeded, he would be as happy as if he had succeeded himself. His interest in his work is entirely a desire to advance the science for the benefit of all mankind. I think this is shown by the fact that he is not a rich man. He could have been a millionaire if he had had any desire to be so."

If he had devoted his time and energies and his inventive genius to money making there is no question but that he would be rich to-day. Tesla can invent anything. Tell him what you want and he will work at it until he accomplishes it. But if he devoted his time to inventions of that sort, the broader propositions and problems would go by the board. He would have no time for them. It is to solve them that he delights to work.

Now, to take up some of the things Tesla has done. It may be said, to begin with, that to talk about Tesla's inventions leads one into a maze of electrical terms that defy the understanding of the mind not educated to the technicalities of his work, his discoveries, and his inventions here would be about as intelligible as a column of Hebrew jargon. Hence, all that will be attempted is to tell what he has accomplished. First, take the transmission of power.

When Tesla came into the field in America, as stated before, little was known of the alternating current. The single alternating current was used, but for the purpose of lighting only. The continuous current was used almost exclusively.

The continuous current system is very good for short lines, but with it energy cannot be delivered successfully at any great distance at high pressure. To deliver the continuous current at high pressure at a distance would require the use of wires so heavy that they would be cumbersome and entirely impracticable for use. Tesla made an alternating current motor that permitted the transmission of energy long distances at high pressure over thin wires, the electricity being used at the same pressure or at a lower or a higher pressure, whichever was desired, by means of a transformer. Thus the bridling of the power in Niagara was made possible, and natural forces everywhere can be similarly harnessed and made to do the work that has been heretofore done at great cost by other forms of force and energy. A great many smaller inventions are included in this great one. Its possibilities are just now beginning to be realized. Tesla's discoveries in connection with this motor, it is said, were the prime cause of the recent consolidation of the Edison and the Westinghouse Electric Companies.

In this motor two wires were used for the transmission of the current. Tesla believed that the extra wire was a useless expense; that all the work could be done with one, and no return circuit was necessary. So he set himself about the work of finding a way to accomplish this. He did accomplish it, and now it is possible through the earth to transmit the energy with the aid of only one wire. This invention, however, has not been of the same practical use as the other. It is now in a state in the direction of accomplishing the third thing that Tesla is aiming at. That is the transmission of power and intelligence without any wires, by means of the earth itself. If such a thing can be accomplished the human mind can hardly conceive of the possibilities. Tesla believes that it can be accomplished. The fact that he believes it is proved by the ten years of work he has devoted to experimenting on that line.

Next in order, as Tesla mentioned them, is the perfection of an apparatus for the production of electrical vibrations. Electrostatics is the science of electricity at rest. Tesla demonstrated that for the production of light waves, primarily, electrostatic effects must be brought into play, and he formed the opinion that all electrical and magnetic effects may be referred to electrostatic molecular forces. In a glass bulb filled with electrostatically charged molecules he found that by agitating them, causing them to vibrate, to strike against each other, brilliant light was produced. No carbon was required, such as is used in the ordinary incandescent light. There was nothing but the glass bulb. Tesla's accomplishment was the making of apparatus to stir up the molecules within that bulb, and apparatus and are ever present, while the carbon heretofore needed is expensive. This apparatus is nearing perfection now, and lamps which furnish light without carbon are in sight. The saving in the cost of electric lighting will be tremendous, and, as measured by Tesla, 100 times the light will be produced with the same energy that is now used in the production of the ordinary incandescent lights. This will mean more light with less power and less expense, because there will be no expensive carbons required.

Last on Tesla's list is the oscillator, now perfected and ready to be put on the market. It is estimated that nine-tenths of all the dynamos in the world are now operating by steam power. Every step in the production of electricity by steam power is attended with waste and loss of power and energy. The problem Tesla set out to solve was the saving of the 95 per cent. of energy that was wasted. Actual tests showed that only 5 per cent. of the energy used in making incandescent lights manifested itself as light. The 95 per cent. was lost. There was loss in every step from the putting of the coal into the furnace to the delivery of the electricity. Tesla has combined an engine and a dynamo. Steam is forced into the engine at high pressure, which produces an extremely rapid vibration of a steel rod, and this rod or piston is so adapted to a set of magnets that the mechanical energy of the vibrations is converted into electricity. Fly wheels and governing balls and eccentrics and valves and all the rest of the complicated mechanism required for the purpose of control or regulation are done away with.

The steam cylinder with its piston is the only thing that does the work about a steam engine. All the rest takes up room and produces nothing, so if they can be done away with the energy that it takes to run them is saved. Tesla's oscillator does away with them. The oscillator converts the energy of steam into electricity directly. It would appear that this invention, if it does all that Tesla claims, will revolutionize all business that requires energy in the form of steam or electric forces to operate it. The machine doesn't take up one-tenth of the room needed by an ordinary engine and dynamo.

Probably the oscillator and the new system of lighting would not have been long in coming if Tesla had it not been for the destruction of Tesla's laboratory last year. He had these and other inventions very well perfected, and in his shop the result of years of work. He had many models of machinery that he could not replace. All that was left to him was the ideas of how these things had to be done over again. He said himself at the time that a million dollars could not repay the loss.

Tesla's work with the Roentgen ray photography and the results he has accomplished have been more extensive than those and results done and accomplished by any other experimenter. His first published statement of what he had done with the rays was made after the discovery of the photography. He had experimented in the meantime incessantly. His pictures and his statements appeared first in the *Electrical Review*. He succeeded in taking the picture of the shoulder of a man showing the ribs and shoulder joint. The upper arm bone was taken through clothing and a board partition at a distance of four feet. His experiments extended over a period of months. In his paper he said:

"The bony structure of birds, rabbits, and the like is shown within the least detail, and even the hollow of the bones is clearly defined. In a plate of a rabbit, under exposure of an hour, not only every detail of the skeleton is visible, but likewise a shadow picture of the abdominal cavity and the location of the lungs, the liver, and many other features. Prints of even large birds show the feathers quite distinctly.

"Clear shadows of the bones of human limbs are obtained by exposures ranging from a quarter of an hour to an hour, and whole plates have shown such an amount of detail that it is almost impossible to believe that we have to deal with shadows only. For instance, a picture of a foot with a shoe on was taken, and every fold of the leather, trousers, stocking, &c., is visible, while the flesh and bones stand out sharply. Through the body of the experimenter the shadows of small buttons and like objects are quickly obtained, while with an exposure of from one to one and a half hours the ribs, shoulder bones, and the bones of the upper arm appear clearly, as is shown in the annexed print. It is now demonstrated beyond any doubt that small metallic objects or bony or chalky deposits can be infallibly detected in any part of the body.

"An outline of the skull is easily obtained with an exposure of twenty to forty minutes. In one instance an exposure of forty minutes gave quite clearly not only the outline, but the cavity of the eye, the chin, and cheek and nasal bones, the lower jaw with its connections to the upper one, the vertebral column and connections to the skull, the flesh, and even the hair. By exposing the head to a longer action still more details have been noted. For instance, I find that there is a tendency to sleep, and the time seems to pass away quickly. There is a sensation of feeling effect, and I have felt a sensation of warmth in the upper part of the head. An assistant independently confirmed the tendency to sleep and a quick lapse of time. Should these results be effects be verified, by men with keener sense of observation, it will be still more likely that in the existence of material streams penetrating the skull. Thus it may be possible by these strange agencies to convey to a suitable chemical into any part of the body.

"Roentgen advanced modestly his results, warning against too much hope. Fortunately his apprehensions were groundless, for although we have to all appearance to deal with mere shadow projections, the possibilities of the application of his discovery are such that I am happy to have contributed to the development of the great art he has created."

Tesla has prepared five plates since, his one, in each of which he has told something about some branch of the new photography that had heretofore been unknown. Some of his pictures he has obtained are wonderful. The last and the one that created the most talk is a picture of a man which shows, among other things, the outline of the heart. Tesla showed this picture to THE SUN reporter, together with a picture of a leg and foot, to show the simplicity of the experiments of the work of the Roentgen photography.

Tesla was once asked if he was well off. His reply was:

"If every man who uses my machine in electro-therapy alone were to give me a quarter I would be a very wealthy man. I never received a dollar for it, and there is no way in which I could. I receive a small income from my invention in the rotating field, and I have a small income from home. All this I spend here."

Regarding the future he has said:

"I expect to live to be able to set a machine in the middle of this room and move it by the energy of the solar agency than the medium in motion around us."

Electrical Progress.

On Apparatus for Cathography.

By NIKOLA TESLA.

In order to produce the most intense effects, we have first to consider that, whatever their nature, they depend necessarily on the intensity of the cathode streams. Then, again, being dependent on the magnitude of the potential, it follows that the highest attainable electrical pressure is desirable.

To obtain high potentials we may avail ourselves of an ordinary induction coil, or of a static machine, or preferably of a disruptive discharge coil. If we put two electrodes in a bulb, or use one inside and another outside electrode, we limit the potential, for the presence not only of the anode, but of any conducting object, has the effect of reducing the practicable potential on the cathode. Thus, to secure the result aimed at, one is driven to the acceptance of a single electrode bulb, the other terminal being as far remote as possible.

Having selected the induction apparatus and type of bulb, the next important consideration is the vacuum. On this subject I am able to make known a fact with which I have long been acquainted, and of which I have taken advantage in the production of vacuum jackets and incandescent bulbs, and which I subsequently found to be of the utmost importance, not to say essential, for the production of intense Roentgen shadows. I refer to a method of rarefaction by electrical means to any degree desirable, far beyond that obtainable by mechanical appliances.

Though this result can be reached by the use of a static machine, as well as of an ordinary induction coil giving a sufficiently high potential, I have found that by far the most suitable apparatus, and one which secures the quickest action, is a disruptive coil. It is best to proceed in this way: The bulb is first exhausted by means of an ordinary vacuum pump to a rather high degree, though my experiences have shown that this is not absolutely necessary, as I have also found it possible to rarefy, beginning from low pressure. After being taken down from the pump, the bulb is attached to the terminal of the disruptive coil, preferably of high frequency of vibration, and usually the following phenomena are noted: First, there is a milky light spreading through the bulb, or possibly for a moment the glass becomes phosphorescent, if the bulb has been exhausted to a high degree. At any rate, the phosphorescence generally subsides quickly and the white light settles around the electrode, whereupon a dark space forms at some distance from the latter. Shortly afterwards the light assumes a reddish color and the terminal grows very hot. This heating, however, is observed only with powerful apparatus. It is well to watch the bulb carefully and regulate the potential at this stage, as the electrode might be quickly consumed.

After some time the reddish light subsides, the streams becoming again white, whereupon they get weaker and weaker, wavering around the electrode until they finally disappear. Meanwhile, the phosphorescence of the glass grows more and more intense, and the spot where the stream strikes the wall becomes very hot, while the phosphorescence around the electrode ceases and the latter cools down to such an extent that the glass near it may be actually ice-cold to the touch. The gas in the bulb has then reached the required degree of rarefaction. The process may be hastened by repeated heating and cooling and by the employment of a small electrode.

I may state here that the experimenter need not be deterred from using a glass bulb, as I believe the opacity of glass, as well as the transparency of aluminum, are somewhat exaggerated, inasmuch as I have found that a very thin aluminum sheet throws a marked shadow, while, on the other hand, I have obtained impressions through a thick glass plate.

The above method is not only valuable as a means of obtaining the high vacua desired, but it is still more important, because the phenomena observed throw a light on the results obtained by Lenard and Roentgen.

Though the phenomenon of rarefaction under above conditions admits of different interpretations, the chief interest centers on one of them, to which I adhere—that is, on the actual expulsion of the particles through the walls of the bulb. I have lately observed that the latter commences to act properly upon the sensitive plate only from the point when the exhaustion begins to be noticeable, and the effects produced are the strongest when the process of exhaustion is most rapid, even though the phosphorescence might not appear particularly bright. Evidently, then, the two effects are closely connected, and I am getting more and more convinced that we have to deal with a stream of material particles, which strike the sensitive plate with great velocities. Taking as a basis the estimate of Lord Kelvin on the speed of projected particles in a Crookes' bulb, we arrive easily by the employment of very high potentials to speeds of as much as a hundred kilometers a second.

It may not be known that even an ordinary streamer, breaking out suddenly and under great pressure from the terminal of a disruptive coil, passes through a thick glass plate as though the latter were not present. Unquestionably, with such coils pressures are practicable which will project the particles in straight lines even under atmospheric pressure. I have obtained distinct impressions in free air, not by streamers, as some experimenters have done, using static machines or induction coils, but by actual projection, the formation of streamers being absolutely prevented by careful static screening.

A valuable evidence of the nature of the radiations and progress in the direction of obtaining strong impressions on the plate might be arrived at by perfecting plates especially sensitive to mechanical shock or impact. There are chemicals suitable for this, and the development in this direction may lead to the abandonment of the present plate. Furthermore, if we have to deal with streams of material particles, it seems not impossible to project upon the plate a suitable substance to insure the best chemical action.
